Key words: Biomechanics, Residual Stresses, Stress Invariants, Patient-Specific Artery

Several experimental studies show that eigenstresses are present in arterial walls. When an axial section is cut in longitudinal direction, the artery springs open, see e.g. [3]. The inherent stresses have a significant influence on the overall tissue behavior since they reduce high stress gradients through the thickness of the wall. The "opened" configuration is often assumed to be stress-free. However, this is only an approximation. In various works dealing with the numerical simulation of arterial walls, as for example [1], it is accounted for residual stresses by closing an opened, unstressed artery by an initial bending to form a load-free, but internally stressed configuration. In this contribution we propose a novel approach for the incorporation of residual stresses in patient-specific human arteries, as proposed in [2]. In contrast to the approach described above, we focus directly on the

\begin{figure}[h]

\end{figure}
gradients of the fiber stresses in radial direction. As an underlying optimization criterion we assume that these gradients have to be smoothed between the inner and outer margins of the individual layers. In order to do so we define sufficiently small radial sections of the media and adventitia, in which this condition has to be enforced independently. After the superposition of residual stresses to the current stress state a new equilibrium state by solving the balance of linear momentum has to be computed. The smoothing process can be repeated several times until a satisfying distribution is present. In Figure 1 the effects of the assumptions made are demonstrated. Due to residual stresses the stress maximum on the innermost layer decreases and a more uniform distribution is obtained. The impact of the different stiffnesses of the material layers, namely media and adventitia, is kept and still visible. In order to prove the accuracy of the proposed model the opening angle experiment was simulated with the calculated residual stresses and the opening angle was investigated, see e.g. Figure 2.

**Conclusion:** Residual stresses can be approximated by smoothing the circumferential stress gradient. The fiber stresses are suitable scalar stress measures in this context. A method to smooth and project them onto the current preferred direction is derived and discussed for a patient-specific artery.
