Various recent initiatives around the world have paralleled our transition to a sustainable society. In the construction industry, efforts have focused on reviewing and optimizing the resource usage of buildings: to this end, priority has been given to improving techniques to repair, renovate, and maintain existing concrete structures to extend their lifespan and ensure their long-term integrity.

Reinforced concrete (RC) buildings are designed with high durability in mind, with purported lifetimes of over 100 years. The fact is, however, that such structures can show signs of degradation such as cracking and peeling very soon after their completion, in as little as 10–20 years. To guarantee the durability and safe usage of RC buildings in the long term, their susceptibility to different deterioration factors present in their environment should be assessed, and used to inform suitable management strategies.

The present study models an RC structure located near the coast, at risk of salt damage from

ambient chloride (Sato. K *et.al.* 2002) Specimens were initially treated using a selection of surface coating and/or patch repair methods and materials, left exposed, and then evaluated in terms of several physical characteristics to characterize the durability afforded by each combination. Exposure tests were performed in a coastal region of Hokkaido, the cold, northernmost prefecture of the long Japanese archipelago. Evaluation data from 25-year-old specimens were additionally compared with those of similar specimens exposed for 4.8 and 8 years.

2 Experimental Overview

Table 1 shows the types of materials used in the repairs. Table 2 details the content and properties of the concrete; Table 3 shows its mix composition. The concrete used had a 28-day compressive strength of 30.8 N/mm^2.Figure 1 is a structural schematic of the RC specimens. First, concrete was chipped away from a designated area of the RC slab, which had two reinforcing steel bars ("rebar") embedded in it. Next, this area was patched and its surface coated using a specific combination of materials. Concrete was removed to two different depths ("chipping depth"), defined relative to the embedded rebar: (A) chipping extended below the bar, allowing it to be completely covered with mortar, or (B) chipping reached the same depth as the rebar axis, meaning only half of it was covered with mortar. Figure 2 explains the notation of the specimen IDs in the Results section. Two-symbol IDs denote RC specimens, while three-symbol IDs denote the rebars embedded in them.

Table 1. Repair materials.

Process	Symbol	Type
Patch repair	N	None
	CM	Cement mortar
	PS	SBR* polymer cement mortar
	PI	SBR* polymer cement mortar with anti-rust additive
	LE	Lightweight epoxy mortar
Surface coating	N	None
	L	Thin textured coat
	S	Multi-layer textured coat

*SBR: styrene–butadiene rubber

Table 2. Concrete content and properties.

Materials	Properties
Cement	Ordinary Portland cement Density: 3.16 g/cm^3
Fine aggregate	River sand Density 2.62 g/cm^3, F.M.2.64
Coarse aggregate	Crushed hard sandstone Density 2.64 g/cm^3, F.M.6.71
Air entraining agent	Natural resinate
Rebar	Round steel bars with mill scale and acetone defatting: φ13 mm, SR235 (SR24) (JIS G 3112)

Table 3. Concrete mix composition.

Target slump (mm)	Target air content (%)	W/C (%)	S/a (%)	Water	Cement	Fine aggregate	Coarse aggregate	AE (*cement weight (%))
				kg/m^3				
180	4.0	65.0	48.0	185	285	862	940	0.020

These 'repaired' specimens were left at the exposure test site for predetermined lengths of time (43.025N, 140.53E, ~40 m from coastline: Figure 3). At each timepoint, several specimens were broken apart and the rebar inside removed to measure the surface area affected by corrosion ("corrosion area") and the weight lost due to corrosion ("corrosion mass loss"). Carbonation depth and chloride penetration were measured in the broken concrete in parallel. Figure 4 shows the mean monthly temperatures of the region where the specimens were left exposed.

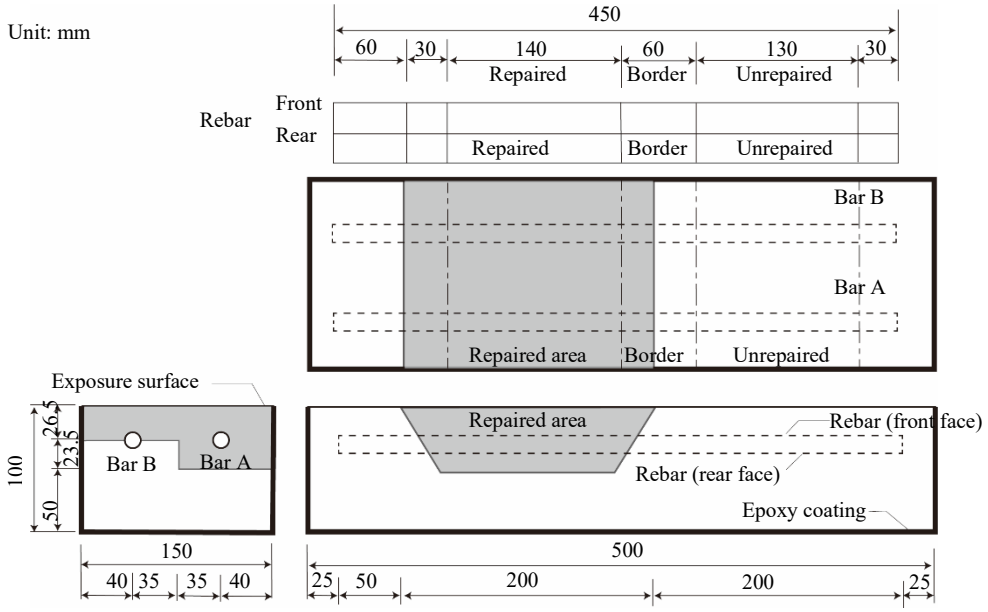

Figure 1. Schematic of RC specimen.

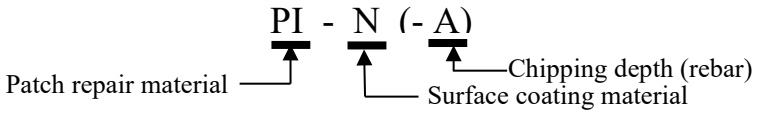

Figure 2. Specimen notation.

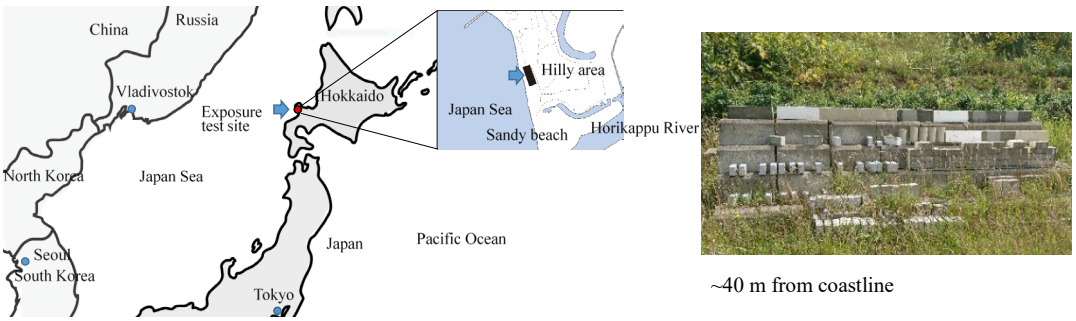

Figure 3. Exposure test site.

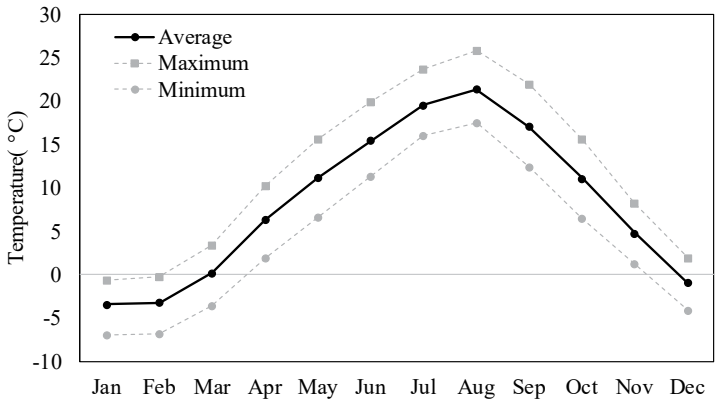

Figure 4. Mean air temperature by month at exposure test site.

3 Results and Discussion

3.1 Carbonation Depth

Figure 5 shows the measurement data for carbonation depth. Carbonation depth was most affected by the presence of surface coating itself, consistently measured deeper in specimens whose surfaces had not been coated at all (-N). When present, multilayer textured coating (-S) provided superior protection to thin textured coating (-L): specimens treated with it experienced almost no carbonation at all, irrespective of patching mortar type, evidencing its excellent resistance to carbonation.

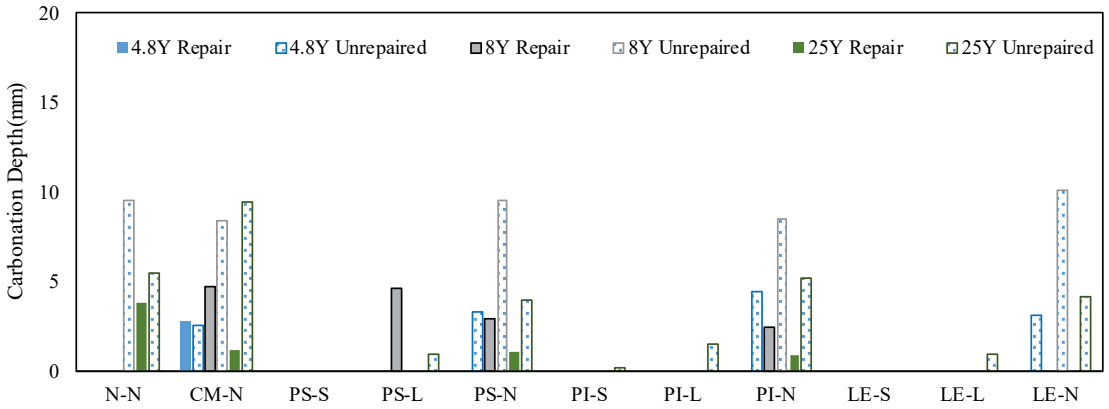

Figure 5. Carbonation depth.

3.2 Rebar Corrosion

Once removed from concrete, steel rebar was first visually graded, and then its degradation quantified by tracing and measuring the surface area of the regions affected by corrosion. Figure 6 contains photos of two bars affected by corrosion taken from a representative specimen (CM-N). Corrosion behavior clearly differs greatly between the repaired and unrepaired regions: interestingly, in the repaired part, it seems dependent on chipping depth (*i.e.* A versus B rebar).

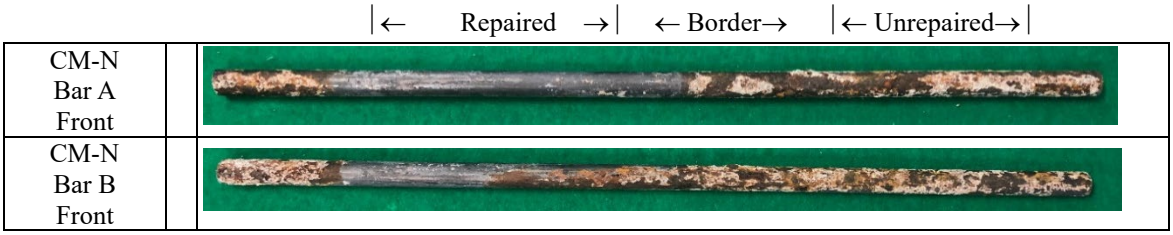

Figure 6. Rebar corrosion (CM-N, 25 years).

Next, rust was removed from the extricated bars by immersion in 10% di-ammonium citrate. Each bar was sectioned into three parts according to Figure 1 (Repaired, Border, and Unrepaired), and the corrosion mass loss calculated for each part (Nishimura N. *et al.*,2012, Kakegawa, M.*et al.*,2012). Corrosion speed was then calculated based on the mass loss using the following equation (Sato K. *et al.*,2002).

$$\Delta Ws = \frac{\Delta Wc \times W_0}{\varphi \times l \times \pi \times t} \quad (1)$$

Where ΔWs is the rebar corrosion speed (10-6g/mm^2/y), ΔWc is the mass loss due to rust (%), W_0 is the initial weight of the rebar (g), φ is its diameter (13 mm), l is its length in the part under analysis (mm), and t is the exposure length (year).

Figure 7 depicts correlations of rebar corrosion speed in the unrepaired versus border and repaired sections. Corrosion was effectively prevented by the repair techniques utilized, by and large proceeding at slower speeds in repaired than unrepaired rebar. Corrosion speed was quite high in the border region after eight years of exposure following repair with the rust-resistant SBR polymer cement (PI). This behavior could be attributable to a macrocell formed by a major differential in corrosion potential between the repaired and unrepaired parts due to the anti-rust additive in the mortar. However, the same tendency was not apparent in the 25-year-old specimens repaired using the same material, suggesting this variation likely originated in individual differences between specimens.

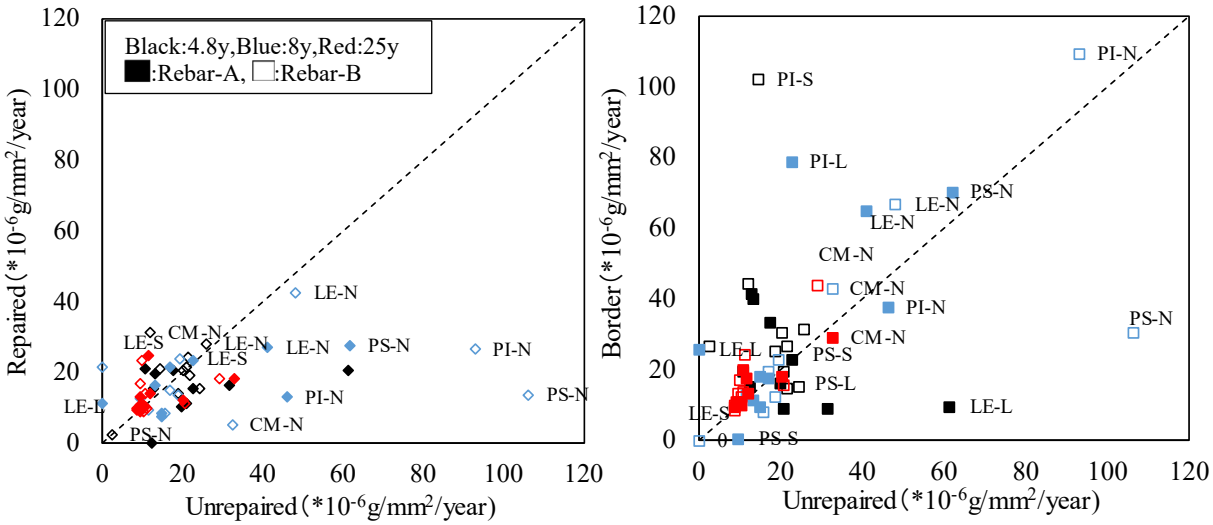

Figure 7. Rebar corrosion speed.

Figure 8 separately depicts the associations between the rebar corrosion area (itself affected by chipping depth) and corrosion mass loss by type of patching material. Specimens not treated by patch repair or surface coating (N-N-) experienced major mass loss, directly proportional to

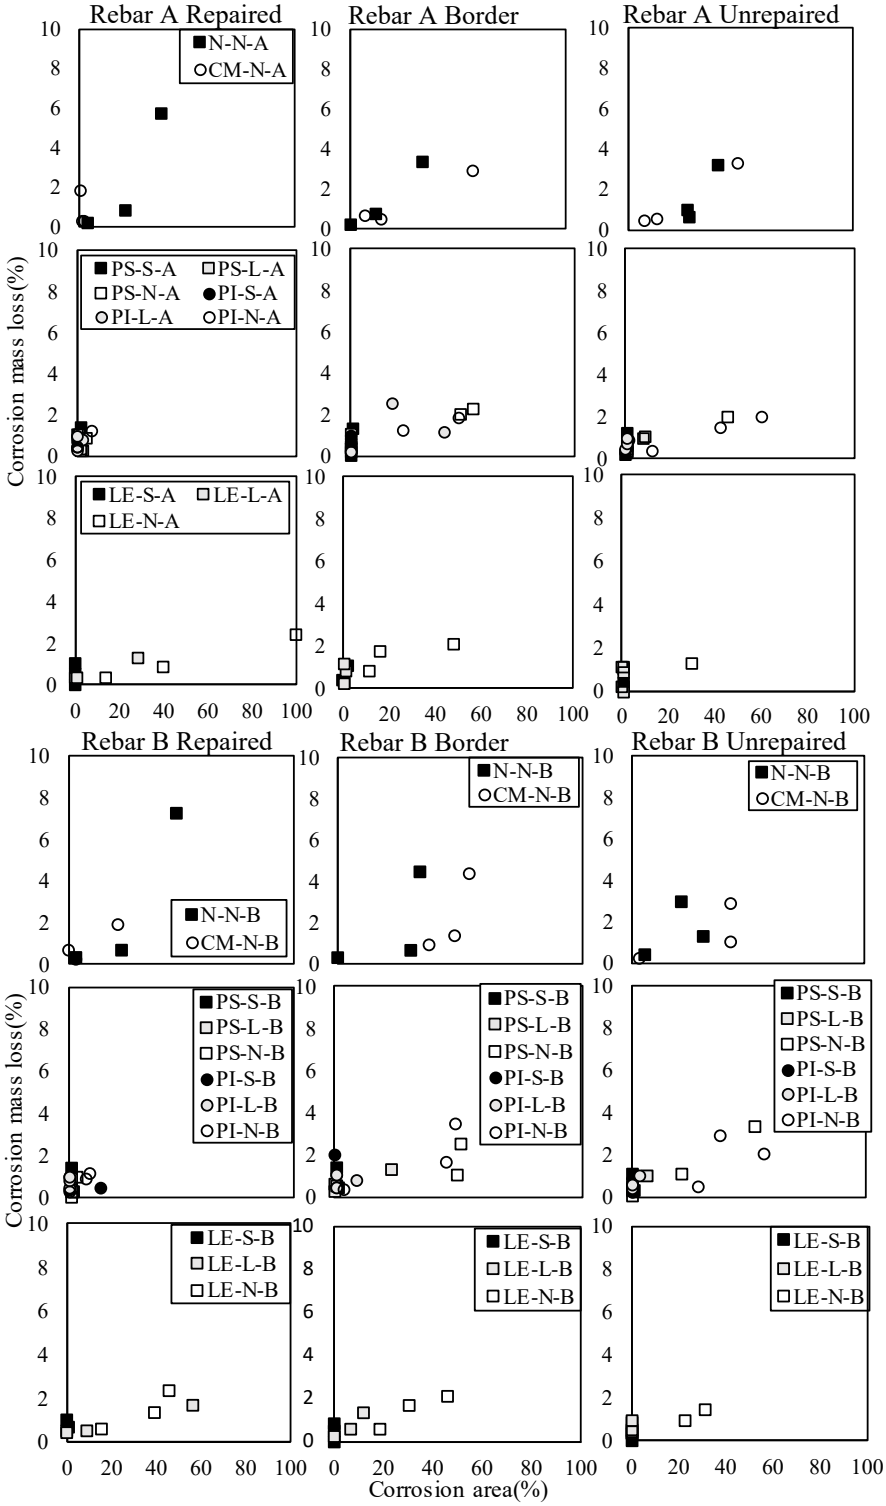

Figure 8. Rebar corrosion area versus mass loss by repair material and chipping depth.

corrosion area. In addition, corrosion progressed not only along the surface of rebar, but also towards its interior. When cement mortar was used for patch repair (CM-), the corrosion area and mass loss of the repaired region tended to be greater for B rebar than for A rebar. This suggests that chipping away enough concrete so that the entire area surrounding the rebar can be coated with patching mortar should effectively protect against corrosion. In addition, the corrosion area and mass loss of the repaired region were lower when SBR-type polymer cements (PS, PI) were used as the patching mortar than for lightweight epoxy (LE), evidencing the former materials' superior ability to protect against corrosion in patch repairs. Corrosion was prevented rather poorly by LE: when it was used, corrosion tended to spread widely across the rebar surface in the repaired region. No matter which material was used for patch repairs, the usage of multi-layer textured coating (-S-) was associated with significant drops in both corrosion area and weight loss, suggesting this material effectively resists corrosion and block the penetration of chloride ions. The only difference between PI and PS is the presence of an anti-rust additive in the former. Figure 8 shows that both materials well protect against rebar corrosion in the repaired region, with only marginal benefits afforded by the anti-rust compound.

However, specimens repaired using PI or PS tended to experience greater rebar corrosion along the border and non-repaired parts, especially in the absence of finish: this suggests the occurrence of macro-cell corrosion due to differential susceptibility to chloride penetration between the repaired and unrepaired segments. Notably, the multi-layer textured finish was the thickest of all types tested, achieving high chloride resistance and little penetration in the border and unrepaired segments on the whole. This characteristic may be why serious rebar corrosion was never really observed in the border and unrepaired parts of specimens coated with it.

4 Conclusion

This study's findings illustrate how the corrosion resistance of a repaired RC structure is affected by the materials chosen for patch repair and surface coating, as well as by chipping depth, based on experimental data from exposure tests lasting ~25 years. They can be summarized as follows:

- Carbonation was most effectively prevented by the multi-layer textured coating material.
- Corrosion protection was greater when concrete chipping extended below the rebar than merely to the same depth.
- Rebar corrosion, as with carbonation, was most effectively prevented by the multi-layer textured coating material.
- Rebar was more resistant to corrosion following patch repair with SBR polymer cements than with lightweight epoxy. However, when surface coating was not performed, macrocell corrosion may have been triggered by a high differential in chloride environment between the boundary/unrepaired and repaired regions.

Going forward, the authors plan to analyze chloride penetration depth in order to further scrutinize its relationship with rebar corrosion.

Abstract. *The purpose of this study was to clarify the internal change of concrete structures during drying. Therefore, we used X-ray CT to investigate water content and volume changes inside cement paste specimens during drying. Changes in the CT image intensities and measurements on the images indicated water content and volume changes, including local changes detected with digital volume correlation. Next steps will be to understand the link between volume changes and the local water content.*

Keywords: *Cement Past, Drying Shrinkage, Moisture Content, X-Ray CT, Digital Volume Correlation.*

1 Introduction

Concrete contains a lot of free water. When free water evaporates by drying, volume changes can occur. Such volume changes due to drying can cause cracks on the surface of concrete structures, resulting in a decreased durability of the structure.

The estimation of volume changes in concrete have usually been calculated based on the length change of a specimen (JIS A 1129-3). However, it is not only the shrinkage of cement paste that should be considered, but also shrinkage and distribution of aggregates also influence volume changes in concrete, for example Zhanga, W. *et al* (2013) and Alexander, MG. (1996). Furthermore, as moisture is transferred from the surface, the moisture content is different between the surface and the interior. For these reasons, it is difficult to estimate the complicated volume change only by the apparent externally measured size change of a specimen.

For the above reasons, we considered that a method that can measure the moisture content and volume change inside concrete in three dimensions (3D) is necessary. Previously, Sant, G. and Weiss, J. (2009). and Hong, S., *et al* (2019) used an X-ray CT apparatus to mesurement changing of water content and cracking inside the specimen. T. Fumoto also developed an X-ray CT system to estimate moisture content and composition of concrete after high temperature heating and to measure 3D volumetric strain fields in concrete under loading stress, for example Fumoto, T. and Hall, S (2019) and Fumoto, T., Mizuno, S. and Ozawa, M. (2016). Here we extend this previous work to examine the moisture content and volume change inside specimens during drying.

In this study we performed a length-change test on a cylindrical specimen of cement paste, which is a basic approach for measuring drying shrinkage, but we study the distribution of volume changes inside the sample using X ray CT and make image measurements at different

stages of the drying.

2 Experiment Methods

2.1 Specimen

To maximise the possibility of being able to make 3D measurements of the internal specimen changes during drying, a paste specimen that would give a large volume change was prepared. In addition, to study the effect of aggregates (crushed stone, in this case) on the internal deformation, paste specimens were prepared with a particle of crushed stone or crushed brick placed in the centre. Only a single particle was included to be able to visualize the effects around the aggregate without the influence of adjacent particles.

Table 1 shows the mixture proportions of the paste used in this study. In addition to ordinary Portland cement, zirconia balls with a particle size of 0.3 mm (density 6.07 g / cm^3) were mixed into the paste (the samples had 0.75% of the paste volume as zirconia balls) to provide more enhanced intensity patterns in the tomography images for improving the accuracy of the image measurements.

Table 1. Mixture proportions of paste.

W/C (%)	Unit content (kg/m^3)				
	Water	Cement	Thickener agent	Thickener agent	Zirconia ball
60	652	1088	32.6	0.326	45.4

5 L of paste was mixed in a planetary mixer, from which three specimens were made. Figure 1 shows an image of one of the specimens and the coordinate system used. The dimensions of the specimens were 75 mm in diameter and 144 mm in height. When placing the paste into the moulds, bolts with a diameter of 6 mm and a length of 35 mm were attached to the upper and lower surfaces of the specimen. For two specimen, crushed stones (surface dry density 2.63g / cm^3, water absorption 1.6%, particle size about 30mm) and crushed bricks were placed in the centre in a saturated surface‐dry condition.

The samples were demoulded the next day and, immediately after, an epoxy resin was applied to the upper and lower surfaces of the specimen so that moisture could escape only from the sides. In addition, a PVC pipe embedded with 12 ceramic balls (diameter 5 mm) was attached to each specimen to reduce mechanical errors and enabling an affine transformation to align images, following Ura, T., Fumoto, T and Takehara, K. (2016). The PVC pipe had 32 holes, with a diameter of 1 cm, arranged from the vertical-centre to the bottom to not prevent moisture dissipation. The specimens were stored in a constant temperature and humidity chamber at a 20 ± 1 ° C and a humidity of 60 ± 5%.

2.2 Measurement Method

Length change measurements and X-ray CT scans were performed after drying periods of 0, 5, 8, 13, 21, 35 and 134 days. Shrinkage strain was measured according to the measurement method of JIS A 1129-3. The X-ray CT imaging was performed using an apparatus that were shows in Fumoto, T. (2013) in detail. For each CT measurements, the center height of the specimen ± 35mm was scanned using the imaging parameters shown in Table 2 and with a

cubic image voxels with a side length of 0.123 mm. 3D deformation measurements inside the specimens were made using digital volume correlation (DVC) with the software *TomoWarp2* of Tudisco et al.(2017). For the DVC measurements, the correlation window for the correlation calculation was a cube of about 3 mm side length and the distance between correlation windows (the node spacing) was about 1.5 mm.

Table 2. X ray scan condition.

Tube voltage (kV)	Tube current (μA)	frame rate (frame/sec)	projection	Resolution (mm)	cupper plate (mm)
170	100	4	2000	0.123	3

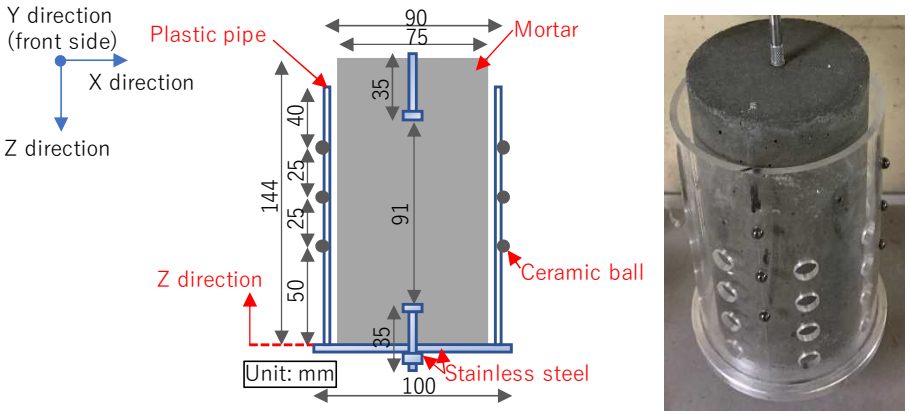

Figure 1. Design and photo of the specimen.

From the measurement results, the apparent length change of the specimen and the internal volumetric strain distribution were calculated. The apparent length change was calculated from the average value of the DVC-derived z-displacement in two cross-sections positioned at ± 20 mm from the centre in the z-direction and dividing the difference between these values by 40 mm. DVC strains were determined from the difference of displacement between adjacent subsets and the local volume strain was calculated by,

$$\varepsilon_{vol} = \varepsilon_x + \varepsilon_y + \varepsilon_z \tag{1}$$

where ε_x, ε_y and ε_z are the normal strains in each direction.

In the X-ray CT images, the intensity indicating the relative value of X-ray absorption is affected by the density and composition. Since the apparent density decreases due to drying from the side of the specimen, the apparent density reduction may be indicated as a decrease in the intensity of the X-ray CT image. Therefore, the moisture content variations were estimated using the intensity distribution in the radial direction over a series of concentric virtual cylinders, centred on the axis of the sample, of 2.5 mm thickness and spanning a height of ± 25 mm from the z-direction centre of the specimen in the X-ray CT images. The average value of the intensity distribution was calculated over each cylinder, and the transition of the average intensity from the surface to the inside of the specimen was calculated.

3 Experimental Results and Discussion

3.1 Shrinkage Strain

Figure 2 shows the shrinkage strain as a function of time obtained from the length change measurements. In the case of the paste, shrinkage strain began to increase from the start of drying and increased linearly until the drying period of 35 days, reaching about 3200 × 10^{-6}. After that, the shrinkage strain increased to about 6000 × 10^{-6} after 134 days of drying and appear to have reach a steady state. The length change for the crushed stone and crushed brick samples was smaller than that of the paste by about 500 × 10^{-6} at 35 days and about 300 × 10^{-6} at 134 days of drying. This is considered to result from the reduced paste volume due to the presence of the stone/brick particles.

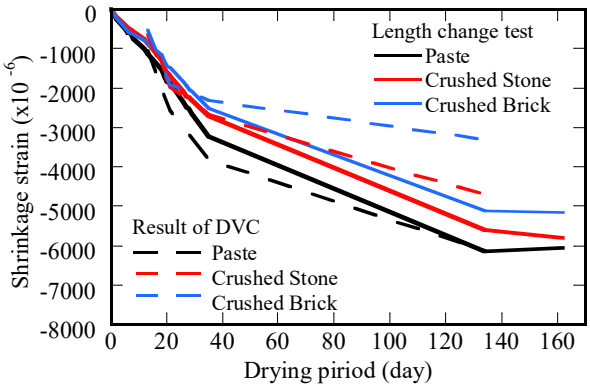

Figure 2. Drying period vs length change.

The apparent length change calculated from the DVC calculation has been included in Figure 2. For the paste, the DVC calculated value was larger than length change value until 35 days of drying period, but it converged to the the same value by the end. On the other hand, for the crushed stone, the DVC calculated length change was about 1000 × 10^{-6} smaller, and for the crushed brick it was about 1700 × 10^{-6} smaller. These tendencies are attributed to the fact that the DVC-based calculation of the length change considered the z-direction displacement over the entire cross section of the specimen and, thus, included changes in the drying condition from the surface as well as expansion due to cracks.

3.2 Observation of X-Ray CT Images

Figure 3 shows XZ cross-section images for each drying time the three samples. For the paste sample, the image intensity is seen to decreased as the drying period increases and the specimen has only a small crack after 35 days of drying. However, for the samples containing a particle, cracks can be seen at early drying stages, which became longer and wider as the drying progresses. Some of the cracks appear to have occurred at positions where there is an abrupt change in the particle surface angle. These cracks are thought to have formed due to constraints through adhesion at the particle surface.

Figure 4 shows the intensity change as a function of position from sample surface for the paste specimen. The intensity can be seen to have decreased near the surface at 5 - 8 days of drying. After about 8 days, the intensity changed significantly near the centre. After 134 days

of drying, the intensity reached almost the same value at the centre as at the surface. As shown in Figure 2, it is expected that the water movement had reached an equilibrium by this time.

Figure 5 shows the intensity rate based on intensity difference between saturation and equilibrium, which can be regarded as the rate of water reduction until reaching equilibrium under this condition. After drying for 5 days, 5 - 50% of the water up to 20 mm depth evaporated through the surface. After 13 days of drying, the water content in the first 5 mm in depth reduced very slowly. On the other hand, the water from more than 5 mm in depth moved rapidly.

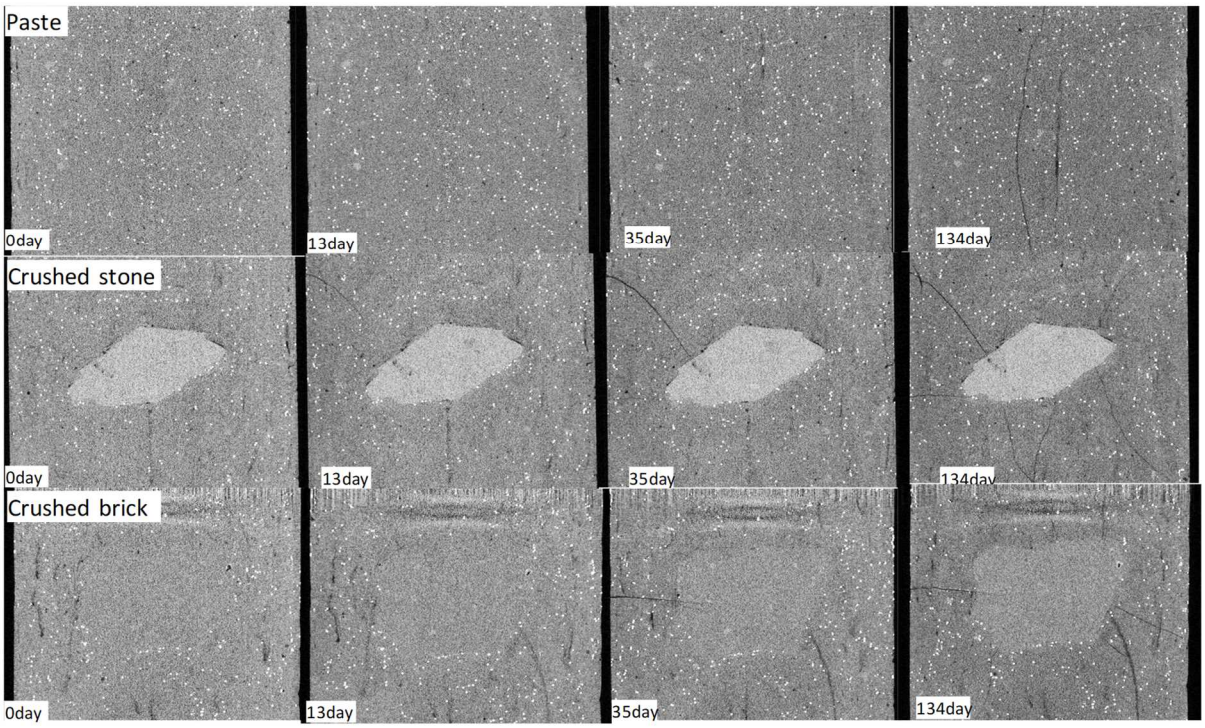

Figure 3. XZ cross-sectional images for each dry material age for paste, crushed stone, and crushed brick.

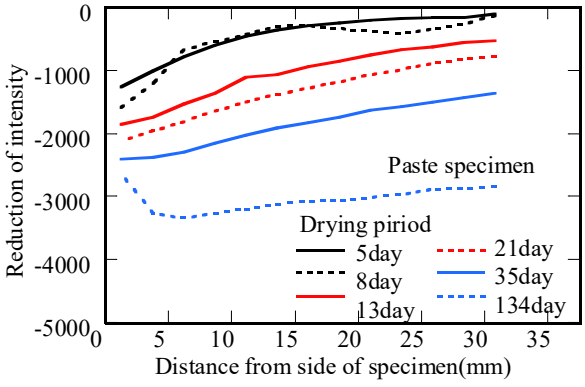

Figure 4. Intensity change from surface.

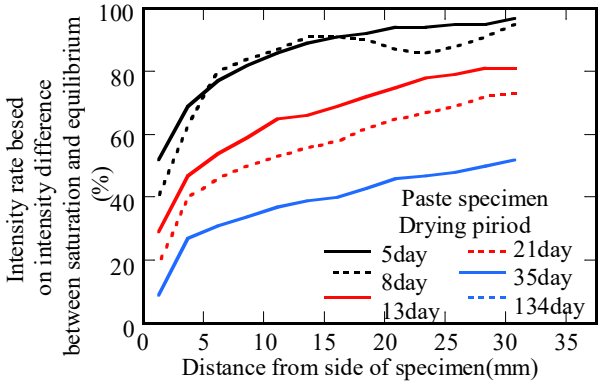

Figure 5. Intensity rate based on intensity difference between saturation and equilibrium.

3.3 Measurement Results Using DVC

Figure 6 shows the volumetric strain distribution inside the 3 specimens based on DVC measurement.

In the case of the paste specimen, there was no particular change over the first 8 days drying period. However, the shrinkage strain region can be seen to extend from the side surface after 13 days and extends to about 20 mm depth from the side at 21 days. From 35 to 134 days of drying, the shrinkage strain region widened on the whole. Localised regions of high dilation indicate the formation of cracks.

In the case of the specimens containing the particles of crushed stone and crushed brick, it can be seen that the shrinkage strain increased with drying, as in the case of paste. However, after 35 days of drying, the shrinkage strain around the particles appears to be smaller than in

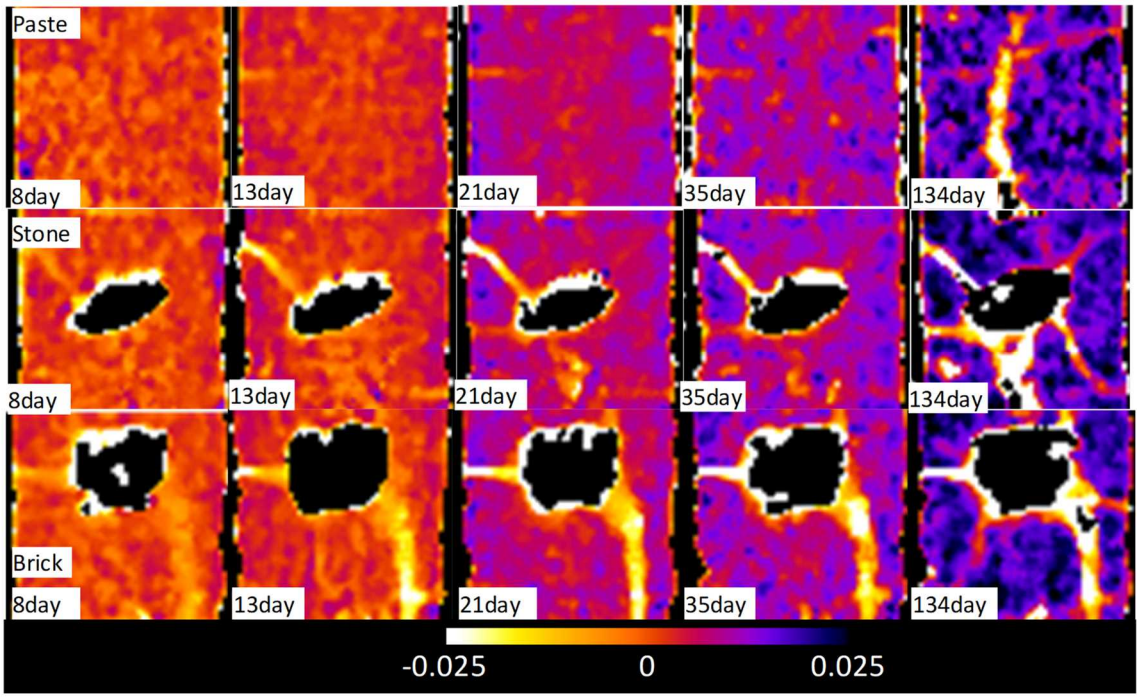

Figure 6. Volumetric strain distribution inside the specimen based on DVC measurement.

other regions. Several areas of minor dilation can be observed after 8 days of drying which evolve to cracks in the later stages, these appear to form from the particle surfaces early in the drying sequence and then their width increases with further drying. It is likely that the cracks initiated at the particle surfaces due to adhesion between the particles and the paste constraining the shrinkage process.

The results presented above show that the shrinkage strain distribution in the cement paste due to drying from the surface could be measured. In addition, the relaxation of the shrinkage strain was observed around particles, but it was obscured, in part, due to the occurrence of cracks. In future work, specimens that do not crack easily, such as mortar specimens, could avoid this issue.

In addition, the results for the paste specimen in Figures 2 and 3 show that a noticeable shrinkage strain occurred when there was over 50 % difference in the moisture content between saturation and equilibrium. This is considered to indicate that relationships between the internal moisture and volumetric strain can be investigated using X ray CT.

4 Summary

The purpose of this study was to perform length change tests on cylindrical specimens of cement paste using X ray CT as a basic study for measuring drying shrinkage distribution inside concrete and to make measurements using X-ray CT images at different stages of drying. The key conclusions from this work are:

- it was shown that the moisture content inside the paste specimen could be estimated from the intensity changes in the X-ray CT images;
- measurement by DVC analysis of the X-ray CT images showed volumetric shrinkage strain distributions inside the paste specimen and the process of cracking due to the restrictions by the aggregates;
- By integrating the results on image intensity changes and the volumetric strain, it will be possible to clarify the coupling of the local the volume change and the local water content change inside a specimen.
- In this study and the given conditions, a noticeable shrinkage strain occurred when the of the difference of moisture content between saturation and equilibrium was above 50 %.

In summary, this study has demonstrated that internal moisture movement and volume changes due to drying can be considered by image measurements on X-ray CT images, which opens the door to further investigations in the future.

Microstructural Evaluation of Durability of Different Cementitious Mixtures in Microbial Induced Corrosion Environments

Chunyu Qiao[1] **and David Rothstein**[2]

[1] DRP, A Twining Company, 80301-Boulder, USA, joe@drpcinc.com

[2] DRP, A Twining Company, 80301-Boulder, USA, petro@drpcinc.com

Abstract. *Sound and durable concrete mixtures are essential in environments where microbial induced corrosion (MIC) is a concern. In this study three concrete mixtures prepared with different binders (ordinary portland cement (OPC), calcium aluminate cement (CAC) and alkali-activated cement (AAC) were petrographically examined after exposure to laboratory-controlled MIC conditions. Analytical techniques included reflected light microscopy, polarized and fluorescent transmitted light microscopy (FLM) and scanning electron microscopy equipped with an energy-dispersive X-ray spectrometer (SEM/EDX). SEM/EDX analyses obtained from the same areas provided information on chemical and mineralogical alteration, while quantitative image analysis with FLM affords an opportunity to quantify the variation in capillary porosity of the paste within alteration zonation. The microscopic observations indicate that the change in normalized capillary porosity coincide broadly with different alteration zones, which are in turn dependent on the type of binder. The OPC concrete shows the greatest deterioration where the paste is largely replaced by gypsum and high capillary porosity is lined to leaching of a calcium. The formation of ettringite densifies the paste and lowers the capillary porosity inboard of the gypsum zone in the OPC concrete. The CAC and AAC mixtures show better resistance to leaching than the OPC mixture, which explains their superior resistance to MIC. These findings are consistent with independent macroscopic observations that indicate the OPC mixture deteriorated more rapidly and severely than the CAC and AAC mixtures.*

Keywords: *Microstructure, Fluorescence Microscopy, Microbial Induced Corrosion, Cementitious Materials, Image Analysis.*

1 Introduction

Microbial Induced Corrosion (MIC) is a significant concern for the condition of concrete infrastructure elements in a variety of environments (Grengg *et al.*, 2015). There is a longstanding recognition that one of the most significant of these environments include wastewater treatment plants (WWTP) and sewer lines, where biological activity from bacteria such as *Acidithiobacillus thiooxidans* lead to rapid rates of deterioration as hydrogen sulfide gas forms sulfuric acid on concrete surfaces above flow lines in sewers and in digesting basins within WWTP (Parker, 1945). In the United States, much of the concrete WWTP infrastructure was built in the 1970s and is approaching its design life of ~ 50 years. Prolonging the use of these facilities and the sustainability of the built infrastructure requires the use of sound and durable repair materials. Because these repairs are often the responsibility of local municipalities with limited financial resources, repair and remediation strategies and materials must also be economically viable.

This study assesses the resistance of three of the most commonly used and widely available (and therefore economic) materials for WWTP facilities: ordinary portland cement (OPC),

calcium aluminate cement (CAC), and alkali activated fly ash and slag (AAC). Optical and electron microscopical methods are used to characterize the response of these materials to MIC simulated in a biogenic corrosion chamber. In particular, we use fluorescence light microscopy to measure the evolution of the capillary porosity of the different binders as they undergo MIC.

2 Mixtures and Experimental Procedures

2.1 Mixtures

This study investigates three concrete mixtures made with different binders: ordinary portland cement (OPC), calcium aluminate cement (CAC), and alkali activated fly ash and slag (AAC). Table 1 summarizes the mixture proportions used to produce specimens that were cast in molds measuring 400 mm by 100 mm by 100 mm. The specimens were demolded after 24 hrs and then cured in a moist room for OPC concrete, in water for CAC concrete and in a regular room for AAC concrete. All of the specimens were cured for 28 days at 22 ± 1 °C. Coupons that measure 100 mm by 70 mm by 70 mm were cut for the biogenic acid exposure testing.

Table 1. Mixture Proprotions of three concretes (kg/m^3).

	OPC concrete	CAC concrete	AAC concrete
Binder	450	450	450
Coarse aggregate	1025	1035	1045
Fine aggregate	730	768	790

2.2 Experimental Procedures

The exposed surface of each coupon was pre-treated to facilitate the growth of the acidophilic microorganisms prior to placement in the corrosion chamber. This involved spraying the surface with sulfuric acid (H_2SO_4) to reduce the surface pH to 2 – 4. The coupons were then partially submerged in real sewage water in an enclosed chamber at 25 °C and 100% relative humidity (RH). The exposure test lasted for 12 months. The coupons were then removed from the chamber and washed to remove loose material. Measurements of the mass of the coupons before, during and after the exposure testing indicated the most significant mass loss and deterioration on a macroscopic scale in the OPC, followed by the CAC and then the AAC.

A slab representing a cross section of each coupon was cut, lapped and polished with progressively finer diamond-embedded pads following procedures outlined in ASTM C457. The polished slabs were oven dried overnight at ~ 40°C and examined using Nikon® SMZ-25 stereomicroscope following ASTM C856.

A billet measuring 40 mm by 25 mm in area was cut from the remaining portion of each coupon. The billets were rinsed in an aqueous solution, oven dried overnight at ~ 40°C and then vacuum impregnated with an epoxy containing a fluorescent dye. Thin sections were prepared from the impregnated billets using a Pelcon® Automatic Thin Section Machine. The thin sections were examined using a Nikon® E-Pol 600 petrographic microscope. Images were obtained in fluorescence mode and image analysis software (Image J) was used to create gray-scale images and make measurements of the capillary of the paste.

Another billet impregnated with fluorescent epoxy was cut and polished for examination using a FEI™ Quanta 250 Environmental Scanning Electron Microscope (ESEM) coupled with an EDAX® Apollo X Silicon Drift energy dispersive X-ray spectrometer (EDX). The specimens were examined under low vacuum conditions (~ 70 Pa) with an accelerating voltage of 15 kV, a spot size of 5 and a working distance of ~ 10 mm.

3 Results and Discussions

3.1 OPC Concrete

Leemann *et al.* (2006) used fluorescence microscopy to investigate variations in porosity across the interfacial transition zone (ITZ) in self consolidated concrete. A similar analysis is performed in this paper to measure changes in capillary porosity across alteration zones. As a benchmark, the grey level histograms of paste (in Fig. 1a) and a void (in Fig.1b) were analyzed and statistically fitted assuming normal distributions, as shown in Fig. 1c. Since the void in Fig. 1b is filled with epoxy containing a fluorescent dye and has 100% porosity, a "normalized capillary porosity" of the paste is proposed by normalize the mean grey level of the paste to that of the air void. The standard deviation is used as the error bar, as shown in Fig. 2g.

Optical and scanning electron microscopical examination of the sample revealed several distinct mineralogical and chemical alteration zones (Fig. 2a-2e). The alteration zones are as follows, moving inward from the exposed surface: (a) coarse-grained gypsum; (b) medium-grained gypsum; (c) a transition zone with ettringite and iron oxide staining; (d) a carbonated zone; and (e) a zone of calcium leaching. Fluorescent transmitted light microscopy reveals changes in the capillary porosity of the paste in these zones (Fig. 2f-2g).

The alteration of the OPC concrete is typical of biogenic sulfuric acid attack commonly observed in OPC concretes exposed to MIC. Menéndez *et al.* (2013) described a sequence of reactions typical of these environments. The formation of gypsum ($CaSO_4 \cdot 2H_2O$) consumes calcium hydroxide ($Ca(OH)_2$) and calcium silicate hydrates (CSH) in the paste matrix. The leaching of cementitious phases and deposition of gypsum produces a higher capillary porosity in Zone (a) and Zone (b). In particular, because Zone (a) is in contact with an acidic solution, there is widespread dissolution of CSH and a dramatic increase in capillary porosity (Fig. 2g). Ettringite forms in Zone (c) because the pH sufficiently high to stabilize it this far inboard of the exposed surface. The iron staining in Zone (c) is due to the oxidization of iron-bearing accessory minerals in the aggregate that is mainly basalt and andesite. These reactions are expansive, which lowers the capillary porosity inboard of the outer alteration zones, compared to that of the intact paste (Fig. 2g). The carbonated zone, which is relatively thin, also shows decreased capillary porosity. Inboard of the carbonated zone, the leaching of Ca^{2+} in Zone (e) results in a slight increase in capillary porosity, compared to the intact paste (Fig. 2g).

3.2 CAC Concrete

Fig. 3a-3d shows the alteration of the CAC concrete exposed to MIC revealed by optical and electron microscopy. The alteration zones are as follows (inwards from the exposure surface): (a) a zone of pervasive cracking with deposition of gypsum (in Fig. 3a), which was lost on the thin section during the sample preparation (in Fig.3b); (b) a transition zone that contains gypsum, ettringite and iron oxide staining; and (c) sulfate diffusion zone. As shown in Fig. 3f, the capillary porosity of the paste decreases from the intact paste to Zone (b). This indicates the sulfate attack lowers the capillary porosity to some extent before there is sufficient internal expansion to crack the concrete.

The main hydration products of the CAC concrete depend on the curing conditions (RH and T), w/b ratio and curing time (Schmitt *et al.*, 2000). The main hydration products of CAC concrete (cured in water at 22 ± 1 °C) include hydrogarnet ($3CaO{\cdot}Al_2O_3{\cdot}6H_2O$, C_3AH_6) and gibbsite ($Al(OH)_3$, AH_3). Khan *et al.* (2019) described the alteration of CAC in such environments. The most significant reactions involve the formation of gypsum and gibbsite from hydrogarnet in the presence of sulfuric acid. These reactions are expansive and lead to cracking in Zone (a). In the transition Zone (b), gypsum reacts with hydrogarnet to form ettringite (Khan *et al.*, 2019), which densifies the microstructure of the paste before the internal stress cracks the concrete. This explains the lower capillary porosity in Zone (b) and Zone (c),

compared to the intact paste (Khan *et al.*, 2019; Nishikawa *et al.*, 1992).

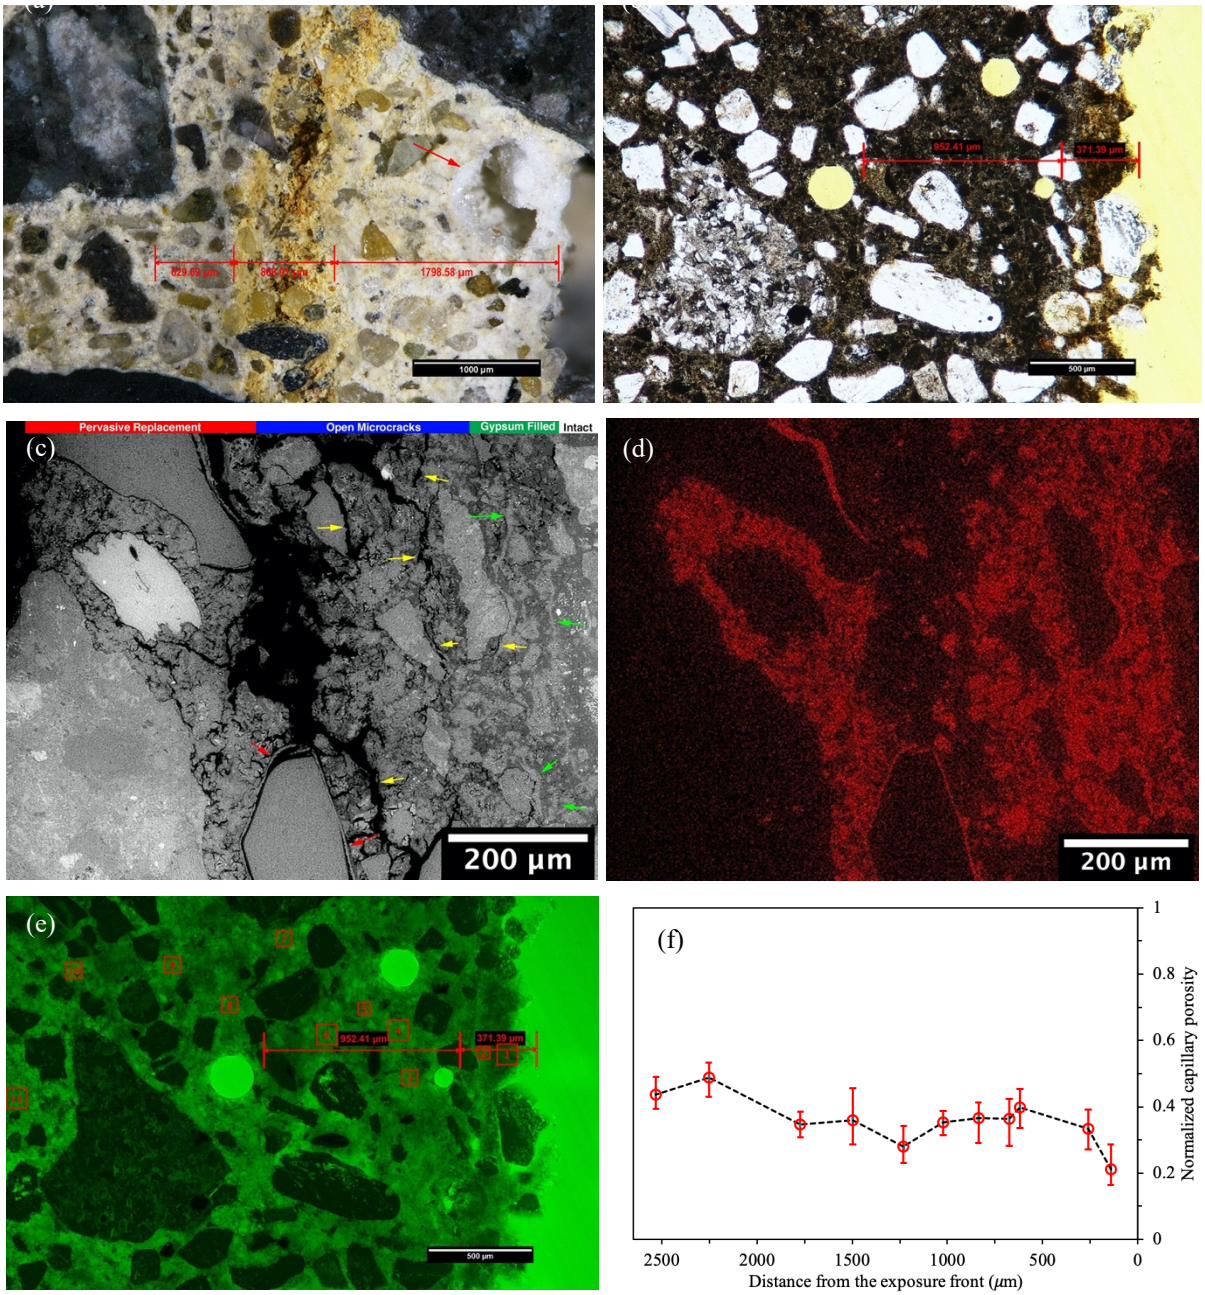

Figure 3. Alteration zones in the CAC concrete. (a) Reflected light photomicrograph of the polished surface; (b) transmitted plane-polarized light photomicrograph of the thin section; (c) backscatter electron image of alteration zones; (d) EDX elemental map for S; (e) transmitted fluorescent light photomicrograph of thin section; (f) Line plot showing changes in grey level and capillary porosity of the paste in the alteration zones.

3.3 AAC Concrete

Fig. 4a-4d shows the alteration zones observed in the AAC concrete exposed to sulfate attack. Similar to the alteration observed in CAC concrete, the alteration in AAC concrete involves the

following: (a) a zone of pervasive gypsum deposition and cracking; (b) a transition zone that contains a mixture of gypsum, ettringite and iron oxide staining; and (c) a sulfate diffusion zone. Calcium (alkali) aluminosilicate hydrate (C-(N)-A-S-H) and monosulfate (AFm) are two of the main hydration products in AAC concrete (Myers *et al.*, 2017). These react with H_2SO_4 to form gypsum, which results in pervasive gypsum deposition, leaching of the paste and cracking in Zone (a). Higher capillary porosity was observed in Zone (a) compared to that of the intact paste (Fig. 4e-4f). In the transition Zone (b) and diffusion Zone (c), the formation of ettringite from AFm densifies the microstructure and a lower capillary porosity, compared to that of the intact paste, is observed.

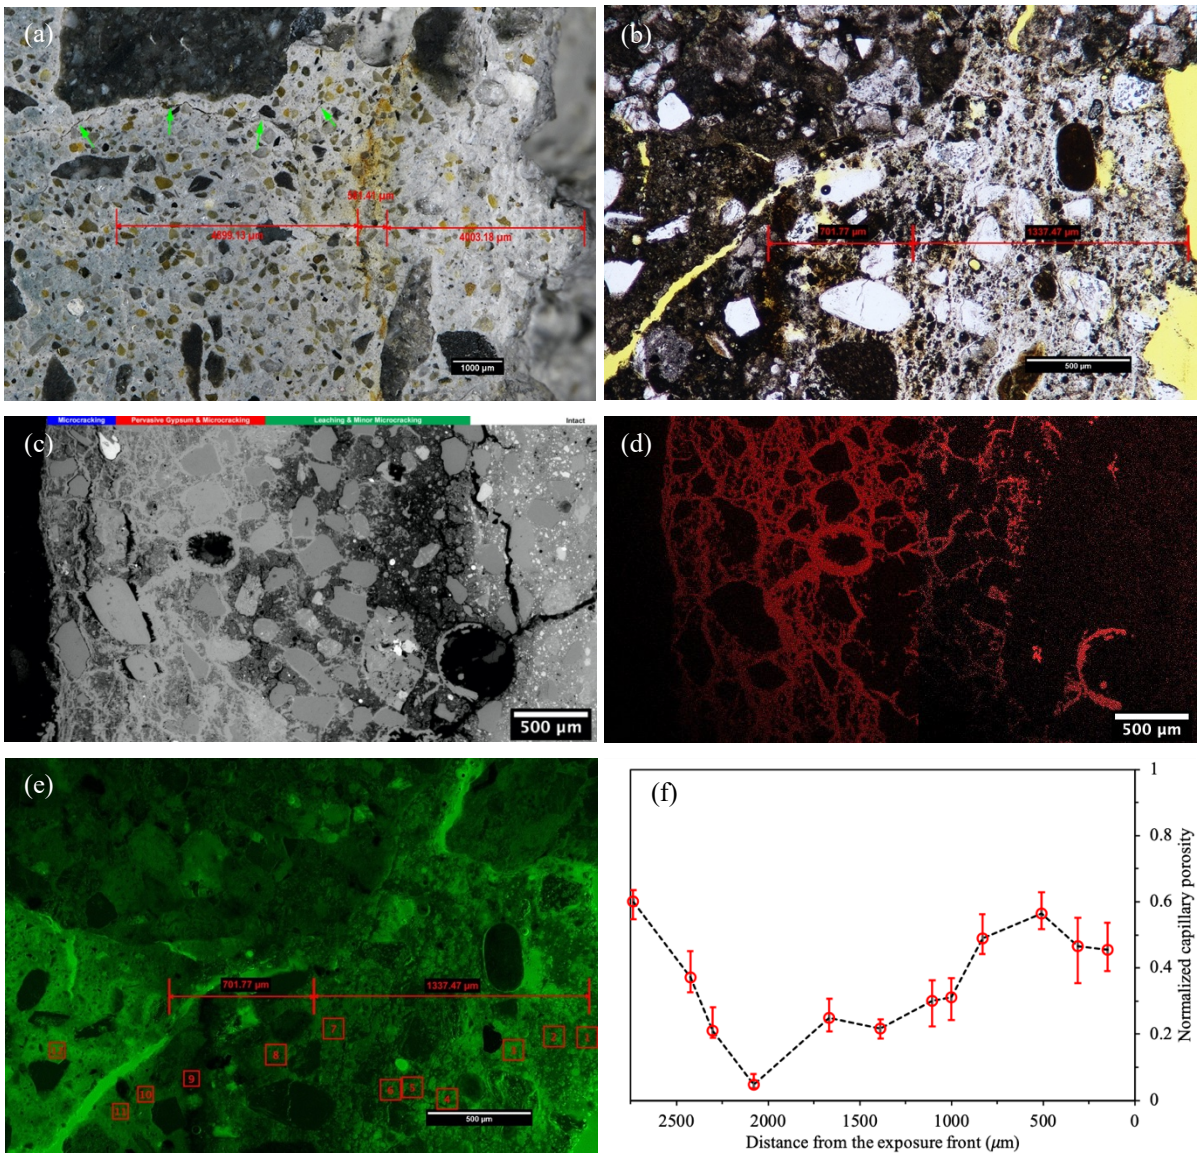

Figure 4. Observations of alteration zones in the AAC. (a) Reflected light photomicrograph of the polished surface; (b) transmitted plain-polarized light photomicrograph of the thin section; (c) Backscatter electron image of alteration zones; (d) EDX elemental map for S; (e) transmitted fluorescent light photomicrograph of the thin section; (f) Line plot showing changes in grey level and capillary porosity of the paste in the alteration zones.

4 Conclusions

Petrographic examination of three concrete mixtures prepared with different binders and subjected to MIC under controlled laboratory conditions provides insight toward the durability of these materials in WWTP environments. Observations obtained from optical and electron microscopy clearly delineate alteration zones characterized not only by distinct mineralogy, but also by distinct changes in the capillary porosity or density of the paste. The OPC mixture shows the great deterioration where the outer alteration zones show both increased capillary porosity of the paste associated with the leaching of $Ca(OH)_2$ and CSH and zones of significant cracking associated with the pervasive deposition of gypsum. Inboard of these zones the formation of ettringite actually densifies the OPC paste. The CAC and AAC mixtures show greater resistance to the sulfuric acid conditions associated with MIC than the OPC mixture. The outermost alteration zones in these mixtures have markedly lower capillary porosity than the OPC mixture. As such, the alteration zones are more cohesive and remain adhered to the intact paste, which explains why these samples show lower mass loss in macroscopic testing. The higher resistance is consistent with better resistance to leaching than the OPC mixtures, which is in turn due to the lack of $Ca(OH)_2$ and CSH in these materials.

Abstract. *Concrete structures are subjected to shrinkage since the moment when the water makes contact with the cement. From that moment on, depending on the concrete composition and its curing conditions, chemical, autogenous and drying shrinkage might increase the risk of early-age cracking. Once a crack is formed, it may become the preferential path for the ingress of many aggressive agents inside the structure increasing the probability of damage due to corrosion, carbonation and other mechanisms. The use of superabsorbent polymers (SAPs) has been extensively studied to reduce the shrinkage cracking risk in mortar specimens by acting as internal curing agent to mitigate autogenous shrinkage. In this paper, a commercially available SAP was investigated as shrinkage reducing agent by means of internal curing in concrete specimens. The shrinkage of the concrete was monitored for 28 days with both a demountable mechanical strain gauge (DEMEC) and optical fiber sensors (SOFO). The SAP-containing concrete showed a complete mitigation of autogenous shrinkage during 28 days of measurement, for both methods. The SOFO sensors showed the occurrence of cracks after 7 days for the reference mixture, while for the SAP containing mixture, no crack was identified during the 28 days of measurements.*

Keywords: *Early-Age Cracking, Superabsorbent Polymers, Internal Curing, SOFO Sensors.*

1 Introduction

Shrinkage in concrete structures has been the focus of many studies, and lately, a lot of attention has been given to autogenous shrinkage. The autogenous shrinkage occurs in all kinds of concrete structures at different levels. In ordinary concrete structures (with water-to-cement ratio above 0.42) it is not such a prominent phenomenon but it may increase the risk of cracking, especially when supplementary cementitious materials are used (Jian *et al*., 2014; Wu *et al*., 2017). On the other hand, it may be the main cause of early-age cracking in systems with water-to-cement/binder ratio lower than 0.42 (ultra-high performance concrete, for example) (Jensen and Hansen, 2001a; Jensen and Hansen, 2001b).

Recently, a lot of research has been developed aiming to use the SAPs to reduce/mitigate shrinkage in cementitious materials, most of it at mortar or paste level (Jensen, 2008; Snoeck, 2015; Snoeck and De Belie, 2015; Snoeck *et al*., 2017; Tenório Filho *et al*., 2018; De Meyst *et al*., 2019; Snoeck *et al*., 2018; Geiker *et al*., 2004) and some in high performance concrete compositions (HPC) (Jian *et al*., 2014; Wu *et al*., 2017; Craeye *et al*. 2011; Pierard *et al*., 2006), all showing that a dosage of SAPs in the range of 0.2-0.6% with respect to the cement mass should be enough to considerably reduce or complete mitigate the deformation due to autogenous shrinkage.

Superabsorbent polymers (or hydrogels) are a natural or synthetic water-insoluble 3D network of polymeric chains cross-linked by chemical or physical bonding. They possess the ability to take up a significant amount of fluids from the environment (in amounts up to 500 times their own weight) (Mechtcherine and Reinhardt, 2012). Once in contact with the mixing water of the cementitious material, the SAPs absorb and retain a certain amount of the water (depending on their absorption capacity), later on acting as water reservoirs for the system, keeping its levels of internal relative humidity high for a considerable time frame (depending on the SAP used, even up to 28 days (Snoeck *et al*., 2017)).

Up to now, most of the studies investigating the deformation due to autogenous shrinkage of concrete have relied on test methods based on linear measurements performed with the use of length transducers placed on the top surface of prismatic specimens, with the measurements starting at different times (for example at 6 h, 9 h and 24 h) (Craeye *et al*., 2011; Pierard *et al*., 2006; Sven and Reinhardt, 2006; ASTM, 2017; Barcelo *et al*., 2005).

For the case of concrete structures, the crack formation or presence of internal voids and discontinuities might lead to different responses in different locations. For that reason, the use of long-gauge deformation sensors allows a more global and precise understanding of the material/structure under investigation.

In this paper, long-gauge deformation sensors based on low-coherence interferometry in optical fiber sensors are used to investigate the influence of superabsorbent polymers on the autogenous shrinkage of concrete mixtures. The material response due to shrinkage deformation is also evaluated by a more traditional approach, using a demountable mechanical strain gauge (DEMEC).

2 Experimental Program

2.1 Materials and Characterization of the SAP

The experimental program consisted of the shrinkage measurement of concrete specimens with and without SAPs by means of manual measurements with a demountable mechanical strain gauge (DEMEC) and automatic measurements with optical fiber sensors (SOFO).

All tests were performed on concrete mixtures produced with cement type CEM III-B 42.5N – LH/SR (CBR, Belgium); a polycarboxylate superplasticizer (Tixo, 25% conc., BASF, Belgium, at a constant dosage of 1.8 % in relation to the cement mass); sea sand 0/4 (absorption of 0.4% in mass); sea sand 0/3 (absorption of 0.3% in mass); limestone 2/20 (absorption of 0.5% in mass) and a commercial superabsorbent polymer identified as SAP1. More details about the compositions of the concrete mixtures are given in Table 1.

SAP1, made by SNF Floerger (France) is a cross-linked acrylate copolymer produced by bulk polymerization and has a mean particle size (d_{50}) of 360 μm. It has been previously studied as internal curing agent and self-sealing/healing promoter for mortar mixtures (Snoeck, 2015; Tenório Filho *et al*., 2018).

Table 1. Composition of the studied concrete mixtures, values in kg/m^3.

Mixture	Cement	Sand 0/3 - Sand 0/4	Limestone 2/20	Superplasticizer	SAP	Additional water	w/c$_{(total)}$ [-]
REF0.46	356	421 - 343	1086	6.35	0	0	0.46
REF0.57	340	406 – 331	1046	6.12	0	0	0.57
C_SAP1	340	406 – 331	1046	6.12	1.70	37.42	0.57

Dry materials were first mixed for 1 min (including SAPs, when present), then the mixing water and superplasticizer were added and mixed for an additional 2 min. When SAPs were present, the additional entrained water was added during the third minute and the mixing proceeded for an additional 2 min. The total mixing time was 3 min for the reference mixture and 5 min for the SAP-containing mixtures. Prior to the concrete mixing and testing, the superabsorbent polymers were tested to assess their absorption capacity. The filtration method was performed in compliance with Snoeck *et al*. (2018). The SAPs were tested in demineralized water and in a cement filtrate solution prepared with the same cement used to produce the concrete mixtures. The cement filtrate was produced with cement and demineralized water at a proportion of 1:5 in mass.

The absorption capacity was also studied in cement pastes and concrete mixtures by means of slump tests. The measurements were performed exactly 10 min after the first contact of the SAPs with the mixing water.

2.2 Shrinkage Measurement

For the measurements with the DEMEC, for each mixture, four prismatic specimens (100 mm x 100 mm x 400 mm) were cast and cured for 23 h in a room with controlled atmosphere of 20 ± 2 °C and RH > 95%. Right after casting, the free surface of the specimens was covered with a layer of plastic foil, attached to the mold with a thin layer of vaseline to improve the adhesion and prevent drying.

After the curing period, the demolded specimens were wrapped with aluminum tape to avoid moisture exchange with the environment, in this way, reducing the effects of drying shrinkage. Two measuring points were glued to the surfaces of the specimens (except for the troweled surface due to the fact of shape irregularities that could hinder the measurements), placed 200 mm apart on the central line of the specimens' surface. In total, each specimen had three measuring surfaces. The measurements were performed once per day for 28 days and started 24 h after the first contact of cement with the mixing water. The test was conducted in a room with a controlled atmosphere of 20 ± 2 °C and 60 ± 5% RH.

For the measurements with the SOFO sensors, given the availability and the costs, only REF0.46 and the SAP-containing mixture were tested. The sensors used were produced by SMARTEC (Switzerland). The sensors consist of an active part, that measures the deformation, and a passive part, which transmits the data to a reading unit (Figure 1). The sensors used in

this investigation had an active length of 250 mm and a passive length of 10 m.

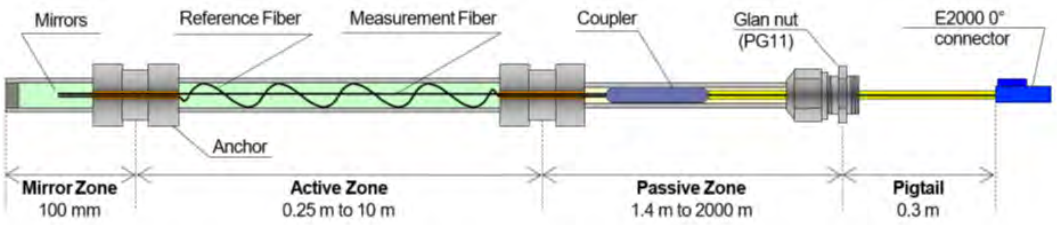

Figure 1. Illustration of the sensor. Courtesy of SMARTEC.

The specimens used for the measurements with the sensors had the same dimensions as the ones used with the DEMEC device (100 mm x 100 mm x 400 mm). The sensors were embedded in the concrete, attached to a steel rebar with a diameter of Ø 6 mm and length of 440 mm, placed at the middle height of the mold in order to ensure a correct position of the sensors. After casting and during the test, the specimens were covered with plastic foil to prevent drying. The specimens were cured for 23 h in a room with controlled atmosphere of 20 ± 2 °C and RH > 95%.

The measurements were performed automatically, every 10 min for 28 days, starting 30 min after concrete mixing. The tests were performed in a room with a controlled atmosphere of 20 ± 2 °C and 60 ± 5% RH. The values of strain were zeroed at the fluid-solid transition point. The transition point was determined considering the moment where the rate of autogenous strain became zero (Tenório Filho *et al*., 2019), corresponding to the knee point in measuring autogenous shrinkage.

3 Results and Discussion

Figure 2 shows the water uptake (g of water/g of SAP) of the SAPs in demineralized water, cement filtrate solution, and concrete.

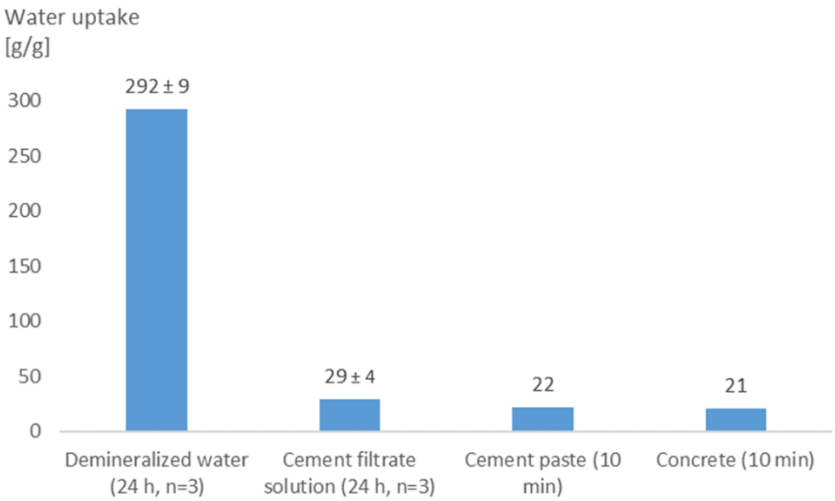

Figure 2. Water uptake [g/g SAP] of the SAP in demineralized water, cement filtrate solution, cement paste and concrete.

The absorption capacity is noticed to decrease from demineralized water to cementitious fluids, which was already expected due to presence of monovalent and divalent ions (i.e. Na^+, K^+, Ca^{2+}) in the cement filtrate, cement paste and concrete (Kang *et al*., 2017; Kang *et al*., 2018). The results with the cement paste show that such method can be used as a suitable estimation for the absorption capacity of the SAPs in concrete.

Figure 3 shows the shrinkage strain measured with the DEMEC for the mixtures REF0.46, REF0.57 and C_SAP1. The reference mixtures shows both only shrinkage during the whole time of tests and the strain values are comparable to those found in literature for concrete mixtures with similar composition and the same type of cement (Lura *et al*., 2001). On the other hand, the SAP-containing mixture show a complete mitigation of the shrinkage strain during the 28 days.

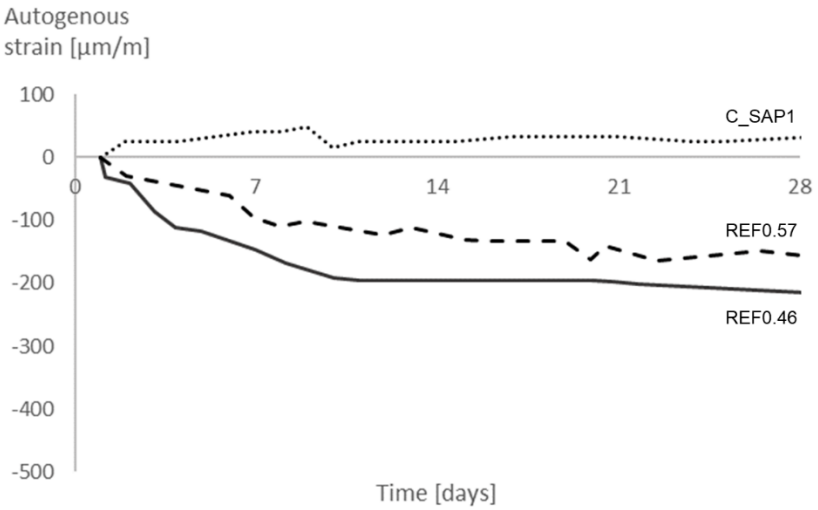

Figure 3. Autogenous strain of concrete specimens measured with DEMEC. Measurements started 24 h after mixing. The lines represent the average values for two specimens with three measurements per specimen. The maximum standard deviation found was ± 50 µm.

When comparing the mixtures REF0.57 and C_SAP1, even though they were produced with the same water-to-cement ratio (0.57), the mixture REF0.57 is not able to mitigate the shrinkage strain (but only to reduce it in comparison with the mixture REF0.46).

In such mixture, the total water content is available for being used in the hydration from the beginning, which might increase the effects of the chemical shrinkage. With the use of SAPs, part of this water is stored inside the polymer particles being released at the appropriate time to mitigate the autogenous shrinkage. In this way, the used SAPs can be considered very efficient to be used as internal curing agent, completely mitigating the autogenous shrinkage and preventing the formation of early-age cracks (which was also verified with the use of the SOFO sensors).

Figure 4 shows the autogenous strain measured with the SOFO sensors for the mixtures REF0.46 and C_SAP1. As also observed in Figure 3, the SAP-containing mixture shows a complete mitigation of shrinkage while the reference mixture (REF0.46) only shows shrinkage. Another interesting feature noticed is the existence of some “jumps” in the graph that are only

observed for the reference mixture. These "jumps" are assumed to be indications of crack-formation.

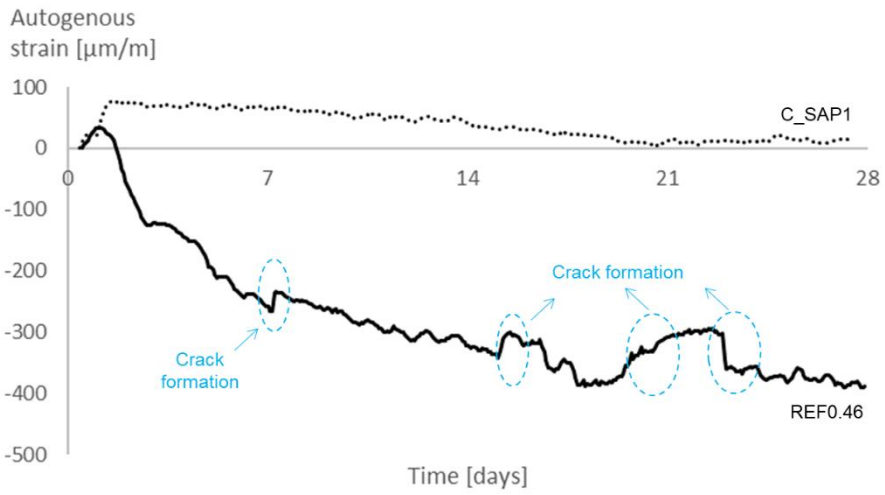

Figure 4. Autogenous strain of concrete specimens measured with SOFO sensors. Measurements zeroed at the fluid-solid transition point for each mixture. Crack formation is also indicated.

To verify whether the samples possessed internal micro-cracking, after the 28 days of measurements, the specimens were cut and investigated by means of an optical microscopy. This analysis confirmed the existence of small cracks (up to 50 µm) in the reference mixture along the length of the sensor (Figure 5). The same cracks were not observed in the mixture C_SAP1. Also, no debonding was noticed between the sensors and the cement matrix.

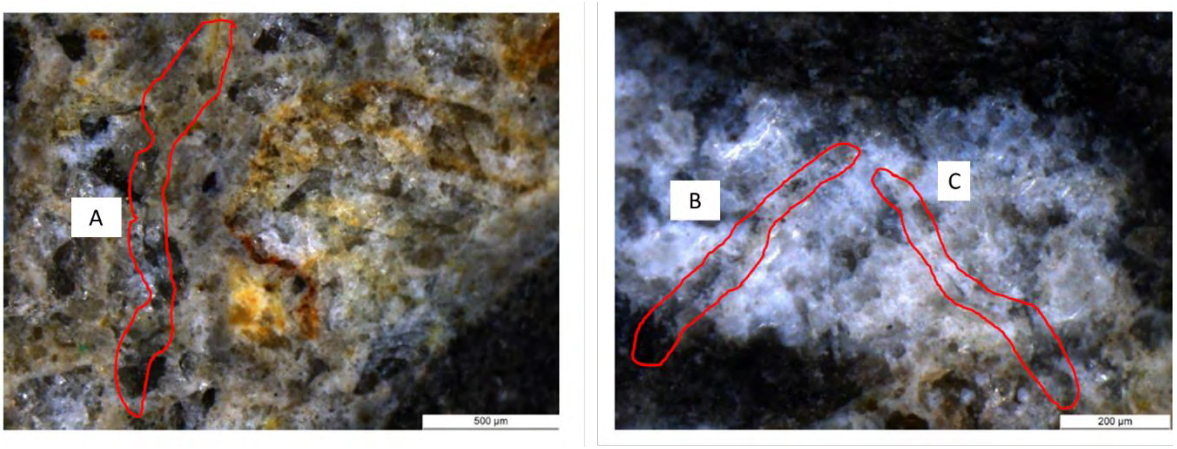

Figure 5. Micro-cracks identified in the cement matrix in the surroundings of the sensor.

4 Conclusions

- The SAP-containing mixture was able to show a significant reduction in the shrinkage strain in comparison to the reference mixtures with and without additional water, fully mitigating the autogenous shrinkage;
- Both the DEMEC and the SOFO sensors efficiently captured the effect of the SAPs in

comparison to the reference mixture, but the absolute values of strain are different. This was the case especially for the reference mixture, as a consequence of the different coverages used to avoid drying;
- The optical fiber sensors were able to provide an indication for the moment of crack formation without the need of additional tests or indirect measurements;
- While they might represent a costly investment, in comparison with other techniques, the use of the embedded sensors brings more advantages, higher level of precision and reduced person-hours in the monitoring of shrinkage deformation in the concrete, which can be even more valuable when considering the monitoring of larger scale specimens and structures.

Abstract. *Many environments to which concrete is exposed are highly aggressive due to various chemical components. In such environments, concrete is subjected to processes of chemical degradation, among which carbonation is one of the most frequently seen degradation processes. Though, the influence of saturation degree (or relative humidity - RH) of the specimen and CO_2 concentration on the carbonation of cementitious materials is still not comprehensively described with respect to carbonation rate/degree as well as alteration in microstructure and mineralogy. This work aims at thoroughly investigating how these two key parameters affect the carbonation under accelerated conditions. Furthermore, the effect of initial moisture state of the specimen on the carbonation rate is also demonstrated. For such purpose, a numerical model at continuum scale is developed to investigate the effects of RH and CO_2 concentration on the carbonation depth, phase changes in phases and porosity of hardened cement pastes due to carbonation under accelerated conditions. Verification with experimental results from accelerated carbonation tests shows a good agreement. The modelling results with supporting experimental data help to better understand the modification of material properties under different carbonation conditions and to optimize the carbonation conditions.*

Keywords: *Carbonation, CO_2 Concentration, Microstructure, Cement Paste, Relative Humidity.*

1 Introduction

The carbonation process in cement-based materials is typically considered as a deterioration phenomenon because it results in a pH decrease, which accelerates the corrosion of reinforcing bars in concrete. On the other hand, carbonation also results in beneficial effects including decreases in transport properties and refines the pore structure of cement-based materials (Phung *et al.*, 2015; Phung *et al.*, 2016b). The extent of modification in transport properties and microstructure significantly depends on carbonation conditions (*e.g.* CO_2 concentration, relative humidity) and cement types (*e.g.* OPC or blended systems). The reduction of transport properties is the result of the precipitation of carbonation products in the pore structure, which leads to a significant reduction of the total porosity (Phung, 2015).

A number of models have been proposed based on Fick's law for diffusion with an analytical relation between the carbonation depth and square root of time. Instead of giving an explicit formula to predict the carbonation depth, a large number of models have been developed in order to solve the carbonation problem numerically (Bary *et al.*, 2004; Muntean *et al.*, 2011). These approaches are based on conservation laws with a complex form to capture the most important factors (including other transport rather than diffusion and time-dependent variables, *e.g.* porosity) influencing the carbonation process. However, identification of parameters for complex models may require several experiments and is not an easy task, for example to parameterize a constitutive relation between relative humidity, porosity changes and diffusivity

of CO_2 during carbonation. In a previous study (Phung *et al.*, 2016a), the authors have successfully developed a comprehensive 1-D reactive transport model accounting for both advective and diffusive transports under an applied CO_2 pressure gradients. The model enables to predict carbonation depth and changes in permeability, diffusivity, and porosity due to carbonation. In this study, a reduced form of the previous model with only diffusive transport is used in order to investigate the key parameters (*e.g.* RH, CO_2 concentration, w/c ratios), which are applied in conventional accelerated carbonation experiments. In such a common way, the samples are put in a controlled chamber at a wide range of CO_2 concentrations (*e.g.* 0.1% to 10%) and an optimized relative humidity (50-70%) to speed up carbonation. Results from such accelerated carbonation data are scattered and sometimes contrary due to wide ranges of carbonation conditions. Moreover, the moisture content of the tested samples is not always similar or even different from the surrounding environment in accelerated carbonation chamber. This leads to a big uncertainty despite of the same carbonation conditions. The above issues are intensively discussed in this work by numerical simulation in combination with preliminary validation with experimental data.

2 Model Development

The proposed model is based on a macroscopic mass balance for CO_2 in gaseous and aqueous phases. The model only considers the carbonation of portlandite and C-S-H, which are the main hydrated phases in CEM I ordinary Portland cement (OPC) paste. Continuous hydration of the samples during carbonation is not taken into account as the experiments were conducted on 28-day-old samples and the time for carbonation was quite limited.

2.1 Mass Conservation of CO_2

2.1.1 Transport of CO_2

The total concentration of CO_2 in the porous media is the sum of the amounts of CO_2 in the gaseous and aqueous phases:

$$c = \phi(1-S)c_g + \phi S c_l \tag{1}$$

where ϕ is porosity; S is water saturation degree; c_g and c_l are the concentrations of gaseous and dissolved carbon dioxide, respectively, which can be related by using Henry law and Clapeyron equation,

$$c_g = c_l K_H / RT \tag{2}$$

where and K_H denotes the Henry constant; R is universal gas constant; T is absolute temperature. The total flux of CO_2 includes both the CO_2 fluxes in the gaseous and aqueous phase, expressed as:

$$J = D_g \frac{\partial c_g}{\partial x} + D_l \frac{\partial c_l}{\partial x} = \left(\frac{K_H}{RT} D_g + D_l \right) \frac{\partial c_l}{\partial x} \tag{3}$$

where D_g and D_l are effective diffusion coefficients of gaseous and aqueous phase, respectively. In porous media, the effective diffusion coefficient depends on the pore structure (Phung *et al.*, 2019a). For the effective diffusion coefficient D_l of dissolved CO_2, we account for the changes in porosity, tortuosity, carbonation degree ($k_{Dl}^*(\phi,\tau)$) and saturation degree ($k_{Dl}(S)$) during carbonation followed as (Phung *et al.*, 2016a):

$$D_l = D_{l0} \times k_{Dl}^*(\phi,\tau) \times k_{Dl}(S) \tag{4}$$

For CO_2 diffusion in the gaseous phase, a similar approach as in the aqueous phase is adopted. However, Knudsen diffusion is taken into account through the factor k_{Knu} because carbonation shifts the pore size distribution towards smaller pores (Phung *et al.*, 2015) which results in a smaller effective diffusivity for carbonated material.

$$D_g = D_{g0} \times k_{Dg}^{*}(\phi,\tau) \times k_{Dg}(S) \times k_{Knu} \tag{5}$$

Details of these models for the diffusivity can be found in (Phung *et al.*, 2016a).

2.1.2 Evolution of porosity during carbonation

The change in porosity is obtained from the change in solid phases by carbonation of portlandite and C-S-H.

$Ca(OH)_2 + CO_2 = CaCO_3 + H_2O$

$$\Delta\phi_{CH} = \left[\left(C_{CH0} - C_{CH}\right)/M_{CH}\right]\left(V_{CH} - V_{CC}\right) \tag{6}$$

$y_0CaO{\bullet}SiO_2{\bullet}z_0H_2O + (y_0\text{-}y)CO_2 = yCaO{\bullet}SiO_2{\bullet}zH_2O + (y_0\text{-}y)CaCO_3 + (z_0\text{-}z)H_2O$

$$\Delta\phi_{CSH} = C_{CSH0}/M_{CSH0}\left[\left(y_0 - y\right)V_{CC} - \left(V_{CSH0} - V_{CSH}\right)\right] \tag{7}$$

where $\Delta\phi_{CH}$ and $\Delta\phi_{CSH}$ are porosity changes [-] due to portlandite and C-S-H carbonation, respectively; y and z are the average Ca/Si ratio and stoichiometric ratio of H_2O in C-S-H, respectively; C_{CH} and C_{CSH} are portlandite and C-S-H contents, respectively; M_{CH} and M_{CSH0} are molar masses of portlandite and C-S-H, respectively; V_{CH}, V_{CC} and V_{CSH} are molar volumes of portlandite, calcite and C-S-H, respectively. Subscript 0 denotes the initial condition. The molar volumes of portlandite and calcite are well defined in literature. However, data for molar volume of C-S-H are scarce and it is a stoichiometry-dependent parameter. An experimental study (Morandeau *et al.*, 2014) showed that the molar volume of C-S-H is proportional to the Ca/Si ratio as:

$$V_{CSH0} - V_{CSH} = \omega\left(1 - y/y_0\right) \tag{8}$$

where $0.02 < \omega < 0.04$ [l/mol]. The total porosity of sample during carbonation is expressed as follows:

$$\phi = \phi_0 + \Delta\phi_{CH} + \Delta\phi_{CSH} \tag{9}$$

where ϕ_0 is initial total porosity. The change in capillary porosity is mainly due to the carbonation of portlandite as majority of portlandite particles are located near the capillary pores (Phung *et al.*, 2015). However, C-S-H carbonation might partially contribute to the capillary porosity change, especially under accelerated conditions. The partial contribution of C-S-H carbonation to capillary porosity is captured by a coefficient υ ($0 \le \upsilon \le 1$) as:

$$\phi_c = \phi_{c0} + \Delta\phi_{CH} + \upsilon\Delta\phi_{CSH} \tag{10}$$

where ϕ_{c0} is initial capillary porosity. The value of υ is set to be 0.5 for OPC cement paste which gives a good fit with capillary porosity change determined by MIP (Phung *et al.*, 2016a).

2.1.3 Carbonation reaction

Instead of separately modelling the carbonation reactions of CH and C-S-H, we combine both reactions as in a single reaction between Ca^{2+} (dissolved from CH and C-S-H) and CO_3^{2-} ions:

$$Ca^{2+}{}_{(total)} + CO_3^{2-} \rightarrow CaCO_3 \tag{11}$$

We consider that the reaction (11) is of the first order with respect to Ca^{2+} and CO_3^{2-} concentration. The rate of the combined carbonation reaction, r, is written as:

$$r = k_C f(S) k_r \frac{C_{Ca}}{M_{Ca}} \frac{C_{CO_3}}{M_{CO_3}} \tag{12}$$

where k_C is the temperature-dependent reaction rate coefficient, M_{Ca} and M_{CO3} are molar masses of Ca^{2+} and CO_3^{2-}, respectively. The factor *f(S)* corrects the kinetic carbonation reaction rate coefficient for the effect of water saturation degree. Following the approach of (Papadakis *et al.*, 1991),

$$f(S) = S^n \tag{13}$$

where the parameter *n* is suggested to be 3.7. The carbonation products are mainly formed around CH/C-S-H particles. Consequently, the reaction rate will reduce because Ca ion and CO_2 have to diffuse through the product layer. Therefore, a retardation factor is added into Eq. (12) as:

$$k_r = \left(C_{Ca}^s / C_{Ca0}^s \right)^{\Theta} \tag{14}$$

where C_{Ca}^s is total concentration of solid Ca except for Ca in calcium carbonate, subscript 0 denotes the initial concentration; Θ is exponential factor which is suggested to be 2 for OPC cement paste (Phung *et al.*, 2016a).

The mass balance of dissolved CO_2 is written as:

$$\frac{\partial \left(\left[\phi(1-S) \frac{K_{CO_2}^H}{RT} + \phi S \right] c_l \right)}{\partial t} - \frac{\partial \left(\left[\frac{K_{CO_2}^H}{RT} D_g + D_l \right] \frac{\partial c_l}{\partial x} \right)}{\partial x} = -f(S) \phi k_C k_r \frac{C_{Ca}}{M_{Ca}} \frac{C_{CO_3}}{M_{CO_3}} M_{CO_2} \tag{15}$$

The partial differential Eq. (15) describes the one-dimensional reaction-transport phenomenon in cement-based materials and is solved numerically using the COMSOL Multiphysics® FEM based simulation tool.

2.2 Mass Conservation of Calcium

Following the same approach for CO_2, the mass balance equation for total dissolved Ca is given as:

$$\frac{\partial \left(\phi S C_{Ca} \right)}{\partial t} - \frac{\partial \left(D_{Ca} \frac{\partial C_{Ca}}{\partial x} \right)}{\partial x} = -\phi r \frac{M_{Ca}}{M_{CO_2}} + r_d \tag{16}$$

where D_{Ca} is the effective diffusivity of calcium ion; r_d is the dissolution rate of CH and C-S-H [kg/m^3.s] which is calculated from the mass balance equation of total amount of Ca in CH and C-S-H as follows:

$$\frac{\partial C_{Ca}^s}{\partial t} M_{Ca} = -r_d \tag{17}$$

Note that in Eq. (17) the release rate of Ca due to hydration is neglected. The solid-liquid equilibrium curve of Ca based on the experimental data collected by (Berner, 1992) is used to establish a relation between the aqueous and solid calcium concentration which is expressed as an mathematical form based on a discretization of the decalcification of CH and C–S–H (Phung *et al.*, 2016a). The Ca fraction in CH and C-S-H can be estimated from the hydration of minerals (C_2S, C_3S) in cement which can be estimated by the Bouge calculation.

2.3 Mass Conservation of Moisture

2.3.1 Liquid water transport

The mass balance equation for liquid water (excluding bound water) is given as:

$$\frac{\partial(\phi S \gamma_l)}{\partial t} = -\mu_E - \mu_R \tag{18}$$

where μ_E is the vapour-liquid water exchange rate; and μ_R is the released water rate due to carbonation. The amount of water released is derived from the carbonation reactions Eqs. (6) and (7), for CH and C-S-H, respectively. For CH, there is a 1-1 relation between Ca consumption and water release. However, for C-S-H carbonation, y mol of Ca in C-S-H will release z mol H_2O. The stoichiometry values of y and z are only slightly different (Allen *et al.*, 2007). Therefore, we assume that ratio $y/z = 1$. With this assumption, it is possible to calculate the amount of released water rate based on the change of total Ca in solid phase.

$$\mu_R = \frac{\partial\left(\left(C_{Ca}^{s} - C_{Ca}^{s0}\right) M_w\right)}{\partial t} \tag{19}$$

where M_W is molar weight of water, C_{Ca}^{s0} is initial Ca content in the solid phases.

2.3.2 Vapour transport

Vapour is transported due to diffusion. The mass balance equation for vapour is given as:

$$\frac{\partial(\phi c_v (1-S))}{\partial t} + \frac{\partial\left(\phi(1-S) D_v \frac{\partial c_v}{\partial x}\right)}{\partial x} = \mu_E \tag{20}$$

where c_v is the concentration of vapour which is calculated as

$$c_v = P_v M_w / RT \tag{21}$$

where P_v is the partial pressure of vapour which is depended on relative humidity,

$$P_v = RH \times P_{vs} \tag{22}$$

where P_{vs} is the average saturation pressure of vapour; D_v is the diffusivity of vapour.

3 Description of Carbonation Experiments

Accelerated carbonation experiments were performed on cement pastes at three w/c ratios of 0.4, 0.5 and 0.6. Type I ordinary Portland cement (CEM I 52.5 N) was used. The chemical and physical properties of the cement can be found in (Phung *et al.*, 2019b). Cement pastes were cast in a cylindrical tube with an inner diameter of 98 mm and cured in sealed conditions. After 28 days of curing, the samples were cut into small disks of 25 mm thick by a diamond saw. Prior to the carbonation experiment, the samples were conditioned to different target internal relative humidity of 55%, 65% and 75% in a climate chamber. Note that sample conditioning is an essential step that would significantly affect the carbonation results as shown later in section 4.4. In our case the samples is ensure to reach the targeted RH when the mass of sample is stable. The accelerated carbonation tests were performed in 28 days at constant temperature of 20°C. Two CO_2 concentrations of 0.3% and 1% and three RH of 55%, 65% and 75% were investigated. Details of the setup and experimental procedure were described in (Varzina *et al.*, In preparation).

After carbonation, a number of post-analysis methods were used to quantitatively and qualitatively analyse the carbonated samples. The carbonated sample was sawn and sprayed by phenolphthalein solution to determine the phenolphthalein carbonation depth (Phung *et al.*, 2015). Portlandite and calcium carbonate profiles of a carbonated sample were quantified by thermo-gravimetric analysis (TGA) of the dust collected at different depths. A hole with a diameter of 10 mm was longitudinally drilled in the carbonated sample. Drilling was halted

every 3 mm to collect the dust before continuing drilling. To prevent cross contamination, the hole was carefully cleaned by compressed air before continuing drilling. TGA was performed in a NETZSCH STA 449F3 thermal analyzer. A weighed sample, usually between 30 and 40 mg was heated from room temperature to 1100°C with a heating rate of 10°C per minute under a constant nitrogen flow rate of 120 ml/min.

Mercury intrusion porosimetry (MIP) provided information on how pore structure changes during carbonation. MIP experiments were performed in a PASCAL 140/440 porosimeter in which the mercury pressure was continuously increased up to a maximum pressure of 200 MPa. The samples were taken from the reactive surface up to 3 mm in depth and referred as "carbonated samples". Furthermore, the mass of samples were followed as a function of carbonation time, which allows calculating the mass gain due to carbonation.

4 Results and Validation

4.1 Carbonation Degree

The term "carbonation depth" is typically determined by a phenolphthalein indicator. However, it is not easy to mathematically define the carbonation depth. In this study, we relate the carbonation depth to total concentration of Ca in the solid phases (C_{Ca}^{s}). In such way, carbonation depth is linked to a maximum depth at which portlandite (CH) is completely carbonated, and referred as carbonation degree of 1. The carbonation degree, d_c, is then formulated as:

$$d_c = \begin{cases} 1 & CH < 0 \\ \dfrac{C_{Ca}^{s0} - C_{Ca}^{s}}{C_{Ca}^{CH}} & CH \geq 0 \end{cases} \tag{23}$$

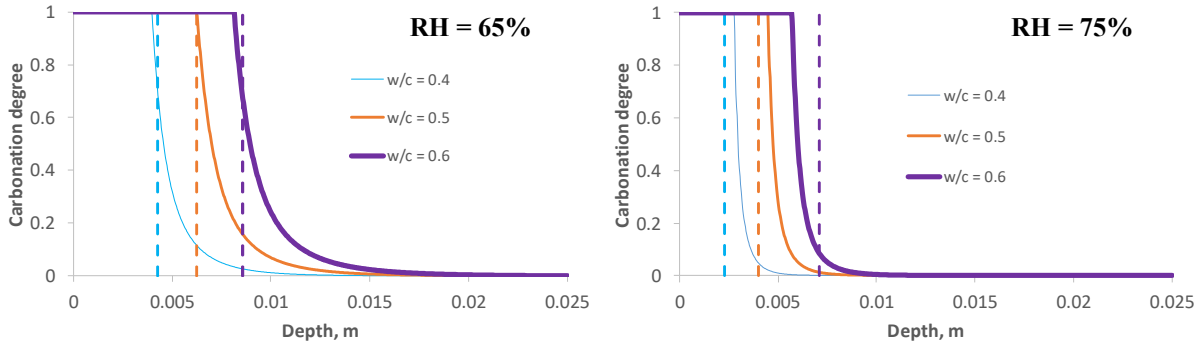

Figure 1. Carbonation degree of samples carbonated at RH of 65% and 75%, CO_2 concentration of 1% - dashed lines mark the carbonation depths determined by phenolphthalein spraying.

The carbonation degree of samples with different w/c ratios carbonated with CO_2 concentration of 1% at RH at 65% and 75% is shown in Figure 1. It is clearly seen that the higher w/c ratios, the larger carbonation degree. A higher RH results in a lower carbonation degree. Interestingly, the transition zone (*i.e.* d_c<1) is wider for carbonation at lower RH, meaning a sharp carbonation front might not be observed in this case. This is explained by a faster diffusion of CO_2 under lower RH condition. Comparing with carbonation depth determined by phenolphthalein indicator, the carbonation degree agrees very well with the phenolphthalein front (i.e. the front is corresponded to carbonation degree of 1) for 65% RH. Results at higher RH is in less agreement, especially for the sample with w/c ratio of 0.6.

4.2 Mass Gain

In this study, the sample mass gain is considered as the sum of CO_2 uptake and change in moisture content of carbonated sample. We can easily calculate the total CO_2 uptake due to the carbonation reactions of portlandite and C-S-H. Considering Eq. (11), the number of moles of solid Ca consumed equals the number of moles of CO_2 uptake. The moisture content change is related to the differences in saturation degree (mass change due to different RH is negligible). Therefore, the mass gain (normalized to initial sample mass) due to carbonation can be expressed as:

$$Mass = 100\% \int_0^L \left\{ \left[\left(C_{Ca}^{s0} - C_{Ca}^{s} \right) + \left(C_{Ca}^{0}\phi_0 - C_{Ca}\phi \right) \right] M_{CO_2} + \left(S\phi - S_0\phi_0 \right) \rho_w \right\} A / m_{sam} dx \qquad (24)$$

where A and m_{sam} are the cross section and initial mass of the sample, respectively.

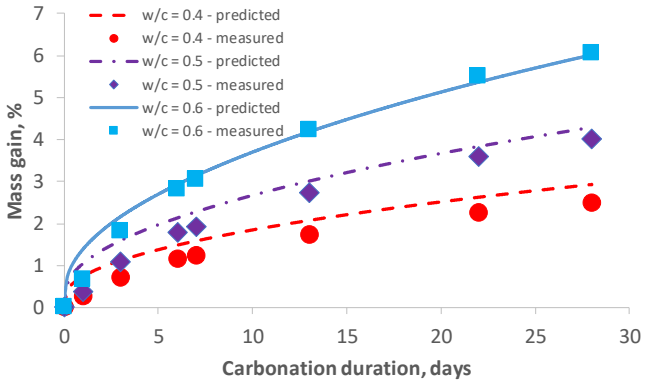

Figure 2. Mass gain of samples carbonated at RH of 65% and CO_2 concentration of 1%.

As expected, higher w/c ratio results in higher mass gain as seen in Figure 2. The predicted results agree very well with the measured data. Note that the mass gain is not equal to the CO_2 uptake because of the moisture content exchange of the samples with surrounding environment during carbonation, which is well captured in the model.

4.3 Effect of Carbonation Conditions

4.3.1 Relative humidity

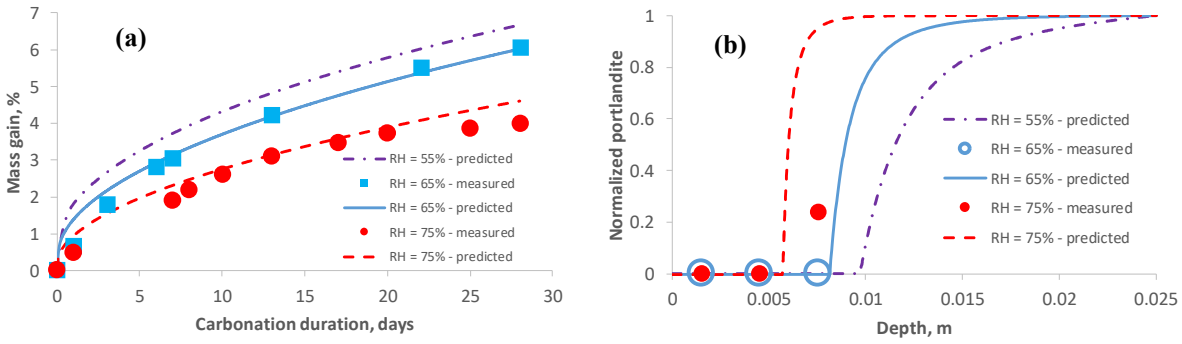

Figure 3. Effects of RH on mass gain (a) and change in portlandite content after 28 days of carbonation (b) – measured data for RH = 55% is not yet available.

Typically, a wide range of RH is used in accelerated carbonation experiments. The European standard EN 12395 even allows the tests performing with RH = 60%±10%. We therefore simulate the carbonation under various RH of 55%, 65% and 75%. Results show that the carbonation rate is significantly depended on the RH of the surrounding environment. The lower

RH, the higher mass gain and percentage of carbonated portlandite (Figure 3). The mass gain is increased 30% if RH decreases from 75% to 55%. Similarly, the depth of complete portlandite carbonation increases from 6 mm to 10 mm with a decrease of RH from 75% to 55%.

As a consequence, the drop in capillary porosity due to carbonation is more visible for lower RH as shown in Figure 4. The effects of RH is much clearer in case of higher w/c ratio.

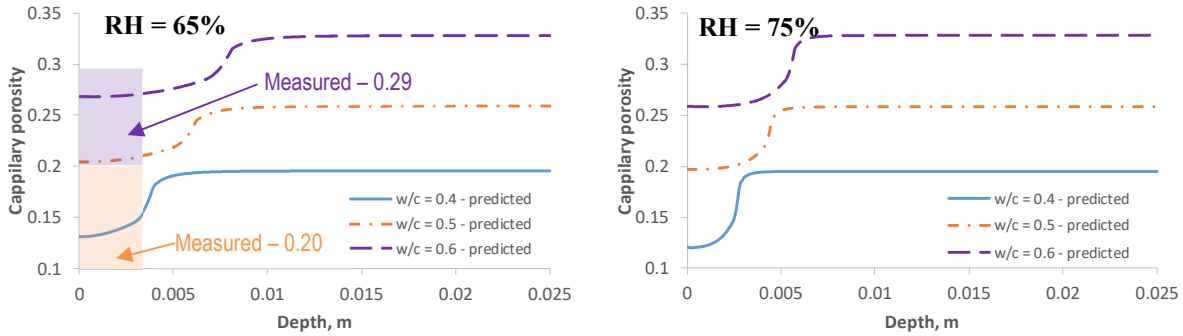

Figure 4. Effects of RH on capillary porosity decrease due to carbonation at 1% CO_2 concentration.

4.3.2 CO_2 concentration

The CO_2 concentration significantly influences the carbonation in terms of mass gain. Increasing CO_2 concentration from 0.3% to 3% triples the mass gain as seen in Figure 5a. This is a consequence of a higher amount of portlandite carbonation as shown in Figure 5b. The C/S ratio of C-S-H is also significantly reduced in the portlandite depletion zone, which is in agreement with thermodynamic modelling results showing that initially no C-S-H should decalcify. However, this sometimes does not comply with experimental findings, e.g. (Auroy *et al.*, 2018; Phung *et al.*, 2015) which showed evidences that carbonation of portlandite and other hydrated phases may occur simultaneously. In case of highest CO_2 concentration, the C/S ratio can be lower than 0.4 near the reactive surface. Interestingly, C-S-H is carbonated with the highest extent not at the reactive surface, but around 3 mm far away the reactive surface indicating that the optimal carbonation conditions (*i.e.* reaction rate, available CO_2 and Ca) occur a bit far away from the reactive surface if higher CO_2 concentration is applied.

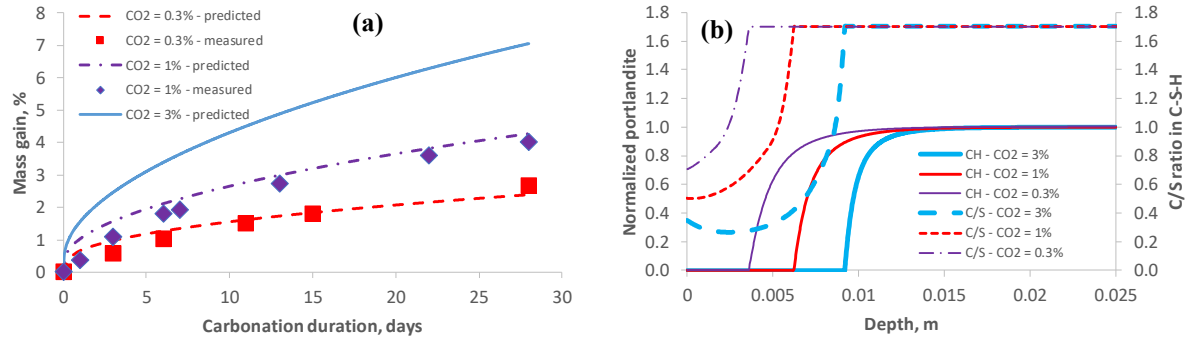

Figure 5. Effects of CO_2 concentration on mass gain (a) and changes in portlandite content and C/S ratio of C-S-H after 28 day carbonation (b) - samples with the same w/c ratio of 0.5 and carbonated under 65% RH, measured mass gain for case CO_2 = 3% is not yet available.

4.4 Effect of Sample Preparation – Initial Relative Humidity

In practice, the samples are not always well-conditioned to reach the targeted RH humidity in the carbonation chamber. The conditioning process could take few weeks to months (depended on sample size and w/c ratio) to bring the initial moisture state (RH>95%) to the optimal

carbonation RH of around 65%. If the initial RH of samples differs from the RH of carbonation chamber, the results can be significantly scattered. Figure 6 illustrates such uncertainty by investigating 3 initial RH levels of 65%, 80% and 85%. All samples with w/c ratio of 0.5 are carbonated under the same conditions with RH of 65% and CO_2 concentration of 1% at 20°C. It is clearly seen that higher initial RHs significantly reduce the carbonation degree. This is because the internal RH and saturation of these samples are much higher than the one with initial RH of 65% (Figure 6b), resulting in much slower transport of CO_2 into the samples. It is interesting to observe that a maximum RH is obtained at the depth where carbonation degree starts decreasing. This is explained by the accumulation of water released by carbonation, which does not have enough time to transport to the surrounding environment. The slower transport of CO_2 in samples with higher initial RH also induces higher C-S-H carbonation resulting in lower C/S ratio as seen in Figure 6a.

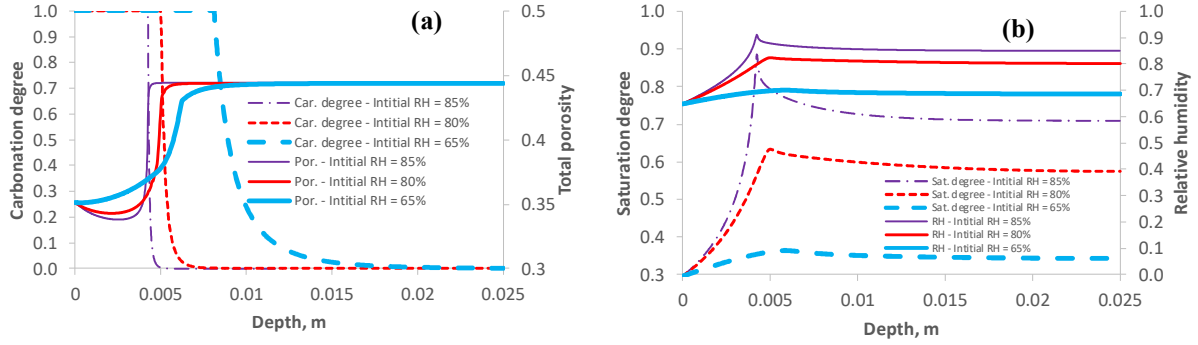

Figure 6. Effects of initial RH of samples on carbonation degree and total porosity alteration (a) and saturation degree and internal RH of carbonated samples (b).

5 Conclusions

A one-dimensional reactive transport model coupling moisture – CO_2 – Ca transport, which is adapted from a previous work (Phung *et al.*, 2016a), is implemented to investigate the effects of RH and CO_2 concentration and initial moisture state of the samples on the carbonation degree, phase changes and porosity of hardened cement pastes due to carbonation under accelerated conditions. The model enables to predict the carbonation degree, mass gain, portlandite content, C/S ratio and porosity change over time and space. A parametric study confirms that two key parameters, i.e. CO_2 concentration and RH, play an important role in accelerated carbonation of cement pastes. Variation of these parameters in a common testing range could significantly change the carbonation degree; however, their effects also depend on the microstructure of the samples which is controlled by the w/c ratios. The higher the w/c ratios, the larger the contribution of RH and CO_2 concentration. The model helps to better interpret the experimental observations and highlights underlying phenomena such as the formation of a gradual carbonation front due to carbonation of both portlandite and C-S-H or changes in moisture state along the sample depth. Furthermore, the modelling results confirm the vital contribution of initial moisture state of the samples to the carbonation process and estimated carbonation rate. Poor sample conditioning (i.e. too short time to lower the initial RH after curing to targeted testing RH) could dramatically reduce the carbonation efficiency.

Preliminary verification of the modelling results with accelerated carbonation experiment gives a good agreement even though more experimental data is still required to validate and improve the model, especially to better capture changes in transport properties due to carbonation.

***Abstract**: The use of light steel frame and wood frame in Brazil is still recent, hence there is little information about the durability of these technologies applied in Brazilian climate conditions. The wood-based boards are used as a part of the light steel or wood frame walls and are designed to contribute to the wall structural behavior (horizontal reinforcement and resistance to suspended loads). Once the information if such boards meet the DL (design life) set in the Brazilian code of residential building performance is still unknown, this paper analyses the technical characteristics of two wood-based boards - OSB and marine plywood - aiming to gather more information concerning durability under liquid water action. Thus, tests were carried out on samples of these two boards to evaluate their behavior against liquid water and after accelerated ageing test. In all cases, OSB showed to be more sensitive to early degradation than plywood.*

***Keywords**: OSB, Marine Plywood, Durability, Light Steel Frame.*

1 Introduction

The use of light steel frame and wood frame in Brazil is still recent. The first researches and publications were conducted in the last decade (Crasto, 2005; Milan, Novello, and Dos Reis, 2011; Oliveira and Mitidieri Filho, 2011; SiNAT, 2016), because of that there is little information about the durability of these technologies applied in Brazilian climate conditions, which can be around 23°C and 76% of relative humidity (RH) in the South East, with an monthly average solar radiation between 16 and 24 MJ/m^2.day (Tiba, 2000).

Wood-based boards are used as a part of the light steel frame or light wood frame walls. Mostly, the outer part of these external walls is formed by four layers (from exterior to interior): basecoat (mortar-based layer around 6mm thick), cementitious board, weather resistive barrier (sheathing membrane) and wood-based board (OSB or marine[1] plywood), the last one improving the wall structural behavior (Campos, 2014; Rego, 2012). The basecoat is directly

[1] In Brazil there is no standard setting the minimum requirements for plywood; however, there are two main types of plywood in the market: one used for making wood-based products, like cabinets (simply called "plywood") and another one, known as "marine plywood", used in situations where the presence of liquid water and high levels of relative humidity are rather frequent, like in boat hulls; hence the designation "marine" before the word plywood. According to APA (www.apawood.org), a product like that could receive the classification "APA marine". The boards used in this paper were supplied by a big manufacturer in Brazil.

adhered to the cementitious board, which is fastened (screws) to the OSB with the sheathing membrane in between. Also, in Brazil is quite common to have a wood-based board (usually OSB) at the inner side of the wall right behind the gypsum board as a way of improving the wall resistance to suspended loads; since shelves, frames and other loads can be fastened everywhere, whether there is a steel stud or not, a continuous layer is a need.

In terms of durability, the outer board might be directly affected by the wind-driven rain and the inner board by the high level of relative humidity (RH) inside the building. Water vapor movement is a matter of vapor pressure and it normally goes from outside to inside during the summer and from inside to outside during the winter (for cold countries). But the thing is not as "simple" as that, since there is no requirement for airtightness of light steel frame walls in Brazil: penetrations, holes and electrical fixtures are not sealed. Hence, air leakage (exfiltration) might be so high that the use of vapor barriers on the inner part of exterior walls is useless and a waste of money. To sum up with, knowing that keeping windows open is a cultural behavior in Brazil, the RH inside the house is probably close to the RH outside during warm seasons, which means that, basically speaking, RH all around the wall will be like the exterior RH. There might be some exceptions, though, mainly during the winter in southern cities, but in any case, interior air conditions are uncontrolled most of the time. A deeper discussion about this subject is out of the scope of this text, but it can be found elsewhere (Quirouette, 1985; Straube, 2002; Kumaran, 2009; Lstiburek, 2009; NRC, 2015; ABCB, 2016).

According to ABNT NBR 15575 (ABNT, 2013), Brazilian code of residential building performance, the design life (DL) of the main structural elements (steel and wood profiles) and of the other elements whose maintenance is not easy is at least 50 years. Since the wood-based layer contributes to the wall structural behavior and its maintenance is quite laborious, the design life (DL) of it should be equivalent to that of the main structural elements (steel and wood studs).

Once the information if such boards meet this DL in Brazilian climate is still unknown, this paper analyses the technical characteristics of two wood-based boards - OSB and marine plywood - in terms of bending strength, MOE - modulus of elasticity, internal bond, swelling in thickness and dimensional changes, all of them according to European Standards, aiming to get more information concerning durability of these boards when subjected to liquid water action. Thus, tests were carried out on samples of these two boards to evaluate their behavior before and after accelerated ageing tests.

2 Experimental Work

Samples of OSB (11.1 mm thick, OSB/3 (APA, 2017) and marine plywood (12 mm thick) were tested according to EN standards to gather information about density, EN 323 (CEN, 1993a); moisture content, EN 322 (CEN, 1993b); swelling in thickness, EN 317 (DIN, 1993); bending strength and modulus in bending, EN 310 (BSI, 1993a); internal bond, EN 319 (BSI, 1993b); dimensional changes, EN 318 (BSI, 2002a) and moisture resistance, EN 321 (BSI, 2002b).

EN standards were used because there is no Brazilian standard about the subject; in addition, regardless of having their own specific standards, samples of plywood were also tested according to OSB standards so that mechanical properties can be compared under the same conditions.

Such mechanical properties were measured for both axis: major strength (L = longitudinal)

and minor strength (T = transversal) using a universal testing machine (EMIC DL 10000). To determine the properties related to dimensional changes, a climatic chamber (model Thermotron 2800 programable controller) was used.

For each panel type, 10 50x50mm samples were used for internal bond and swelling in thickness; 10 50mm wide samples for bending properties and ageing and 4 (four) 50mm wide samples for dimensional changes. For the sake of simplicity, the terms mass and weight will be used interchangeably in this text.

2.1 Results and Discussion

2.1.1 Properties of the boards

After reaching constant mass at 21ºC and 65% RH, the main properties of the boards were evaluated, and the results can be seen in Table 1.

Table 1. OSB and marine plywood properties (average).

Board type	Density (kg/m^3)	Layers	MC (%)	MOE (N/mm^2)	BS (N/mm^2)
OSB	639.9 ± 24.6	Homogeneous	10.5 ± 0.3	4607 ± 649	32.7 ± 6.4
Plywood	623.9 ± 20.9	Five	10.3 ± 0.4	7039 ± 559	60.3 ± 8.6

MC - moisture content BS - bending strength MOE - modulus of elasticity

2.1.2 Swelling in thickness

The thicknesses and weights of the specimens (50x50mm) were taken seven times during the 24h bath at 20 ± 2ºC so that was possible to see the increasing rate of both (Figure 1).

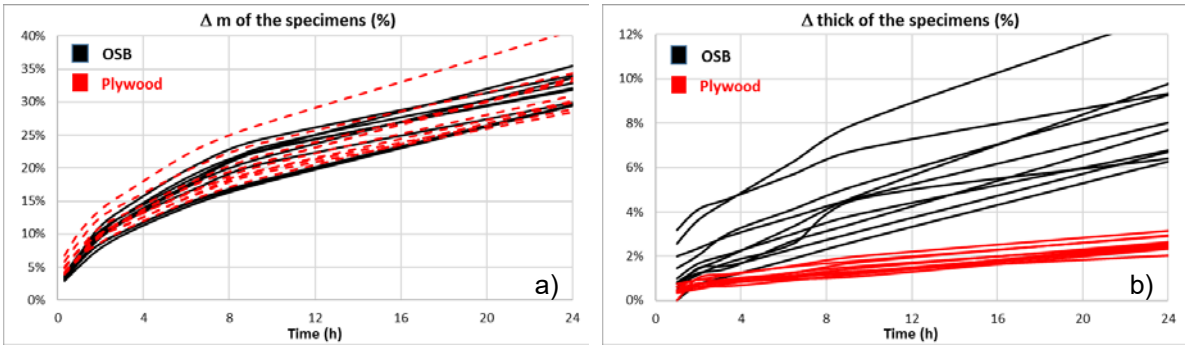

Figure 1. Changes in the a) weights and b) thicknesses of OSB and plywood for the first 24 hours.

In Figure 2 is possible to see the total thickness of all the specimens when put together side by side. It is rather evident the difference between OSB and plywood.

After the first 24h of the soak bath, all the specimens were kept under water for more 24h and, then, remained inside a room at 20 ± 2ºC and uncontrolled RH levels (around 55%) for a drying session. The results are shown in Figure 3 and here it is important to notice that the moisture content is related to the initial weight of the specimens, not to oven-dry weight. It is possible to see that both OSB and plywood show almost the same wetting and drying curves and practically the same water uptake coefficient (note that X-axis is the square root of time).

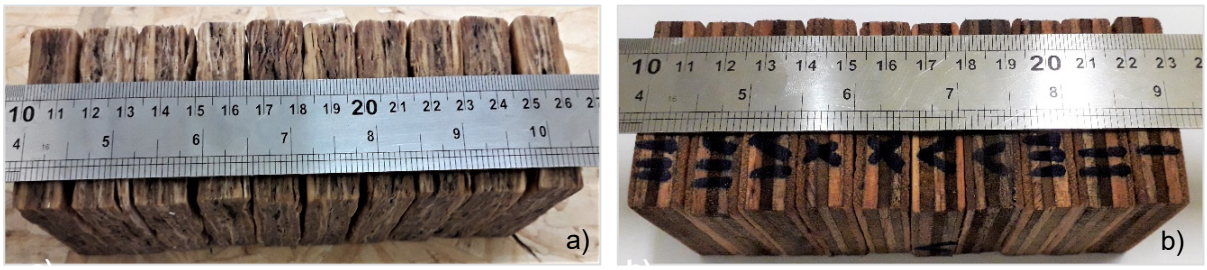

Figure 2. Appearance of a) OSB and b) Plywood after swelling.

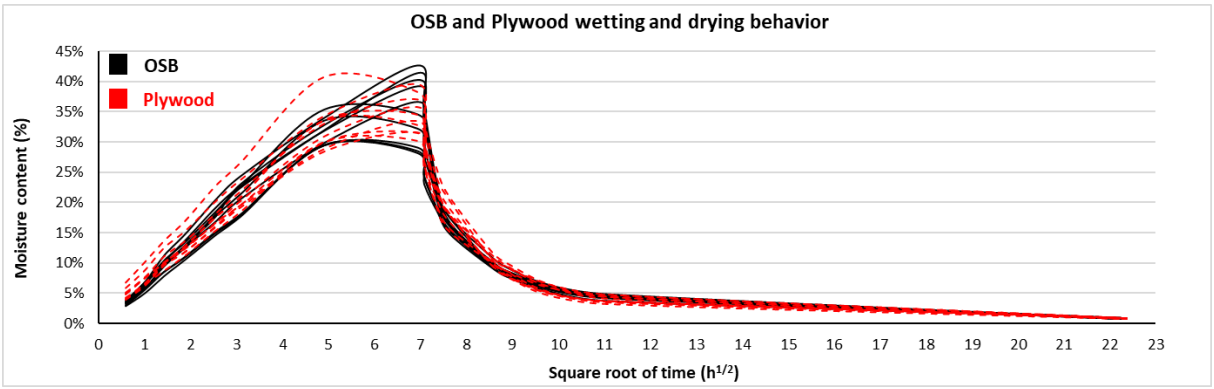

Figure 3. Wetting and drying time of OSB and plywood.

Although both OSB and plywood show quite the same water absorption and drying curves, OSB samples went through a much higher swelling after only one cycle, which can lead to problems with loose screws and nails.

2.1.3 Modulus of Elasticity (MOE) and bending strength

These tests were carried out in three conditions: with the samples acclimatized to 65% RH at 21ºC (Natural), after cyclic test (Aged) EN 321 (BSI, 2002b) and with the samples after 24h under tap water (Soak). For each set, 10 specimens were tested, which meant a total of 120 specimens (two boards, three conditions, two axis and 10 specimens each).

The distance between the supports was 20 times the thickness, i.e., 222mm for OSB and 240mm for plywood and both loading head and supports had a diameter of 20mm. Figure 4 presents the retention rate for MOE and bending strength (BS) for each set according to the axis: L stands for longitudinal and T stands for transversal (longitudinal means the axis with the highest strength).

Since the mechanical strength is deeply related to the moisture content of the specimens, the moisture contents of OSB and plywood after soak bath were determined as follows: values taken immediately after the bending test and, then, after 48h in an oven at 103ºC. So, when soaked, moisture contents (in percentage, oven-dry basis) were 36.9 ± 2.1 for OSB and 41.8 ± 4.0 for plywood.

All OSB samples presented great deterioration after soaking and cyclic test, so it was difficult to reach good accuracy and precision when measuring the thickness, which means the values presented in Figure 4 vary around ±5%. Mechanical strength loss due to water action is also described by other authors (Kojima and Suzuki, 2011; Korai, Kojima and Suzuki, 2015)

and the results in this paper are in good agreement with those ones; more similar results are also described by Okino et al (2004), when studying OSB with Brazilian wood strands.

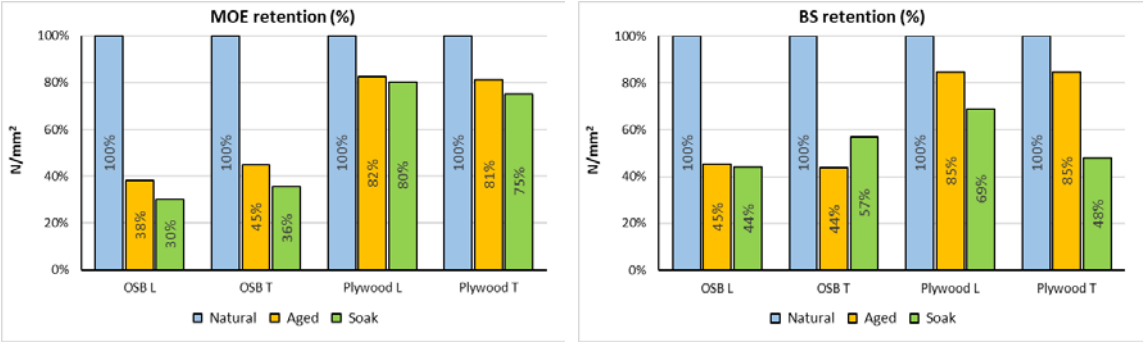

Figure 4. MOE and BS retention rates for OSB and plywood.

2.1.4 Internal bond

Internal bond tests were carried out under five circumstances: 1) original board acclimatized at 65% RH, 21ºC (Natural); 2) after swelling (soak bath); 3) after boiling; 4) oven-dry after swelling and 5) oven-dry after boiling (Figure 6). Specimens in situation 4) and 5) were oven-dried for 48h after swelling and boiling tests; then, all the samples from 2) to 5) were acclimatized at 65% RH and 21ºC before the internal bond test. Due to the mechanical damage OSB samples went through during swelling and boiling tests (see Figure 2), it was not possible to measure their internal bond.

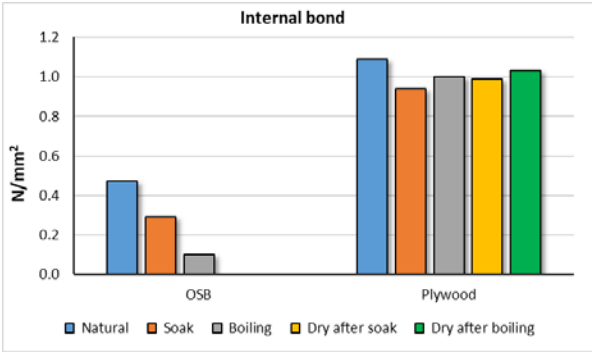

Figure 5. Internal bond of OSB and Plywood under different conditions.

2.1.5 Dimensional changes

All the samples in this test had the nominal dimensions of 300x50mm and the following charts show the mass of each specimen over time (dashed line, right vertical axis) and also the percentual variation of the mass in the last 24 hours (solid lines, left vertical axis). These last ones are important to see how long the specimens take to reach the equilibrium as required by EN 318 (BSI, 2002a): up to 0.1% in 24 hours. While Figure 6 shows the result for the cycle 30-65-85, Figure 7 shows the data for the cycle 85-65-30.

All the charts follow the same reasoning as explained here for the cycle 30-65-85: the specimens were taken from room temperature and put into the climatic chamber at 30% RH.

After the mass reaches the equilibrium, the RH level is changed to 65% and the charts show this as the first bump. Afterwards, the RH level is increased to 85% and a second bump show up; then, the specimens remain in the chamber until equilibrium.

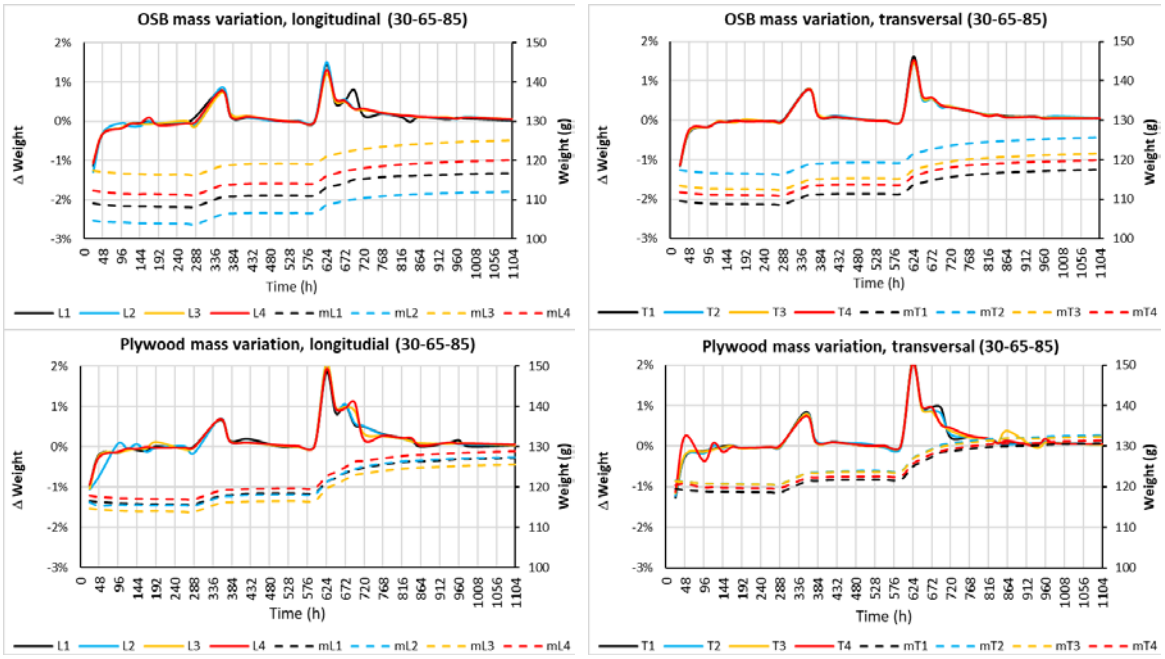

Figure 6. OSB and plywood mass variations under the cycle 30-65-85.

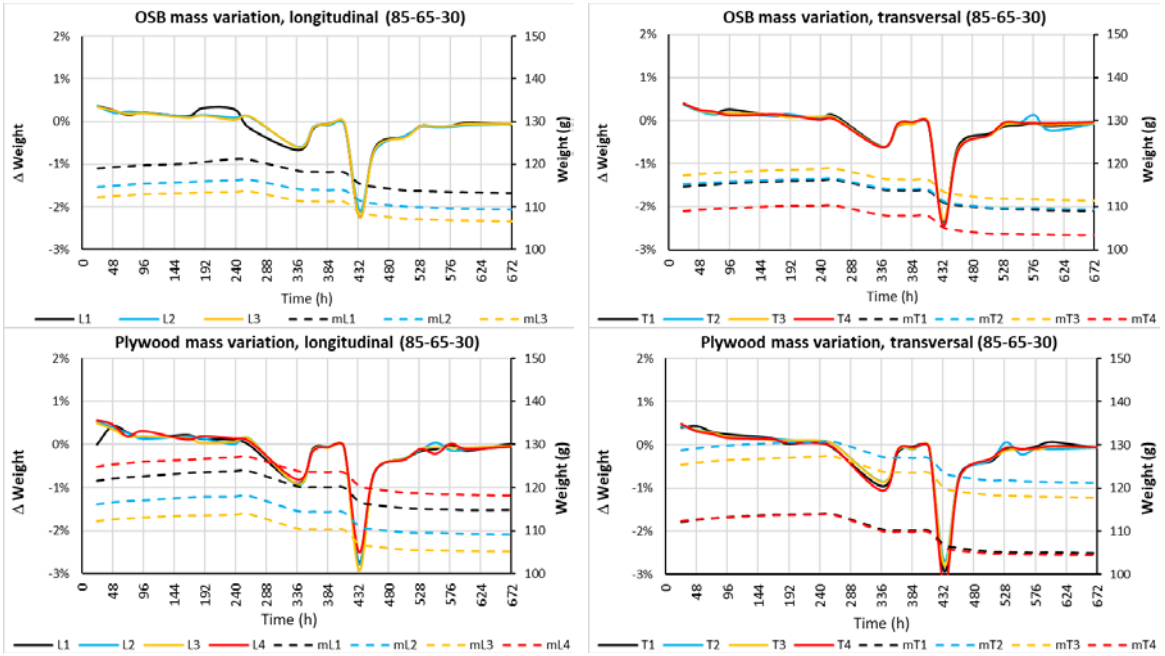

Figure 7. OSB and plywood mass variations under the cycle 85-65-30.

The two following charts, in Figure 8, show the changes of the samples length for both cycles

as well: set 1 for $L_{65,85}$ and set 2 for $L_{65,30}$.

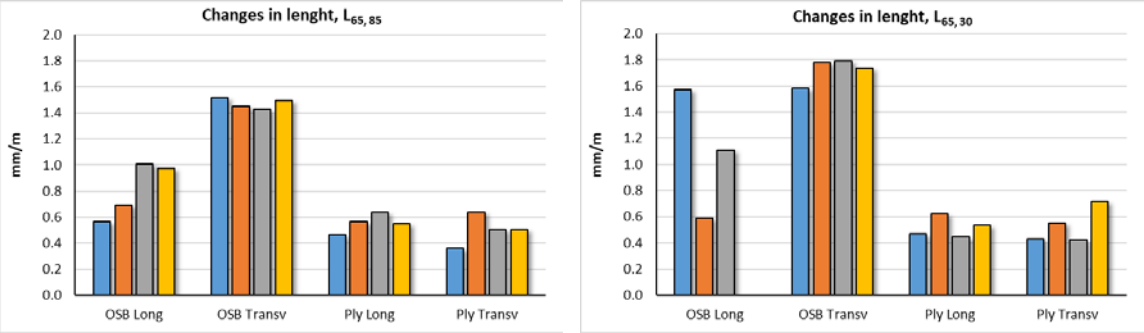

Figure 8. Changes in length of OSB and plywood: $L_{65,85}$ and $L_{65,30}$.

3 Conclusions

- Water can reach wood-based boards either due to high levels of relative humidity or because of wind-driven rain infiltration, usually taken as 1% of the rain load over the wall (ASHRAE, 2016), whether through crackings, openings, sealant failures and so on. Regarding the materials evaluated in this experiment, OSB is much more sensitive to water than plywood. Hence, its low resiliency against the most abundant degradation agent, together with the fact maintenance is not a common action in Brazil, is an alert that OSB might not the best option for a country whose climate is hotter and more humid than cold countries that already have issues with wood-based boards;
- Even with boards intended for use in humid conditions, it is important to note that "humid" means "temperature of 20°C and a relative humidity of the surrounding air only exceeding 85 % for a few weeks per year" according to EN 300 (CEN, 2006). Since in most cities of Brazil the relative humidity goes beyond this level many weeks per year, the conditions are very good to obtain high levels of mold index (ASHRAE, 2016; Ojanen et al., 2010); also, temperatures in Brazil are almost always above the minimum threshold for mold growth;
- In all tests OSB showed lower performance when compared to plywood, even where there was no direct contact with liquid water but only with different humidity levels, which means a higher stress level over time due to the greater dimensional changes.

Performance of European Wood Species in Above Ground Situations After 10 Years of Weathering: Evidence of a Positive Impact of Proper Design

Magdalena Kutnik, Martine Gabillé and Mathilde Montibus

Technological Institute FCBA, Allée de Boutaut, BP 227, 33028 Bordeaux Cedex, France.
magdalena.kutnik@fcba.fr, martine.gabille@fcba.fr, mathilde.montibus@fcba.fr

Abstract. *Most of European native wood species used outdoors are expected to last less than 10 years if left untreated and exposed to severe environmental conditions such as high humidity and biological agents. However, the current classification of wood's natural durability based on EN standards does not fully reflect real end-use conditions, often underestimating wood's performance in use. In addition, the importance of design details and the role they play in enhancing service life, especially in the case of outdoor applications, is often neglected. With the aim of evaluating the positive impact of proper design on wood's service life, large-scale experimental devices, manufactured according to different designs (water draining / trapping) from six native wood species, were installed in 2009 in two French cities benefiting from different climatic conditions (oceanic / continental). The results of the evaluation carried out after 10 years of natural weathering demonstrated that (1) significant differences in the ability to withstand decay over time exist depending on the selected design details and the climatic conditions encountered in the experimental fields; (2) high variability in the resistance of non-durable spruce and poplar wood against fungal decay was noticed for each tested design, but with an unexpected high percentage of elements performing very well; (3) the moderately durable heartwood of larch, maritime pine and Douglas fir was mostly unaffected by decay even under severe conditions of exposure to rain (decking modules), suggesting these species may have greater value for outdoor applications without any preservative biocidal treatment than previously assumed.*

Keywords: *Natural Durability, Service Life, Performance, Design, Natural Weathering, Decay.*

1 Introduction

The service life of a wooden structure is the period of time after installation during which it meets the initial performance requirements, such as mechanical strength, and before replacement is needed. This depends on many factors, some being natural and beyond human control, such as wood's inherent characteristics and environmental factors (wind, rain, sun, biological decay agents), and some a result of man's actions, such as design and maintenance.

The majority of European native timber species of economic importance for the building sector are regarded as naturally moderately or poorly durable with regards to biological degradation when used for outdoor applications, such as cladding and decking. In geographical areas where biological risk is high, they are frequently expected to last less than 10 years when left untreated and exposed to severe environmental conditions such as high humidity. As a consequence, in order to ensure long-lasting products, architects tend to choose durable tropical hardwoods or native woods with enhanced durability (modified or preservative treated) rather than moderately durable European wood species whose performance over time is doubtful.

However, the importance of design details and the role they play in enhancing wood's service life, especially in the case of outdoor applications, is often neglected. Indeed, premature fungal degradation of wood is frequently the consequence of inappropriate use, poor design or mistakes made during the installation, generating water traps and thus increasing the wood's

moisture content up to a level allowing the initiation of decay.

The performance of wooden structures in terms of service-life relies both on wood's natural durability and on its exposure to weathering and biological risk. Natural durability is beyond our control, but the severity of exposure to environmental parameters can be reduced by good practices such are proper design, proper installation and proper maintenance. The objective of this study is to demonstrate that proper design of wooden structures meant for outdoor use is crucial to providing products whose service life meets the market's needs and the final users' expectations.

2 Experimental Set-up

Large experimental structures were constructed from six wood species, selected for their economic importance for the construction industry and different natural durability against fungal decay according to EN 350 (2016). They mimicked wooden constructions used outdoors above ground: cladding, decking, posts, inclined beams, assemblies, and log house outer walls (Figure 1). In order to compare their performance under different climatic conditions, the test devices were installed in 2009 in the French cities of Bordeaux and Charrey-sur-Saône (oceanic and continental climates, respectively). The full description of the experimental set up is given in Kutnik *et al.,* (2011).

2.1 Selected Timber Species

Douglas fir (*Pseudotsuga menziesii*), maritime pine (*Pinus pinaster*) and larch (*Larix decidua*) are commonly used for manufacturing outdoor structures, mainly for cladding and decking. The natural durability of their heartwood against Basidiomycete decay fungi ranges from moderately (DC 3) to poorly (DC 4) durable (EN 350, 2016), which makes them hardly suitable for use class (UC) 3.2 and UC 4 applications (EN 335, 2013) without any preventative preservative treatment, especially where long service life is expected (> 10 years).

Spruce (*Picea abies*) and poplar (*Populus sp.*) are classified as poorly (DC 4) to non-durable (DC 5) against fungal decay. In practice, they are not used untreated for UC 3.2 and UC 4 applications. In our study spruce and poplar were used as reference non-durable species, expected to decay to some extent over a period of 10 years of exposure to weathering. Different levels of decay were expected depending on the design selected for manufacturing particular experimental devices. European oak (*Quercus robur*), classified as durable (DC 1-2), was used as the reference durable wood species.

2.2 Design Details

Each type of construction comprised both water-trapping and water-draining design details. The results presented in this paper mainly concern the decking modules and the post-to-beam connections, with the design details used for manufacturing them being described in subsequent sections. Since, based on visual inspection only, the remaining construction types (log walls, posts and inclined beams) provided less interesting input, it was decided that they will be the subject of further investigation involving other tools later on.

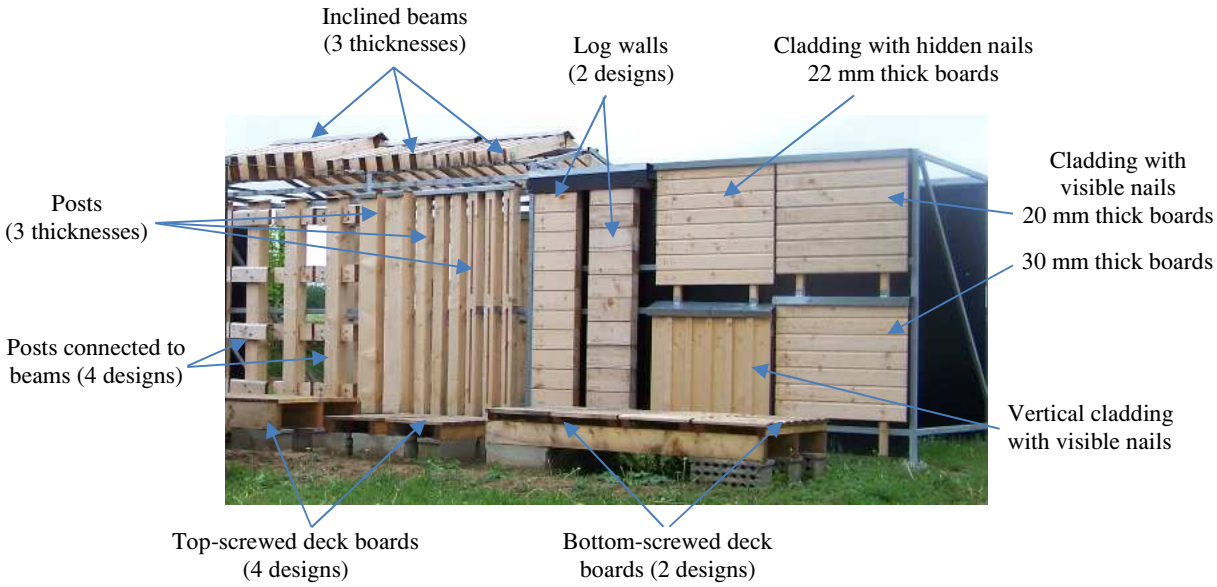

Figure 1. Experimental site in Charrey-sur-Saône, France – examples of devices made from poplar.

2.2.1 Decking Modules

The decking modules were designed to simulate exterior residential decking. They consisted of deck boards fixed on wooden joists, placed on concrete blocks to avoid direct contact with the ground. The four corners of the decking modules were also placed on concrete masonry so that their bases were at least 20 cm above ground (Figure 1). Fifty-centimeter-long boards were cut as much as possible from heartwood, pre-drilled with one or two holes near each end and mounted in two uniformly spaced rows of 5 to 16 replicates on a sub-frame (joists and/or beams) using stainless steel screws.

The modules were manufactured according to designs simulating either UC 3.2 (outdoor unprotected, without permanent water accumulation) or UC 4 (horizontal, above ground, with water accumulation over long periods of time) conditions according to the French FD P 20-651 (2011), thus representing different levels of risk with regard to the probability of fungal decay. The differences between the selected designs were the thickness, width and shape of the deck boards, the way of screwing the boards on the joists beneath (top or bottom screwing) and the typology of the wood-to-wood contact zones (water draining or water-trapping).

Design A, being the most traditional decking design, was expected to represent the worst-case scenario of exposure to water accumulation (on the wood's surface, on the screws' top, at the interface between the boards and the joists beneath). Designs B and C employed thicker boards, wider (B) or thinner (C) than design A. Designs D, E and F included different details avoiding water trapping and/or improving water drainage of the deck's surface and thus were expected to perform better than designs A, B and C.

Six decking modules were constructed from spruce and poplar (one according to each design type). Two modules were constructed from maritime pine, larch, Douglas fir and oak, according to designs A and F, expected to represent respectively the worst and the best case scenario with regard to fungal decay. The construction details are described in Kutnik and Montibus (2019).

2.2.2 Cladding Units

Cladding units of 1m x 1m were built according to four different designs, the main differences being the thickness (20 or 30 mm) of the test boards, the way of assembling and screwing them on the battens (tongue and groove boards with visible nails or lap joint boards with hidden nails) and the orientation of the wood's fibers (three horizontal and one vertical cladding) (Figure 1). Sixteen cladding units (8 spruce + 8 poplar) were installed in a setting that either allowed (4 + 4) or prevented (4 + 4) their direct exposure to wind-driven rain. The end-grain of the vertically exposed boards was protected from rainwater by stainless steel sheets.

2.2.3 Posts Connected to Beams

Posts were screwed to metallic frames, with end-grain protected from rainwater by stainless steel sheets. Beams were connected to posts using two joining types representative of traditional carpentry: the mortise-and-tenon joint and the cross lap joint. Two innovative types of joints, reducing the wood-to-wood contact zones and allowing for efficient water drainage from the two connected elements, were manufactured as well (Figure 2). All elements were connected using stainless steel fasteners. Sixteen posts (8 spruce + 8 poplar) were installed in a setting that either allowed (4 + 4) or prevented (4 + 4) their direct exposure to wind-driven rain.

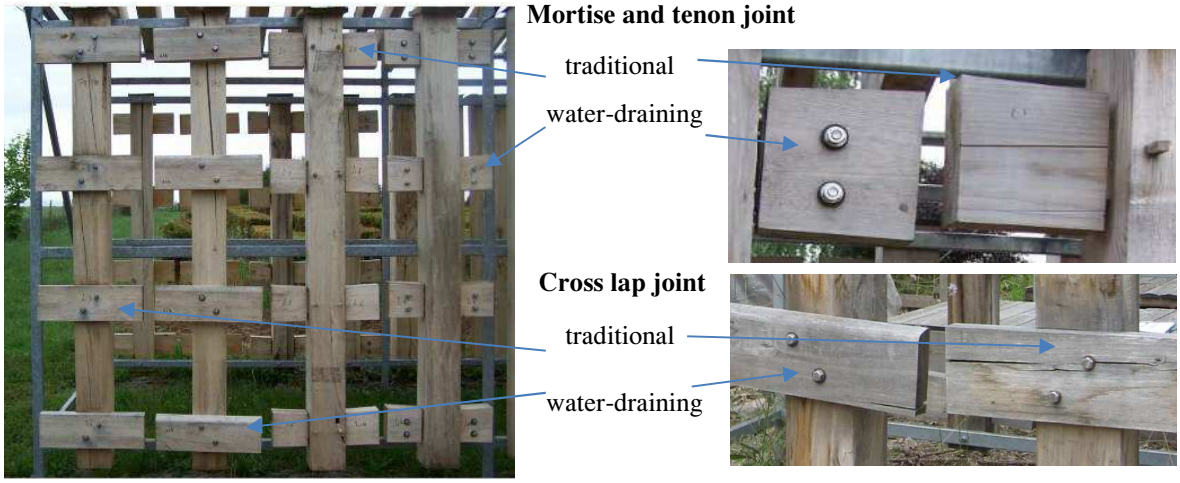

Figure 2. Poplar posts connected to beams in Charrey-sur-Saône, France.

3 Rating of the Fungal Decay

Non-destructive inspections of the deck boards were performed periodically according to a procedure similar to the one recommended in the standard AWPA E25-13 (2014). The decay inspection method consisted of gentle probing of board surfaces, checks and end-grain with a dull metal spatula for signs of softening or cavities. Special attention was paid to areas of high moisture content, discoloration or collapse that were visible on the surface and to areas sounding hollow or dull when tapped with the blunt end of the spatula.

The fungal degradation of exposed wooden elements was evaluated in 2019, after 10 years of exposure to weathering, following a rating scale ranging from “0” (sound, no evidence of fungal attack) to “4” (structural breakdown caused by decay). The rating scale used was adapted

from EN 252 (2014) and AWPA E25-13 (2014) (for more details see Kutnik and Montibus, 2019). The scale and the description of the corresponding damage are presented in Table 1.

Table 1. Description of the rating scale used for the assessment of fungal decay.

Rating level	Description of boards' degradation
0 – not degraded	• Little/surface checks • No evidence of decay, no degradation of the fixation points
1 – slight degradation/very limited extent, no immediate impact on boards' usability, no maintenance action required	• Numerous surface checks and/or few deep checks • Maximum 1 fixation point with evidence of decay • Minor softening on end-grain or on sides of checks • Decayed area <2 cm^2
2 – moderate decay, no immediate impact on boards' usability, maintenance action might be required within the next few years	• At least 2 fixation points with evidence of decay • Decayed area: max depth 2-3 mm over max 5 cm^2 OR depth of 5 mm over max 2-3 cm^2
3 – severe decay, replacement to be scheduled shortly	• All fixation points decayed OR extensive decay area > 5 cm^2 and/or > 3 cm^3 • Visible fungal activity and/or mycelium and/or fruiting body • Severe decay, likely to seriously affect the loadbearing capacity but not broken when stepped on sharply by a person of moderate weight
4 – failure, replacement needed	• Very severe decay with greater than 50% of a cross section affected • Breakage of the board or severe surface collapse • Failure when stepped on sharply by a person of moderate weight

4 Results of the Inspection Carried Out After 10 Years of Weathering

The cumulative impact of wood's natural durability, exposure conditions and effectiveness of design-based protective measures on the service life of the tested wooden constructions were quantified based on the evaluation of fungal decay. The results presented are those of the evaluation of the decks and the post-to-beams assemblies.

4.1 Assessment of the Decking Modules With Regard to Fungal Decay

The results of the evaluation are presented in Table 2 for each wood species, design type and location ("Bord" for Bordeaux and "Charr" for Charrey-sur-Saône).

The upper surface of the decks manufactured from oak, Douglas fir, larch and maritime pine (the latter in Charrey-sur-Saône only) showed either no or very little visible decay or decay limited to parts of the boards which were assumed to be residual non-durable sapwood. For this reason, the decks were left in place in order to allow future evaluation and only the top side of the boards was rated. After 10 years of weathering, the impact of the selected design details used in the decks manufactured from these four wood species was not measurable yet.

Oak (the durable reference species) resisted fungal deterioration over time, with 14 out of the 16 boards rated "0" for both design A and F in Bordeaux and all 16 in Charrey-sur-Saône rated likewise. Deck boards made from moderately to slightly durable larch and Douglas fir resisted deterioration over time on both test sites, the great majority of deck boards being rated "0" for fungal decay. A few boards reached the decay level of "2" and "3", but this degradation concerned only the residual sapwood parts. Deck boards made from maritime pine resisted degradation in Charrey-sur-Saône to the same extent as larch and Douglas fir, but high

variability was observed in Bordeaux (deck boards rated from "0" to "4"). Maritime pine boards comprised a lot of sapwood and this is certainly the main cause of their premature decay.

Table 2. Number of deck boards of each wood species and design type rated 0 to 4.

Wood species	Design type	Location	Number of boards per rating level					Number of boards
			Rating 0	Rating 1	Rating 2	Rating 3	Rating 4	
oak	A	Bord	14	1	1	0	0	16
		Charr	16	0	0	0	0	16
	F	Bord	14	2	0	0	0	16

		Charr	0	6	6	2	2	16

Bordeaux/Charrey: dark orange/green colour = highest number of decks with the same rating; light orange/green colour = dispersion of ratings over the deck boards

Non-durable poplar and spruce decks were dismantled and the boards were individually rated for fungal decay. High variability was recorded in the extent of fungal degradation depending on the tested design and exposure site.

Spruce bottom-screwed deck boards (design types E and F) were significantly less decayed (high number of boards with no - rating "0" - or very little - rating "1" - decay) than top-screwed ones, except boards assembled according to design C (5 cm wide, 1 screw at each end). These boards showed high variability in their resistance to fungal decay and better overall performance than types A, B and D, especially in Bordeaux. The general trend is that decks installed in Bordeaux were slightly less decayed than in Charrey-sur-Saône.

Poplar deck boards were significantly less decayed in Charrey-sur-Saône than in Bordeaux. However, the impact of the design was less obvious than in the case of spruce. Similar performance was found for all decks irrespectively of their design in Charrey-sur-Saône and slightly better performance of bottom-screwed boards was observed in Bordeaux.

4.2 Post–to-Beams Assemblies

The assemblies evaluated on the test devices made from oak, larch, Douglas fir and maritime pine were all found sound after 10 years of exposure, irrespective of the tested design.

Spruce and poplar wood mortise-and-tenon and cross lap assemblies constructed according to water-draining designs were all sound in both test sites, irrespective of whether they were or were not directly exposed to wind-driven rain. Assemblies constructed according to water-trapping designs were decayed to different extent, depending on the wood species (spruce was less decayed than poplar) and test site (test devices installed in Charrey-sur-Saône were less decayed than those in Bordeaux). Decay fungi degraded the wood-to-wood contact zones of both elements (posts and elements connected to them) leading in many cases to the breakdown of the assembly. Figure 3 shows that mortise-and-tenon (1) and cross lap (2) assemblies were either sound, when constructed according to water-draining design (WD) or extensively decayed by fungi, when constructed according to water-trapping design (WT).

Several wooden elements connected to the posts were affected by superficial decay (larch, maritime pine, poplar and spruce), located mostly on their upper part and/or in sapwood parts.

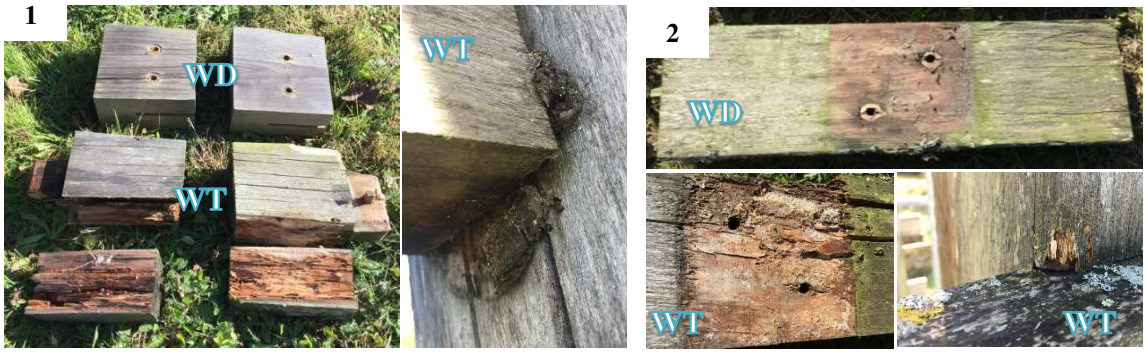

Figure 3. Poplar posts connected to beams in Charrey-sur-Saône, France.

13 Conclusions

- Significant differences in the ability of wood to withstand decay over time were observed depending on the selected design details used and the surrounding climatic conditions, especially in the case of non-durable spruce and poplar wood;
- The continental climate was less favorable to decay fungi than the oceanic one;
- A positive effect of the water draining designs was demonstrated for decks and assemblies made from non-durable spruce and poplar wood, with fewer elements being affected by fungal decay and lesser extent of decay;
- The moderately durable heartwood of larch, maritime pine and Douglas fir was unaffected by decay, even under severe conditions of exposure to rain and water accumulation (decking). This suggests that these wood species could be used without any preservative treatment, provided the sapwood has been removed, for manufacturing outdoor structures whose service life could by far exceed 10 years;
- Wooden structures made of non-durable spruce and poplar showed high variability in terms of resistance against fungal decay, but with a high percentage of elements being still sound or below their limit state of use after 10 years;
- European standards provide keys to proper selection of timber species (EN 350:2016), understanding of the biological risks associated with their use (EN 335:2013) and proper treatment where necessary (EN 599-1:2014). However, given the diversity of conditions under which wood may be in service, there is no direct, simple and reliable method to predict service life under real-use conditions based on durability classification alone. To accomplish this more reliable service life prediction tools need to be developed.

Abstract. *The main aim of the work is to study the effect of different fibres (steel, glass and basalt) on resistance of blast furnace slag-based alkali-activated mortar in acidic environment. The alkali-activated slag mortars were exposed to 5% sulfuric and acetic acid solutions for 30 days. Mass change, compressive strength and microstructural changes were evaluated. In plain mortar, it was observed that 70% of the strength was retained in acetic acid environment whereas only 20% of residual strength remains in sulphuric acid environment. FTIR spectroscopy shows the degradation of the matrix, which implies the alkali-activated mortar was more vulnerable in sulphuric acid environment due to its aggressive nature compared to acetic acid. Decalcification and formation of calcium acetate also hinders the further progress of damage in acetic acid attack. Fibres helped in improving the performance of the mortar by holding the matrix together when the degradation occurred in acidic environment. Compared to plain mortar, incorporation of steel fibres exhibited a maximum strength retention of 19% in acetic acid and 7% in sulphuric acid, followed by glass and basalt fibres. SEM images clearly show the debonding of fibres and disintegration of matrix in acidic environment, which resulted in strength loss.*

Keywords: *Slag, Alkali Activation, Fibre-Reinforced Mortar, Acid Attack, Durability.*

1 Introduction

Interaction of cementitious materials with acidic environment is an important factor to be considered for the durability of structures exposed to harsh environment such as industrial waste water, sea water and acid rain. Alkali activated materials (AAM) are alternative cementitious system that is extensively studied in recent years (Mehta and Siddique, 2016). AAM does not involve Ordinary Portland cement (OPC) and can use 100% industrial side streams as the binding material, making them an energy efficient alternative for construction (Heath *et al*., 2014). The properties of AAM are mainly affected by the type of binder material used. AAM shows similar mechanical characteristics as that of OPC concrete, however still further studies are needed about its long-term durability performances (Provis *et al*., 2007). In specific, the chemical attack in aggressive environments like acidic, chloride, sulphate and carbonate, are to be focused.

In OPC concrete, calcium is considered to be the weakest link in the hydration product as it leaches out in acidic environment (Bernal *et al*., 2012). Though there are published studies on the low solubility and high resistance of AAM in aggressive environments (Aiken *et al*., 2018; Fernández-Jiménez and Palomo, 2009), there are also limitations in understanding their

performance in the presence of different type of fibers. In this study, an effort is made to study the effect of sulphuric (H_2SO_4) and acetic (CH_3COOH) acid on alkali activated slag (AAS) mortar with steel, glass and basalt fibers. Mainly, strength retention, microstructural changes associated with the structural damages are focused.

2 Experimental

2.1 Materials

Alkali activated slag mortar (G1) was made with ground granulated blast furnace slag (GGBFS) which was obtained from Finnsementti, Finland. Granules of anhydrous sodium metasilicate (SS, 1 mm size) with SiO_2/Na_2O ratio of 0.9 was procured from Alfa Aesar. SS was mixed with GGBFS in the ratio of 1:9 and co-grinded in a ball mill for 30 mins. Four different fibers were used in this study (Fig. 1). Table 1 lists the properties of these fibers. Fiber reinforced mortar can be identified by a nomenclature that G1S6 represents G1 mix with steel fiber of 6 mm length. Similarly, G and B were used for glass and basalt fibers, respectively. Additionally, a mix with combination of 6 mm and 12 mm steel fibers in the ratio of 1:1 (G1SM) was made. Deionized water was used for mortar production.

Figure 1. Different type of fibers.

2.2 Methods and Test Procedures

To produce mortar specimens, co-grinded slag and fine aggregate in the ratio of 1:2 was dry mixed for about a minute. Water was added to it (water-binder ratio = 0.35) and further mixed for 3 min. Fibers (1% weight of binder) were introduced to this slurry gradually while mixing was continued until a homogenous distribution was achieved. The fresh fiber-reinforced alkali-activated slag mortar was cast into cubic (50 × 50 × 50 mm^3) molds. The specimens were demoulded after 24 h and cured in 20 ˚C with 100% RH for 28 days.

Table 1. Properties of fibers.

Properties	Type of fibre			
	Steel		Glass	Basalt
Length (mm)	6	12	6	6
Density (g/cm^3)	7.88	7.85	2.68	2.67
Modulus of Elasticity (GPa)	200	200	72	85
Tensile strength (MPa)	2200	2000	1400	3500

Compressive strength before exposure (three cubic specimens) to acidic environment was determined using 3000 kN capacity with a displacement rate of 1.8 mm/min. Resistance to acid attack was studied by exposing three cubic specimens each in 5% acetic (pH 2.4) and sulphuric (pH 0.8) acids for 30 days. Later, compressive strength of the acid attacked specimens were measured. Broken pieces after testing the strength were milled to powder and used for further analysis. Deterioration mechanism of the acids in different mixes were further investigated using X-ray diffraction (XRD), Fourier transform infrared spectroscopy (FTIR) and scanning electron microscopy (SEM).

One of the cubic specimens was reserved for image analysis. Images of the cross-section of the specimen was captured as 1 cm cubes with optical microscope. Hence 25 images for each mix was analyzed and used to quantify the area of deterioration in the acid medium. In the color-based image analysis, the k-means clustering is an oft-used algorithm (Qi *et al.*, 2016). In one of each partition, the algorithm detects 'k' centroid from the 'n' number of datasets (here, pixel value), k<n. This algorithm is an iterative process which updates its centroid based on squared Euclidean distance of the data from the centroid within the cluster. Concrete is a composite with many particles of different colors and acid attacked region is not uniform in color too. However, the undisturbed core can be identified as a first step. The 'k' value has been chosen randomly and subsequently the clusters are arranged in order to minimize the intra-cluster variances and maximize the inter-cluster variances. The square error function ($\boldsymbol{E_{sq}}$) of the algorithm is given by equation (1),

$$E_{sq} = \sum_{j=1}^{k} \sum_{i=1}^{n} \left\| x_i^{(j)} - C_j \right\| \quad (1)$$

Where, C_j is the centroid,

$$C_j = \frac{1}{n_j} \sum_{i \in S_j} x_i^{(j)} \quad (2)$$

$\|-\|$ is the distance measurement (here, Euclidean distance), between centroid C_j and the data $x_i^{(j)}$ in the cluster S_j.

3 Results and Discussion

3.1 Influence of Type of Acid

Visual examination of the AAS mortar shows very small change in appearance with acetic acid environment, however there is visible disintegration of the specimen when exposed to sulphuric acid (Fig. 2). This is because acetic acid is a weak acid (only partially deprotonated), whereas sulfuric acid is a strong acid (complete deprotonation). Further exploring the chemical/ mineralogical changes on the acid exposed specimens explains that the reaction products formed by interaction of different acids plays an important role. Most important changes of acid attack would be the decalcification of the calcium silicate hydrate (C-S-H) in the hydration product. This resulted in shifts in aluminosilicate spectral bands that happens in the region 900 to 1200 cm^{-1} of FTIR curves of the acid attacked samples (Bakharev, 2005). Further, the formation of calcium acetate with acetic acid is confirmed with the presence of a C-O stretching vibrations at 1556 cm^{-1} (Fig. 3 (a)). This can also be clearly identified with XRD peaks in Figure 3 (b). The dealumination and condensation caused increase in siloxane chain length and

corresponding increase in intensity at 980 to 1100 cm^{-1}. This is not significant in sulphuric acid samples, rather shifting of peak at this region was observed. This shows that sulphuric acid resulted in delamination due to depolymerization of the AAS binders.

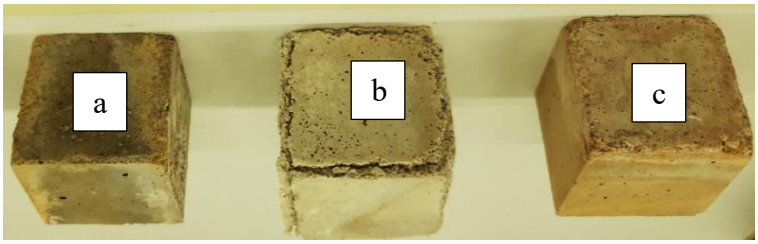

Figure 2. Cubic specimen before (a) and after 30 days exposure in sulphuric (b) and acetic (c) acid.

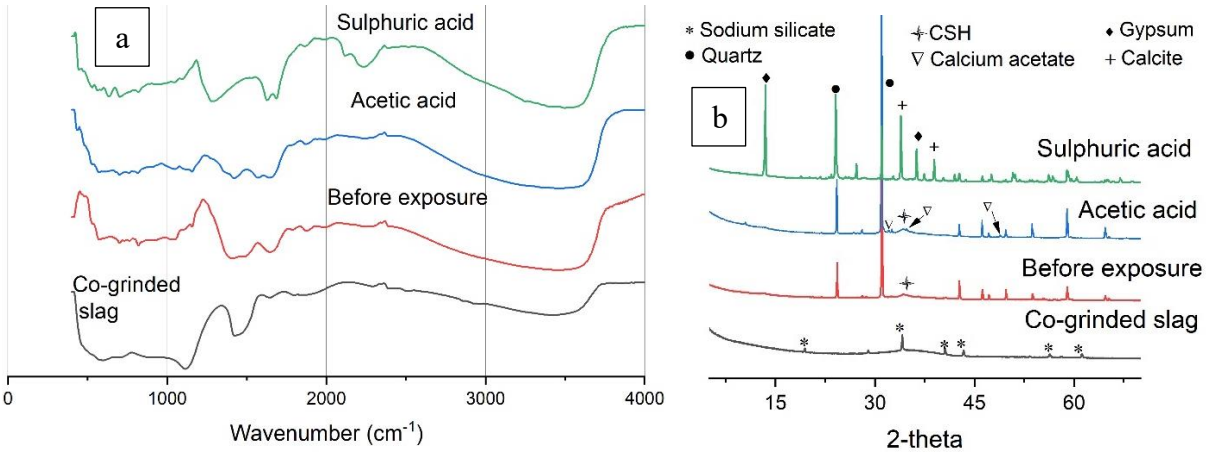

Figure 3. FTIR (a) and XRD (b) spectra of AAS mortar before and after exposure to acid.

SEM images of the acid attacked samples are shown in Figure 3. In both cases, damaged layer and the core area can be identified in the microstructure level. However, it is clearly visible that the sample is vulnerable for debonding in sulphuric acid (Fig. 4 (c)) than in acetic environment (Fig. 4 (a)). The formation of calcium acetate as an intermediate layer (Fig. 5, L2) is well observed in the optical microscopic image of acetic samples. This layer, infact acted as a protection to the core matrix from further attack (Fig. 4 (b)). Though there is also formation of similar layer with sulphuric acid, the reaction products are mainly gypsum and calcite (Fig. 3 (b) and 4 (d)) which were not stable enough to stop the progress of the sulphuric acid in to the core (Koenig and Dehn, 2016; Khan *et al*., 2018).

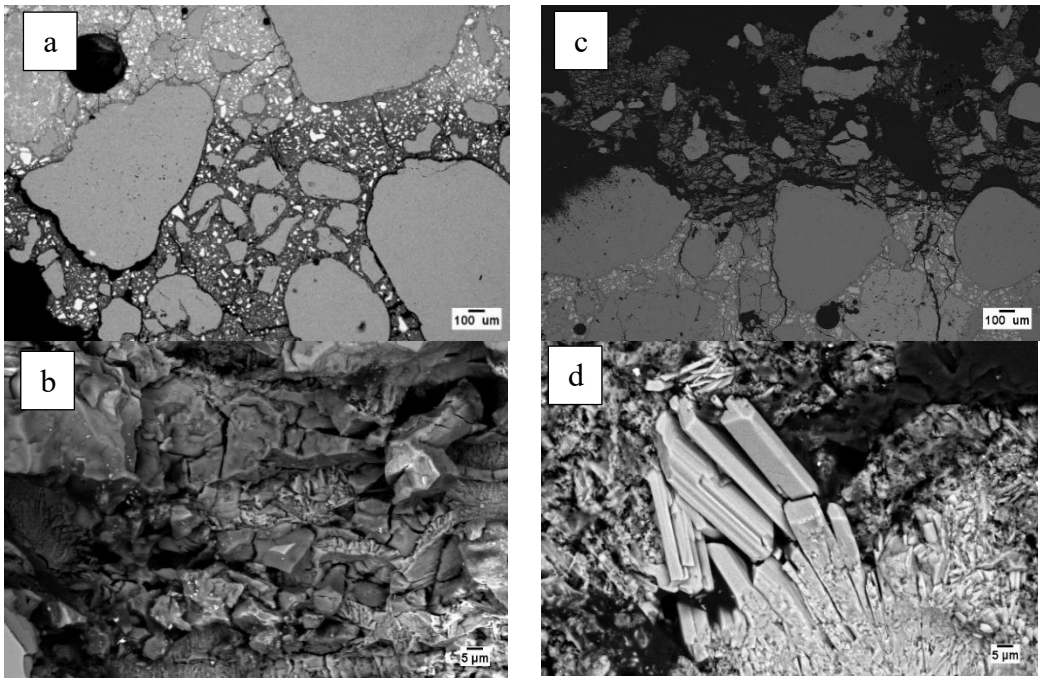

Figure 4. Representative SEM images of AAS mortar exposed in acetic (a,b) and sulphuric (c,d) acid.

An attempt was made to further quantify the different layers formed and their effect on the binder matrix in Figure 5. Based on the image analysis, core area (27%) is similar in both the acid medium. However, the damage caused by these acids looked different. Layer L2 (7%) in the acetic sample looks denser which could be due to the filling up of pores with calcium acetate. Layer L1 in both the samples looks disintegrated and deteriorated with lower binder content.

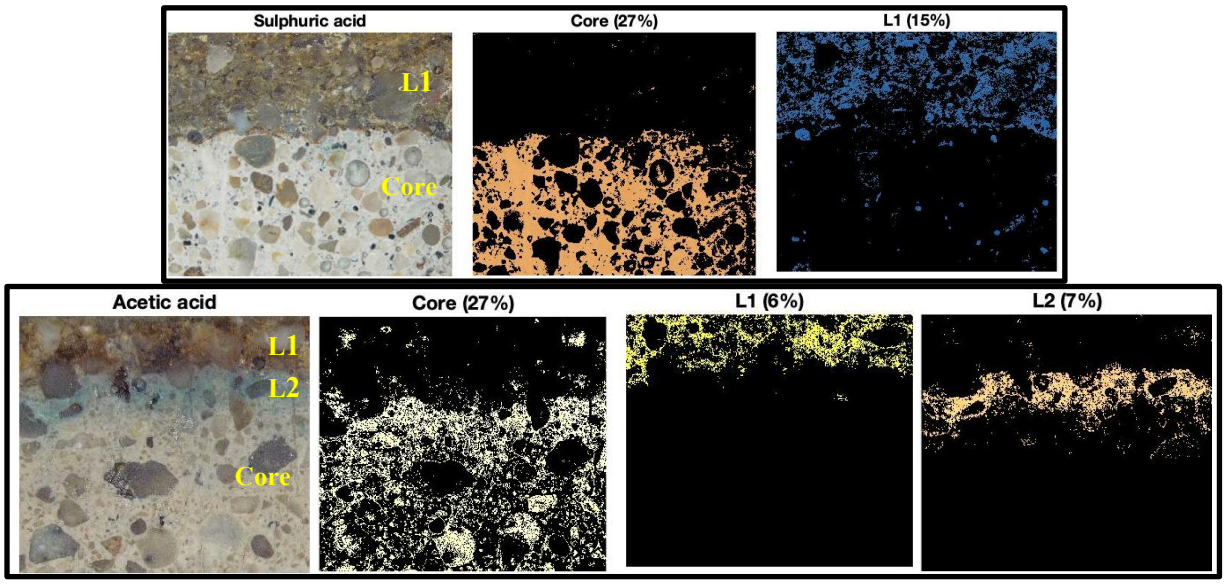

Figure 5. Representative image analysis of acid attacked AAS mortar specimens.

3.2 Role of Fiber and Their Type

Figure 6 (a) displays the effect of fibers on the compressive strength of AAS mortar before and after exposed to acetic and sulphuric acid. It also indicates the percentage reduction in strength with different mix in acidic medium. The addition of steel fibers increased the compressive strength of AAS mortar significantly whereas it was not the case with glass and basalt fibers. Strength reduction with acetic acid exposure is within 10% for the fiber reinforced AAS mortar except basalt fiber. This could be due to the use of uncoated basalt fiber which might have been damaged in the high alkaline medium (Wei *et al*., 2010). However, SEM microstructure shows the presence of basalt fibers in the matrix of the acetic attacked samples (Fig. 9 (b). Residual strength of the specimens corroded by acetic acid depends on the fiber used and it is in the order, mixed steel > 6 mm steel > 6 mm glass > 12 mm steel > 6 mm basalt. This could also be related to the unaffected area and area of the second layer (L2) which protects the core unaffected area from further corrosion (Fig. 6 (b)). SEM images of the acetic affected mixes (Fig. 9 (b), (e), (h)) shows similar structural damage as that of plain AAS mortar (Fig. 4 (a)). The improvement in residual strength of fiber reinforced AAS mortar could be due to the physical action of fibers in holding the disintegrated binder phase to some extent (Kim *et al*., 2015).

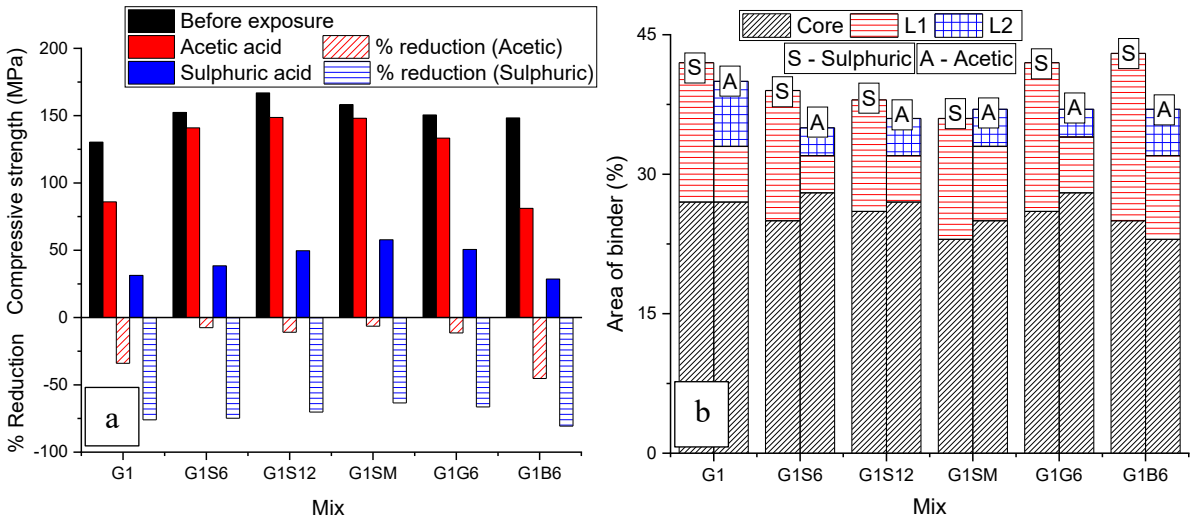

Figure 6. Compressive strength (a) and acid affected area (b) of alkali activated slag mortar.

As mentioned earlier, the effect of sulphuric acid on the AAS mortar was detrimental which is also the case with fiber reinforced AAS mortar. However, with incorporation of fibers, the residual strength improved in the corroded specimens irrespective of the type of acid. The order of resistance to sulphuric acid attack by fibers are, mixed steel steel > 6 mm glass > 12 mm steel > 6 mm steel > 6 mm basalt. This order is also maintained in the unaffected area (core) as identified in image analysis (Fig. 6 (b)). It can be seen from the SEM images that sulphuric acid corroded the sample and debonded the fibers completely (Fig. 9 (c), (f), (i)). The basalt fibers could not be even located in the corroded samples, making it clear that they need to be treated for such harsh environments (Fig. 9 (i)).

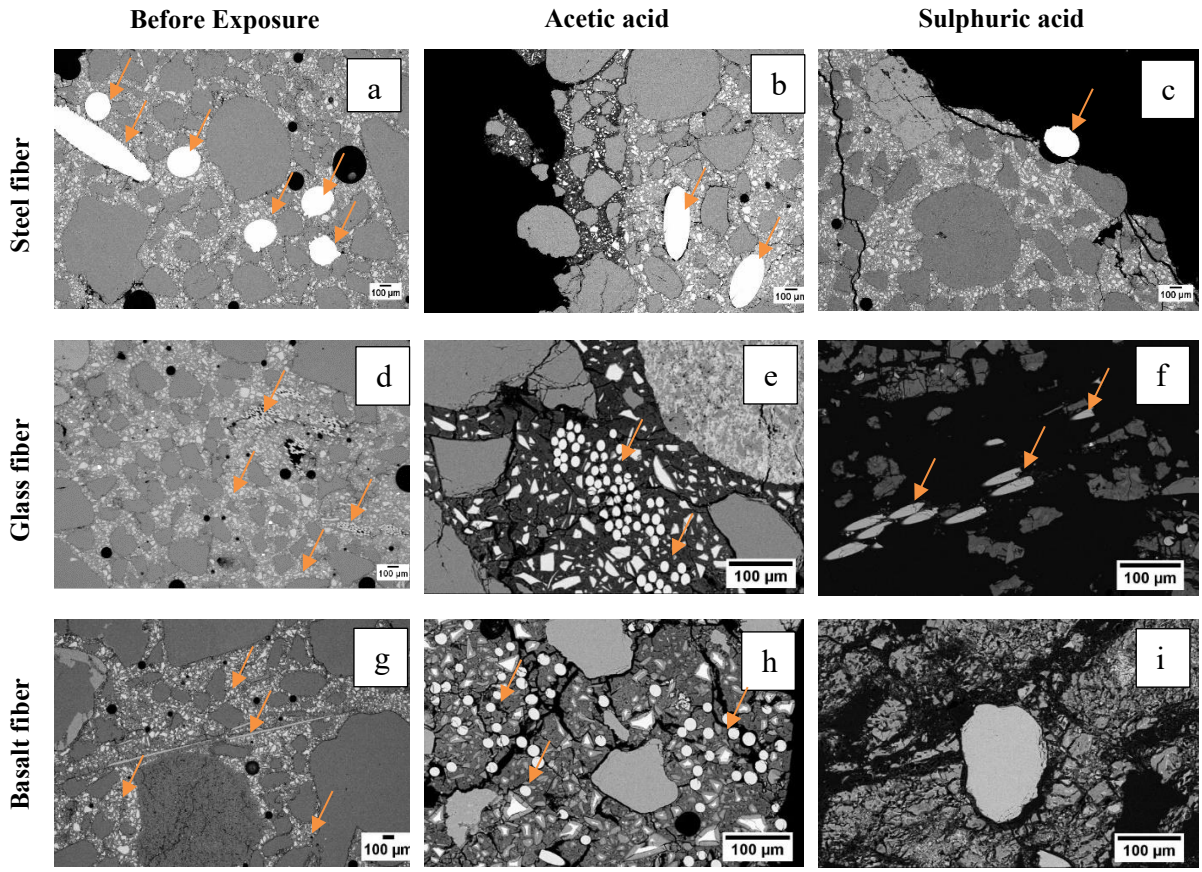

Figure 9. Representative SEM images of AAS mortar with (steel, glass, basalt) fibers before ((a), (d), (g)) and, after exposure in acetic acid ((b), (e), (h)) and sulphuric acid ((c), (f), (i)).

4 Conclusions

The influence of acetic and sulphuric acid on alkali activated slag mortar is investigated. Damage of alkali activated slag can be related to the decalcification and dealumination of the calcium silicate gels and the aluminosilicates, respectively. In acetic environment, the formation of calcium acetate acted as a barrier for further diffusion of acid protecting the unaffected core. However, sulphuric acid is corrosive and resulted in disintegration of binder matrix. Presence of fibers improved the performance of AAS mortar in corrosive environment. Residual strength of AAS mortar specimens are 19% and 7% higher with the reinforcement of mixed steel fibers (6 and 12 mm) in acetic and sulphuric acid exposure, respectively. Basalt fibers needs to be coated to use them in highly corrosive environment.

Abstract. *Alkali-activated materials (AAM) are now seriously considered by the cement industry as an economical alternative to Portland cement, especially for its low CO_2 footprint. However, their durability still remain to be assessed in more details. The aim of this study is to focus on the sample preconditioning conditions required for testing, especially the drying stage involved in most of the current tests. Four alkali-activated binders were studied: a geopolymer (Na-silicate activated metakaolin), a Na-carbonate activated slag (GGBS), a Na-silicate activated slag and a Na-silicate activated mixture of 50% metakaolin with 50% GGBS. After an endogenous cure of 28 days at 20°C, mortar specimens were dried at different temperatures (from 20°C to 125°C) until mass stabilization. Drying kinetics and released water contents were evaluated, as well as physical, mechanical and mineralogical analyses at the end of drying. Optimal drying temperature for each alkali-activated binder was determined by coupling mechanical strength measurements and mercury intrusion porosimetry. This study revealed that an inappropriate drying temperature could modify the porosity of some classes of AAM, and reduced the compressive strength by up to 30 to 40%. Antagonistic behaviors were observed in the four alkali-activated materials studied, therefore one should be careful about selecting preconditioning protocols for assessing the properties and the durability of these binders.*

Keywords: *Alkali-Activated Binder, Geopolymer, GGBS, Drying Conditions, Durability.*

1 Introduction

Alkali-activated binders are produced from a source of aluminosilicates (precursor) mixed with a highly alkaline solution (*e.g.* sodium (Na) or potassium (K) silicate solutions) called the activating solution (Davidovits, 1991; Provis and Van Deventer, 2009). There are two main types of alkali-activated binders, based on the calcium content of the precursors. They differ from the chemical mechanism that takes place and from the reaction products. For those rich in calcium, such as ground granulated blast-furnace slag (GGBS), chemical reactions are based on dissolution/precipitation steps. The main reaction products are C-A-S-H type phases (CaO-Al_2O_3-SiO_2-H_2O) (Pacheco-Torgal *et al.*, 2015). For precursors with low calcium content, such as metakaolins and type F fly ashes, the term geopolymer is used (Davidovits, 1991). This time, the chemical reactions consist in a dissolution/polycondensation steps, leading to a 3D-aluminosilicate network. In this network, silicon and aluminium are IV-fold coordinated and the alkali cation plays the role of a charge-balancing ion (Rowles *et al.* 2007).

An abundant literature is available regarding the alkali-activated materials (AAM) formulation, but only few studies deals with durability (Luukkonen *et al.*, 2018). Accelerated procedures for durability testing of Portland cements mixtures are often applied to AAM

without any modification, although the raw material used and physico-chemical reactions are different. These tests usually require a preconditioning of the specimens at temperatures ranging from 45°C (*e.g.* accelerated carbonation XP-P-18-458_2008), 80°C (*e.g.* permeability XP-P-18-463_2011), or even at 105°C (*e.g.* porosity NF-EN-18-459_2010). Alkali-activated binders contain gels and hydrates that can be affected and even destroyed at these temperatures (*e.g.* Zhang *et al.*, 2019). Thus, the effects of the preconditioning conditions on AAM need to be assessed, in order to avoid a deterioration of the specimens that could lead to misleading interpretations of durability tests.

2 Material and Methods

2.1 Samples Preparation

The raw materials used are Argicem metakaolin from the ARGECO Company; GGBS from ECOCEM; Betol 47T Na-silicate solution from Woellner (SiO_2/Na_2O = 1.7), Na-carbonate powder (Na_2CO_3) from Solvay, tap water from Toulouse city and standardized sand (NF EN 196-1_2016 and ISO 679_2009). Metakaolin and GGBS properties are available elsewhere in literature (*e.g.* Sabir *et al.*, 2001; Pouhet and Cyr, 2015; Pouhet and Cyr, 2016a; Samson *et al.*, 2017a).

Four alkali-activated mortars with a water/binder ratio of 0.4 were studied (see Table 1). The first formula is a metakaolin-based geopolymer developed by Pouhet *et al.* and which has been the subject of several publications (Pouhet and Cyr, 2014; 2015; 2016a; 2016b; Cyr and Pouhet, 2015a; 2015b; Pouhet *et al.*, 2019). Two formula of activated GGBS were prepared, with either a Na-Carbonate or a Na-silicate activating solution (GGBS-carbonates and GGBS-silicates). Finally, a mixture of 50% metakaolin with 50% GGBS activated by silicates is proposed in this study (Mk-GGBS-silicates) to test the coupling of the two hardening systems (based on Ca or Na). This formula has been previously tested on paste (Samson *et al.*, 2017a).

Table 1. Mix design, masses in grams.

	Metakaolin	GGBS	Na-silicate	Na-carbonate	Tap water	Sand
Geopolymer	450		354.9		46.2	1350
GGBS-silicates		450	101.3		141.8	1350
GGBS-carbonates		450		45	198	1350
Mk-GGBS-silicates	225	225	228.1		94	1350

Mortar specimens 4x4x16 cm^3 were made according to the standard protocol NF EN 196-1_2016. Most of samples were demolded 24 hours after pouring, except the GGBS-carbonates formula which was demolded at 48 hours because of its low mechanical properties at early age. The specimens were then endogenously cured (wrapped in plastic film and sealed in humidified plastic bags) for 28 days at 20°C. After this cure, some samples were kept in endogenous conditions, other were dried in different environments (20°C-95% RH, 20°C-50% RH, 20°C under vacuum, 40°C, 60°C, 80°C, 105°C and 125°C). Depending on the drying rate, the mortar specimens were analyzed at different times (the drying time varies from 12 to 49 days) and most of them at 60 days, and then compared to the mortar specimens kept in endogenous conditions for each due date. As regards the geopolymer specimens

placed in the vacuum desiccator, the pump operated only during laboratory's office hours (8 hours a day, otherwise the vacuum was maintained over the test period).

2.2 Characterizations

Several analyses were carried out in order to assess the effect of drying on the four alkali-activated materials:
- Mass monitoring was performed until mass stabilization, *i.e.* until the mass loss is less than 0.01 % between 7 consecutive days (except with 20°C-50%RH conditions which would take months to dry).
- Compressive strengths were determined using a standardized 3R press (NF EN 196-1_2016). Three measurements per mortar prism were made using a ramp of 5 kN / second. Measurements were carried out on the dry specimens as well as on control ones stored under endogenous conditions over the same period. In order to evaluate the dispersion of data, three specimens by drying condition were analyzed for each formula.
- Mercury intrusion porosimetry was performed using an AutoPore IV 9500 Porosimeter from Micromeritics according to the ISO 15901-1_2005 standard. Unlike what is recommended in the standard, samples did not undergo pretreatment for mercury intrusion analysis (*i.e.* 110°C heating in a vacuum oven at 3 Pa for 4 h). Endogenous samples containing water are therefore not dried, but dehydrated during evacuation step in the porosimeter. In order to be consistent for all samples, the test did not start until the exhaust pressure was ≤ 50 µmHg assuming complete removal of pore water.

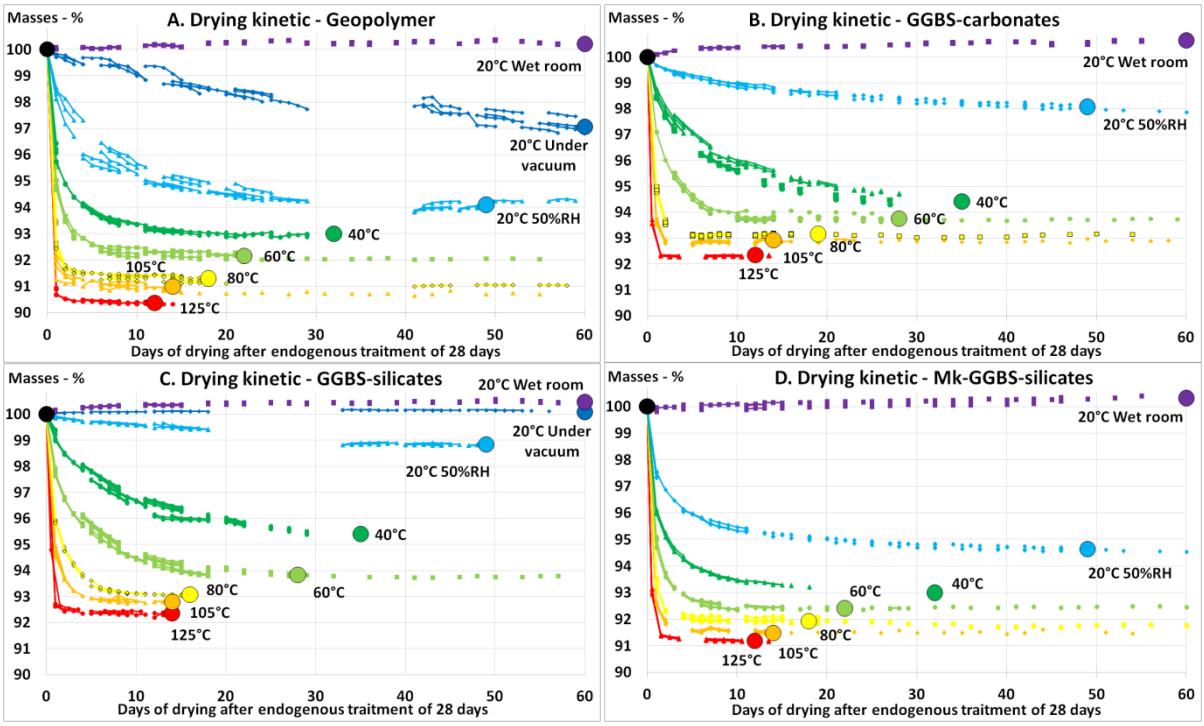

Figure 1. Mass evolution during drying at different temperatures of Geopolymer (A), GGBS-silicates (B), GGBS-carbonates (C) and Mk-GGBS-silicates (D). The circles represent the mass stabilization point.

3 Results and Discussion

3.1 Mass Monitoring

The mass variations recorded during the different drying processes show that the higher the temperature, the faster and more important the drying process (Figure 1). The comparison between the four materials shows different drying kinetics and different water content trapped in the structure of the material depending on the type of AAM. The drying rate is quicker when metakaolin is used as a precursor (Figures 1A and 1D), especially at lower temperatures, *i.e.* 20°C, 40°C and 60°C. Besides, almost all the mixing water has been evaporated in geopolymers at 105°C while almost 8% is remaining in GGBS-silicates (results not shown here). This can be explained because in geopolymers, all the water initially introduced is located in the porosity of the materials or in the alkali hydration sphere in the structural cavities of the Si-Al network (Rowles *et al.*, 2007), while in GGBS systems part of the water is bound in reaction products (C-A-S-H).

3.2 Mechanical Compressive Strengths

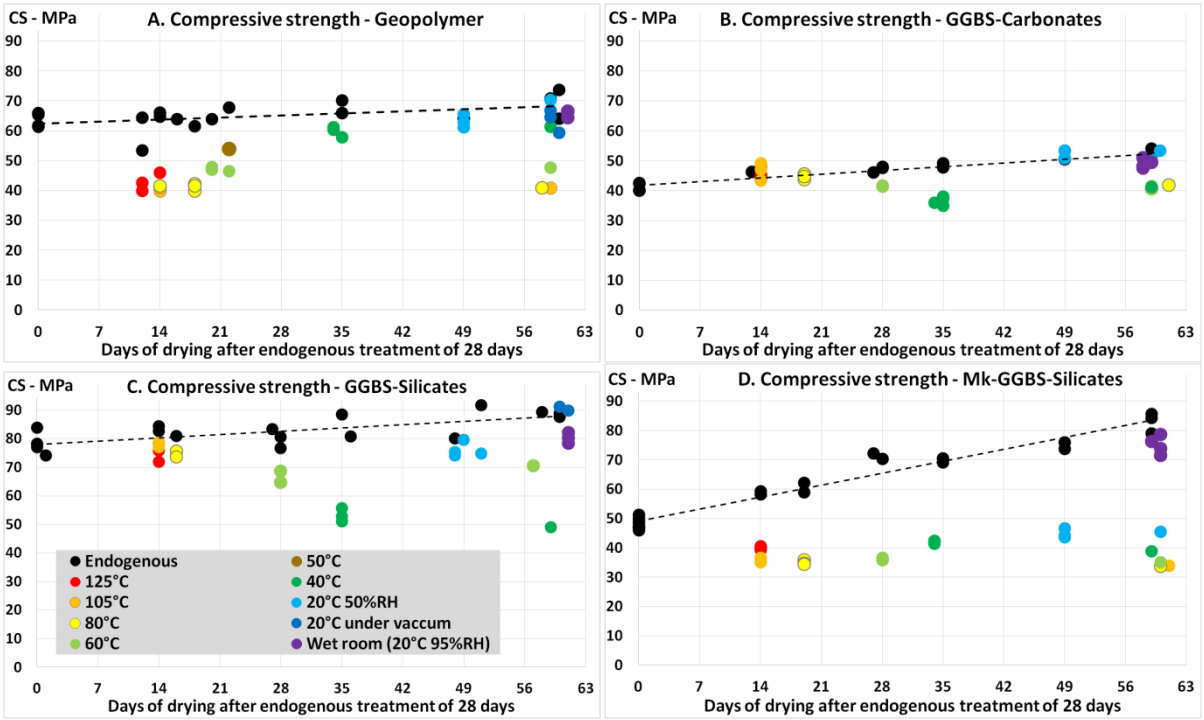

Figure 2. Compressive strengths (CS) of mortars cured in endogenous conditions (black spots) or dried at different temperatures (after endogenous treatment of 28 days). Geopolymer (A), GGBS-carbonates (B), GGBS-silicates (C) and Mk-GGBS-silicates (D). The legend inserted in C is valid for all figures.

In endogenous conditions, geopolymer samples show a slow increase of mechanical compressive strengths (CS) from 61 ± 6 MPa at 28 days to 70 ± 5 MPa at 88 days (Figure 2A). This increase seems to be stabilized after three months, as confirmed by six-months sample analyses. For GGBS-carbonates and GGBS-silicates, CS start from 41 ± 2 MPa and

77 ± 6 MPa at 28 days, respectively, then reach 54 ± 2 MPa and 89 ± 4 MPa two months later (Figure 2B-C). The CS increase is greater than for the geopolymer, and seems stabilized beyond 6 months. CS of the Mk-GGBS-silicates formulation increase from 49 ± 1 MPa at 28 days to 75 ± 4 MPa at 77 days (Figure 2D). To conclude, all four formulations show a progressive CS increase during the first months in endogenous conditions, probably linked to the pursue of chemical processes with time.

When the mortar specimens are dried (after endogenous curing for 28 days), the mechanical strength depends on both formula and drying conditions. For a drying temperature ≥ 50°C, geopolymer shows an important CS loss (up to - 36 %), even if the temperature conditions are extended for several weeks (Figure 2A). On the other hand, at drying temperature ≤ 40°C, CS were similar to endogenous ones. For GGBS-carbonates and GGBS-silicates, drying with temperature ≥ 80°C or at 20°C (with several humidities) does not decrease the CS, which are similar to those of samples stored under endogenous conditions (Figure 2B-C). However, drying at 60°C or more significantly at 40 °C decreases the CS up to -24% and -29% for GGBS-carbonates and GGBS-silicates, respectively. As for geopolymer, when the drying is maintained for a longer period than required, CS do not evolve anymore whereas in endogenous conditions the CS slightly increases, probably due to the wet storage that enable the further reaction of the materials. Finally, drying of the Mk-GGBS-silicates formulation considerably reduce CS (from - 30% to - 50%) whatever the temperature used (Figure 2D). Only samples cured in wet room (20°C 95% RH) retain similar mechanical strengths before and after curing.

3.3 Hg Porosity

In endogenous conditions, the total porosity of the four formulas does not change significantly between 28 and 88 days. Also, only the average value has been reported in Figures 3 and 4. Mean porosity is closed to 18 % for geopolymer, 15 % for GGBS-carbonates, 12.5% for GGBS-silicates and 15.5 % for Mk-GGBS-silicates. GGBS blends therefore have a lower porosity due to the formation of hydrates, when in geopolymers the water expulsed during condensations reactions is responsible for more porosity.

In drying conditions, the total porosity evolves differently for each system, as it seems to increase with the temperature level for the geopolymer (Figure 3A, 3B and 4A), to be quite stable for GGBS-carbonate (Figure 4B), having a maximum value for a drying temperature of 40°C as regards of GGBS-silicates (Figure 4D) and to be higher but stable for Mk-GGBS-silicates (Figure 4D).

Concerning the pore size distribution, geopolymer kept in endogenous conditions has half of the porosity attributed to pores < 10 nm, a quarter to 10-100 nm and the last quarter to > 100 nm (Figure 4A). However, this does not mean that half of the porosity is < 10 nm, but that the access to half of the porosity is possible by a diameter lower than 10 nm (according to inkbottle effect, *e.g.* Benavent *et al.*, 2016; Muller and Scrivener, 2017). Except desiccation under vacuum which is not an efficient drying, even a smooth drying at 20°C has the effect of replacing all the porosity < 10 nm by the category 10-100 nm. A strong drying replaces half of the 10-100 nm by the 0.1-1 µm and there is an increase of the 1-10 µm pore size. In summary, for the geopolymer, the more intense the drying, the greater the pore size (or at least the size of the necks).

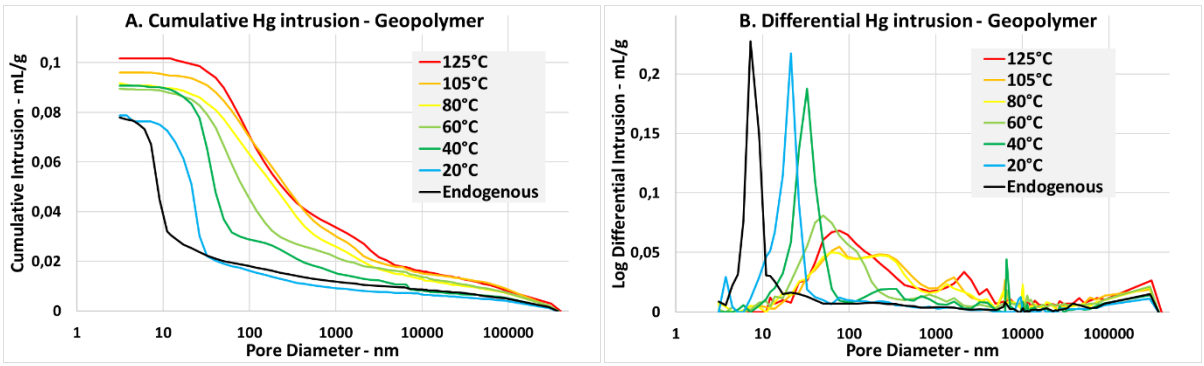

Figure 3. Geopolymer mortars mercury porosimetry as a function of drying: cumulative intrusion vs. pore diameter (A); differential intrusion vs. pore diameter (B).

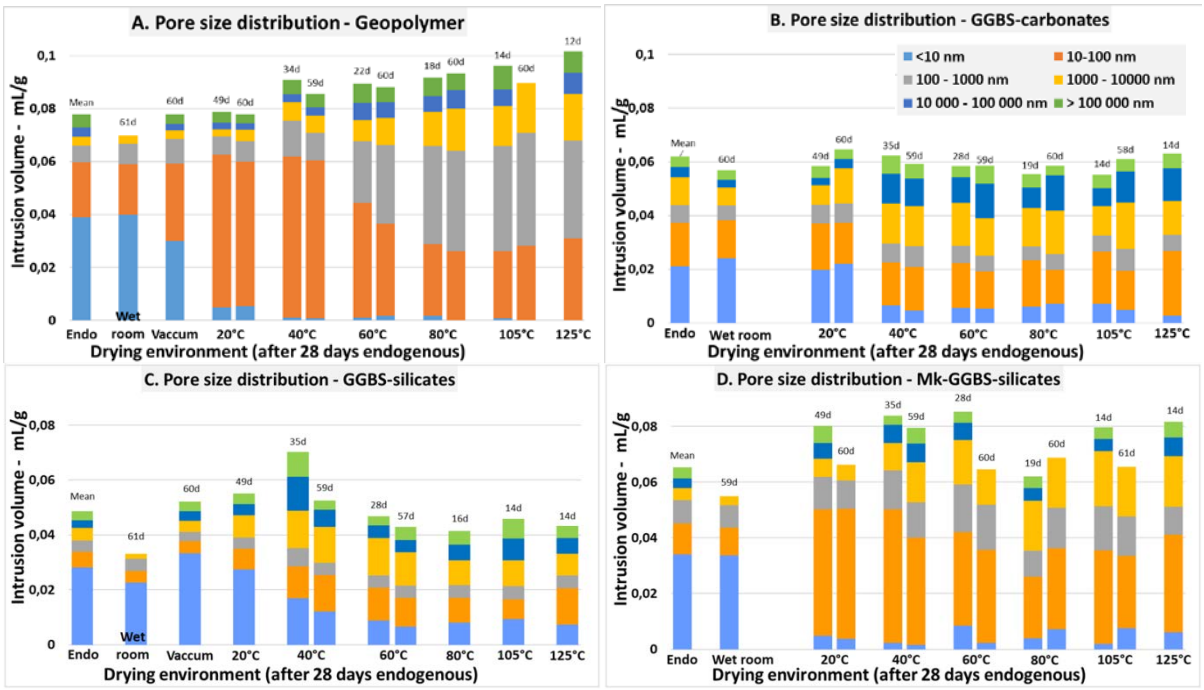

Figure 4. Pore size distribution for mortars of geopolymer (A), GGBS-carbonates (B), GGBS-silicates (C) and Mk-GGBS-silicates (D). Endo column represents the average of the samples conserved under endogenous conditions, analyzed at different ages (28 to 88 days), and showing similar properties. 50% RH for 20°C column. Up to 10 µm porosities are sometime missing due to porosimetry low vacuum problem.

Globally the same pore size distribution trend was observed for the other three formula, *i.e.* a pore size augmentation linked with drying temperature strength. However, pore size distribution modes slightly differ from one formula to another, for example with a < 10 nm pore contents varying from one third to half of the total porosity in endogenous conditions. Furthermore, the change in pore size family towards bigger sizes occurs starting from 20°C for the metakaolin materials, and from 40°C for the GGBS ones (Figure 4). Both geopolymer and Mk-GGBS-silicates show an evolution of the porosity with the increase of temperature from 20°C up to 125°C, while this evolution is limited to the range 20-60°C for GGBS materials (the pore size distribution remains constant for temperatures ranging from 60°C to

125°C). It should be noted, however, that the GGBS-silicates has a sharp increase in porosity for a drying temperature of 40°C, possibly related to micro-cracking induced by mineralogical transformations as suggested on GGBS alkali-activated concrete (Azar *et al.*, 2020).

Preconditioning recommendations must be a compromise between the drying efficiency and the impact on both the porous structure and the mechanical resistances. However, in the absence of mineralogical and microstructural data, results presented in this study should be interpreted with caution. As it has been demonstrated on Portland cements, capillary stress, the loss of physically or chemically bonded water from gels or hydrates, the potential micro-cracking as well as mineralogical changes within the material can lead to misestimating pore volumes (Gallé, 2000).

4 Conclusions on Preconditioning Drying

The effect of drying 4x4x16 cm samples at different temperatures has been assessed on four alkali-activated materials, in order to give recommendation for durability test preconditioning. The drying rate and level depend not only on the nature of the binder, in particular if chemically bonded water is present or not, but also on the porous arrangement. The results showed AAM mortars are sensitive to drying, with modifications of porosity and mechanical strengths. From mercury intrusion measurements, the pore diameter access increases starting from a drying at 20°C for the formula containing metakaolin as a precursor, and from 40°C for formula containing GGBS only.

Geopolymer drying at a temperature above 60°C is fast, but increases the measured pore size, and affects the compressive strength by 40% as a consequence. It is likely that this will affect the permeability of the material. Using a temperature below 20°C takes a lot of time, is not efficient, but does not affect the CS and the pore size. Between 20°C and 60°C there may be a drying optimum to find. A drying temperature of 40°C may be more appropriate for geopolymer, as it has less impact on the mechanical strength. Drying ramps could be tested to see if the fall of strength is due to the kinetics of drying or to the temperature itself.

As regards to GGBS-carbonates and GGBS-silicates, drying at $T \geq 80°$ C is fast, does not affect CS and slightly increases the measured pore size. In contrast, this study highlights that the material should not be dried at temperature closed to 40°C, otherwise it could lead to significant loss of mechanical strengths.

Finally, the Mk-GGBS mixture activated with silicates seems to cumulate the drawbacks of both alkali-activated systems. Whatever the temperature used, a high degree of damage to the mechanical strengths is observed, correlated with an increase of the porosity. For such mixtures, a drying by solvent exchange or by freeze-drying might be interesting, but this type of drying can only be performed on small samples.

Prolonging the Durability and Conservation of Historic Materials by Microclimatic Monitoring in the Archaeological Areas

Elisabetta Rosina and Alessandra Pili

Politecnico di Milano, ABC Dept. Piazza Leonardo da Vinci 32, 20133 Milano; email elisabetta.rosina@polimi.it, alessandra.pili@polimi.it

Abstract. *Many factors have to be considered for the correct conservation of cultural heritage, in particular, the exposition of the object/site to open air, as the archaeological sites have. The risk factors can be intrinsic (durability of materials, construction and decorative techniques) and extrinsic (environmental and microclimatic conditions). The consideration of the conservation issue regarding the second has to take into account the effects the microclimatic parameters on the objects and the variation of microclimate for the use, as well as the modification due to the improvement of accessibility, safety and installations (for example plant and architecture addition/modification). In fact, the main objective of the conservation/fruition of the archaeological areas is achieving the project choices most integrated, functional and adequate to meet the needs of conservation. Monitoring and diagnostics are a necessary condition to be able to correctly define the design choices. The proposed contribution aims to specify how monitoring the microclimatic values play a fundamental role in the whole process of conservation, since the early study to the management of the site, to ensure the greater conservation and durability of the material and, ultimately, the best fruition at present and in the future.*

Keywords: *Archaeological Site, Historic Materials, Roman Tombs, Accessibility, Durability, Management Plan.*

1 Introduction

The valorization of cultural heritage, achieved together with the conservation goals, must take into account the control of the condition of use.

The valorization of the wide range of types of cultural heritage includes many different possible uses, always respectful of the compatibility with the cultural goods and sites. In all the cases, the proper management of cultural heritage includes the conscious use(Sanchez-Moral, 2005), and it is a warrant the conservation: the use is opposed to abandonment, that causes consequently to the loss of historical material, due to the natural effects of aging, waste, human activities etc.

The final goal is to achieve an integrated design that manages to coexist the architectural and plant engineering aspects with the cultural value that the site represents.
In the case of archaeological sites, it is evident that re-use is not functional as it is in historical buildings (Thompson, 2007); however, valorization activities include the correct management of the site, for achieving the conservation goals and economic sustainability.

The Conservation Plan, defined in the cultural heritage code as the tool of the conservation process, includes information related to the constant control of the asset; among these, the code lists diagnostics and instrumental monitoring.

Figure 1 and 2. Aerial view of the archaeological area of Tuvixeddu in Cagliari and sign of the paths and open tombs at the park entrance (credits to Intercral Ass.).

The different complexity of the archaeological sites, compared to other cultural assets, requires to articulate the design to solve the specific problems, above all the mitigation of the effects of the environment and the context (Huisman *et al.,* 2009) including also how the site is used. In fact, the estimation of risks necessarily includes the evaluation of the impact of visitor presence on microclimatic conditions and therefore on the conservation of historical materials: together with the microclimatic perturbance, the accessibility of visitors can require more modifications than in Historical buildings, especially if the archaeology site is underground or if it is a ruin. Additional fragility of open air sites consists of the continuous ageing, weathering, growth of vegetation and in isolated places random or usual passage/nesting of animals too.

Therefore, in the project of conservation and valorization, it is fundamental to recognize, know and understand these factors and the interferences they can generate. Diagnostics and monitoring are in a key position for acquiring that information, therefore they have an important role in the design and management of sites.

The biggest challenge, still ongoing, is to find an optimal threshold between conservation and valorization. The contribution presented here aims to understand the role of diagnostics and microclimatic monitoring within the cognitive process, both in the preliminary and fruition phases. The final goal is to prolong the durability of the materials, assuming that the material is the manifestation of cultural and historical value. Diagnostics and monitoring are therefore a fundamental activity for understanding and mitigating risk factors that affects the durability of goods and sites (Rosina *et al.,* 2011; Cecchini, 2012; Rosina, 2012; Camuffo *et al.,* 2015; Rosina *et al.,* 2019). In the following, the paper presents the investigation, monitoring, management of an underground Roman tomb in the Necropolis of Tuvixeddu in Cagliari (Figures 1 and 2).

The tomb is built inside a limestone bench and the internal surfaces are decorated with wall paintings and lime mortar stuccos.The assessment of the site regarded materials (surface sampling and chemical analysis for the characterization), degradation (sampling and chemical and biological investigations), archaeological (excavation and acquisition of results), environmental and microclimatic. The latter, which began in July 2017, includes continuous monitoring of microclimatic values (still in progress) and various psychrometric and

thermographic campaigns with the aim to understand the behaviour of the microclimate at static conditions, how it varies during the seasons, the effects of opening and presence of visitors inside it. Regarding this last aspect, continuous monitoring has allowed the recording and analysis of data also during the phases of archaeological excavation and restoration of the surfaces, when up to 10 people remained inside for many hours a day. The monitoring lasted during the discovery of new burial environments and the lowering of the walking surface to the original height, that changed of the air volume. The measurement made it possible to verify the trend of the microclimatic parameters as the volumetric conditions changed, as well as the variations due to the ventilation conditions and the presence of people.

The microclimatic data were cross-checked with the results of the chemical and biological analyses, that supported also the choice for design and size of the light system (type, lighting localization and time), air conditioning and control to be installed.

2 Method and Tools

Diagnostic and monitoring of the tomb case study cover a time span of 30 months. During this period several analyzes and data collection were carried out:
- Monitoring of T and RH by means of sensors
- Monitoring of T and RH by means of a psychrometer
- Thermography scanning
- Sampling and measurement of the quantity of water present on the surfaces - Sampling and quantification of the salt content
- Sampling and characterization of the biological degradation phenomena

Thermography and psychrometric measurements were performed on a seasonal basis. In particular, the thermograms recaptured wall and ceiling surfaces a to investigate any variations due to the presence of water in the limestone rock bank due to rain, natural sources and the above garden that has been regularly watered for years. The seasonal acquisition campaigns with psychrometer were carried out in double stroke, in the morning and in the afternoon, and detecting the values at two different heights (about one meter from the floor and near the ceiling). Finally, biological analyzes were performed for the characterization of some fungal formations that occurred only in certain periods and at specific external climatic conditions. All instrumental analyzes and investigations were carried out according to the regulatory standards contained in UNI 9252/88, UNI EN 16.714-1: 2016, UNI EN 13187: 2000.

3 Results

3.1 Monitoring

Prolonged monitoring over time has allowed researchers to build the so-called ”historical climate” (Camuffo *et al.,* 2015). The goal was to understand how and under which events the values of T and RH varied over time. The evaluation included the comparison with the environment data outside the tomb; a main the result was the identification of the time windows throughout the year in which the values of the microclimatic parameters were

almost similar, leading to the consideration that any opening could not cause large imbalances and therefore potential risk situations for the interior decorated surfaces.

Moreover, the data processing made it possible to observe the distribution of the T and RH values within the room and the side niches: the greatest variations resulted near the entrance. In that area, the imbalance is due to the poor insulation of the door and the presence of a closing wall made of concrete and brick blocks (that was built years ago to close the tomb after the demolition of a part of the rocky bank). The variations in the temperature parameters, evident in the thermograms, are clearly due to the different thermal transmittance of the concrete and the brick compared to the limestone. The phenomenon of the temperature increase is also favored by the orientation of the entrance front to the south-west without any screen or shadowing object, therefore it is subject to solar radiation in the hottest hours of the day.

Today the conformation of the tomb has changed compared to the situation in which the psychrometric and thermographic shot were made. New sepulchral rooms and the original level of the floor, that over time had been covered, emerged during the archaeologicalexcavation carried out before the restoration works. Furthermore, the presence of archaeologists and restorers made it necessary to open the tomb with a much higher frequency than in the previous period. After the works inside have been completed, a new campaign of measurements with the psychrometer and thermographic acquisition is planned, to compare and analyse the changes that have taken place and formulate the appropriate design choices for the use of the site.

The acquired data have shown that the distribution of temperatures is almost homogeneous throughout the whole year, with seasonal variations of around 2°C and Relative Humidity between 90% and 100%. The thermograms made it possible to highlight some thermal anomalies near the entrance wall, for the reasons described above, and in some points of the vaults of the side niches. This last phenomenon can be explained by a probable variation in the thickness of the rocky bank. In addition, the moisture could be due to the presence of a private garden above, which is regularly watered also in the periods of absence of rain. As a conclusion, it is probable that the concomitance of the presence of water in the ground practically constant and the reduced rock thickness make the infiltrations possible in some weak points.

As regards the laboratory analyzes carried out on the samples, it emerged that the quantity of water is particularly high, also confirming the humidity values detected with continuous monitoring and with the psychrometer. The analyzes however revealed a difference in the results between the samples taken near the entrance and those taken in the innermost parts. An explanation is that the ventilation conditions are different; in fact, the brick and block masonry and the uninsulated door felt higher ventilation than inside, thus favoring the surface evaporation of humidity. In natural conditions, the analysis of the internal values showed a variation of 0.5° C every ten days, approximately. After reporting the internal data compared to the external data, it emerged that the internal average values have variations that do not follow the external ones, as well as having a delay between the peaks (both maximum and minimum) of about two months compared to those detected externally. Instead, during the permanence of the archaeologists and restorers (December 2018) monitoring registered higher variations in temperature and more modest variations in humidity.

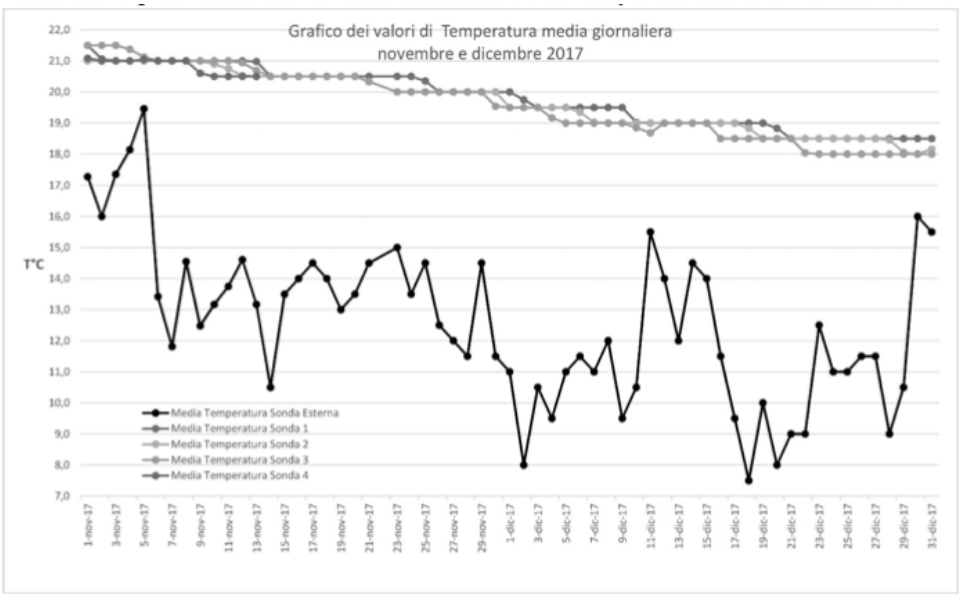

Figure 3. Graph of the daily average Temperature values recorded between November and December 2017 .

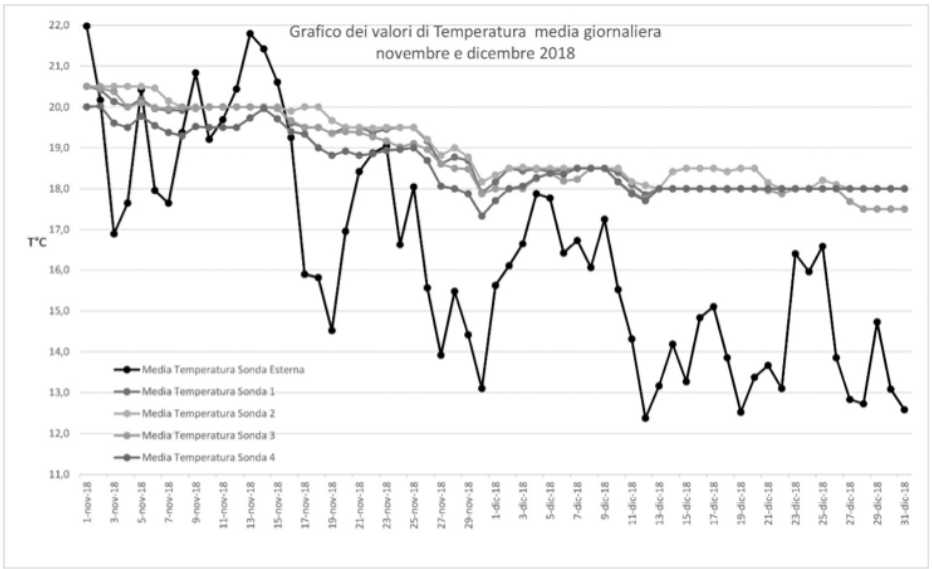

Figure 4. Graph of the daily average Temperature values recorded between November and December 2018.

3.2 Risk Factors

Concerning the above and the results obtained from the diagnostics, the following risk factors have been identified:

- Variability of microclimatic values in different conditions
- Different conditions of exposure to the presence of water in the overlying layer (heterogeneity of shapes and dimensions of the rocky bank)
- Presence of people within the site

To the first point, in addition to the implementation of an air control system, the insertion of an inlet bush that acts as an isolation environment for the passage of people could be particularly effective to avoid instantaneous and frequent imbalances in ventilation and microclimatic values. This aspect is strictly connected to the good knowledge of the optimal valuesthat must be respected for the conservation of the surfaces.

To the second point, particular attention must be paid to the critical points when designing the systems which, due to the intrinsic construction characteristics, are more exposed to infiltrations.

Last aspect, the presence of people (meaning both visitors and other subjects who can access the rooms for various reasons), in addition to an accurate programme of times, frequency and maximum number of people admitted, the systems should guarantee the possibility of adjusting the air control according to the changes to maintain the optimal conditions stably, avoiding unbalances that are harmful to the surfaces.

4 Opening Versus Conservation?

The availability of scientific literature and the present capability to conduct more appropriate restorations with the investigation of the chemical-physical properties allowed to safely open some tombs, through the study of air control and the management of the number of accesses. The environments resulted with good thermal inertia due to the thickness and the quality of the rocks. On the contrary this determines that the environments are particularly humid and, with scarce possibility to reduce the humidity. The major thermal unbalances are located near the entrances and during their opening.

Therefore, to improve the durability of historic materials in such severe ambient conditions, the scientist and competent authorities took the choice to open only the tombs with more durable materials in open air and provide a consistent plan of conservation for periodic inspection and preventive activities.

Moreover, another analysis conclusion is that only few people at time can access. The installation of a narrow suspended path above the floor has been another help to reduce the passage of many visitors at the same time. The material of the walkway will be aesthetically compatible and waterproof to stand the high humidity and do not stain with rusty the underneath structure of the tomb. Special care has been devoted, design the entrance room, with the aim to create a double space isolate the microclimate from the external variation and guarantee an intermediate space for disables Although conservation goals seem to contrast the valorization ones, that include to visit the site, the experiences conducted in the last decades showed that is possible to combine such divergent issues by keeping under control the condition and constantly updating and revising the management plan. Especially in a time

of possible variation in the climate, monitoring ambient conditions is crucial for any decision regarding the management of the fragile heritage exposed outside. The installation of visitor centers, in which it is possible to have virtual visits, watch videos, documentation and any multilevel shared knowledge, can highly decrease the pressure of real visitors. Nevertheless, opening the tombs remains a necessity that has to take into account and be possible also for technical purposes of the conservation itself. The design of the accessibility and its boundary remains one of the central focus of the conservation of archaeological sites, although sharing experiences and knowledge is far from any possible standardization of the solutions. What is possible, instead, is to share the best practices for acquiring data and monitoring in any phase of the long process of conservation, starting from the preliminary overview up to the maintenance and regular inspection after the restoration.

Abstract. *Fabric Reinforced Cementitious Matrix (FRCM) and Composite Reinforced Mortar (CRM) systems are used as Externally Bonded Reinforcements (EBR) in civil and historical construction. These materials are made by fibrous reinforcement, in forms of dry (FRCM) or cured (CRM) meshes embedded in a cementitious/hydraulic lime matrix. At present, this technology is considered very promising in the field of structural strengthening, retrofitting and repair existing structures. This is true especially in those cases of masonry and historical buildings, due to the specific criteria of conservation and compatibility with the substrate that need to be fulfilled. These materials, in fact, results more compatible with masonry substrate because of the inorganic matrix, instead of polymeric resin used for the well-known FRP systems (Fiber Reinforced Polymers). The recent use of these new materials in civil engineering needs appropriate and complete guidelines, that regard not only the design aspects but also the durability features. This paper presents the results of a large experimental program focused on the durability of FRCM and CRM systems and their single components, in different alkaline environments. For the whole experimental campaign, the samples have been immersed into three different alkaline solutions, for four exposure times (500, 1000, 2000 and 3000 hrs). In addition, in order to study the different accelerating effects due to temperature, three different temperatures were maintained during the ageing periods: 23°C, 40°C and 70°C. The results about the mechanical characterization of residual properties are discussed in order to highlight the influence of alkaline environments on the mechanical properties of single elements and the whole strengthening systems that were tested herein.*

Keywords: *Durability, FRCM, CRM, Alkaline Environments, Accelerated Aging.*

1 Introduction

Masonry buildings are a significant part of the architectural heritage in Europe and all over the world. A large number of these buildings, in consequence of earthquakes or other degradation processes, require repair and reinforcement because of their high seismic vulnerability and brittleness. In the last 20 years, innovative systems called EBR (Externally Bonded Reinforcement) became a common strengthening solution to replace the ordinary techniques and traditional materials in retrofitting of existing buildings. EBRs are typically composite materials, constituted by fibers of various nature (carbon, steel, basalt, glass, aramid or natural

fiber) embedded in a matrix. The most common systems are known as FRP (Fiber Reinforced Polymers), in which the matrix is constituted by a polymeric thermoset resin. During the last years, a new generation of fibrous materials was conceived and designed, by replacing the polymeric resin with inorganic matrix. These materials are called FRCM (Fabric Reinforced Cementitious Matrix) or CRM (Composite Reinforced Mortar). The difference between them is that in FRCM a soft dry net of fibers constitutes the internal reinforcement, while in CRM a rigid FRP grid is used as internal reinforcement embedded in a cementitious or lime mortar. This last technique can be considered a replacement of the traditional reinforced plaster, in which steel grid is replaced by FRP mesh. The mortar-based strengthening materials represent a valid alternative to the well-known FRP in those cases of reinforcement of existing masonry buildings. In fact, FRCMs and CRMs ensure compliance with the requirement for the conservation of architectural heritage (ICOMOS/ISCARSAH 2005). The application of FRCM and CRM provides a better compatibility with masonry substrates because of the high vapor permeability of mortar, but not only. In fact, these materials are sustainable and reversible, can be easy applied also on irregular substrates, on wet support and have better performance at elevated temperature. Due to the low costs, to the absence of galvanic corrosion (as same as traditional composites) and to the installation requirements that recall the traditional mortars, the interest of many researcher was addressed to these materials. However, many issues still require further investigation in order to guarantee the effectiveness of this technique. In fact, for both types of inorganic EBR systems, the investigation on short- and long-term behavior is essential. The durability of polymer composite materials was investigated in depth. Instead, the long-term behavior of FRCM and CRM systems represents a new research frontier, because of the lack of experimental data and poor knowledge of the possible chemical or physical degradation mechanism that may be activated in harsh environments. Only few works exist in technical literature about this important issue. Most of them are focused on Carbon (Arboleda 2014; Nobili and Signorini 2017; Donnini *et al.* 2017) and AR-Glass (Nobili 2016; Colombo et al. 2011) FRCM, in some cases following the procedures defined by Acceptance Criteria (AC434 2011), and others include the study of the durability of the constituent materials, fibers (Nobili 2016; Micelli and Aiello 2017) and mortar (Nobili 2016). In order to better understand all the possible effects due to aggressive environments in which these external reinforcement systems may work during the service lifetime, a large experimental program is presented in this paper. The research was focused on the durability of FRCM and CRM systems and their single components, namely dry glass fibers, pre-cured glass fiber grids and mortar matrix, in alkaline environments. In fact, it is important to investigate in depth, not only the behavior of the entire system, but also the effects on the chemical, physical and mechanical properties of constituents. The obtained results, in terms of residual mechanical properties and physical damages, are discussed in the paper in order to highlight the influence of alkaline environments on the mechanical properties of the tested specimens.

2 Materials and Method

The experimental program for the determination of FRCM/CRM's mechanical properties after alkaline attack consisted of two different groups. The first, called System 1 is a FRCM reinforcement while the second one, labelled System 2, is a CRM material. For both groups, not only the systems have been considered, but also their constituent elements (matrix and

reinforcement). For System 1, in fact, FRCM, dry grid of AR (alkali-resisted) glass fiber and mortar samples have been tested. The System 2 consists only of dry yarns and the corresponding pre-cured mesh of E-CR (electric grade) glass fibers reinforced polymer (GFRP), utilized to make CRM.For both groups, the alkaline treatments had been performed by immersing the samples in three different alkaline solutions, varying the chemical ions and the pH values. The first solution, called A, wanted to simulate the lime mortar matrix, with a pH equal to 12.6 (Micelli and Aiello 2017). The solution B, corresponding to Portland matrix, is a saturated solution of 0.16% $Ca(OH)_2$ + 1% Na(OH) + 1.4% K(OH) in weight, achieving a pH=12.8 (Litherland et al. 1998; Micelli and Aiello 2017). The last one, solution C, follows the standard protocol (ASTM D7705/D7705M - 12 2015), with the highest pH equivalent to 13.8. Four periods of treatment are considered, i.e. 500, 1000, 2000 and 3000 hours. In addition, with the aim to accelerate the ageing, the solutions were maintained at three incremental temperatures, 23°C, 40°C and 70°C.The samples have been labeled using the following alphanumeric code: first part means the type of specimens (for System 1 DG=Dry Grid, M=mortar, FRCM=Fabric Reinforced Cementitious Mortar; for System 2 GG=GFRP Grid, DY=Dry Yarn); second part states for treatment temperature (U=Untreated sample, 23, 40, 70°C); third letter distinguishes the alkaline environments (A=lime solution, B=Portland solution, C=standard alkaline solution); fifth part sets out the ageing time (500, 1000, 2000, 3000 hrs.). The whole experimental program consisted of 824 samples, of which: 23 untreated specimens, i.e. 5 samples for DG_U, FRCM_U, DY_U, GG_U and 3 samples for M_U); 801 aged specimens, i.e. 5 samples for each type of materials excluded mortar M (3 samples), for each alkaline environment, for each temperature and for each time. The mechanical properties of untreated samples, that constituted the reference ones, have been preliminary determined.

Single yarns of DG_U materials, i.e. the internal fibrous reinforcement of FRCM samples, have been cut from the dry grid, obtaining samples 350 mm long, and tested by performing direct tensile tests. The mechanical properties acquired are the follows: tensile strength, $\sigma_{f,DG}$, 1373 MPa (CoV=9%); maximum strain, $\varepsilon_{f,DG}$, 1.6 % (CoV=4%); elastic modulus, $E_{f,DG}$, 91 GPa (CoV=7%). The matrix of System 1 is a typical pre-mixed mortar based on lime and cement. Prismatic samples, that have the standard dimensions for three-points flexural tests, according to (CEN 1999 1999), i.e. 40x40x160 mm, have been tested for three-point bending test and the flexural strength has been determined. The compression test was carried out on the two parts of each mortar prisms derived from the flexural tests. A maximum compressive stress, $f_{c,M}$, of 20.6 MPa (CoV=7%) and a maximum flexural stress, $f_{f,M}$, of 4.0 MPa (CoV=12%) were experimentally measured for the mortar. The reinforced system was made by one sheet of DG embedded in 10 mm of mortar. Two thin layers of water-based adhesion promoter were applied before and after the introduction of the glass fabric, as recommended by the manufacturer. The dimensions of FRCM were 440x50x10 mm. They have been tested following the Italian guidelines (Consiglio Superiore dei Lavori Pubblici 2018) and the mechanical properties obtained are: ultimate stress, $\sigma_{u,FRCM}$ = 1632 MPa (CoV=16%) and corresponding maximum strain $\varepsilon_{u,FRCM}$ = 1.3 % (CoV=29%). For the second group of specimens, a pre-cured mesh of glass fibers reinforced polymer (i.e. GFRP grid) and the dry glass yarns have been tested, carrying out tensile test in both cases. The mechanical properties of GG samples result the follows: elastic modulus, $E_{f,GG}$, 48 GPa (CoV=6%); tensile strength, $\sigma_{f,GG}$, 1485 MPa (CoV=5%); the corresponding strain, $\varepsilon_{f,GG}$, is 3,0 % (CoV=8%). The dry yarns DY, that are used to manufacture the GFRP grid (GG), have been characterized, according to the Italian

technical standard. The ultimate tensile force, obtained from tensile test, was equal to 617.2 N (CoV=10%) and the elongation at break resulted 19.1 mm (CoV=19%). To immerse samples in the three different alkaline solutions, ad-hoc supports have been designed and fabricated, in order to promote a uniform distribution of the ageing solutions. All samples have been located into different stainless steel containers with transparent and plastic lid, for each alkaline solution and for each temperature.

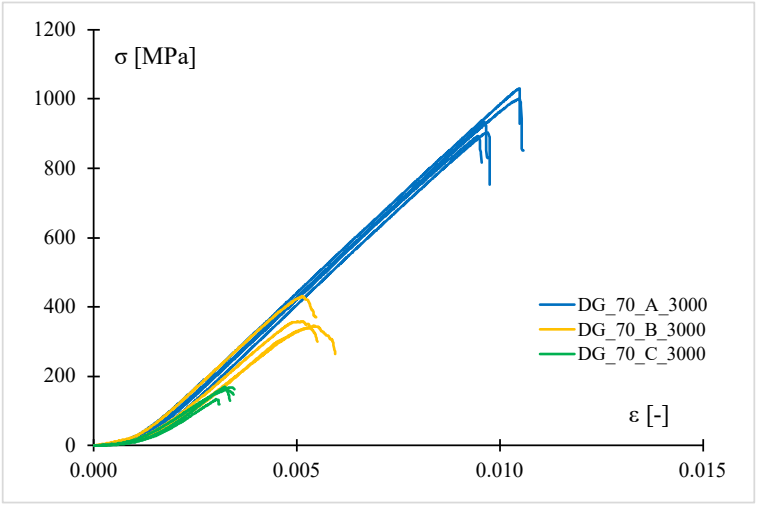
3 Experimental Results and Discussions

After each curing period, DG, FRCM, DY and GG samples have been tested by performing direct tensile tests, while for mortar specimens (M) both three-points flexural test and compressive test have been carried out. In this way their principal mechanical properties have been determined and compared with those of control specimens. In the following section, a synthesis of the numerous outcomes has been reported.

3.1 DG Samples

The stress vs strain behavior of glass fibers yarns was pseudo-linear. At high loads, prior to failure, in some cases, sudden discontinuities were found in the curves. This was due to the progressive rupture of single filaments. In fact, the failure mode (Figure 1a) was characterized by a gradual tensile rupture of single filaments of the yarns, regardless of the alkalinity of the solution or the immersion time. With the increment of the temperature, the alkalinity of the solution C has caused the higher reduction of the mechanical properties of DG samples, while for the solution B the alkaline products have been less damaging. At the higher treatment temperature, i.e. 70°C, the tensile behavior is still linear (Figure 1b), but the influence of the different alkalinity of the three solutions, with the increase of curing time, results more evident regard to the treatments at 23°C and 40°C.

(a)

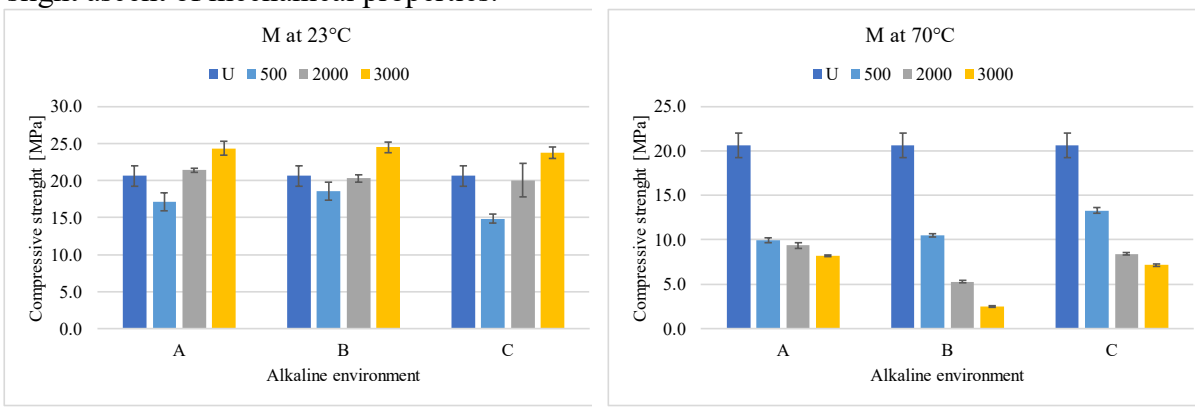


(b)

Figure 1. Typical failure mode of DG samples (a) and an example of stress-strain curves, for specimens aged at 70°C after 3000 hours (b).

3.2 M Samples

For mortar samples, the solution B turned out to be the most aggressive alkaline environment. The detrimental effects of its alkaline ions (Ca^{2+}, Na^{+} and K^{+}) are improved by the high temperature, causing the loss of compressive strength equal to 88%, after 125 days of treatments (Figure 2b). For shorter period of immersion, the reduction of the mechanical properties was obviously less (Figure 2a). In this case, after an immediate decrease of both flexural and compressive strength of mortar, no matter the alkalinity level, the immersion in aqueous solutions allows the delayed hydration of inorganic matrix and its self-healing. This results into a slight ascent of mechanical properties.



(a) (b)

Figure 2. Comparison of compressive strength of (c) M_23 and (d) M_70.

3.3 FRCM Samples

The three alkaline solutions at room temperature (23°C) seem to be not very aggressive against the tensile properties of FRCM coupons, even after 3000 hours of immersion. This is underlined by the histograms in Figure 3a, in which the values of strength of FRCM_23 samples have been plotted together with the reference one. By comparing the three solutions, the second one, that reproduces the Portland cement, has caused the greater damaging effects on the treated specimens, but, even in this case, they are very limited. The behavior of samples resulted more deformable but also more brittle. The formation of the first crack in the matrix often corresponds to the ultimate condition of samples cured for longer time. In fact, very few cracks predict the tensile failure of glass yarns.

3.4 DY Samples

The decay of mechanical features of DY specimens, contrary to what obtained from mechanical tests on dry glass fabric (DG), was activated to room temperature as early as 500 hours. This could be related to the different nature of glass fibers. Indeed, DG are constituted of alkali-resistant (AR) glass fibers, that are made by a specific formulated glass composition with addition of Zirconia (ZrO_2), and they are suitable for use in inorganic matrix. On the other hand, DY consist of the ordinary electrical grade glass fibers (E-glass). This kind of fibers are a low alkali glass, without any inclusion of Zirconia and then they are prone to chemical degradation in presence of alkaline species. The evident degradation of DY samples is due to a combination of mechanisms which may occur within the microstructure of the composite materials, i.e. an

effect of the ions $(OH)^-$, which produces corrosion of the fibers, and a second effect due to the precipitation of hydration products, which may reduce the flexibility of the fibers (Bentur 2000; Majumdar, West, and Larner 1977). All of this has been evident carrying out SEM (Scanning Electronic Microscope) analysis on damaged glass filaments. Figure 4a-b, which relate to specimens treated with CVD (Chemical Vapor Deposition) of gold particles (O'Brien 2001), show the typical morphology of the etching on the glass surface, as also seen by (Guo *et al.* 2018) in glass and basalt, and by (Aghamohammadi *et al.* 2018) in basalt fibers. In the present case, the attack appeared more extensive due to the extreme ageing conditions adopted by enhancing the temperature up to 70°C.

(a) (b)

Figure 4. Images of DY_70_A_3000 specimen with (e) 1001x, (f) 1999x of magnification.

3.5 GG Samples

As underlined by the histograms in Figure 5a, the most aggressive treatment is constituted by the solution B: σ decreases drastically already after 500 hours of immersion at 23°C (decline of 20%). As expected, higher temperature accelerates the detrimental effect of ions dissolved into the solution and the gap between the mechanical feature of reference samples and

GG_40_B_3000 is more that 80% (Figure 5b). The different between the maximum tensile stress of untreated samples (blue column) is more than 95% for samples treated at 70°C. For the two other solutions, A and C, the reduction does not exceed the range of variability of the standard deviation, for treatments at standard temperature, while increase at the highest temperature (-77% and -73% for the solution A and C respectively), however less than in case for solution B.

4 Conclusions

In the present paper, a large experimental program on long-term behavior of composite systems has been briefly reported. Two groups of samples, called System 1 and System 2, have been treated into three different alkaline conditions and four exposure times (500, 1000, 2000 and 3000 hrs.). The ageing was accelerated by increasing the temperature, from 23°C to 40°C and 70°C. The outcomes of the mechanical characterization of residual properties of two different systems highlighted what in the follow:

- Aging at 23°C results not very aggressive for samples of System 1, while the effects were more visible for dry yarns of E-glass fibre and the GFRP specimens (System 2)
- A particular behaviour has been observed in case of mortar samples, especially when they have been aged at 23°C. The immersion in an aqueous solution leads to self-healing process and the mechanical properties do not decrease because of the alkaline environments, but rather increase as effect of the delayed hydration of inorganic matrix.
- The treatments at 70°C, as expected, have provoked an extremely detrimental impact and until the completely break-up of the E-glass dry yarns.
- For these last samples SEM analysis has been performed, in order to detect the surface morphologies and fracture surface of E-glass corrupted filaments. In particular, in case of solution A, at 70°C and after 3000 hours of immersion, the filaments result completely covered by precipitated calcium carbonate and the massive damage that occurred have caused an evident reduction of the cross section, almost to zero in some regions. This is due to etching on the glass surface and to the extreme ageing conditions adopted by enhancing the temperature up to 70°C.

Resistivity Measurements to Assess the Freeze - Thaw Attack on Concrete – Lab Specimen and Real Structure

Frank Spörel

Federal Waterways Engineering and Research Institute (BAW), Kussmaulstraße 17, 76187 Karlsruhe, Germany, frank.spoerel@baw.de

Abstract. *Waterway structures like locks are exposed to a severe freeze-thaw-attack. A sufficient resistance of concrete against this exposure has to be assured. In Germany the concrete for the exposure class XF3 of federal waterway structures has to be tested in the laboratory by the CIF-Test in addition to descriptive requirements. To establish this procedure experiences on concrete mix designs which have been applied in the past were considered as well as research concerning the transferability of laboratory tests to practical experience. One important aspect was a service life study on the degree of water saturation of the concrete under practical conditions in combination with the temperature exposure. The paper presents the results of freeze-thaw tests on lab specimens and cores of concrete elements stored differently and tested at different ages. For a better understanding of the processes of the freeze-thaw attack during the freeze-thaw tests monitoring data of resistivity has been analyzed and compared to hardened concrete properties. The water absorption inside the specimen during capillary suction and the freeze-thaw-cycles could be monitored at different distances to the surface. Correlations of the water absorption to the initiation and development of internal damage were observable. A consideration of the results of the freeze-thaw tests and the resistivity measurements enables a better evaluation of long-term resistivity monitoring data of a lock. It allows for an assessment of the transferability of results of the CIF-Test to practical experience.*

Keywords: *Freeze-Thaw Attack, Resistivity, Monitoring, Concrete Core, Lab Specimen.*

1 Introduction

In Germany for hydraulic structures like locks or weirs there are special requirements concerning concrete properties. As they are massive structures a low heat of hydration of the concrete to reduce restrain is important and on the other hand a high durability for a service life of hundred years. Freeze-thaw resistance is a very important durability aspect for those structures as the high water saturation of the lock chamber walls between head and tail water results in a severe freeze-thaw attack. During the initial test of the concrete intended for parts of the structures in XF3 exposure a performance test is required for new structures under the responsibility of the Federal Ministry of Transport and Digital Infrastructure. The CIF-Test according to (BAW, 2012) has to be passed. The procedure is similar to the RILEM recomendation (Setzer *et al.*, 2004).

Before the mandatory introduction of this test questions concerning the transferability of the results of laboratory tests to practical experience were intensively discussed. To address that question the monitoring of the temperature and moisture exposure of real structures was supposed to be an adequate way to get reliable information on this question. Different structures like bridges, tunnels and locks were equipped with sensors for long term monitoring campaigns. A detailed analysis of the freeze-thaw attack on concrete structures based on monitoring data of real structures is published in (Spörel, 2013). The main

differences between XF1 and XF3 exposure have been worked out for an example of a lock. The monitoring of the lock has been continued for 16 years during the whole service life of the lock so far and can be evaluated. As the monitoring data gives an impression of the complete history of the freeze-thaw attack during the previous service life of the structure (Spörel, 2016) it can be considered in evaluating the surface scaling observed at the structure.

To support the evaluation of the long-term resistivity monitoring of the lock the paper describes resistivity monitoring results on the freeze-thaw attack during the CIF-Test on lab specimens and concrete cores which were equipped with the same sensors as the lock.

2 Principles to Monitor the Freeze-Thaw Attack on Concrete

2.1 General

Concerning freeze-thaw attack the temperature and the degree of saturation are decisive parameters. If a critical degree of saturation is reached a freeze-thaw damage can occur (Fagerlund, 1977). As a continuous direct measurement of the degree of saturation is not possible an indirect determination of the degree of saturation by means of resistivity measurements was chosen. A calibration is required to account for different influencing parameters on the resistivity (Elkey and Sellevold, 1995; Spörel, 2013).

2.2 Monitoring System

The resistivity measurement was conducted using a multiring electrode (MRE). The MRE is a sensor consisting of several rings of stainless steel, each with a thickness of 2.5 mm, with an insulating plastic ring between two steel rings. It enables AC resistance measurements of the concrete between two adjacent steel rings in eight steps at a frequency of 10.8 Hz and at a distance of 7 to 87 mm to the concrete surface (Raupach, 1992). A multitemperature probe (MTP) is installed near the MRE. The MTP is equipped with eight PT 1000 sensors to enable temperature measurements at eight different distances to the concrete surface. A typical arrangement of a measuring point is shown in Figure 1.

Figure 1. MRE and MTP (left), Sensor installation in a structure (right) (Spörel, 2019).

2.3 Focus of Data Evaluation

One aspect to evaluate the intensity of a freeze-thaw attack is the number of freeze-thaw cycles. As the freezing temperature of water in the pore structure of concrete depends on the pore size (Brun *et al.*, 1977; Setzer, 2000) a simple evaluation of temperature data might be

misleading concerning the intensity of a freeze-thaw attack. The freezing of water in the pore structure is decisive to activate the micro-ice-lens pump according to (Setzer, 2002). Resistivity measurements indicated that a minimum degree of saturation is required for the freezing of water in the pores (Spörel, 2013). In a hygroscopic saturation state only finer pores are filled with water and no freezing of water was observed at certain temperatures below 0 °C. The approach of (Brun *et al.*, 1977; Setzer, 2000) could be detected by resistivity measurements (Spörel, 2013; Spörel, 2016).

The effect of temperature on the resistivity has to be compensated to monitor concrete saturation. The investigations have shown that the Arrhenius approach (equation 1) is working well at concrete temperatures higher than 0 °C if the activation energy is determined and considered adequately (Spörel 2013, Spörel 2016). The constant b correlates to the degree of saturation of the concrete and has to be adapted at changing degrees of saturation.

$$\rho_{el} = \rho_{el,0} \cdot e^{b \cdot \left(\frac{1}{T} - \frac{1}{T_0}\right)} \quad (1)$$

ρ_{el} Resistivity at temperature T in Ωm
$\rho_{el,0}$ Resistivity at temperature T_0 in Ωm
T, T_0 Absolute temperature in K
b Constant in K

At temperatures below 0 °C the Arrhenius approach is not effective if the degree of saturation of concrete is high. There is an abrupt increase of the temperature compensated resistivity if temperature decreases below 0 °C. This takes place in a much shorter time than observed when wet concrete is drying. These observations were attributed to freezing of water in the pore structure (Spörel, 2013; Spörel, 2016) and are very helpful as it enables to monitor freeze-thaw attack in laboratory tests as well as for the data interpretation of the long-term monitoring of the lock. The potential of resistivity measurements to detect freezing of water was also observed for cement pastes (Sato and Beaudoin, 2011; Wang *et al.*, 2016).

To evaluate the intensity of a freeze-thaw attack an analysis of meteorological data is not sufficient. There are relevant differences between freeze-thaw-cycles analyzed on meteorological data and on the temperature measured in the concrete cover zone. The difference even rises if freezing effects detected by resistivity measurements in the concrete are compared to meteorological data (Spörel, 2013).

Using this approach resistivity measurements by means of MREs were used for monitoring the freeze-thaw attack in lab specimen, small concrete elements and concrete cores. This enables to evaluate the transferability of results of freeze-thaw lab test to practical application.

3 Investigation Concept

The transferability of results of freeze-thaw tests to practical experience has always been discussed concerning adequate testing ages and storage conditions of the lab specimens. The pore structure of the concrete is influenced by that and important as transport mechanisms play an important role. In (BAW, 2012) the storing conditions for the CIF- and CDF-test are described for different testing ages. As usually concrete with a slow strength development is used for hydraulic structures the standard testing age is 56 d after storage in water for 14 d.

To address this question investigations were realized on a concrete with the same composition and the same source of raw materials as used in the lock described in (Spörel, 2013; Spörel 2016). A concrete with 270 kg/m³ CEM III/A 32.5 N LH, 80 kg/m³ fly ash, a water content of 143 kg/m³ and an aggregate content of 1876 kg/m³ was investigated.

A set of five lab specimen for the CIF-Test at different ages were cast as well as two concrete elements. The concrete elements and two additional lab specimens for each test series were equipped with MREs and MTPs to monitor the resistivity during the CIF-Test and the storage of the elements under natural exposure up to a distance to the surface of 42 mm. The testing ages were set at 28 d, 56 d and 365 d for the lab specimens. At the testing age of 365 d two different storing conditions were applied (demoulding after 14 d; 351 d 20°C, 85 % rel. humidity; demoulding after 2 d, water storage at 20 °C for 321 d, 20°C/65% rel. humidity for 42 d). Additionally concrete cores were taken from the concrete element stored in the field. The cores were tested at an age of 56 d, 365 d and 6.5 a. As example results of the 6.5 years old cores are presented. The design of the element and the position of the cores and sensors are shown in Figure 2.

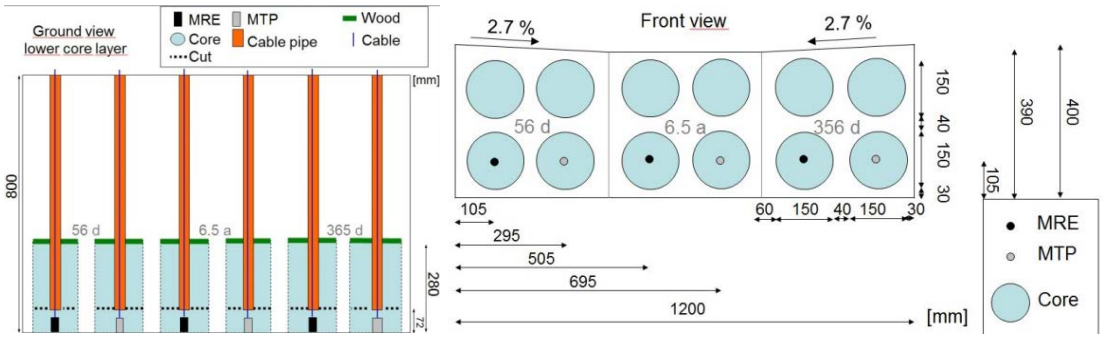

Figure 2. Dimensions of the concrete element and positions of the sensors and cores.

4 Concrete Properties

Additionally the strength development of the concrete was determined and summarized in Table 1 for cylindrical specimens with a height to diameter ratio of 2.0 for the lab and core specimens. The strength of the core specimens is lower than of the lab specimens. This confirms findings in the literature (The Concrete Society 2004; DIN EN 13791/A20 (2017).

The carbonation depth was determined on slabs 100x100x500 mm which were stored under the same conditions as the specimens for the CIF-Test and the concrete element. For slag cement concrete the carbonation depth might influence the scaling of concrete during the CIF-Test. Results are summarized in Table 1.

Table 1. Test Results for compressive strength and Carbonation.

Concrete age	f_{cm} [N/mm²]		d_c [mm]			
	Lab specimen	core	20/65	20/85	water	outdoor
56	37.3	31.8	**1.8**	1.0	0.0	2.7
365	47.4	37.2	5.4	**4.3**	**1.0**	5.1
6.5 a	-	33.3	13.0	-	8.0	**8.0**

Results of the CIF-tests for selected storage and testing age versions according to section 3

are presented in figures 3 and 4. Besides the standard testing age of 56 d two test series at an age of 365d and results of cores at a high age of 6.5 years representing a situation at a structure at a higher age are compared as examples. The test results are evaluated concerning scaling and internal damage measured by the relative dynamic Young´s modulus. The testing of cores of a structure in a freeze-thaw test includes effects of concrete casting, curing and exposure as well as influences of the coring process on the freeze-thaw resistance. This has to be kept in mind when comparing the results to those of standard lab specimens at a defined testing age and storing conditions.

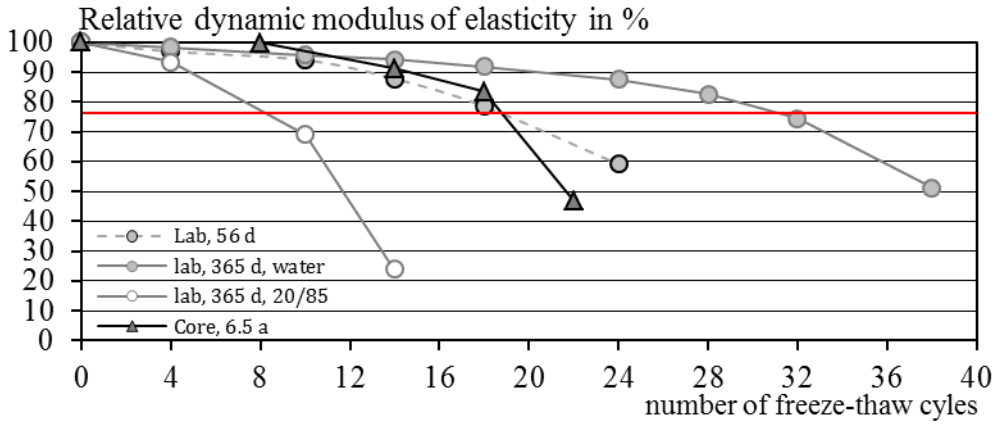

Figure 3. Relative dynamic modulus of elasticity.

Concerning internal damage the significantly lowest freeze-thaw resistance was observed for the concrete stored in climate 20/85 for one year. After 10 freeze-thaw cycles the results fall below the criteria of 75 %. The highest resistance was determined for the water stored specimens. The results of the standard conditions were congruent with the cores at high age.

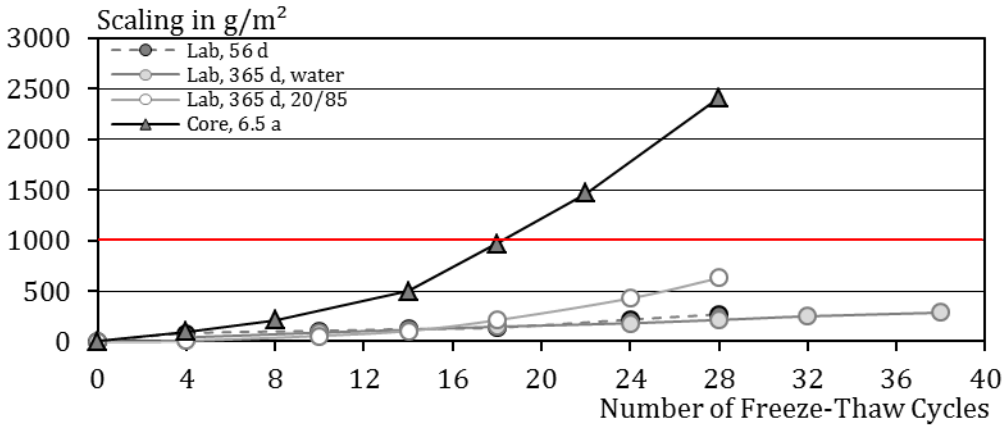

Figure 4. Scaling during the CIF-Test.

Looking at the lab specimens scaling was affected only slightly by the investigated storing conditions. The lab specimens tested at standard age and curing conditions showed

comparable results to the water stored specimens tested at an age of 365 d. The storage in climate 20°C/85% rel. humidity resulted in the highest scaling for the lab specimens but still passed the criteria of 1000 g/mm² according to (BAW 2012). Considerably higher scaling was observed for the cores tested at an age of 6.5 years correlating to the carbonation depth.

Both for the scaling and the internal damage development the testing age is not the decisive parameter concerning the freeze-thaw resistance of the concrete. The effect of the curing regime on the internal damaged was very dominant for the lab specimens. The stronger impact of the storing conditions than the testing age was observed for the scaling as well. The scaling results of the cores yet showed a strong deviation of the lab specimens. Influences of the carbonation depth at the start of the CIF-Test might have an impact on the test results. A low carbonation for the standard and water storage, and higher values for the storage at 20 °C and 85 % rel. humidity and for the cores were measured (Table 1, Bold type values).

5 Resistivity Measurements

For a better understanding of the processes during the CIF-Test the monitoring data was evaluated. An important parameter is the water absorption during the capillary suction phase and during the freeze-thaw cycles. As an example in Figure 5 results of the resistivity measurements in a distance of 32 mm to the surface and the weighing of the samples for the period of capillary suction before the start of the freeze-thaw-cycles are shown. The weighing data illustrate the great influence of the storage conditions of the specimens. By oven drying at 105 °C the degree of saturation of the differently stored specimens was determined before and after capillary suction (Table 2). The degree of saturation of the water stored specimens is already high before the capillary suction starts whereas the specimens stored for one year in climate 20° C/85% rel. humidity has a very much higher absorption potential.

Table 2. Degree of saturation at the beginning of capillary suction.

	Storing conditions			
	56 d, 20/65	365 d, 20/85	385 d, water	6.5 a, outdoor
Degree of saturation before capillary suction [%]	51	57	82	67
Degree of saturation after capillary suction [%]	63	79	90	78

The resistivity data illustrate that in a measuring depth of 32 mm from the surface only for the concrete stored for one year in climate 20 °C/85 % rel. humidity a decrease in resistivity is observed during the capillary suction period. The decrease of resistivity is caused by a rising degree of water saturation in that measuring depth of 32 mm. The resistivity of the other specimens was not affected by water absorption in that measuring depth. According to Table 2 the highest rise of the degree of saturation during the capillary suction phase was observed for the specimen stored in 20 °C/85 % rel. humidity. This indicates that it might be plausible that only this specimen showed a change in resistivity at that measuring depth. Closer to the surface also for the other specimens a decrease of resistivity was observed.

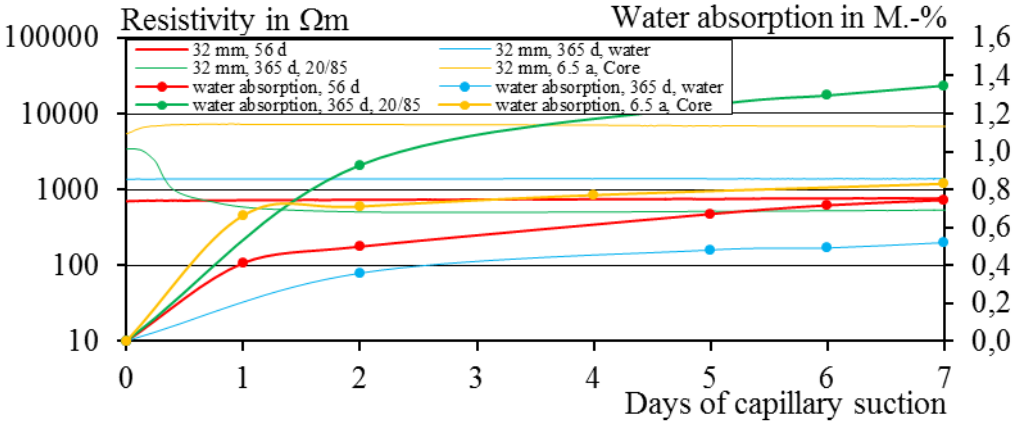

Figure 5. Water absorption during capillary suction.

Figure 6 shows the resistivity in a measuring depth of 42 mm during the freeze-thaw-cycles which was compensated for temperature effects according to equation (1) and the development of the relative dynamic modulus of elasticity. As described in (Spörel, 2013; Spörel, 2016) a typical increase and decrease of the resistivity is observed during the freeze-thaw cycles caused by freezing and melting of water in the pore structure. High resistivity is measured at concrete temperatures down to –20 °C when water in the pore structures is frozen and low values are measured at temperatures between 0 and 20 °C when the water is present in a liquid state. The Arrhenius approach is unable to compensate the effects of the freezing of water on the resistivity.

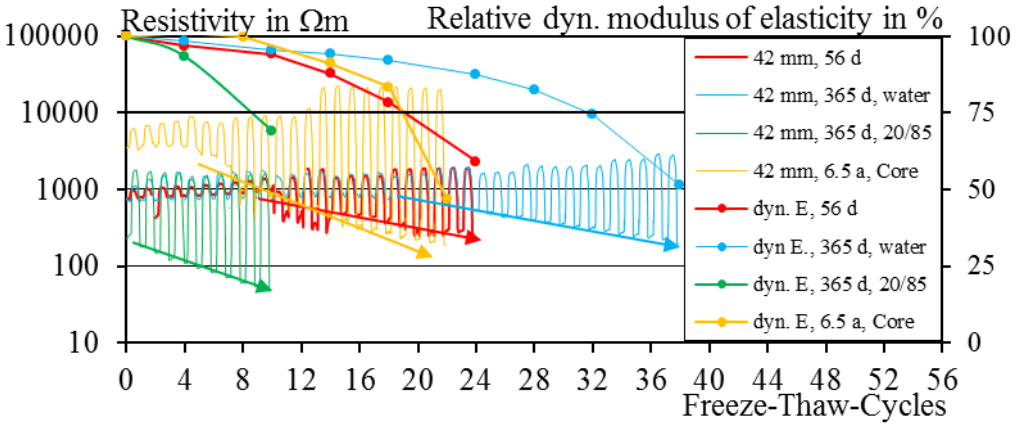

Figure 6. Temperature compensated resistivity and dynamic modulus of elasticity during the CIF-Test.

The low resistivity values decrease over time which is marked by arrows. This indicates the rise of the degree of saturation in that measuring depth. Analogue with that the dynamic modulus of elasticity starts to decrease. For the water stored concrete at an age of 365 d the decrease of resistivity starts at about 20 freeze-thaw cycles in that measuring depth. About at that time the relative modulus of elasticity also starts to decrease more rapidly as before. For the other samples similar correlations are observed. As proposed by (Fagerlund, 1977) the

results seem to confirm that after reaching a critical degree of saturation the concrete is damaged. The water absorption according to the micro-ice-lens theory (Setzer, 2002) also seems to be confirmed. At certain distances to the surface no water transport was detectable during the capillary suction whereas during the freeze-thaw cycles a water transport occurred.

6 Conclusions

By means of monitoring the resistivity of concrete at different distances to the surface the micro-ice-lens theory (Setzer, 2002) and the theory of the critical degree of saturation (Fagerlund, 1977) seem to be comprehensible. The effect resulting from the freezing of water in the pore structure of concrete on the resistivity will be a helpful tool to further analyze the monitoring data of the lock concerning the frequency of such freezing incidents under practical conditions. The results of the resistivity monitoring in lab tests and the long-term monitoring of a lock in combination with a consideration of the surface damages at the lock enable to better evaluate the transferability of results of the CIF-Test to practical conditions.

Restoration of Historic Windows: Methodology and Case Studies

Edward A. Gerns[1] **and Sarah K. Van Domelen**[2]

[1] Wiss, Janney, Elstner Associates, Inc., 10 South LaSalle, Suite 2600, Chicago, Illinois, USA, egerns@wje.com

[2] Wiss, Janney, Elstner Associates, Inc., 10 South LaSalle, Suite 2600, Chicago, Illinois, USA, svandomelen@wje.com

Abstract. *All too often, the original windows are unnecessarily removed and replaced from historic buildings. In some instances, replacement is justified due to the extent of deterioration resulting from years of deferred or inappropriate maintenance. However, often historic windows are unnecessarily replaced as a result of incorrect assumptions or misinterpretation of their condition. Alternatively, a designer may believe that a new window will perform better, require less maintenance, increase energy efficiency, or just last longer than the existing original windows. This may not be the case. This paper will address issues related to the evaluation and restoration of historic wood and metal windows. An overview of the methodology used by the authors to evaluate the condition of windows and determine repairs that are necessary to maintain structural integrity, repairs that are necessary to address air and water infiltration, and repairs relative to aesthetics and function, will be presented.*

Keywords: *Wood Windows, Steel Windows, Evaluation, Restoration.*

1 Introduction

Windows are a character defining architectural feature of almost all buildings. At a functional level, windows provide natural light and fresh air, and sometimes a means of egress, to interior spaces. Over the years, many building owners have opted to replace rather than restore original historic windows. Replacement window manufacturers tout these products as a means of providing increased thermal performance and 'no maintenance.' However, in reality, replacement windows may have unrealistic payback periods, and many new windows are actually 'not maintainable.' Alternate materials such as aluminum, and more recently vinyl and fiberglass, have been used to replace historic original windows. In many instances, when considering life cycle costs as well as maintaining historic fabric, repairing and restoring historic windows is not only environmentally and preservation sensitive, but also economical. Thermal upgrades are also possible by installing storm windows at a macro scale, or replacing or installing weather-stripping at a micro level.

2 Evaluation Methodology

Determining the general condition of any historic window is critical to developing a restoration program. The condition of windows can vary significantly based on orientation and location within the facade. Often, coatings and/or previous interventions may be misleading relative to the actual condition of the window components. Determining the extent and location of hazardous materials is also critical to accurately developing an appropriate scope of work. Based on the findings, special provisions for remediation may be required. In some instances,

hazardous materials may have been installed during original fabrication or installation and may be concealed by the various components of the windows.

The general methodology used by the authors when evaluating historic windows includes document review, comprehensive or representative close-up interior and exterior surveys, investigative openings, and partial or complete window disassembly. Based on the available funds and access, all of these tasks may not be possible or practical. Much like any aspect of building restoration, building owners should understand that gathering more information during the initial evaluation can reduce the potential for unanticipated added costs once work begins.

2.1 Document Review

When existing building drawings or specifications exist, review of these documents can provide insight into the construction of the windows, as well as the method of anchorage to surrounding construction. Particularly in the case of wood windows, the windows were often constructed onsite to accommodate variation in the as-built openings, and original drawings may be limited or nonexistent. In the case of metal windows, the original manufacturer can sometimes be determined by comparing window profiles with resources such as Sweet's Catalogue. Review of documents detailing past maintenance or repairs can also help identify existing conditions.

2.2 Visual Survey: Exterior

Close-up observation of the exterior portions of the windows is critical to determine the extent of intervention that may be required. While a comprehensive review of all windows is ideal, selected review must often suffice due to access considerations. If possible, windows from all facades and different floors should be reviewed. If there are different types of windows, a sample of each should be included. Observations should include the condition of the coatings, perimeter seals, and glazing putty and stops, but perhaps more critical is the evaluation of the substrate material. Peeling paint and missing putty can often be misleading when the substrate materials are actually in relatively good condition. Typically, the lower portions of the jambs and side rails of the sash, and the sill and bottom rail of the sash exhibit the most deterioration. Probing these areas with an awl can be an effective means to assess the condition of the substrate for both wood and metal windows. In the case of wood windows, the awl will readily penetrate rotted areas. Areas of corrosion or section loss in metal windows may be visually apparent, previously installed fillers can often be detected by tapping areas with the awl.

If the water resistance of the windows is in question, performing water testing using various techniques can provide an indication of the source(s) of the leakage. It is important to understand, however, that historic windows cannot meet standardized testing criteria for new windows, and that failure to meet current standards for water resistance is not a basis or justification, in and of itself, to replace the windows.

2.3 Visual Survey: Interior

A close-up examination from the interior is also critical to evaluate the existing window conditions. Depending on the building occupancy, it may be easier to perform a comprehensive survey from the interior, but if that is not possible, rationale similar to that described above should be applied when selecting specific locations for review.

Review of the windows from the interior can provide an indication of the water resistance of

the existing assemblies. Damage such as peeling paint, blistering plaster, and discoloration of finishes may be an indication of water infiltration. Review of the specific location of the damage can provide an indication of the source of water. While the window itself may be the source of the infiltration, other factors may be contributing including lack of flashings, failed perimeter sealant, condensation, or thermal bridging. Inventorying the existing hardware and operation of the sash should be included if the intent is to restore functionality of the windows. Often the windows have been painted or sealed closed, so evaluation of functionality can be challenging.

2.4 Investigative Openings and Disassembly

Investigative openings can be helpful in determining window anchorage details, as well as the configuration of the window-to-wall interface at the perimeter of the assembly. Concealed conditions and deterioration may also be revealed. Removing selected windows, in part or as a whole, can also provide valuable information with respect to the assembly and components. The geometry of weather-stripping and component profiles can be difficult to determine without removing operable portions and the frames.

3 Restoration Approaches

Once the investigation has been completed, gaining an understanding of the Owner's expectations is necessary to develop an appropriate restoration approach. While comprehensive restoration is ideal to achieve a consistent end result, it is often not necessary or justified. The approach will determine the maintenance cycle for the windows. Less invasive approaches will have a lower initial cost, but a shorter service life. Likewise, more invasive approaches will have higher initial costs, but a longer service life prior to required maintenance. Regardless of the approach, the cost of access and general conditions will generally be consistent. A combination of approaches could also be appropriate based on available funds, window location or exposure, or other factors. A brief description of various restoration approaches follows.

3.1 Scraping and Painting

If the substrate is generally in good condition, removing areas of loose coating, sanding, and applying a new coating system can protect the historic fabric of the windows. Replacing deteriorated glazing putty is often performed concurrently. This approach is obviously the least invasive and lowest cost when considering the entire window assembly.

3.2 Stripping and Painting

Based on the condition of the substrate material, or to determine the condition of the substrate, complete removal of the existing coating may be necessary. In the case of wood windows, paint strippers are most effective. If the existing coatings contain lead, certain strippers can both remove and capture the coatings for disposal. For steel windows, paint strippers can also be used, but abrasive blasting can frequently be more effective and economical. If performed properly, blasting can effectively remove existing coatings at inside corners and crevasses. For wood windows, hand tools are often necessary to remove remnants from these areas. It is important that all chemicals and other residue be completely removed from the surface of the window prior to performing repairs or applying a new coating system.

3.3 Localized Repairs, Dutchman Repairs, and Component Replacement

Depending on the size and extent of substrate deterioration, repairs can vary from patching of localized areas of rotted wood or corrosion, to replacement of complete members. Localized rot in wood windows and corrosion of metal windows can be removed and the area filled with a compatible repair material such as an epoxy filler. In both instances, particularly wood, it is important avoid applying the filler as a means of building up the surface of non-deteriorated areas. This can lead to accelerated deterioration of the wood, since the filler can trap moisture. This is less of an issue with metal windows, but achieving a uniform surface is not necessary unless the area has the potential to hold water (e.g. the upward facing surface of a sill).

More extensive deterioration may require replacing portions of a member (dutchman repair) or a complete member. The most common application of dutchman repairs is for the lower portions of jambs, while complete replacement is often necessary for sills. Ideally, rot resistant old growth woods such as mahogany are desirable for dutchmen in wood windows. Deteriorated portions of the members are cut away and the new piece is anchored to sound substrate. Treatment of the joint between the dutchman and the original material should be considered to limit the potential for water to reach the untreated end grain of both pieces. Fasteners can be countersunk and concealed with a wood plug.

In the case of steel dutchmen, it is likely that the original profile of the steel assembly is no longer manufactured, and the new pieces may need to be fabricated by building up smaller pieces to generally match the profile. A perfect match using this approach is typically not possible due to the differences in fabrication. Welding is typically the preferred installation approach for steel dutchmen. Testing the original steel for compatibility and determining a weld procedure should be part of the process. Once the welding is completed, the area can be ground smooth to the adjacent material and coated.

3.4 Glazing

Removing the existing glass in a window that is being restored, either temporarily or for replacement, is preferred to achieve optimal performance. By removing the glass, the glazing pocket can be prepared and coated prior to reglazing. From a preservation perspective, the glass should ideally be retained and reused. However, a relatively high rate of breakage is almost unavoidable in many instances, which can increase the appeal of comprehensive reglazing.

Often, installing replacement insulating glass units (IGUs) is considered as a thermal improvement. This approach can introduce challenges relative to the width of the glazing pocket and the weight of the sash. Conventional IGUs are typically 1 inch thick, while historic glass is typically between 1/8 inch and 1/2 inch thick, depending on the size of the opening. With thicker replacement glass, the glazing pocket must be made wider by either modifying the sash component, reducing the profile of the putty and glazing points, or modifying the glazing stops, all of which have the potential to significantly reduce the wind load resistance of the window. The frame and hardware should also be evaluated to ensure that they can support any added weight. Recently, glass manufacturers have introduced thinner IGUs that can fit into existing glazing pockets, but at a significant cost increase over reusing the existing glass or using conventional IGUs. Other replacement glazing options, such as laminated glass, can also be considered, but many of the same considerations discussed above will still apply.

3.5 Hardware

Based on the condition of the existing hardware, replacement hardware may be necessary. Matching original hardware may be possible, but is often challenging if the components are no longer manufactured. Options can include salvage sources or potentially using hardware from other windows on the building. If limited original hardware is available, sets of original hardware and replacement hardware can be grouped by window.

3.6 Weather-Stripping

Historic windows typically used metal weather-stripping at all operable interfaces. For wood windows, the geometry of the weather-stripping is somewhat forgiving, and a similar metal profile is often available that can fit the assembly. At concealed interfaces, modern weather-stripping materials such as foams and plastics may also be used. Historic weather-stripping for metal windows was typically fabricated specifically for a particular profile, and is most likely no longer available. Salvage and reuse of weather-stripping may be possible under certain circumstances, but given the tolerances of fabrication and operation, once removed, it is likely not realistic to reinstall. For this reason, weather-stripping options for metal windows generally include custom fabrication of new weather-stripping to match the original, or creative application of readily available modern components.

4 Case Study: Wood Windows

Second Presbyterian Church, located in Chicago, Illinois, is a National Historic Landmark that was constructed in 1874. Bell tower facade repairs, including masonry and window restoration, were recently performed. Because the interior of the bell tower encompasses predominantly unoccupied space, and the height of the tower makes exterior access challenging, maintenance of the existing historic windows had been infrequent over the years (Figure 1).

Figure 1. Typical window conditions before (left) and after restoration (right).

The exterior evaluation of the windows was performed from an aerial lift, which allowed access to all of the tower windows. The surfaces were probed with an awl, but no investigative openings were created. On the interior, access was limited based on the proximity of an interior stair. Conditions included wood decay at various exterior locations including sills, the base of jambs, and at decorative tracery. Several of the sash were missing, and the frames had been boarded up. Portions of the leaded art glass were broken or missing. Since the windows were likely built on site during construction, no original drawings or specifications existed.

Based on the owner's inability to ensure that resources could be dedicated to future maintenance of the windows, a comprehensive restoration approach was selected to maximize service life. Repairs included complete removal of existing coatings using a chemical stripper, replacement of deteriorated sills and tracery, dutchman repairs at the lower portions of jambs, replacement of sash, hardware, and weather-stripping, removal and restoration of the art glass, interior and exterior painting, and perimeter sealant replacement (Figure 2). The replacement sash were fabricated to match the profiles of the limited sash that remained. Although the original sash were likely glazed with leaded glass based on historic photos, the new sash were glazed with clear laminated glass due to budgetary constraints. The decision was also made to seal the perimeter of the glass with silicone sealant, rather than traditional glazing putty, to reduce the overall maintenance cycle. Based on the location of these windows, the substitution is not visually apparent. Finally, the colors of the new exterior coatings were selected based on paint analysis performed on other windows at the church and the historic photos.

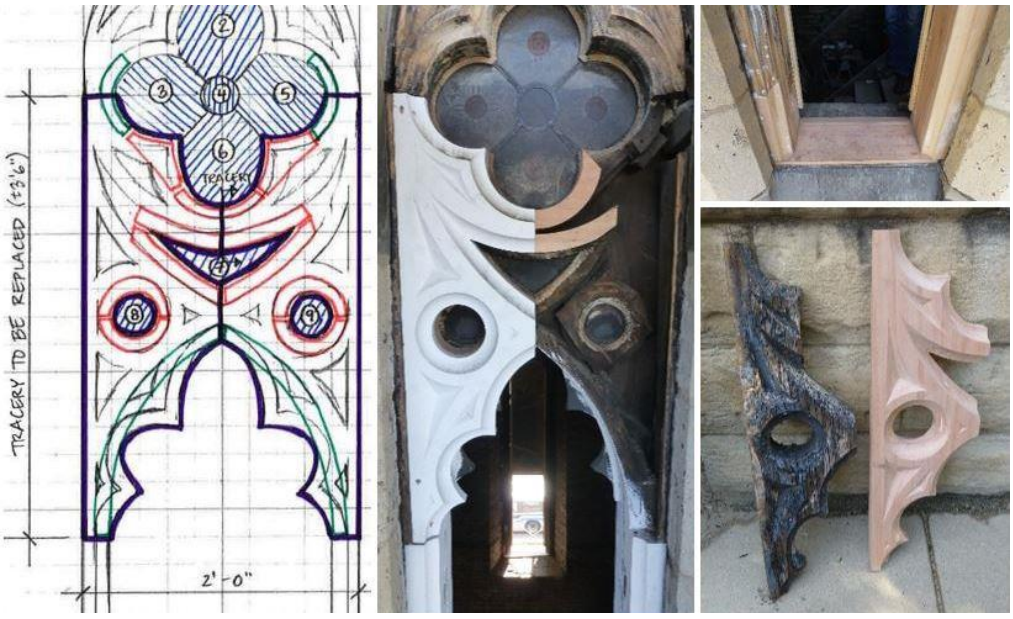

Figure 2. Sill replacement and jamb dutchmen (upper right) and tracery replacement.

Various challenges were encountered throughout the project. At the outset, it was difficult to find an experienced window restoration contractor that could perform the necessary onsite restoration of the existing frames. Once on board, the contractor encountered challenges obtaining the desired wood species for replacement elements and dutchmen. In the end, the challenges were overcome, and the end result was a successful wood window restoration.

5 Case Study: Steel Windows

30th Street Station, located in Philadelphia, Pennsylvania, is the second busiest train station in the United States. The building is iconic in the Philadelphia community and is listed on the National Register of Historic Places. Constructed in 1934, one of the defining architectural features is the fenestration system, which includes rolled steel casement windows set into cast iron curtain walls that are located between limestone clad piers (Figure 3). As part of a comprehensive facade restoration project, an evaluation of the windows was performed. Due to security and access restrictions, the evaluation was limited. The window assessment included a visual survey of select areas on the interior and exterior. In addition, one of the steel windows was removed to document the interface geometry and concealed conditions. Materials testing of the steel and cast iron, and a finish analysis to determine the original color scheme, were performed. A hazardous materials survey and testing were performed by the owner.

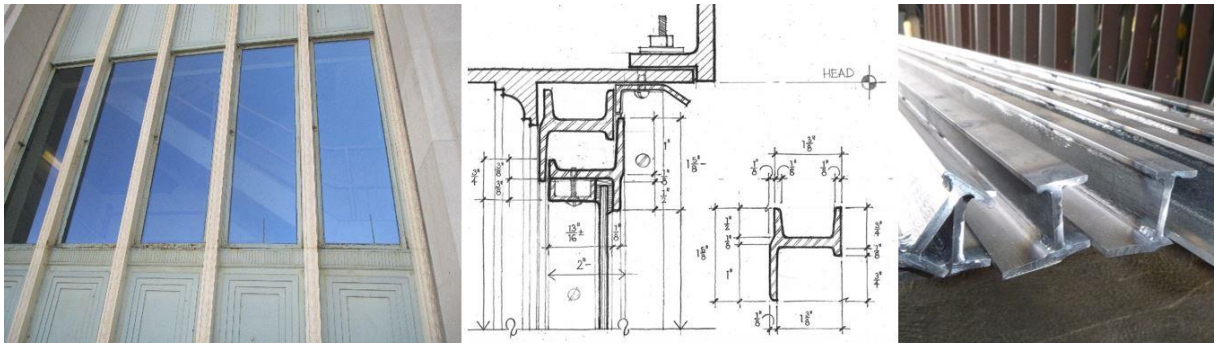

Figure 3. Cast iron curtain wall and steel casement windows (left and center); built up dutchman sections (right).

Our investigation revealed that limited repairs and intervention could extend the service life of the system, but a more comprehensive restoration could provide a significantly longer service life and limited maintenance schedule that were more in line with the owner's goals. Detailing and profiles were found to be generally consistent throughout the station, but window sizes varied. The original manufacturer of the windows was determined through archival research, and product data, including original profiles, was located in historic product literature.

A comprehensive facade restoration program, including the stone masonry facade, steel frame windows, and cast iron curtain wall, began in 2012. The restoration scope included off-site restoration of the steel sash and frames, including comprehensive glass replacement, and in-situ restoration of the cast iron curtain wall. Coating removal was accomplished by abrasive blasting with a garnet media to achieve SSPC-SP10 (near white metal blast with a surface profile between 1 and 2 mils). Where necessary, dutchmen were created by building up steel plates and stitch welding them to mimic the original profile. The original steel was tested for weldability and a weld procedure was provided. A high performance coating system was applied to the blasted surface, consisting of a zinc-rich primer, epoxy intermediate coat, and fluoropolymer top coat. Finally, a blast and solar protection film was applied to the new glass prior to being glazed into the restored sash. To improve the overall thermal performance of the building, custom fabricated aluminum storm windows were installed on the interior of the building at office locations.

Figure 4. Steel frame blasting and surface profile measurement (left and center); coating mockup (right).

Several challenges were encountered at the beginning of the project that had to be resolved. Hazardous materials were found in concealed portions of the window assembly that required remediation. In addition, the weather-stripping had to be custom fabricated, as an off-the-shelf product replicating the profile could not be located by the contractor. A comprehensive quality control and quality assurance program was also established that included inspection and surface profile measurements of the window frames following blasting, and coating thickness measurements following each layer of coating application.

6 Conclusions

A successful historic window restoration project requires a clear understanding of the existing window conditions and the owner's expectations for window maintenance and service life. When possible, a comprehensive investigation of the existing windows can more accurately customize a restoration approach that achieves the desired end result.

Abstract: *This contribution presents previous results of a study carried out with the aim of achieving better results in the restoration processes by replacing the tiles of an exterior mosaic tiling of the Trencadís type of Catalan Modernism. In this case the trencadís tiles come from the cutting of pieces, called piastras, of opaque and mass-colored glass called Smalti Murano glass. These companies have extensive color catalogs that, although not exactly the same as they were a century ago, are close enough for these replacement tasks. Each color corresponds, however, to a different composition of glass and a slightly different manufacturing process. These differences favor that the differences of color always go accompanied also of differences of superficial aspect. However, not all color references currently available have the same surface quality since this product, during its manufacture, acquires primary defects typical of artisanal processes. So far the predominant criteria for the selection of the new references of piastras that must replace the product damaged by the extensive exposure to the weather as a coating are based primarily on color. However, durability requirements must also be part of the selection criteria for substitution references. The primary defects that a product already presents in its superficial quality are often indicators of either a more irregular quality or of circumstances that favor the early appearance of secondary defects throughout its useful life. The main objective of this study is to ensure, in restoration work by substitution, the selection of the best piastras from the point of view of surface quality, to apply on site the most similar tiles of tone and with greater durability. This study is part of a collaboration between the study group LiTA (Laboratori d'Innovació i Tecnologia de l'Arquitectura) (UPC) and a private non-profit organization.*

Keywords: *Colour, Murano Glass, Smalti, Trencadís, Preliminary Alteration Patterns.*

1 Introduction

Murano Smalti glass has been used for centuries as a tile in colored mosaics as a coating for interior walls. Smalti glass, by its nature is very bright, chemically stable and has a solid color mass. Given its intense mass coloration, the glass tiles were placed sideways with what they always had small dimensions (of the order of the thickness of the glass) and parallel faces.

The trencadís is a coating typical of the architecture of Catalan Modernism that is composed of small pieces of materials, irregularly cut, such as enameled ceramics or marble, arranged randomly supported by its main face (table) on a layer of mortar forming a colorful polygonal mesh that has three-dimensional architectural motifs. It thus differs from the traditional historical mosaic by the arbitrary arrangement of the carved tiles with irregular shapes, by its ability to solve the coating of three-dimensional surfaces and because it is very often in situations of full weather where it manifests itself with all its brightness and color. (Fig.1)

The uniqueness of Murano Smalti glass is due to the fact that this mass-colored opal glass is still handcrafted today using traditional techniques. The same techniques used during Catalan Modernism. The producing companies continue to supply hundreds of different colors that cover almost all shades.

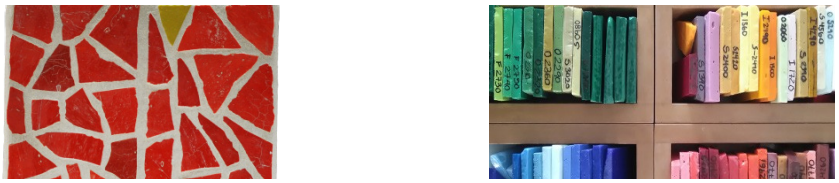

Figure 1. Left: test piece for trencadís coating tests made with smalti Murano glass tiles. Right: referenced glass samples analyzed in this study(source: authors).

2 The Material

In this study the piastras are made of opal glass, called Smalti. In the world of glass mosaics, smalti indicates a bright, opaque, mass-colored glass with high lead content, generally obtained by adding a crystalline material (*corpo*) and colored crystals (*anima*) to a molten transparent glass.

Figure 2. Left: Murano Smalti glass forming process by lamination until flat piastras are obtained. Center: glass piastras shown on Side 1. Right: manual cutting process (source: authors).

The traditional coloring agents commonly used for glass are a limited number of metal ions which, by absorbing part of the incident light, give rise to a great diversity of colorations. The apparent color of each glass depends on the nature of the ion, its oxidation state and the composition of the glass in which it melts.

Once the desired mixture is mixed in the corresponding crucible, homogenized and reached the appropriate temperature, masses of molten material are removed from the oven to form the piastras.

During the process of mixing, melting, forming and subsequent cooling of the piastras, they acquire various primary defects that alter their surface quality. These primary defects not only devalue their appearance but can also reduce their durability expectations as they are the source of new secondary anomalies that appear with the passage of time and exposure to the weather.

Due to the glass forming process, the surface quality obtained on both sides is not the same as that the face in contact with the table is kept in contact with the metal while the face in contact with the laminator is kept in contact with the atmosphere of the premises.

Since the face of the Murano glass in the trencadís lining will not be the edge but the table of the piastra, it will be necessary to select the one with the least primary defects present. This is how the face of each piastra is seen, called (A) in this study and the hidden face of each piastra, called (B) in this study.

The visual difference (brightness, color, surface homogeneity) of the faces is significant and should be taken into consideration at the time of restoration, since it can alter the assessment of the final overall quality of the trencadís lining.

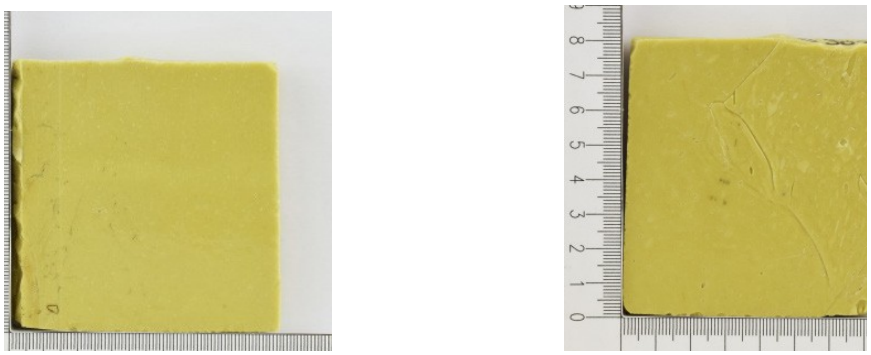

Figure 3. On the left the Face (A) of the reference glass S 3020 and on the right the Face (B) of the same glass reference where bubbles and folds often present in the hidden face of these glasses are appreciated (source: authors).

The objective of this research is to develop a procedure that allows grouping and ordering the various references available according to their apparent surface quality, so that artisans can select and use those references that, for the same color, have fewer primary defects. In order to favor this objective, the following inspection methodology, census and assessment of surface quality were proposed.

3 Methodology

With this objective a campaign was made to capture digital images on a universe of 77 references and 2 pieces for each reference, of approximate dimensions 8x8 cm, which constitute the basic sample ceded for this study by a company mainly oriented to the elaboration of this product.

Each of the 77 references has a different tonality, but these can be grouped into 11 color ranges:

Brown (17 references), violet (3 references), white (5 references), blue (11 references), green (16 references), orange (7 references), yellow (5 references), red (5 references), pink (4 references), black (2 references) and gray (2 references).

The samples are identified according to the manufacturer's catalog code. These codes are composed of an initial letter and 4 numbers, the letters refer to the type of smalti, differentiating them into: C: Skin (3 references), F: Smalti Fino (9 references), I: Imperial (25 references), OR: Ordinary Smalti (28 references), S: Special (12 references), and the numbers below identify the hue of the color.

This leads us to show that the same color range can be found in different types of smalti glass. Since the same color can be prescribed in different types of glass, it is about adopting the one that presents less primary defects and that is probably why it will age more adequately throughout its useful life, increasing its durability.

3.1 Digitization

All received parts have been digitized using a scanner corresponding to the "HP Deskjet F2200 series" model. The image has been executed following the following process:

- Cleaning the face of the piece of glass to be scanned with a fiber cloth, including the removal of the identification sticker if necessary.
- Placement of the pieces on the scanning area (each piece on both sides), forming sets of 20 pieces chosen at random, without corresponding to any sorting or classification.
- Scan of the set of parts, using the software "HP Solution Center", typical of the hardware referenced above and used for that purpose. Generating JPEG files with a horizontal and vertical resolution of 600 dpi and a variable dimension, about 10 MB.

3.2 Digital Image Editing

The JPG files corresponding to the scans of the groups of 20 glass samples and the subsequent edition of the images of the individual samples have been treated with the software "Adobe Photoshop CS6 version: 13.0.1 service pack: 1".The result of this work was the images of individual pieces, making a distinction between the two faces of each piece and calling them "sight" for the face generated by having a work view (face A), and "hidden" for the face generated to be arranged in contact with the mortar (face B). Generating jpg files of 1146 x 1146 pixels and a horizontal and vertical resolution of 600 dpi.

Figure 4. Overall images of the various image scanning processes with flatbed scanner (source: authors).

3.3 Characterization of the Identifying Color of the Samples

The characterization of the identifying color of the samples has been made from the images obtained in the previous process, and responds to the following sequence:

- superposition of 5 arbitrary markers on all images of individual samples.
- measurement of RGB color values in the center of each marker superimposed on the image of the sample piece, with the aim of parameterizing its color.
- overlay the histogram, in each of the images of individual samples.

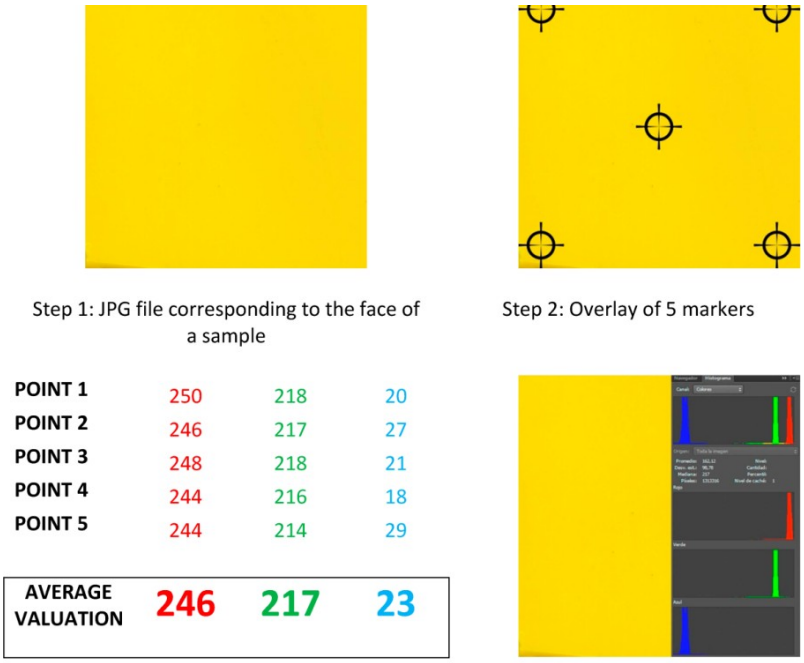

Figure 5. Model type of file for the evaluation of the color of the sample (source: authors).

3.4 Sample Defect Assessment

To assess the visible surface quality of each sample on each face:

- An initial value of 10 has been granted to each face
- For each face of each piece examined, a qualitative assessment of each defect has been made, giving a value of -1 if the said defect is generalized or 0 if it is punctual or non-existent.

3.5 Census of Surface Defects

The 10 primary defects observed on this face during the visual inspection are listed below, accompanied by their description:

- A1 Scales: Presence of half uncoiled sheets of the sample piece.
- A2 Fissures: Presence of marked fissures in the observed face of the sample.
- A3 Cracks: Presence of lesions with differently separated lips and variable depth.
- A4 Polygonal microfisuration: Presence of microcracks showing a cracking structure on the observed face.
- A5 Wound: Presence of discontinuities more or less deep and with well-defined lateral limits.
- A6 Longitudinal mark: Presence of unidirectional longitudinal marks, often accompanied by air pockets and very elongated spots.
- A7 Stain: Presence of spots of different coloration, more or less rounded.
- A8 Color: Presence of traces of colors other than the color of the piece, in the form of water or stains with a certain contour definition.
- A9 Flatness: Presence of irregularities in the plane of the analyzed face.
- A10 Bubbles: Presence of discontinuities in the material of the analyzed face, of more or less depth and with a rounded shape.

4 Evaluation and Interpretation of Results

The first interpretation of the results (Table 1) shows that there are different evaluations:

Table 1. Average concurrence of defects on both faces.

	View face (A) analysis	Hidden face (B) analysis
Concurrence of more than 5 defects	6.17%	24.69%
Concurrence of 5 defects	20.99%	22.22%
Concurrence of 4 defects	22.84%	17.90%
Concurrence of 3 defects	21.60%	24.07%
Concurrence of 2 defects	18.52%	7.41%
Presence of a single defect	7.41%	3.70%
Without any defect	2.47%	0%

About the analysis between different samples of a same reference, the average additional defects on both faces (Table 2) are the following:

Table 2. Average additional defects on both faces.

	View face (A) analysis	Hidden face (B) analysis
The same defects are found	30.86%	33.33%
There is 1 additional defect	35.80%	32.10%
There are 2 additional defects	12.35%	14.81%
There are 3 additional defects	14.81%	13.58%
There are 4 additional defects	6.17%	2.47%

Since the objective of the study was to order the different references observed according to their surface quality (primary defects), to offer information to the artisan before the task of transferring the color's design choice to the product code for the highest quality execution, has been considered a new variable that corrects the scores regarding the characterization of this material. This variable is the variability of defects observed in different samples of the same code.

Thus, understanding that a lower variability of valuations between different samples of the same code is preferable, from the point of view of the reliability of the valuation performed, and a greater variability of valuations is inconvenient due to the lower reliability of the same valuation, the criterion of correcting the results has been adopted according to the following criteria:

Table 3. Criteria of modification of the sample's score.

Criteria	Modification
If the difference in defects between the various samples is 0	+1
If the difference in defects between the various samples is 1 or 2	±0
If the difference in defects between the various samples is 3	-1
If the difference in defects between the various samples is 4 or 5	-2

5 Final Qualification of References

The absolute final qualification of the samples, for pragmatic reasons, has been reduced to a double score for each company code: a preponderant score for the face and an accessory score for the hidden face, based on a 5-star system such as maximum and 1 star minimum. To capture this fact graphically, generic files have been formulated that contain the information for each code of the company analyzed.

Finally, a relative final qualification of the samples with respect to the results of the samples belonging to codes of the same color range has been established. The objective is to help the selection of codes in the translation of the design color to the nomenclature of the execution material:

- A high quality code, that is, the best quality available (green color rating),
- A medium quality code (orange rating): its substitution is recommended with the recommended green references ordered.
- A low quality code (red rating): mandatory replacement is prescribed by the ordered orange references.

About the references of Murano glass, the results are as follows:

Table 4. Average distribution of quality by smalti types.

	C: Skin	F: Fine	I: Imperial	O: Ordinary	S: Special
High quality	0%	0%	20%	14.29%	8.33%
Medium quality	100%	88.89%	60%	53.57%	50%
Low quality	0%	11.11%	20%	32.14%	41.67%

And in terms of color spectrum:

Table 5. Average distribution of quality by colours.

Quality	Brown	Violet	White	Blue	Green	Orange	Yellow	Red	Pink	Black	Grey
High	11.76%	33.33%	40%	9.09%	0%	14.29%	60%	0%	0%	0%	0%
Medium	52.94%	66.67%	40%	54.55%	68.75%	57.14%	40%	60%	100%	100%	100%
Low	35.28%	0%	20%	36.36%	31.25%	28.57%	0%	40%	0%	0%	0%

6 Conclusions

Murano Smalti glass has been revealed as a material with a high amount of concurrent surface primary defects, defects that affect similarly to its two faces, although they predominate on its face (B). It can be concluded because most of the primary defects observed are inherent to the product as it is currently produced and few others are inherent to the face (B), which is in contact with the forming table.

The results of this preliminary study, although they illustrate quite clearly the primary defects that this material suffers, should still be considered indicative, since several limiting causes must be considered:

- these are parts from references of a single manufacturer and have been voluntarily selected by the manufacturer itself to be a sample.
- these are cut pieces of larger piastras; In the reality of the work, this intermediate format is not used, but each tile is extracted, by fractionation, from any area of the piastra.
- the number of references and colors analyzed in each range is not equivalent.

Study of Autogenous Self-Healing in Different Mortar Formulations

Nohelia Gutiérrez, Laia Haurie, Antonia Navarro and Joan Ramon Rosell

Universitat Politècnica de Catalunya, Barcelona School of Building Construction, Av. Doctor Marañon 44, 08028 Barcelona, Spain, csn.gutierrez@gmail.com, laia.haurie@upc.edu, antonia.navarro@upc.edu, joan.ramon.rosell@upc.edu

Abstract. *Autogenous self-healing of cement-based materials is a topic of current interest. This research evaluates autogenous self-healing in four types of mortars based on Portland Cement, one containing CEM II and the other 3 formulated with CEM I and different additions: fly-ashes; nanosilica and hydraulic lime. The evolution of longitudinal cracks caused by a point load has been evaluated measuring the water absorption by capillarity and studying the evolution of the crack by optical microscopy. Besides the mortar composition, it has been evaluated the effect of the environmental conditions on the crack repair. The different specimens were exposed to three different environments: water immersion, curing chamber at 20 ± 2°C and 95 ± 5% of relative humidity (RH) and the laboratory at 25 ±5°C and 65% ± 5% RH. The results obtained allow us to establish that constant hydration is an essential factor for the development of self-healing mechanism. If the samples are kept in water immersion self-healing occurs no matter the additions of the mortar formulation. Size of the crack is also an important factor to allow self-healing. The product formed during self-healing to fill the crack is mainly calcium carbonate.*

Keywords: *Self-Healing, Cement, Environmental Conditions, Cracks, Water Absorption Test.*

1 Introduction

Currently, several research fields have been dedicated to studying self-healing materials; among these smart materials are cement-based materials. Cracking is inherent to the material, however, the crack width should not exceed a prescribed limit because it can affect its durability and resistance against aggressive substances (Ghosh, 2009).

This research focuses on the autogenous self-healing of the cracks of mortars based on Portland cement at early stages. Autogenous self-healing is a natural phenomenon (Joseph, 2008) and this process mainly relies on chemical, physical and mechanical interactions (Kishi, Ahn, Hosoda, Suzuki, and Takaoka, 2007).

Several authors have demonstrated that the presence of water is fundamental in order to obtain autogenous self-healing. For instance (ter Heide and Schlangen, 2007) concluded that hydration was the mechanism for crack healing that leads to the strength recovery of the prismatic specimens. Similarly (de Rooij, Schlangen, De Belie, and Van Tittelboom, 2011) indicated that one of the two chemical processes for self-healing is the continuous hydration of cement. Regarding the influence of environmental conditions, the investigation of (Argouges, 2012) showed evidence of natural self-healing in cracked specimens stored in a humid environment 23º C and 100% RH, for up to 5 months. The incorporation of cementitious materials is another factor influencing self-healing. The investigations of

(Huang, Ye, and Damidot, 2014) and (Van Tittelboom, Gruyaert, Rahier, and De Belie, 2012) studied the effect of blast furnace slag and fly-ash on self-healing of cracks in cementitious materials. Likewise, the research of (De Nardi, Cecchi, Ferrara, Benedetti, and Cristofori, 2017) showed that the presence of crystalline admixtures speeds up the sealing of the cracks and the recovery of the mechanical properties. In order to evaluate self-healing ability there are several methods, (Wang, De Belie, and Verstraete, 2012) used the capillary absorption test to show that the specimens had a low water absorption, which indicated that the precipitation inside the cracks increased the water penetration resistance of the cracked specimens. In the same way, (Qureshi, Kanellopoulos, and Al-Tabbaa, 2016) concluded the improvement in terms of capillary absorption of healed samples was significant after 28 days of healing. Microscopic methods had also been used extensively to evaluate both autogenous and autonomous self-healing. The specimens are observed before and after the healing process (Tang, Kardani, and Cui, 2015).

In this study, the effect of different environment conditions on the autogenous self-healing of different Portland mortar admixtures was evaluated by means of the capillary absorption test and by optical microscopy.

2 Experiment

2.1 Materials

In this study, there were used four mortar formulations based on Portland Cement, one containing CEM II /A-V 42,5 R and the other 3 formulated with CEM I 52,5 R and different additions: fly-ash from the Bocamina Thermoelectric Power Plant of Chile; nanosilica with a SiO_2 content of 99.998% and calcium hydroxide CL-90. The mass ratio between sand and cementitious conglomerate (s/c) was 3 and it was established a superplasticizer/cement mass ratio (sp/c) of 0.012. Table 1 presents the composition of the different mortars. The specimens were cast in large plastic molds of 100x100x500 mm^3 and were reinforced with electro-welded galvanized steel mesh (12.7 mm x 12.7 mm and Ø 0.8 mm), which was embedded at the top and the bottom of the pieces as can be seen in figure 1a. The pieces were kept 2 days in the mold and after demolding were cured 5 days in the curing chamber at 20 ± 2° C and 95 ± 5% of relative humidity (RH). The next day, the pieces were removed from the curing chamber and divided into small specimens of 100x100x40 mm^3. Mortar specimens were fabricated to evaluate cracks at very early stages; therefore, at the age of 9-d, longitudinal cracks were caused to the specimens by a point load (figure 1b). The cracking process started with a constant average loading speed and then it was decreased to 0.2 mm/s.

2.2 Environmental Exposure

The effect of the environmental conditions on self-healing of concrete has been previously reported (Suleiman and Nehdi, 2018). Therefore, cracked specimens of the four mortar formulations were exposed for 60 days to 3 different environments: water immersion at laboratory conditions, curing chamber at 20 ± 2°C and 95 ± 5% of RH and the laboratory at 25 ±5°C and 65% ± 5% RH. This last group received a weekly amount of water to simulate an environment with the presence of average humidity.

In addition, in each environmental condition, the specimens were divided into two groups: cracked and control specimens (without cracks). The comparison between both specimens reaffirmed the evolution of the longitudinal cracks.

Table 1. Mix design of the four mortar formulations.

Material (g)	Formulation M1	Formulation M2	Formulation M3	Formulation M4
CEM II/A-V 42,5 R	7000			
Natural sand	21000	21000	21000	21000
Water	3710	3850	4760	4550
Superplasticizer	84	84	84	84
CEM I 52,5 R		5950	5950	5950
Fly-ash		1050		525
Nanosilica			700	
Filler			350	
CL-90				525

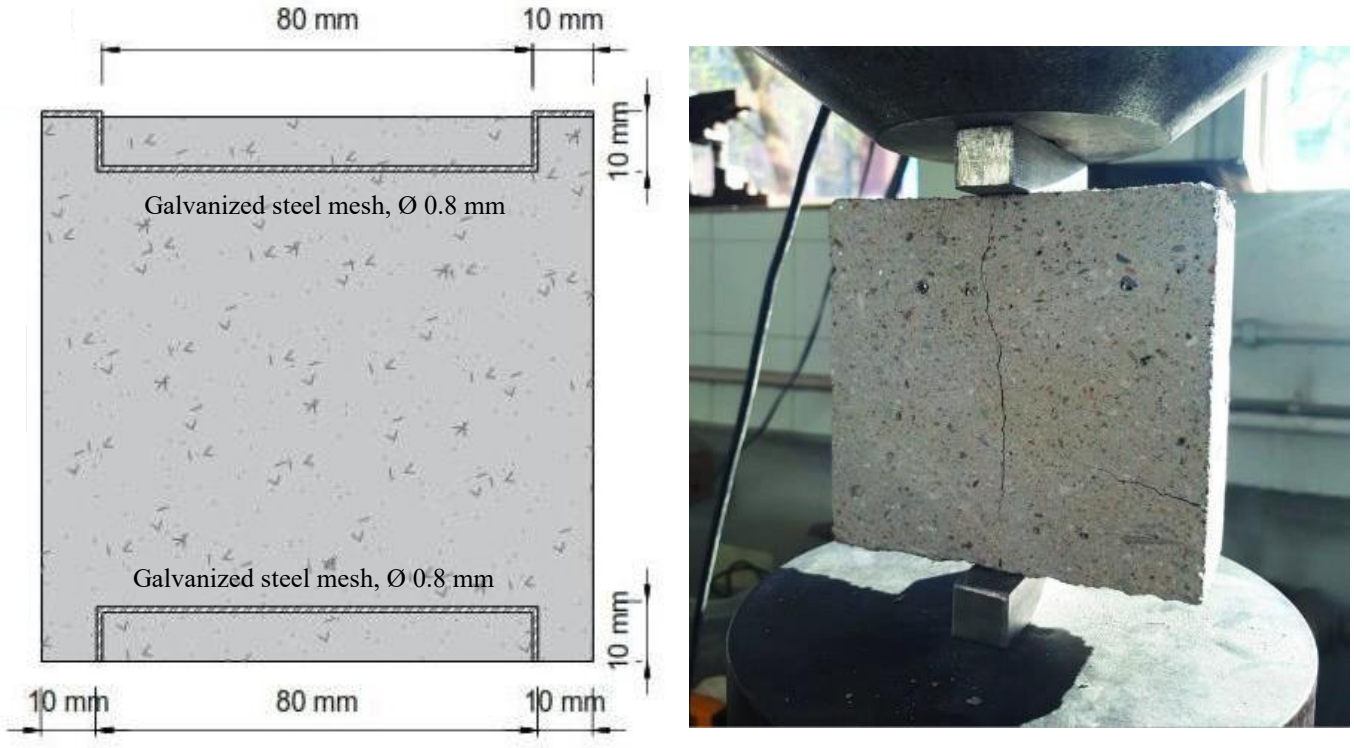

Figure 1. (a) Steel mesh scheme and (b) cracking of the specimen by a point load.

2.3 Analysis of Self-Healing Products

2.3.1 Water absorption test by capillarity

The water absorption test could effectively evaluate the self-healing performance of cement-based materials (Park and Choi, 2018). This test was performed according to UNE-EN 1925 *Natural stone test methods. Determination of water absorption coefficient by capillarity*. All 100x100x40 mm^3 specimens were oven-dried at 70 ± 5º C. The samples were weighted and the bottom surface was measured before they were immersed in water at a depth of 5 ± 1mm. The mass of water absorbed by the samples was measured at: 1, 9, 16, 36, 49, 64, 81, 121, 225 and 361 minutes. The test was carried out before cracking, upon cracking and after 7, 15, 30 and 60 days of exposure to the three different environmental conditions.

The mass of water absorbed per square meter was plotted against the square root of time and the water absorption coefficient (S) was determined using linear regressions.

2.3.2 Self-healing evaluation by optical microscopy

Optical microscopy was used to observe the cracks surface (Homma, Mihashi, and Nishiwaki, 2009). In this investigation the evolution of the longitudinal cracks surface was monitored just upon cracking, and after 7, 15, 30 and 60 of exposure to the different environments. The device used was a Motic Stereoscopic Microscope with Euromex 10 Megapixel Image Sensor. Each crack was divided into sectors to analyze the evolution of the cracks in each specimen.

3 Results and Discussion

3.1. Autogenous Crack Healing

3.1.1 Water absorption test

The results showed the relationship between the self-healing efficiency and the variation of the absorption coefficients over time (before, upon, and after cracking) of the specimens in the three different environmental conditions (immersion, humidity chamber and laboratory). With this information, for each environment and for each mortar formulation, exponential adjustments were made and the mean of the cracked and control (non-cracked) specimens was calculated, as can be seen in figure 2.

A first general observation was that all cracked specimens that were fully immersed in water showed absorption coefficients that decreased over time, this confirmed the crack healing and the formation of hydration products. In the case of cracked specimens exposed to the curing chamber, the absorption coefficients also decreased over time. However, the absorption coefficients were higher than for the immersed samples. This could be due to an incomplete crack healing of the mortars. For cracked specimens conditioned in the laboratory, their absorption coefficients remained almost similar over time and were higher than the aforementioned cases. This was attributed to the absence of crack healing in the specimens conditioned in the laboratory.

Another remarkable observation, were the differences between control and cracked

specimens. At the beginning of the test just upon cracking, the absorption coefficients of the cracked specimens were always higher than that of the control specimens. However, after 60 days, the absorption coefficients of the cracked specimens that were fully submerged in water were lower or similar than that of control specimens. This observation clearly indicates that a mechanism of self-healing had occurred, and furthermore, the cracks had a major influence on the capillary water absorption of cementitious materials (Van Belleghem, Van Tittelboom, and De Belie, 2018).

The properties of each mortar formulation were part of this investigation, one of the essential characteristics that make a significant impact on water resistance of mortar is porosity and pore structure (Gulbe, Vitina, and Setina, 2017), graphically it was observed the absorption coefficients of the M2 specimens were higher than the other mortar formulations. This fact indicated that at early ages, fly-ash increases the porosity of the mortar, however, it decreased as the age increased (Termkhajornkit, Nawa, Yamashiro, and Saito, 2009). On the other hand, the absorption coefficients of the M3 and M4 specimens were lower than the other mortar formulations. This was because nanosilica diminishes the total volume of accessible pores in cement mortars (Tobón and Kazes, 2008) and the addition of hydrated lime lowered the total porosity of fly-ash cement pastes (Barbhuiya, Gbagbo, Russell, and Basheer, 2009).

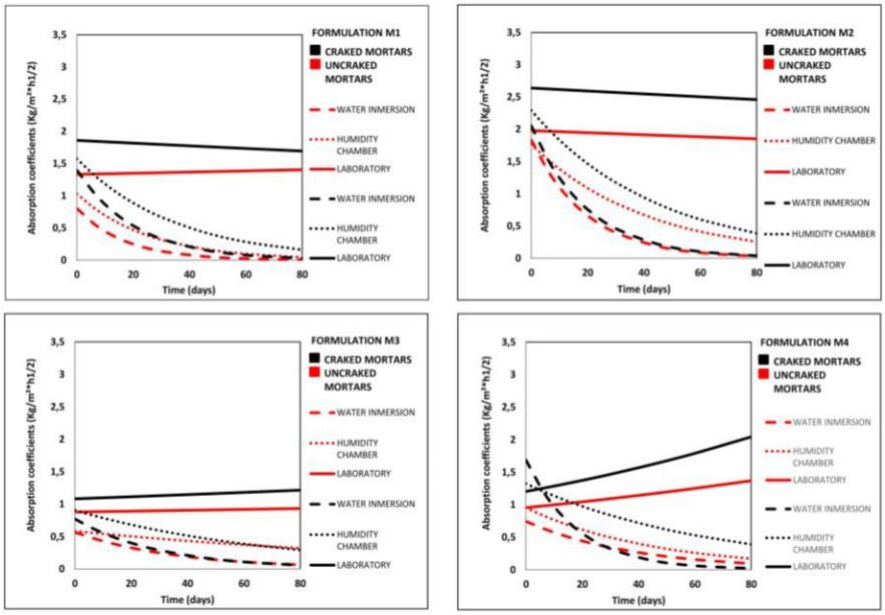

Figure 2. Exponential adjustments that show the variation of the absorption coefficient of the cracked and control specimens exposed to water immersion, humidity chamber and laboratory for a period of 60 days.

3.1.2 Optical microscopy

The evolution of the surface crack width of the specimens was measured using a microscope. Four sector images were taken along the crack, before and after the healing

process. After 60 days, cracks of the specimens immersed in water showed sealing or the formation of healing products along the surface of the crack of the specimens (inside and outside the crack). It must be highlighted that only cracks with a width smaller than 150 µm exhibited sealing. The images of the crack evolution can be observed in figure 3. In the case of the cracks of the specimens exposed to the curing chamber, only in some of the cracks occurred healing. For all the cracks of the specimens conditioned in the laboratory, no evolution or healing products were observed, due to the minimum contact they had with water. These findings were in good agreement with the results of the water absorption test by capillarity.

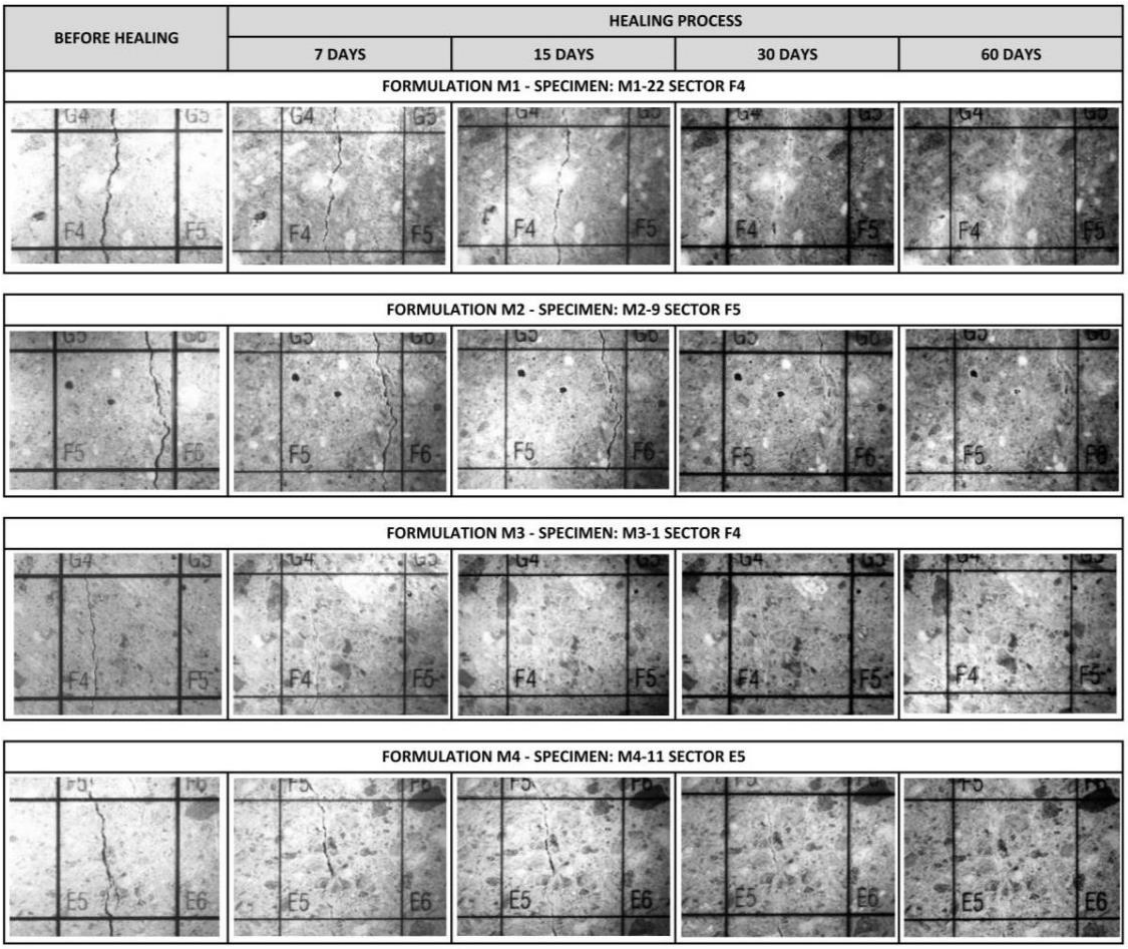

Figure 3. Evolution in the surface crack of different mortar formulations exposed to water immersion. The evolution was analyzed upon cracking and during the healing process.

4 Conclusions

This research analyzed the self-healing ability of four mortar formulations of cracked specimens exposed to different environmental conditions. Based on the experiments, the following conclusions were obtained:

- Constant hydration was an essential factor for the development of the autogenous self-healing mechanism.
- Width of the crack was an important factor to allow self-healing and from the absorption coefficients could be concluded that wider cracks exhibit higher absorption rates. Nevertheless, the form and path of the cracks were other parameters that had a big influence on self-healing.
- The product formed during self-healing to fill the crack was mainly calcium carbonate.
- The incorporation of additions to cement-based mortars did not influence self-healing of the mortars. In the cracked specimens that were kept in water immersion, self-healing occurred no matter the additions of the mortar formulation.
- High humidity environment conditions influenced only in some of the cracked specimens, probably in a longer period of exposure, the self-healing of the cracks could be carried out completely.
- Although the water absorption test by capillarity measured effectively the self-healing performance of the cracked specimens, in some cases, the evaluation by optical microscopy was more accurate to validate self-healing.

Abstract. *Durability in aggressive environments is an important factor to extend the service life of concrete and the use ternary blended cements (limestone filler + calcined clays) can contribute to this purpose. In sulfate environments, the effects of supplementary cementing materials depend on the concentration, Portland cement and the progress of hydration reactions. Low level of limestone filler replacement influences the stabilization of AFt due to formation of monocarboaluminate, but high replacement increases the effective w/c and the capillary porosity promoting sulfate penetration. The use of active pozzolans suppresses the sulfate attack by minimizing both ettringite and gypsum formation. It is generally assumed that curing prior to sulfate exposure should be extended to allow the development of the pozzolanic reaction and subsequent reduction of portlandite content, pore size structure refinement and permeability reduction. However, in most field applications, concretes exposed to sulfate attack are cast in situ and thus, these are exposed to sulfate since early ages. This paper evaluates the sulfate resistance of an illitic-calcined clay and limestone filler when the cement is exposed immediately to aggressive environments. In this paper, the external sulfate resistance of blended cements containing 30% replacement of limestone filler and/or calcined clay (C30F, C30CC and C15F15CC) are analysed. Two different calcined clays from Buenos Aires, Argentina were selected. Mortar prisms and cement paste cubes were fabricated and exposed to a sodium sulfate solution after 2 days. Comparison of sulfate resistance was based on the expansion, mass variation, visual appearance and compressive strength . Furthermore, the evolution of microstructure of blended cements exposed to sodium sulfate solution was characterized by XRD tests on the external surface and the core of cement-blended pastes*.

1 Introduction

Illite is one of the most abundant clayed minerals of the earth's crust coming from the alteration of feldspars and micas of rocks due to the weathering process. Illite clays develop pozzolanic properties when are thermally treated at 950 °C (Lemma *et al*, 2015) causing dehydroxylation and collapse of its structure to form a metastable or amorphous aluminosilicate (Ramachandran, 1995). These pozzolanic properties combined with the large availability of this mineral place illite calcined clays as a key supplementary material for the future mineral admixtures used in concrete.

Despite the promising characteristics of calcined clays described, a safe introduction of these

materials in the concrete technology requires the assessment of other aspects, such as the durability against different aggressive environments. External sulfate attack (ESA) has been recognized as a complex degradation phenomenon that may cause severe damage in cement based materials (Neville, 2004). High resistance to ESA in Na_2SO_4 solutions is normally associated with a segmented pore structure and low levels of portlandite (CH) and aluminate phases available to limit sulfate ingress and ettringite formation (Wild *et al*, 1997). Another important issue hardly ever evaluated for ESA resistance is the early sulfate exposure. In reality, the source of external sulfate ions is usually found in sulfate-rich soils and underground waters in contact with concrete. Therefore, ESA is especially significant in underground structures like foundations, tunnels or waste containers. Due to their large size, these structures are usually build in situ, hence being exposed to sulfates since casting. However, currently most studies about the ESA performed in laboratory rely on testing specimens cured several days in lime water prior to immersion in the aggressive sulfates solution (Ikumi *et al,* 2017).

The aim of this paper is to make a comparative study of the performance of blended cements with the addition of filler and two different illite calcined clays against sulfate attack without the previous curing prescribed by the standards to evaluate sulfate resistance when supplementary materials are used. Different proportions of cement, filler and calcined clay were used to make pastes and mortars to evaluate the mineralogical changes (X-Ray diffraction) and the evolution of physical and mechanical properties (mass variation, visual aspect, expansion and compressive strength) during ESA.

2 Materials and Methods

Portland cement (CEM I 52.5 R) with high C_3A-content (8.2%), limestone filler composed by high purity calcite (LF) and two different illitic calcined clays (ICC) were used. Calcined clays are identified by their colour: Red (ICCR) and Orange (ICCO). Their chemical composition determined by XRF are reported in Table 1. These two different illitic clay-stones are from quarries near to Olavarria, Buenos Aires Province (Argentine) and were calcined in oven at 950 °C and ground in laboratory ball mill until 90% of particles were less than 45 μm. Both calcined clays meet the chemical requirements for Class N pozzolan (ASTM C 618): S+A+F > 70%; SO3 < 4 % and LOI < 10%. XRD analysis reveals low intensity peaks of dehydroxilated illite in both clays and the associated minerals are quartz and hematite for ICCR and, quartz, hematite, oligoclase and spinel for ICCO. For these two ICCs, the Frattini test was positive after 14 days. Additionally, strength tests were performed and presented in another publication (Lemma *et al*, 2015).

Table 1. Chemical composition and mass loss on ignition of cement, filler and ICC, %.

Material	CaO	SiO_2	Al_2O_3	Fe_2O_3	MgO	SO_3	K_2O	Na_2O	LOI
Cement	60.92	16.58	4.21	1.80	2.16	1.77	0.67	0.28	2.05
Filler	59.53	<0.01	1.10	0.52	0.48	0.06	0.060	<0.01	39.98
ICCR	0.33	66.30	16.28	9.23	1.46	<0.01	5.60	0.08	0.58
ICCO	1.13	63.43	13.82	7.89	2.71	0.04	4.29	1.52	0.2

Physical characteristic of the materials are summarized in Table 2. Density was determined by the ASTM C 188 procedure, retained on 75 and 45 µm sieves (ASTM D 422 and C 618) and Blaine specific surface (ASTM C 204) and the particle size distribution (PSD) were determined using the laser granulometer (Malvern Mastersizer, 2000). The particle size distribution by volume of materials are shown in Figure 1.

Table 2. Physical characteristic of cement, clays and filler.

Property / Material		Cement	Filler	ICCR	ICCO
Density		3.10	2.70	2.63	2.65
Particle size distribution	Dv10, µm	1.8	1.7	1.6	1.3
	Dv50, µm	20.1	6.6	8.8	7.3
	Dv90, µm	65.1	72.2	33.7	36.9
Specific Surface Area	BET, m^2/g	1.10	3.74		
	Blaine, m^2/kg			522	724

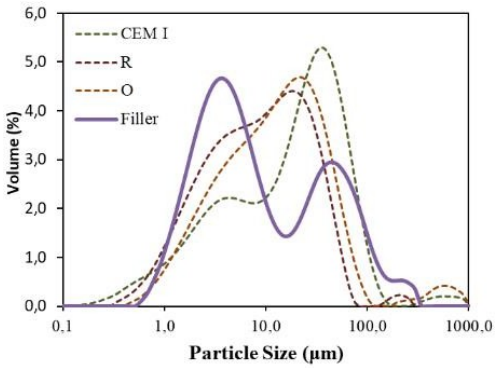

Figure 1. Particle size distribution of materials.

For this study, the SCM replacement in all binders was set to 30% by cement weight. By this way, all compositions present the same initial C_3A content and thus, the different behaviours observed can be solely attributed to the effects of the SCMs introduced. Five different blended cements were prepared: a binary filler cement (70% CEM + 30% LF), a binary illitic red calcined clay cement (70% CEM + 30% ICCR), a binary illitic orange calcined clay cement (70% CEM + 30% ICCO), a ternary red illitic blended cement (70% CEM + 15% ICCR + 15% LF) and a ternary orange blended cement (70% CEM + 15% ICCO + 15% LF). The nomenclature adopted is C30F, C30CCR, C30CCO, C15F15CCR and C15F15CCO, respectively.

Pastes were prepared using a water to binder ratio of 0.485 (as prescribed by ASTM C1012) and mixed using high speed mixer. Eighteen cubes of 20 x 20 x 20 mm were cast for each blended cement and cured in moist cabinet. After 24 hours, cubes were demolded and immersed in water for 24 hours to ensure full saturation of the samples prior to sulfate exposure. Then, twelve cubes were immersed in 50 g/l Na_2SO_4 solution and the remaining cubes in water at 20 °C. At 7, 14, 28, 56, 96 and 204 days, the change of mass and the visual appearance was evaluated. Both sulfate solution and water were replaced after each determination.

Changes in phase composition were examined using X-ray diffraction (XRD) at 28 and 204

days. Surface and core samples of the same size were cut from the paste cubes, dried by solvent exchange with acetone, crushed and the powder was pressed in cylindrical standard sample holders of 16 mm diameter and 2.5 mm height. XRD measurements were made using a PANalytical X'Pert PRO MPD Alpha Θ/2Θ.

The evaluation of expansions during sulfate exposure was based on the mortar bar expansion tests defined by the ASTM C 1012. Mortar specimens of 25 x 25 x 297 mm elaborated with w/c=0.485 and cement:graded sand = 1:2.75 were cast. Before sulfate immersion, the standard proposes a 24 h curing in molds at 38°C and further curing after demolding in lime water until the compressive strength reaches 20 MPa. For this experience, the initial curing was made in the molds during 24 hours in a moist cabinet at 20°C. After one day, the specimens were demolded and immersed in lime-water at 20°C during 24 hours. Finally, the initial length was measured and the bars were immersed in the 0.352M Na_2SO_4 solution (50 g/l) at 20°C. The expansion was determined at 7, 14, 21, 28, 56, 91, 105, 120 and 180 days and the solution was renewed after each measurement period. Reported expansions are the average of six specimens. According to ASTM C 1157, blended cement is sulfate resistant (HS) when the expansion does not exceed 0.05% at 6 months and 0.10% at 1 year.

For compressive strength, mortars bars were cast following the procedure described above and cut with diamond saw in 25 mm-cubes before immersion in the sulfate solution. Complementary, a set of 12 cubes continues curing in lime-water. These cubes allow comparing change mass and compressive strength on the specimens with the same dimension when they were exposed to sulfate solution.

3 Results and Discussion

3.1 Mass Variation of Paste

Figure 2 shows the relative mass variation rate for each blended cement immersed in sulfate solution (grey-red-orange) and in water (blue bar) during 6 months. As can be seen, all pastes presented positive relative mass variations throughout the period evaluated, which indicates increments of mass during the attack. However, this mass increment is produced at different rates depending on the binder composition. During the first 28 days, all specimens follow similar trends, with a gradual decrease on mass gain over time, regardless of the binder and the exposure condition. This behaviour is associated with the pore filling caused by normal hydration processes, relevant here as the samples were immersed only 2 days after casting.

After 28 days, the specimens submerged in non-aggressive conditions maintain similar mass variation rates until the end of the test, as the main hydration reactions occur during the first weeks. However, the samples stored in sulfate solution show an increase of mass gain from this age, which is more significant in the composition C30F, followed by the C15F15CC (more in R than O) and C30CC (again more in R than O). This mass gain observed after 28 days of aggressive curing is associated with the sulfate uptake and the progressive formation of sulfate attack compounds such as gypsum and ettringite. These results suggest that the use of calcined clay reduces the amount of sulfate ions penetrating the matrix and delays the formation of expansive phases. The higher weight gain over time in pastes with ICCR versus ICCO could be attributed to a different interaction of the red calcined clay with sulfates than the orange calcined clay, but this interaction would not be related to greater damage.

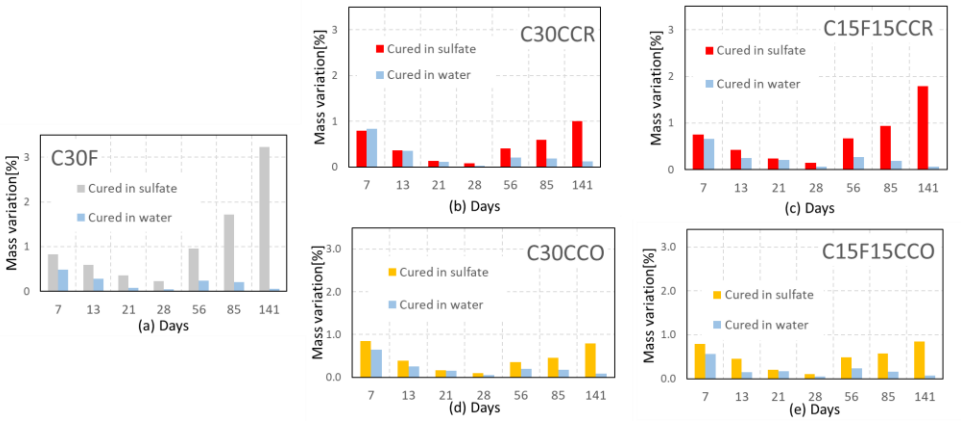

Figure 2. Relative mass variation of pastes cured in water and in sulfate solution.

3.2 Visual Appearance of paste

Figure 3 shows the evolution of visual appearance of paste cubes immersed in sulfate solution for some selected photographs at 28, 90 and 180 days. Figure 3 shows that the integrity of cubes for all blended cements is not compromised during the first 28 days of sulfate exposure. At 90 days, C30F presents a remarkable cracking along the edges, which is the typical cracking pattern associated with the ESA. At this age, pastes with ternary cements (C15F15CCO and C15F15CCR) show a slight cracking near the corners of the cubes, being its intensity considerably lower than for C30F. On the other hand, the composition with 30% ICCR presents no signs of damage after 90 days of sulfate exposure, but for the 30% of ICCO a small crack can be seen at the edge. At 180 days, C30F cubes are completely cracked as the external layers and regions close to the corners can be easily shelled by hand. The damage in the composition C15F15CCO and C15F15CCR has progressed after 180 days of exposure and the initial cracks observed at 90 days are now connected throughout the entire external edges of the cube. On the other hand, the C30CCR and C30CCO cubes only developed very slight and fine cracks along the edges, being slightly more developed in C30CCO pastes. These results suggest that the incorporation of calcined clays up to a 30 % replacement limit significantly more the amount of cracking developed during the ESA than the use of limestone filler.

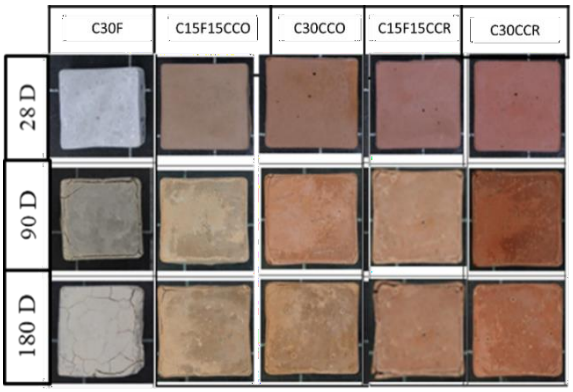

Figure 3. Visual appearance of paste: photographs of cubes at 28, 90 and 180 days.

3.3 XRD-Analysis of Pastes

Figure 4 shows the XRD patterns obtained from the surface and core samples of the paste cubes exposed to sulfate attack at 204 days. On the surface (Fig. 4a), ettringite and gypsum formation are detected in all samples. Peaks of ettringite and gypsum were more intense for C30F. In this paste, gypsum is confirmed by the presence of peak at 20.72° 2θ. For paste containing 15% of ICC, a hump before the quartz peak at 20.82° 2θ is detected; also, the high peak intensity at 31.16° and 33.36° 2θ is attributed to gypsum. For C30CCR and C30CCO pastes, the hump and secondary peak of gypsum have a weak intensity, and some doubt to assign completely the 11.63° and 23.3° 2θ peaks to gypsum arise due to a possible mismatched with the monocarboluminate. In the core of the cubes (Fig. 4b), ettringite and monocarboaluminte were assigned as the peak hump at 20.7° 2θ is absent, the peak intensity at 31.16 and 33.36° 2θ were too weak. In addition, the intensity of CH peaks were too large in the core of the specimens, indicating its consumption on the surface to from ettringite and gypsum. Some reduction of CH is attributed to the pozzolanic reaction of illite calcined clays.

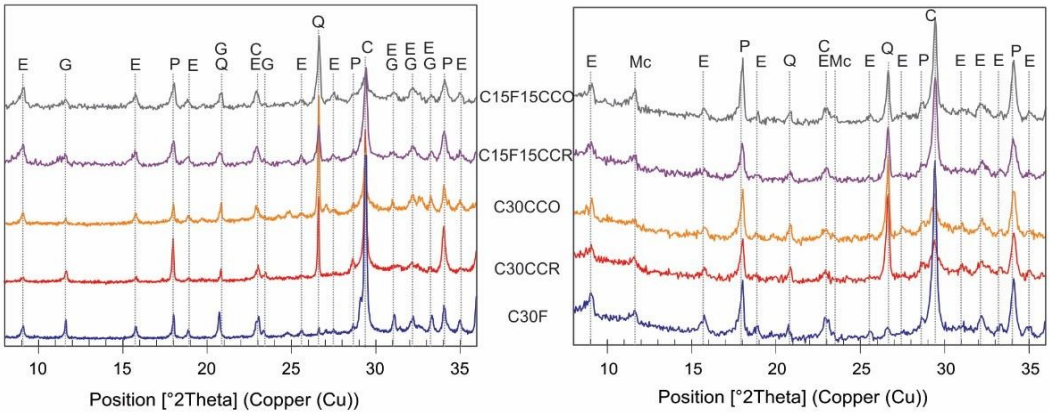

Figure 4. XRD pattern on pastes exposed to sulfate solution for 204 days. (a) Surface and (b) Core.

3.4 Expansion of Mortar

Expansions of mortar bars in sulfate solution are shown in Fig. 5. During the initial exposure up to 28 days, the expansions of the five blended cements present a similar rate, being slightly higher for C30F. After 28 days, the C30F expansion rate increases exponentially reaching the limit of 0.10% at 38 days. At 90 days, the attack on C30F has been so severe that it is no longer possible to measure the length variations since the specimens are practically disintegrated.

On the other hand, C30CCR mortars show a very slow expansion rate and the limit of 0.05% is only reached at 252 days, which is after the threshold of 6 months established by the ASTM standard to be considered as a sulfate resistant cement. For the C30CCO the expansion is also lower but the limit of 0.05% is overpassed at 3 months, so this blended cement is not sulfate resistance according to the standards. The low expansion when 30% of ICC (O and R) is mixed with the cement is attributed to the pozzolanic reaction of the calcined clays, which consumes the CH formed during hydration and reduce the availability of calcium for ettringite formation and specially blocking the pores to prevent the ingress of sulfates into the matrix. This pozzolanic reaction progresses after the immersion in the sulfate solution as occurred in non-aggressive water curing.

For C15F15CCR mortar, the expansion is similar to C30CC up to 90 days, but from this point, the slope increases and exceeds the limit of 0.10% at 161 days, qualifying this cement as not sulfate resistant. The C15F15CCO mortar, the expansion is similar to C30CC up to 56, then the expansion grows faster than the other ternary cement and the limit of 0.05% is passed at this age. Here it can be seen that the ICCR has better pozzolanic activity than the ICCO, because it produces lower expansion on sulfate for the binary and ternary cements.

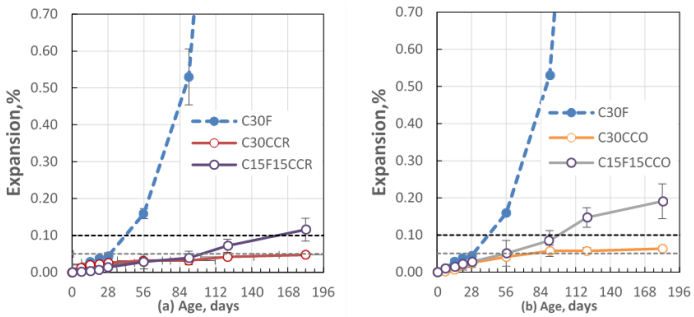

Figure 5. Expansion on sodium sulfate of mortar following ASTM 1012. (a) Blended cements with ICCR and (b) blended cements with ICCN.

3.5 Compressive Strength

Figure 6 shows the compressive strength of mortar for blended cements immersed in sulfate solution (Fig 6 a and c) and in distillate water (Fig 6 b and d). For C30CCR and C30CCO, the compressive strength of mortar cubes cured in water and those cured in sulfate increases from 28 to 90 days confirming the pozzolanic reaction. On the other hand, C30F shows a slight increase due to the dilution caused by limestone filler addition.

At 90 days, C30F cured in sulfates has practically lost its compressive strength, indicating severe degradation caused by ESA. Compositions with the 30 % ICC replacement (C30CCR and CC30CCO) present a significant increase of the compressive strength during the 28 - 90 days period in aggressive conditions. At 90 days, the strengths obtained even reach higher values than the ones obtained in non-aggressive conditions. This behaviour might be attributed to ettringite formation in quantities below the damage onset threshold, which only causes a densification of the matrix. Mixtures with 15 % ICC replacement also develop strength improvements from 28 to 90 days. However, in this case the strength gained is lower than the one observed in 30 % ICC replacement mixtures, specially in the ICCO material.

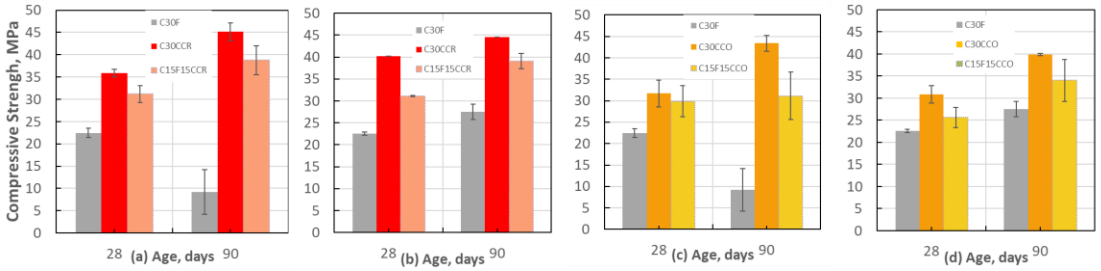

Figure 6. Compressive Strength of mortars, (a) C30CCR, C15F15CCR cured in sulfate, (b) C30CCR, C15F15CCR cured in water, (c) C30CCO, C15F15CCO cured in sulfate, (d) C30CCO, C15F15CCO cured in water.

4 Conclusions

Preliminary results of this study related to the sulfate attack with limestone filler and two different illitic calcined clay exposed immediately to the aggressive environment shows that:

- Limestone filler addition to Portland cement causes the formation of monocarboaluminate, which is unstable in sulfate environment and rapidly forms ettringite causing cracking and massive influx of sulfate ions promoting the gypsum formation, expansion and compressive strength reduction.
- The pozzolanic reaction of calcined clay in mortars is similarly developed in aggressive and non-aggressive curing conditions, consuming the CH and blocking the sulfate ingress due to pore size refinement. The AFm phases formed during hydration in water were converted to ettringite when pastes are exposed to sulfate solution, but the mortar shows no expansion and retains the compressive strength at 6 months.
- These experiences show that despite the lack of curing prior to sulfate exposure, cement with the replacement of 30% of an illitic calcined clay (in this case the ICCR better than ICCO) shows great resistance to ESA, while limestone cements presented a worse performance.

Abstract. *This article describes testing of peel and shear resistance and airtightness of joints of air and vapour barrier systems before and after artificial aging. The testing of peel and shear resistance was based on standardised methods while the test of airtightness was a method invented for this project. The results show that while peel and shear strength increased with aging, the airtightness was significantly reduced. As these two results seem to contradict each other, the methods are discussed, especially whether the standardised tests are too far from the conditions on site or joints should be tested on other materials as well. Furthermore, weaknesses in the airtightness method is also pointed out.*

Keywords: *Peel Resistance, Shear Resistance, Airtightness, Artificial Aging, Air and Vapour Barrier.*

1 Introduction

To reduce energy consumption some building regulations (*e.g.* BR18, 2017) require test of airtightness in newly erected buildings. Membranes are widely used to ensure the required airtightness but often their purpose is twofold; increased airtightness and reduced diffusion. Independently of whether a vapour barrier or an air barrier is needed, the tightness of the joints is crucial. Furthermore, the joints must stay tight throughout the service life of the membrane.

By joints are meant joints between two lengths of membrane and joints between membrane and other building parts. Tapes or adhesives can be used as sealants, most manufacturers sell membranes and sealants as systems, preferably including collars for pipes that may penetrate the membrane. This is a way to ensure that membrane and sealant are compatible. In Denmark, an independent company (DUKO) classifies vapour barrier systems and roofing underlays, the requirements for obtaining classification include tests of peel and shear resistance.

There are different standardised ways to test joints, *e.g.*:

- Peel resistance according to EN 12316-2:2013 or E DIN 4108-11:2016
- Shear resistance according to EN 12317-2:2010 or E DIN 4108-11:2016

Systems can be tested just after installation or after ageing. Although tests of airtightness are only required in new buildings, evaluation of durability requires tests of performance of aged joints. Methods for artificial aging are described by Møller and Hansen (2017), together with detailed descriptions of resistance test methods and a new way of testing airtightness.

This article describes the outcome of tests of resistance against peel and shear of nine vapour or air barrier systems before and after aging and the result of the non-standardised test of airtightness. It also discusses whether the result from standardised test methods corresponds to what can be observed on building sites and the new way of testing airtightness.

2 Method

All test methods are based on the standardised methods described in ISO or DIN standards except for the test of airtightness, which has been invented for this project. To ensure a uniform pressure when taping the joints, samples for peel or shear resistance testing were placed on a plane surface and a 50 mm wide 2 kg rubber coated roller was pulled over the joint.

2.1 Materials

Nine air or vapour systems were selected for testing, the selection was made by contacting manufacturers and suppliers of air or vapour barrier systems. It was asked whether they would be interested in having their product tested. The characterisation of the materials as given by the manufacturers is shown in Table 1. All systems used tape for joints.

Table 1. Materials used for testing with descriptions given by the manufacturers, VB and AB denotes Vapour Barrier and Air Barrier, respectively. PE = Polyethylene, PP = Polypropylene.

ID	Description	Membrane material	Thickness [mm]
A	VB	PE	0.11
B	VB	Multi-layer PE	0.20
C	VB	LDPE	0.15
D	VB	PE	0.12
E	VB	PE	0.15
F	AB	3-layer with woven reinforcement	Unknown
G	VB	3-layer: PE, PP (reinforcement and fleece)	0.20
H	VB	PP nonwoven + PP foil	Unknown
I	AB	PP fibre cloth with PP coating	0.20

2.2 Artificial Aging

All tests were performed on non-aged as well as aged samples, except peel resistance for membrane joint with membrane, which were only tested on non-aged samples. The artificial aging was performed by placing the samples for 84 days in a climate chamber at 70 °C and 90 % relative humidity followed by 84 days in a ventilated oven at 70 °C.

2.3 Peel Resistance

Peel resistance was tested on joints of two membranes and joints of membrane and aerated concrete (AAC). The tests were performed according to EN 12316-2:2013 that specifies how to test peel resistance of a joint between two pieces of a membrane. A sample was placed in a testing machine with the grips 200 mm apart. During testing the grips moved apart at a constant speed. The force used for peeling was recorded. The method was adjusted for the test with AAC because of the thickness of the AAC.

In addition, the speed of the tests was reduced from a separating speed for the grips from 100 ± 10 mm/min to 10 ± 1 mm/min. Samples used for membrane/AAC tests were approx. 14 cm wide instead of the standardised 50 mm, that were used for the membrane/membrane joints. The measured force was converted to the equivalent force for 50 mm samples. Figure 1 shows the principle of the tests as well as pictures from the testing. Five samples were tested for each material combination.

Figure 1. Test of peel resistance, sketch from the side and photo from the front. Left: Membrane taped to AAC. Right: Two pieces of membrane taped together.

2.4 Shear Resistance

Shear resistance was tested on aged and non-aged joints of membrane/membrane (see Figure 2) and according to EN 12317-2:2010. Similar to the peel test, the ends of the samples were placed in the grips of a testing machine with a constant separating speed and the shear strength was recorded. The separating speed was reduced from 100 ± 10 mm/min to 10 ± 1 mm/min.

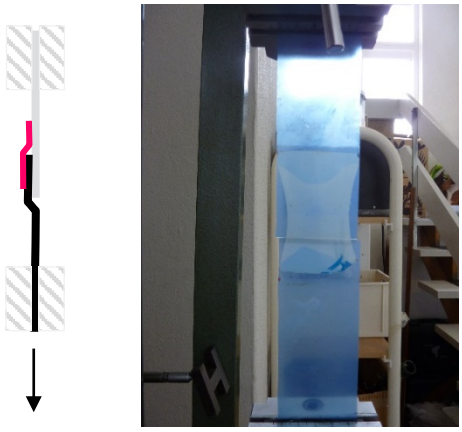

Figure 2. Test of shear resistance, sketch from the side and photo from the front.

2.5 Test of Airtightness

The test of airtightness was not a standard test but a test especially invented to simulate conditions in an older attic where it would be difficult to establish an airtight barrier. The aim was to test airtightness before and after artificial aging. The method is described in (Møller and Hansen, 2017). In short, it consisted of a wooden frame supplied with angled boards and a pipe in the middle. The inside of the frame was lined with the membrane to be tested and fixed to the frame with the system's tape. To secure airtightness around the pipe the system's collars were used and the pipe sealed. The frame was placed in a box leaving a small space between membrane and box, see Figure 3. It was ensured that the frame was airtight and so was the

connection between box and frame. Through a hole in the box a ventilator created a pressure difference between box and frame. The flow necessary to obtain pressurisation of 10, 22, 34, 46, 58, 70 and 82 Pa was recorded. The test was repeated three times and again three times with the same negative pressure differences. By linear regression, the results from the different pressure differences were combined to a single value for a pressurisation of 50 Pa. The test was inspired by the blower door test (EN/ISO 9972: 2015). After 164 days of artificial aging, the tests were repeated. One frame of each system was tested.

Figure 3. Test equipment for test of airtightness. Left: wooden frame with lining of membrane taped to the frame, pipe with collar in the middle. Right: wooden frame placed in box, a ventilator created a pressure difference between frame and box through a hole in the box (not visible on photo).

3 Results

To evaluate the tests results, these are compared to the requirements given by DUKO (2014) when manufacturers want to obtain a certification of their product. Therefore, a line, representing the requirements given by DUKO, has been added to the presentation of results.

3.1 Peel Tests

The DUKO requirements for non-aged joints of membrane/membrane and membrane/AAC is > 10N/50 mm. There are no requirements for aged joints. The results of the peel resistance tests are shown in Figure 4. All systems fulfilled the DUKO requirements. Except for system B, all membrane/ACC became stronger with aging. All non-aged membrane/membrane joints, except for system C, were more than 20 % stronger than non-aged membrane/ACC joints.

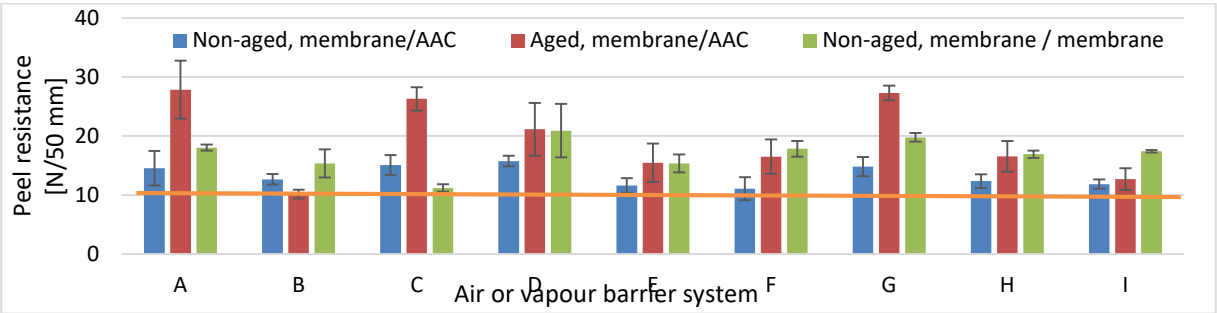

Figure 4. Result of test of peel resistance, average of five samples, with standard deviations. The orange line marks the DUKO requirements for non-aged joints, there are no requirements on aged joints.

Tapes consist of an adhesive and a carrier layer. As shown in Figure 5 there were different places where the adhesive could fail; either the bonding to AAC or to the carrier layer. Where the adhesive stayed showed where the best bonding took place.

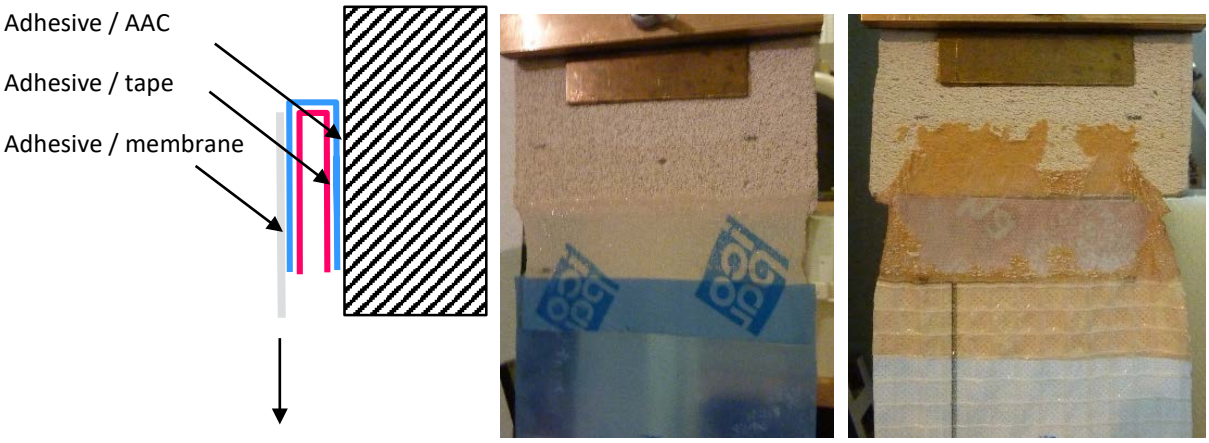

Figure 5. The failure of the adhesive could appear in different places, the sketch shows three possibilities in membrane/AAC connections. The photos show examples, Left: Failure between adhesive and AAC (very little adhesive left on AAC). Right: Failure between adhesive and tape as the adhesive left the carrier layer of the tape.

In some tests, the failure was not clearly between two layers, but parts of the adhesive would stay at the tape and other parts would be peeled of the tape or the failure layer was not the same in all tests of the same system. Consequently, some systems have two failure modes, which can be seen in Table 2, where the failure modes are presented.

Table 2.Point of failure in peel test. In no test did the membrane break.

	Point of failure	A	B	C	D	E	F	G	H	I
Non-aged, membrane/AAC	Adhesive/tape			x						
	Adhesive/AAC	x	x	x	x	x	x	x	x	x
	Adhesive/membrane									
Aged, membrane/AAC	Adhesive/tape	x	x			x	x	x	x	x
	Adhesive/AAC	x			x			x		
	Adhesive/membrane			x						
Non-aged, membrane/membrane	Adhesive/tape	x				x	x		x	x
	Adhesive/membrane	x	x	x	x			x	x	

3.2 Shear Tests

The results of the shear tests are shown in Figure 6, all systems fulfilled the DUKO requirements. The non-aged samples of system A did not come apart; the membrane, however, was stretched to more than the double of its length, without enhancing the force of the machine. In the rest of the systems, the adhesive did not stick to the tape. In the aged samples, the tape broke in system A and G, in the other systems the adhesive did not stick to the tape.

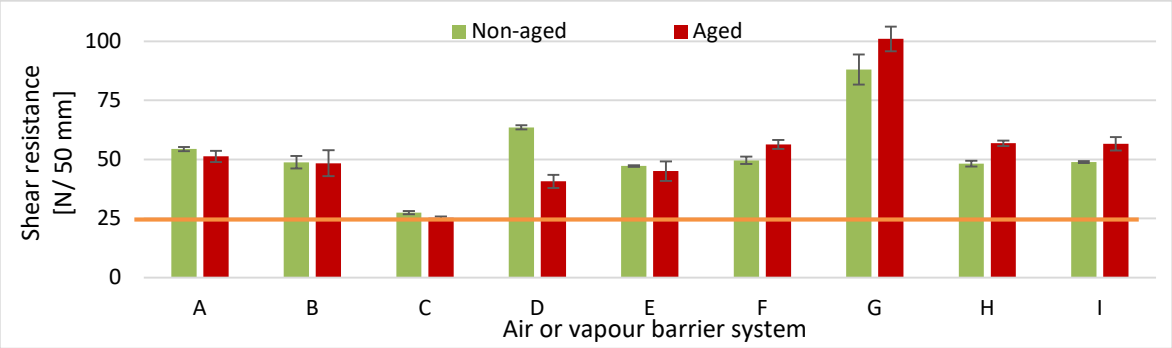

Figure 6. Shear strength, average of 5 samples with standard deviations. Orange line: DUKO requirements for non-aged and aged joints.

3.3 Airtightness

The results of the airtightness tests are shown in Figure 7. All systems needed higher air flow after aging, i.e. all systems were leakier after aging, typically 2-3 times more than before aging.

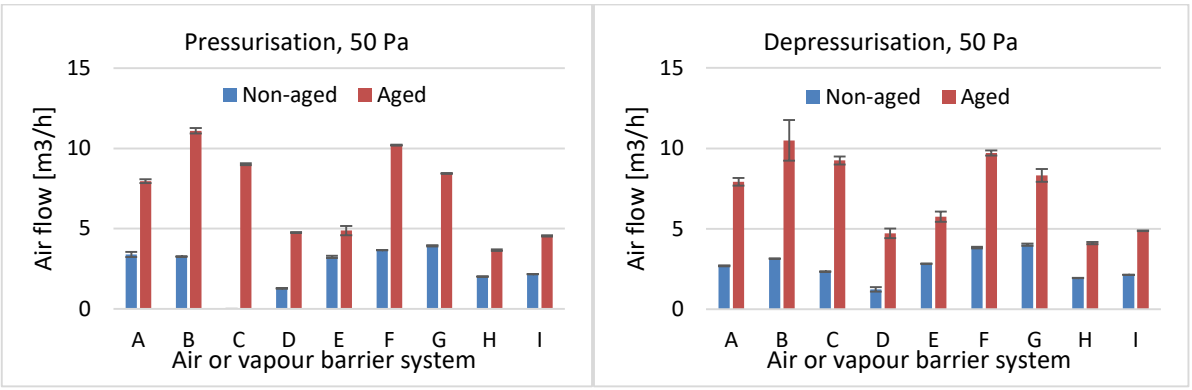

Figure 7. Test of airtightness of non-aged and aged systems, positive and negative pressure difference of 50 Pa. With standard deviations.

4 Discussion

Whether the aging method is the most relevant will not be discussed here, as this method has been discussed by Møller and Hansen (2017). Furthermore, there is no clear picture of which systems perform best, consequently, the discussion is limited to general results and the methods.

4.1 Testing of Peel and Shear Resistance

Although the testing of peel and shear resistance are two different tests, there are many similarities between the results, therefore, these are discussed collectively.

It was expected that peel and shear strength would decrease because of aging. However, the results contradict this; except for system B, peel strength on AAC was generally enhanced and shear strength on membrane/membrane was enhanced or only reduced by less than 10 % in all cases except system D where the shear strength was reduced by more than 1/3.

This is surprising, as practitioners have reported how some tapes, with time lose their ability to adhere to membranes, and from that generalised to all types of surfaces. Unfortunately, these

statements have not been verified systematically, and are only built on specific cases that experienced craftsmen have come across. Change of bonding may vary with aging and be surface/material dependent. Therefore, testing with a larger variety of surfaces seems needed.

However, it also raises the question whether the tests can predict the behaviour of the systems on site. The samples were made under ideal conditions: The joints were assembled on a plane horizontal support with a 2 kg roller under relatively clean laboratory conditions; this ensured the reproducibility of the test. Unfortunately, this may be in contradiction to conditions on site, where there should be a solid support, but the surface may not be plane and clean, the pressure used on the tape is not well defined. Hence, air leakage may not only be related to aging but to bad adhesion in the first place and consequently more sensible to aging than the tests foresee. It underlines the importance of correct workmanship, but questions the relevance of the tests.

In the peel tests of non-aged samples with AAC the adhesive was generally peeled of the AAC, while in the aged test the adhesive was more often peeled of the tape; apparently bonding to the AAC grew with aging. It is not clear why; maybe the heat decreased the viscosity of the adhesive, consequently, the adhesive could penetrate the pores of the AAC and thereby enhance the bonding. Maybe the outcome would have been differently if beech had been used instead of AAC, as prescribed in E DIN 4108-11:2016, the pores in beech are much finer than in AAC.

In the aged samples and most of the membrane/membrane joints, the failure occurred between the adhesive and the carrier layer of the tape. This means that it is not a problem to ensure bonding to membranes in shear tests or to AAC in general; the weak spot is in the tape itself, a better tape would be one where the adhesive bonds better to the carrier layer.

4.2 Testing of Airtightness

While the peel and shear tests are standardised, the test of airtightness was a new method, it is therefore relevant not only to evaluate the results but also the method itself.

The results of the airtightness tests were reproducible; each test was performed at least three times and the results were very close to each other; apparently, tests with pressure difference of up to 82 Pa did not influence the airtightness in the following test. The outcome of the test did also not depend on the operator, something that was also tested.

Contrary to the peel and shear tests, the testing of the airtightness showed a significant reduction caused by aging. Probably the uneven support made it impossible to make as perfect joints as in the standardised plane test samples; possibly tension in the joints caused leakage if these tensions opened the joints over time. The test was designed to simulate realistic conditions in a building and - contrary to the standardised peel and shear tests - the results agreed with statements from practitioners. The test might therefore be relevant. Unfortunately, the samples were not tightened to the same level of tightness level before testing, but only tightened to a level, where it was possible to obtain the needed pressure difference. In many cases additional tightening had to be done immediately before testing the non-aged samples. Consequently, the test only shows the influence of ageing of systems with a tightness above a certain level. Artificial aging seemed to be important, however, it is possible that the release of tension in the joints happened within relatively short time. The testing should probably have been performed more than 24 h after final tightening just as the peel and shear tests were. Other test methods that involve membranes, e.g. test of radon membranes, require a relaxation period of at least 40 hours after installation (Rasmussen and Cornelius, 2017).

DUKO (2014) has a method of testing airtightness that involves a mock-up of a wooden framework resembling a 12 m² wooden building. It is tested for airtightness twice with one week apart, but no artificial aging. By comparing the two tests methods, it might be possible to determine if artificial aging is important for the test.

5 Conclusion

The tested systems all fulfil the requirements for obtaining a DUKO certification on peel and shear resistance. In peel tests of aged samples on AAC and almost all shear tests, the weak layer was at the intersection between carrier layer of the tape and the adhesive, thus, improvement of the peel resistance should be an improvement of the tape itself not the bonding to AAC.

Surprisingly, the peel resistance increased with aging for taped joints to AAC, and shear resistance increased generally. Contrary to this, the test of airtightness showed significant loses in airtightness after aging performed in a wooden box. This raises the question whether the standardised tests of peel and shear resistance are performed under conditions that are too far from the conditions on site and therefore irrelevant. Additionally, it may be necessary to test on more surfaces than only membrane and ACC, *e.g.* wood.

The airtightness test was an attempt to find a different but relevant and reproductive test method. The method still needs to be improved, and compared with other test methods, but the result seemed to be reproductive and in concordance with experience from practice.

Abstract. *The fly ash concrete (FAC) has often been used in chloride contaminate environments. The aluminates present in fly ash (FA) react with free chlorides binding them and reducing the amount of chlorides able to penetrate into concrete. However, $Ca(OH)_2$ present in FAC is easily consumed by pozzolanic reactions, making easier the advance of carbonation. In this context, it is important to know the FAC behaviour in environments subjected simultaneously to chlorides and carbonation. Chloride diffusion coefficient (D) increases in environments containing chlorides and CO_2 when compared to one containing only chlorides. This increase is related to the effects of carbonation on concrete. Therefore, this paper investigates the efficiency of FAC in context of the combined action of chlorides and carbonation. Two different concretes were cast, a FAC (40% FA) and a reference concrete (RC), that is a concrete with similar properties to FAC but without FA. After 90 days humid curing, half of specimens were subjected to accelerated carbonation (20ºC, 55% RH and 4% CO_2) during 1, 2 and 7 months. The other half was protected and remained in laboratory during the same period. Afterwards, non-steady-state migration tests were performed. The results show that, under the studied conditions, the efficiency of the FAC against chloride penetration is not affected when compared to the results obtained for RC. The carbonation depth in FAC is higher than in RC, but the D in FAC remain lower than in RC. This behaviour can be attributed to the higher capacity of FAC binding chlorides.*

Keywords: *Chloride, Carbonation, Fly Ash, Combined Action, Migration Test.*

1 Introduction

The building sector plays a significant role in the global energy use and carbon emissions. The concrete is one of most consumed materials in the world and the annual worldwide CO_2 emissions from cement manufacturing, main component of concrete, add up to almost 2.3 billion mt, which is nearly 7% of the global emissions from fossil fuel combustion (Mehta & Monteiro, 2014). To reduce the environmental impact of the building sector is essential to reduce the cement consumption and to guarantee the long-term durability of concrete structures.

The incorporation of fly ash (FA) in cementitious matrices has been used in two main ways. First, to reduce the cement consumption without loss of mechanical strength. Second, to increase the concrete structures durability, making its cementitious matrix more resistant to the action of chlorides. The SiO_2 present in FA reacts with $Ca(OH)_2$ resulting from cement hydration and produces C-S-H structures that strongly decrease the concrete porosity and hence reduces the transport of aggressive agents such as chloride ions. In addition, the aluminates present in FA chemically react with free chlorides binding them and reducing the amount of free chlorides able to penetrate into concrete (Alonso Alonso, Acha and Andrade, 1994).

Therefore, the FA concrete has showed a high perform in chloride presence (Cheewaket, T., Jaturapitakkul, C. and Chalee, 2010; Chindaprasirt, Rukzon and Sirivivatnanon, 2008; Varga, I., Spragg, R., Bella, C., Castro, J., 2014). However, the consumption of $Ca(OH)_2$, due to the pozzolanic reactions, decreases the alkalinity of the concrete and resulting in a more rapid carbonation when compared to a concrete made without FA (Neville, 1997). In this sense, it is necessary to investigate the efficiency of FA concrete in the context of the environment containing chlorides and carbon dioxide.

In the present work, an experimental investigation is carried out to understand the behaviour of FA concrete against the coupled effect of chloride and carbonation. The effect of carbonation on chloride diffusion coefficient is evaluated.

2 Experimental Program

2.1 Materials and Concrete Mixtures

Ordinary Portland Cement (OPC), CEM I 42.5R, and FA were used as binder materials in the concrete specimens, which chemical compositions are presented in Table 1. The chemical composition of FA was determined using x-ray fluorescence spectroscopy. In addition, Scanning Electron Microscopy was used to observe FA morphology (Figure 1), revealing that it is mainly composed by cenosphere particles (Malheiro *et al*., 2018). These FA were obtained from the burning of South African and Colombian coal in Portuguese thermoelectric power plants.

Table 1. Chemical composition of OPC and FA.

	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	K_2O	Na_2O	Cl^-	TiO_2	P_2O_5	LOI	IR	RE
OPC (%)	20.33	4.59	3.06	62.30	2.12	3.10	0.76	0.19	0.07	-	-	1.78	1.21	0.49
FA (%)	55.10	26.60	5.70	2.58	1.30	-	1.41	0.26	-	1.33	0.73	3.07	-	1.92

LOI – Loss on ignition IR – Insoluble residual RE – Remaining elements

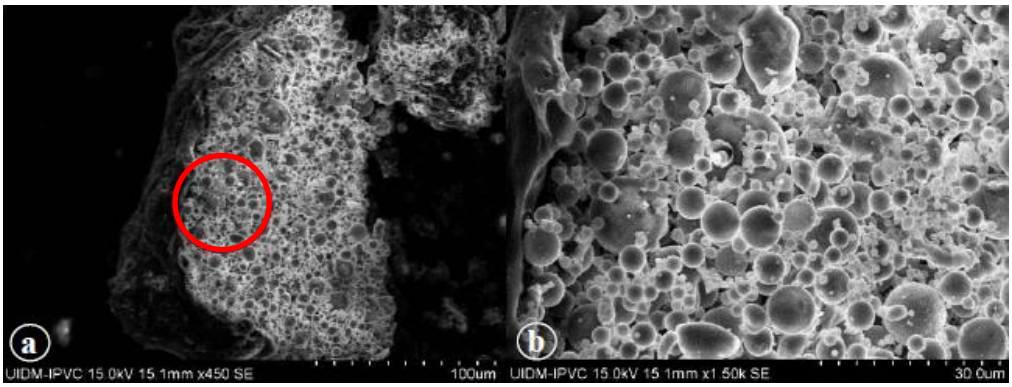

Figure 1. SEM FA images: a - 100µm (x300) and b – 30µm (x1500).

In addition to knowing the behavior of FAC under combined situation, it is also important

to compare its behavior to RC behavior, that is a concrete with similar properties to FAC but without FA, under same situation. Thus, two mixtures were adopted in this study, which are presented in Table 2. Crushed sand with a fineness modulus of 2.96 and two types of granitic crushed coarse aggregate, one with fineness modulus of 6.07 and the other with 6.94, were used. Tap water, maximum value of chlorides in the water was 10 mg/l, was used for mixtures.

Table 2. Materials and main properties of the mixtures.

Properties	FAC	RC
FA (%)	40	0
Cement (kg/m^3)	228	380
FA (kg/m^3)	152	0
Water/binder ratio	0.50	0.50
Slump (mm)	110	95
Compressive strength 365 days (MPa)	51.59	53.45
Immersion water absorption (%)	9.99	10.75
Capillary water absorption (kg/m^2/min$^{1/2}$)	0.116	0.104

Cylindrical concrete specimens with ϕ100x200 mm were casted with the mixtures presented. After casting, the specimens were covered with a plastic sheet and were stored in a humidity chamber (21 ºC and 98% RH) for one day. Then, they were removed from the moulds and were cured immersed in water for 90 days. The choice of this curing period was to give enough time for pozzolanic reactions in specimens containing FA to occur. After the curing period, all specimens were cut in three slices (ϕ100x50 mm). The top and bottom of the samples were discarded.

2.2 Accelerated Tests

The efficiency of FAC in the context of the combined action between chlorides and carbonation was studied in two ways: combined situation and reference situation. In the combined situation the specimens were subjected to carbonation test and, after, to chloride migration test. In the reference situation, the specimens were subjected only to the chloride migration test. The Figure 2 shows the test scheme.

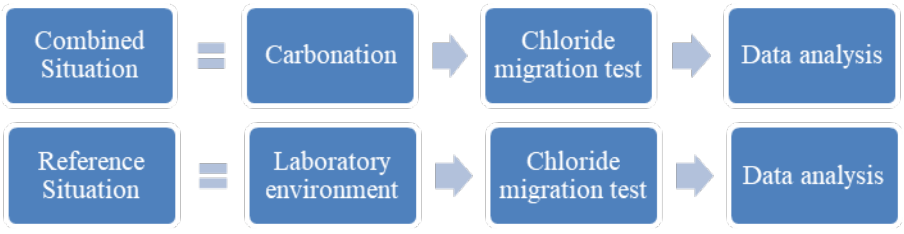

Figure 2. Laboratorial procedure scheme.

Before the tests, the specimens (FAC and RC) were subjected to preconditioning procedures

in order to achieve the equilibrium with environmental humidity near 60% and accelerate the carbonation process (in the combined situation case). This preconditioning had three stages. In the first stage, the specimens remained in a chamber with controlled temperature and humidity (20ºC and 60% RH) until reaching constant mass. Second, they had the lateral and the bottom face covered with paraffin in order to guarantee the one dimensional attack of aggressive agents through the top of the specimen. Third, in order to distribute the humidity inside the concrete specimens, they were protected with several layers of plastic film and put in a ventilated oven (40ºC), for 20 days. The specimens were weighed before and after being in oven and one has verified that the water loss was not bigger than 0.1%.

In the combined situation, after preconditioning procedures, the plastic film was removed and the specimens were subjected to accelerated carbonation in carbonation chamber (4% CO_2, 20ºC and 55% RH), following the recommendations of the European Standard (CEN/TS12390-12, 2010), during three different periods: 1, 2 and 7 months. Finished the test, the specimens were not broken and the paraffin coating was removed in order to permit the chloride migration test to be carried out. In the reference situation, the specimens remained wrapped in laboratory environment (20ºC and 60% RH) until chloride migration test time.

After, the chloride migration test was performed according the Portuguese specification (LNEC E 463, 2004). Finished the test, the specimens were broken perpendicular to the penetration direction of the aggressive agents. In the combined situation, the specimens were tested after each carbonation period studied. In this case, the halves were used in different ways: one half was sprayed with a solution of 1% phenolphthalein in 70% ethyl alcohol (RILEM TC CPC-18, 1988) in order to determine the carbonated front and the other half was sprayed with 0.1 N $AgNO_3$ to determine the chloride penetration depth. In the reference situation, the halves were used to determine the chloride penetration depth.

2.3 Capillary Water Absorption Test

The capillary water absorption test was carried out in order to study the open porosity of concrete (LNEC E 393, 1993). The test consisted in measuring the amount of absorbed water through only one face of a no saturated concrete specimen immersed in a water film of 5 ± 1 mm. The absorption of water through capillarity is the difference between concrete hardened mass, M_i (g), that had one face in contact with water during a time ti and the dry concrete mass, M_0 (g), divided by the superficial area that was in contact with water, a (mm).

3 Results and Discussion

3.1 Effect of Carbonation on the Chloride Diffusion Coefficient in Specimens with FA Incorporation

The effect of carbonation on the chloride diffusion coefficient in FAC is evaluated in Figure 3. This figure gathers the chloride diffusion coefficient values achieved for concrete subjected to the combined situation and reference situation. The values were determined for the three different carbonation test periods studied: 1, 2 and 7 months.

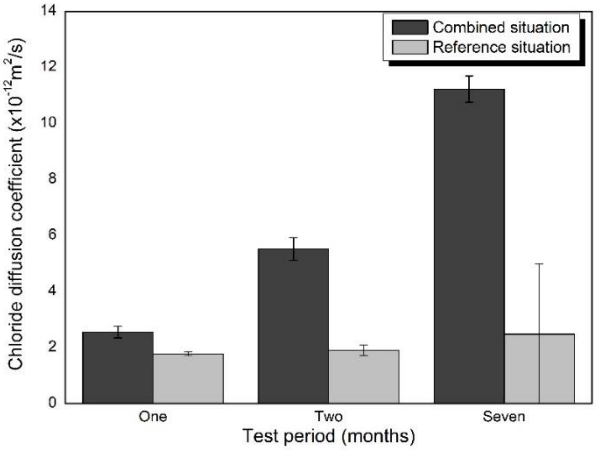

Figure 3. Chloride diffusion coefficient for FAC for the different situations: combined and reference.

According Figure 3, under conditions studied, there is a significant increase in chloride diffusion coefficient for FAC subjected to the combined situation when compared to the reference situation. This increase is quite high since the first month and gradually increases, until reaching the value of 352% in the seventh month.

The relationship between chloride diffusion coefficient and carbonation depth for FA concretes studied is showed in Figure 4. In this case, the chloride diffusion coefficient is closely related to the carbonation depth, through of an exponential equation with high coefficient of determination, $R^2 = 0.93$. In this sense, the increase in the carbonation depth leads to a significant increase in the chloride diffusion coefficient for FAC.

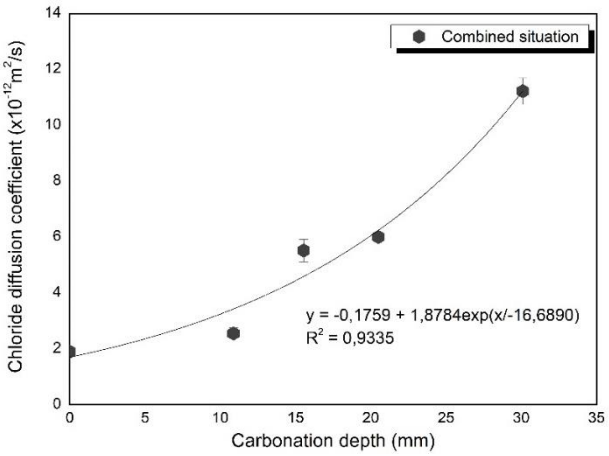

Figure 4. Relationship between chloride diffusion coefficient and carbonation depth for FAC.

The increase in the chloride diffusion coefficient can be related to: the increase in the large capillary pores, caused by carbonation (Ngala, V. and Page, 1997), which, in this case, can provides a "privileged path" for the chlorides penetration; and the chloride binding capacity reduction in carbonated concrete, consequently, there are more free chlorides available to penetrate in the cementitious matrix. The hypothesis of the increase in the large capillary pores

is investigated through the study of open porosity. The Figure 5 shows the capillary absorption results, after seven months, for FAC.

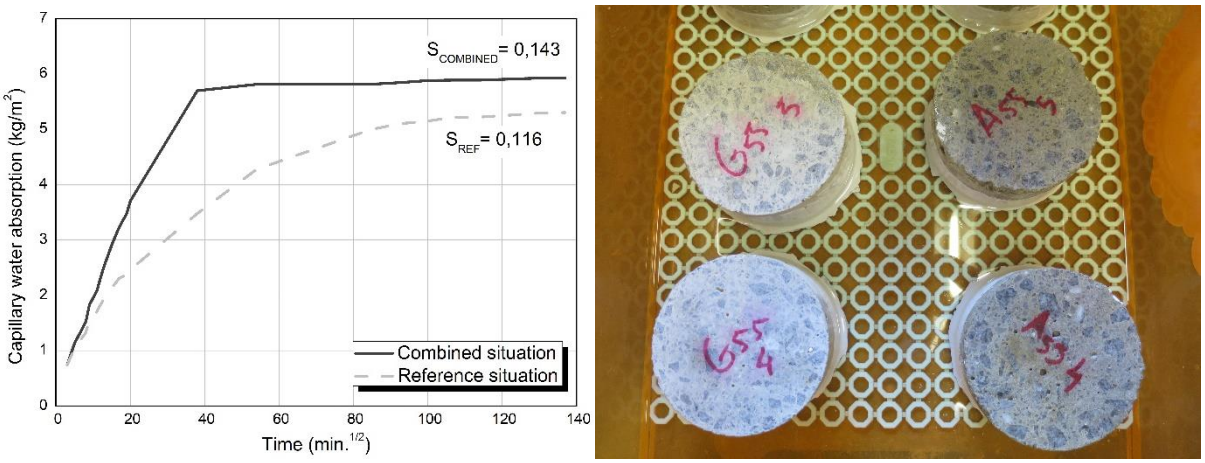

Figure 5. Capillary water absorption kinetics (left) and capillary water absorption test (right) after seven months testing.

In Figure 5 (left) is observed a higher capillary absorption coefficient for the specimens under combined situation when compared to the specimens under reference situation. It can indicate an increase in the fraction of the large capillary pores in FA concrete carbonated. Furthermore, the specimens subjected to the combined situation reached the stability (capillary pore saturation) more quickly, around 40 $min^{1/2}$, than ones under reference situation. The "superficial perspiration" verified in the specimens subjected to the combined situation (Figure 5, right) can be related to this capillary pore saturation. The results corroborate the hypothesis that the increase in the large capillary pores was one of the responsible for the increase in the chloride penetration in the carbonated FAC.

In this sense, it is possible to say that the FAC carbonated, under studied conditions, can work as a "privileged path" for the free chlorides penetration. This path can be seen in FAC specimens after combined test (Figure 6): XM1 is carbonation depth (left) and XM2 is chloride penetration depth (right). The chlorides completely cross the carbonated front, XM1, but only penetrate a few millimeters (XM2 - XM1) after this front.

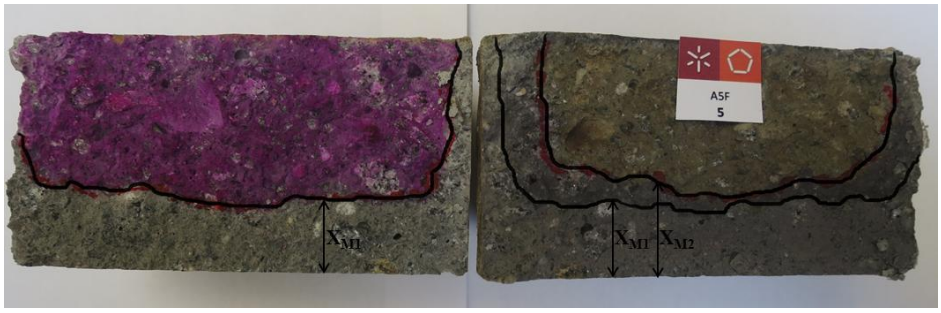

Figure 6. FAC specimens after combined situation (carbonation plus migration test).

3.2 Comparison between the Results Obtained for Specimens with FA Incorporation and Equivalent Specimens without FA

It is important to understand the FAC behavior in environments containing chloride and carbon dioxide but it also important to compare its performance to RC performance in the same environment. The Figure 7 gathering the chloride diffusion coefficients and the carbonation depths achieved for these two types of concrete in different test periods.

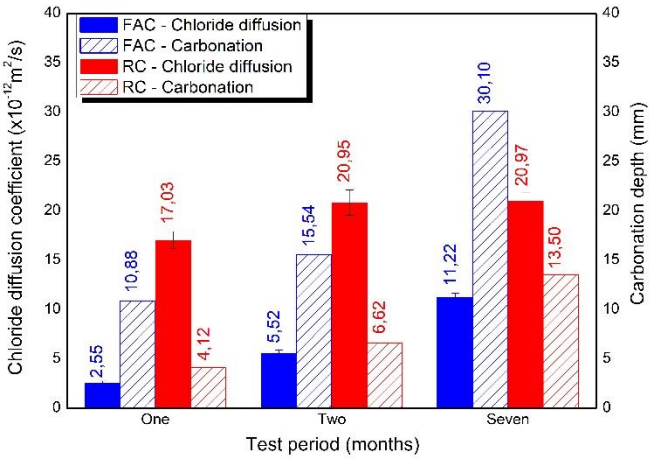

Figure 7. Chloride diffusion coefficients and carbonation depths achieved for FAC and RC under combined situation.

Regardless the test period and carbonation depth, the chloride diffusion coefficients for FAC is always less than the chloride diffusion coefficients for RC. This difference in chloride diffusion coefficients values tends to decrease over time, from 85% in the first month of testing to 53% in the seventh month (it is still a very significant difference). This result corroborates the efficiency of FAC against the chloride penetration, under conditions studied, even when the concrete structures are inserted in environments subject to chloride ions and carbon dioxide.

However, it is important to note that, regardless the test period, the carbonation depths for FAC is always higher than the carbonation depth for RC. In the seventh month, the carbonation depth for FAC is very close 30 mm. Taking into account the minimum coatings recommended by standards for carbonation environment, 25 – 40 mm (LNEC E 464, 2007), in this case, carbonation front can be close to the concrete reinforcement.

4 Conclusions

By experimental investigations on FAC subjected to chloride and carbonation environment, under conditions studied, the main conclusions can be drawn:

- There is a significant increase in chloride diffusion coefficient for FAC subjected to the combined situation when compared to the reference situation. This increase is related to the carbonation depth through an exponential relationship.
- This increase can be related to the increase in the large capillary pores, caused by carbonation, and the chloride binding capacity reduction in carbonated concrete.
- Despite the increase mentioned above, under chloride and carbon dioxide presence, the

chloride diffusion coefficient for FAC is always less than the chloride diffusion coefficient for RC. However, the carbonation depth is significant.

Abstract. *The Palace of Westminster, commonly known as the Houses of Parliament, serves as the meeting place of the House of Commons and the House of Lords and is situated on the north bank of the River Thames in London, England. The site is part of the UNESCO Westminster World Heritage Site. The building was constructed of magnesian limestone, selected following a nationwide survey of building stones carried out by a Government Select Committee. However, some of this stone began to decay soon after construction in the mid 1800s. As the majority of the stonework has survived very well the aim of the work was to source a demonstrably durable material with characteristics which align with the majority of the existing stonework. Samples were taken from the building for petrographic analysis in order to identify compatible material in quarries, either working or which could be re-opened. Durability of the magnesian limestone was assessed using both accepted tests and novel methodology. Large scale walls were constructed in the laboratory and exposed to accelerated frost weathering with realistic temperature parameters. The logistical problems with sourcing the original building material, the nature of the transport and the masons' unfamiliarity with the stone may all have played a part in undermining its durability. When magnesian limestone is properly selected and used correctly, its reputation for being of poor durability is largely unfounded. Suitable sources for replacement stone were located which provided several options for both immediate and long-term sourcing for repair and conservation.*

Keywords: *Magnesian Limestone, Durability, Restoration, Weathering, Freeze Thaw.*

1 Introduction

As with all historic buildings, natural wear and tear results in the necessity of repairing the fabric of the Palace of Westminster from time to time. Wherever possible this is undertaken with either the original stone where this is still available, or a stone which is petrographically, chemically and visually similar to the original, when the original source is unknown or has been worked out or sterilised by development. Unfortunately, over the years a number of stories regarding the unsuitability of the stone used by Barry to build the 'New' Houses of Parliament after the disastrous fire of 1834, have become to be regarded as fact (Shenton, n.d.).

2 The Historic Construction

The original stone for the Palace of Westminster selected by the Commissioners appointed by Parliament, was magnesian limestone from Bolsover Moor. The rate of extraction of acceptable stone with suitable bed heights could not be maintained and production was switched to Mansfield Woodhouse. The required bed heights again proved impossible to achieve. In 1834, only three years after the foundation stone had been laid, and with the walls of the new building about four to five metres in height, all the external stone was being supplied from the Anston

area. The Anston quarries finally fulfilled one of the main criteria for the supply of stone, being both of acceptable bed height and able to meet a supply rate which matched the planned speed of construction.

Stone was transported from the site using horse-drawn wagons to the Chesterfield canal and loaded into boats at Dog Kennel's Wharfe after storage at Kiveton Park. (Richardson, 1999). From there it was carried to West Stockwith to be transferred on to Trent sloops for the rest of the two-week journey to the Humber and then down the North Sea coast to the Thames and Westminster. Lott and Richardson (1997) highlight the 'formidable' scale of the operation as 400 imperial tons were carried by barge each month (approximately 4880 metric tons per annum). Anston Stone was used in the whole building except 'the upper part of the towers and the front towards Abingdon Street' (Elsden and Howe, 1923).

Soon after the building was completed signs of degradation started to appear on some of the stonework. These problems were almost certainly a result of the demand for large quantities of stone in relatively short time, compounded by the complexities of the formation of the of magnesian limestone (Smith, 1995). While acceptable building stone is available, in a range of bed heights, its quality can be variable and requires careful selection of appropriate material.

There were pressures to complete the building quickly and at minimum cost. Many of the masons involved in constructing the building would have been unfamiliar with magnesian limestone. A government select committee in 1861 reported that there were 17 beds in various thicknesses from 1 ft to a few inches but that both the good quality Anston and the poorer were 'worked indiscriminately' with no supervision within the quarries and as a result "*So little stone was rejected at the quarries that almost the only waste was that derived from the cutting of the blocks*" following which "*the stone was sent to London within a fortnight of quarrying, even throughout the Winter*" i.e. without seasoning to allow any weak material to fail before processing (Elsden and Howe, 1923). The stone had not been marked to show the bed orientation and thus much of the ashlars "*were sur-bedded – an example of unpardonable slackness*" (Elsden and Howe, 1923).

Despite often repeated comments that the magnesian limestone was not suitable for use in the polluted atmosphere of London, the majority of the stonework has survived extremely well. The quality of properly selected Anston stone was demonstrated by Sir Henry de la Beche, the first Director of the Geological Survey, who was involved in selecting the stone for the Palace of Westminster, when he used it for the new Museum of Practical Geology on Jermyn Street. Magnesian limestones have been used successfully in polluted atmospheres outside London; in Mansfield and Doncaster for example. Petrographic and electron microscope studies have shown that one reason for this durability may be the thin layer of crystalline gypsum which can develop on the surface of the stone, protecting it from further reaction.

3 The Original Stone

The magnesian limestones were originally formed in a shallow near-shore environment, ranging from sabkha muds to lagoonal oöidal banks, shell banks, patch reefs and detrital deposits. These strata were petrographically variable even before dolomitisation which overwrites original depositional fabrics. Thin beds of marl are not uncommon, and this clayey material is also present as very thin films within some of the limestone. In terms of petrography, chemistry and physical properties, a considerable range of stones exists as is evidenced by the colour and texture of the stones in historic buildings from Nottingham to the Tyne. The fine-grained nature of some of the stones and dolomitisation often make it impossible to identify the type and source of stone purely from a visual study of the surface alone. There are probably as many different types of magnesian limestone in the area from which the stone was sourced as there are different

types of ordinary limestone in the UK.
In order to determine the types of stone which may be required for the conservation work in the Courtyards, and elsewhere on the exterior of the Palace, it is first necessary to study and sample all the stonework within the seven courtyards, aiming to identify the existence of significant variations and, if they do exist, the number of stone types present and their distribution. Although all the fabric is relatively contemporaneous, the problems encountered with the supply of stone to the 'New' Houses of Parliament between 1839 and about 1852, and possible modifications since that time, may well have resulted in individual elevations utilising different building stones (Bolsover Moor, Mansfield Woodhouse, North Anston), and all three magnesian limestones may conceivably be present in at least some of the elevations.
Careful sampling of the fabric was therefore undertaken and 15 samples of magnesian limestone were taken from locations in the Chancellor's Court, The State Officers Court, The Peer's Court and The Star Chamber Court. A further piece of stone was provided, having become detached at some point in the past. The original context of this stone was unknown and was found to be Caen and not magnesian limestone (Yates, 2014; Palmer 2014) and is not discussed further. The lack of supervision and selection throughout the process in an attempt to finish the original work as speedily as possible and at minimum cost can be witnessed upon survey of the fabric of the building. It appears likely that the most damaged stonework involving the Anston stone is where softer material has been used for carved work, where poor stone selection has allowed flawed stone to be inserted in the building and where the stone has been incorrectly laid.
Petrographic analysis indicated that all the stones were originally detrital limestones formed in a lagoonal environment which were heavily recrystallised during the dolomitisation process. Three of the samples were relatively coarse-grained, the remainder finer grained, the typical clast size being about 140 microns. The original sediment consisted largely of spherical and sub-spherical particles, the exact nature of which cannot be determined due to the effects of the recrystallisation. However, when considered in the context of the Permian limestone elsewhere along its outcrop, these grains are most likely to be a mixture of rounded intraclasts, shell and other fossil fragments, spherical algal bodies and coated grains as well as true oöids. Some of the samples indicate that some of the shell and other fossil fragments could have been quite large. Although the finer-grained matrix is largely amorphous due to the dolomitisation, there are areas which suggest that algal mats may have been present. Overall, the assemblage suggests a typical Permian shallow water reefal and lagoonal environment, typical of the much of the Permian magnesian limestone outcrop.
There was no pattern in the use of the stone according to the study of the petrography and the fabric from which the samples were obtained. This apparent mixing of stone types within the fabric does have an advantage when conservation is undertaken. Due to the variation in the fabric there is no requirement for the exact matching of petrographies when a stone is repaired or replaced. Providing that the replacement material originated in a similar limestone facies to the original stone, and the degree and type of dolomitisation together with its physical characteristics, is similar, the most appropriate new stone for the location within the building can probably be selected.

4 Locating Replacements

Given the importance of the building, very careful consideration must be paid to the potential sources which most closely matched the fabric both visually and petrographically, and with acceptable chemical characteristics (*e.g.* the concentrations of silica, magnesium and iron),

similar porosity, permeability and compressive strengths, and of the same geological age. Sources that most closely matched these were available from quarries not operating commercially at the time of assessment. The type of dolomite fabric seen in the samples from the Courtyards, and elsewhere on the exterior of the building, is typical of that found in the area between Doncaster and Mansfield. However, the colour of the stone within this area can vary between pure white and pale brown. Obtaining a good colour and texture match restricts the search area for new stone to within about 20 kilometres of Anston.

All the magnesian limestone quarries within the target area were visited in order to determine whether or not stone with the correct texture and colour was potentially available. This included closed and mothballed quarries, as well as ones which were operating. Where it was not possible to obtain permission for access to a quarry, the visual appearance of the stone, and in particular its colour, bed height and jointing, was observed from the perimeter. Closer analysis of the stone in such cases was obtained by studying exposures outside, but close to, the quarry. Although there were a considerable number of quarries in the area in the second half of the 19th century, very few now remain. The result of the field studies indicated that Tarmac's quarry at Harrycroft was potentially a suitable source of stone for the repairs and conservation at the Palace of Westminster. Although not active at the time of the survey, reserves of stone remained in a consented area. The quarry is now fully consented and operational. The geology of the site is complex, with the rock being a mixture of patch reefs separated by bedded lagoonal deposits. Structurally the stone is also variable, being cut by faults and, more importantly, by joint features caused by differential compaction within and round the perimeter of the individual reefs. The reef limestones are not suitable for use as a building stone and any resource must therefore be extracted from the inter-reefal areas.

While the petrography of the material was consistent with that sampled from the palace, an assessment of the durability of the magnesian limestone was required and sample blocks were collected and tested by Sheffield Hallam University using an environmental chamber. At the request of the architects and following Stage 1 of the work, a second stage used stone from the commercially operating Cadeby Quarry.

5 Durability Assessment

For the first stage of work, four blocks of magnesian limestone were selected. These were chosen in order to represent the variation within the non-biohermal beds at the quarry. The bioherms, or patch reefs, have not been sampled since the stone is irregular and unbedded and contains numerous joints and cracks, probably due to the irregular compaction suffered after burial; it is not suitable for masonry use. The blocks were cut at the masonry yard at the Dean and Chapter quarry at Lincoln Cathedral. All cut blocks were 350mm length, 200mm depth and 200mm height. Block 1 was slightly variable and produced 14 blocks. Block 2 was far more uniform and yielded 8, Block 3 was found to contain a number of vent features in the stone and block 4 was very fractured and contained cavities and both were deemed unacceptable. Block 5 was from a different quarry in the Warmsworth area which was also under consideration at Phase 1 (should there be any problems with obtaining stone from Anston). From each set (1,2 and 5) a total of three blocks were selected as representative for inclusion in the first stage wall. Type-t thermocouples were embedded in one block of each stone type to allow the monitoring of response to freezing and ensure that the conditions required for damage were created, while working within realistic temperatures. A test wall was built using 1:3 St Astier NHL 3.5 and coarse graded sand which has been used in previous work and was found to be of suitable strength to prevent premature sacrificial weathering of mortar (Laycock *et al*, 2008; Laycock, 2002). Panels were isolated from the

surrounding chamber using polystyrene sheeting and were sealed to prevent water ingress from above or around the sides of the panels (Figure 1). Chamber conditions were verified by test run with the wall in situ to confirm thermal performance. Testing commenced as soon as chamber conditions were confirmed. A study of data from the Meteorological Office suggested that a moderate frost cycle should be utilised. Chamber temperatures were initially set at -4 but the frost front did not penetrate deeply enough into the stone to initiate damage (Laycock, 1997). It was therefore incrementally lowered when the panel was in situ in order to ensure that the frost front passed through the block to a depth of 30mm and released during the thaw cycle. This regime was found in previous work on the Magnesian Limestone to cause damage. This resulted in a final cycle between +8 to -10ºC, cooling and warming at 0.45ºC/min, 2 minutes of simulated rain and 10 cycles per day. The chamber was maintained at -10ºC for 14 minutes. A total of 300 freeze/thaw cycles were carried out. Phase 2 repeated this regime with 9 blocks of Cadeby stone cut to the same sizes as before.

5.1 Salt Resistance Test

Analogous stones from the fabric of the building were tested with a variety of salt solutions identified from the literature as having significant deleterious impact. Samples are created such that the salt solution is forced to evaporate through the faces of the exposed prism, thus simulating conditions required to produce efflorescence and sub-florescence. The experimental method for salt decay by capillary rise and evaporation was used by Scherer (2004) and Lee and Kurtisb (2017). Salt concentrations were based on those used by other authors (Table 1).

Table 1. Salts selected for resistance testing

Salt	Relevance to decay	Conc.	Examples of previous work
NaCl	commonly used as a de-icing salt, may be present in older brickwork	5%	Goudie (1986) Lopez-Arce (2008) *
NaSO4	Salt used in standard testing as known to have highly deleterious effect.	14%	EN 12370 Benavente et al (2001)
MgSO4	Decay product from deterioration of dolomite	35%	Cardell et al (2008)

*used 5.3 wt.% NaCl

6 Results

Visual logging using the method reported in Laycock *et al.* (2008) of over 300 cycles of simulated weathering confirms that the performance of the Cadeby stone and types 2 and 5 were of similar and low order of deterioration both in terms of area and extent (Figure 2a) and severity of damage. Type 1 manifested significantly more severe damage, over a greater areal extent. This is in direct contrast to the performance of Type 1 in the EN 12370 sulphate crystallisation test (Figure 2b) in which types 2 and 5 demonstrated variable and poorer performance. However, when compared to other samples of magnesian limestone building stone tested in the same way indicate that all types tested in both phases of this work demonstrated excellent resistance to deterioration. The material from Cadeby was found to perform consistently well in all tests carried out.

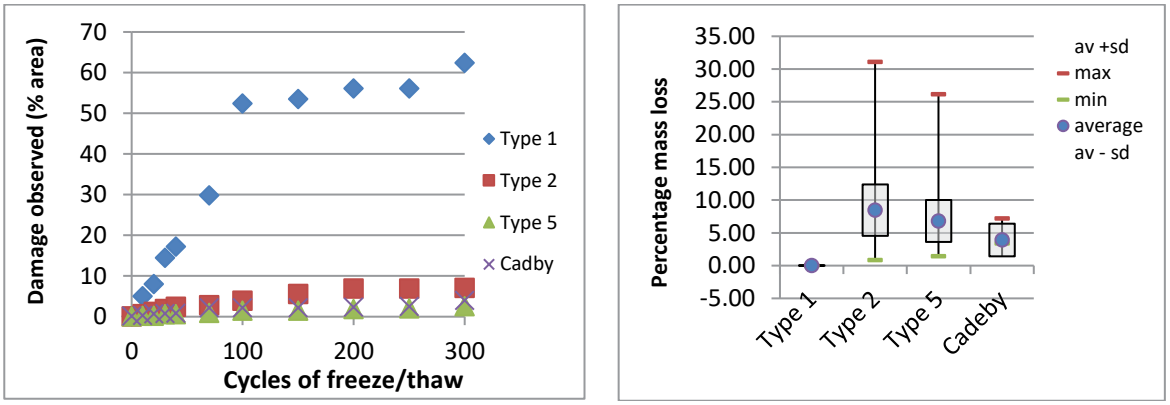

Figure 2. Comparison of the results (Phase 1 and 2). Left:2a) Freeze Thaw testing. Right: 2b) Sodium sulfate crystallisation test.

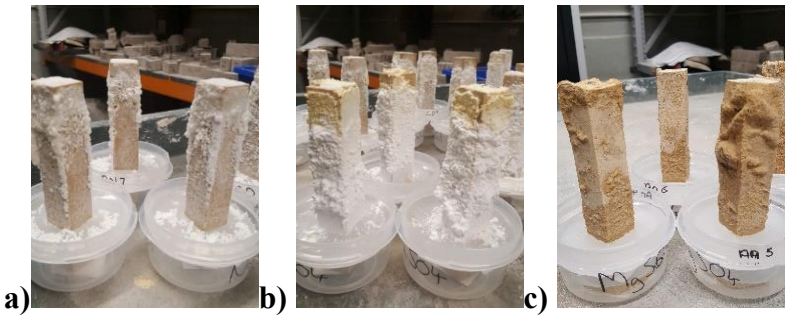

Figure 3. Salt resistance. 2a Anston (type 1) after 120 hours NaCl; 2b Anston (type 1) after 120 hours after 22 days $NaSO_4$; 2c Anston (type 1) after 30 days $MgSO_4$

Results from the capillary rise and evaporation test included prisms of Clipsham stone, a non-magnesian stone of good reputation previously used in repair interventions. In this test the Clipsham showed noticable material loss from crystallisation of magnesium sulphate after 24 hours and sodium sulphate after 48 hours. In contrast the Cadeby and Anston stones were affected to a much lower degree by these salts. All stone types tested in the 5% NaCl showed low rates of material loss despite rapid evaporation and crystals tended to form as efflorescence rather than sub-fluorescence. Magnesium sulphate solution caused no early damage to the samples, however blistering of the Cadeby was noted in one prism by 120 hours. This test confirms that the Cadeby and Anston stones provided show good resistance to decay by the development of salt crystallisation.

7 Conclusion

The bulk of the original stone for Barry's Palace of Westminster was obtained from quarries at North Anston west of Worksop. Although some of the stone reportedly failed soon after its inclusion in the building, this was almost certainly due to poor quality control during extraction and shipping as well as during construction. This could be attributed demands for a high quantity of stone required in a relatively short period and with a tight budget. This poor project management is evidenced by the mixture of stone petrographies, a result of the distance the stone had to be brought and the likelihood of mixing of stone from different extraction areas at the loading wharf on the Chesterfield canal, again when being off-loaded and re-loaded on to sea-going barges, and again when stockpiled at Westminster. This contrasts with accepted good practice to select the appropriate stone for a specific location in the fabric at the quarry. Furthermore, as stone was used and replaced with new stocks shipped in from Anston, the range of various types of petrography would also vary with time. These problems may well have contributed to the reported weathering of some of the stone soon after the building was completed, potentially unsuitable stone being used on occasion for features such as windows or copings.

Where used elsewhere, and with due diligence, magnesian limestone has had a perfectly acceptable durability. There is no reason why the fabric should not be repaired with magnesian limestone with due consideration to the factors outlined in the Technical Advice Note 2016 (Jefferson and Henry, 2016). While some authors have suggested to the contrary (Hunt, 2015), it is completely unacceptable to repair such as building in this with a pure limestone, even one of the highest quality (Jefferson, 2015). Fortunately, the use of the Clipsham stone introduced into the Palace has largely been for the construction of extensions to the building in some of the courtyards, in order to provide increased accommodation. Only a relatively small quantity of the Lincolnshire limestone has actually been used for repairs to the Anston, and other, magnesian limestones in the original fabric.

This work assessed sources of carefully selected magnesian limestone which was deemed to be compatible with the original stone from South Yorkshire. In the large-scale frost testing very little damage was observed to the stone. Where damage did occur during the frost testing this was of a cosmetic nature rather than causing severe material loss. Salt crystallisation testing also showed low levels of losses in standard and non-standard regimes. The Cadeby stone is likely to decay eventually by surface blistering due to magnesium sulphate crystallisation, but this is not anticipated for an extended interval. In conclusion both Anston (Harrycroft) and the Cadeby magnesian limestone materials tested were found to be durable. Both quarries contain variable stone, Cadeby has produced six different types of building stone. If the stone tested is representative of the materials exploited from the quarries, then an extended life span in use is suggested. The work highlights the difficulties in evaluation of likely stone performance from a single test. By using a variety of methods, the differential performance observed can be balanced. The results show that the magnesian limestone can be expected to be durable, but that the natural variability of the stone is such that considerable care must be exercised to ensure that the correct quality of stone is used. Durability is not the only consideration when selecting a stone for conservation use; petrographic, permeability, strength and colour after a period of weather are all important factors.

Acknowledgements

The authors wish to acknowledge T Brindley for construction of the wall, the input of the Harmer 2004 technical team (particularly Carl James for supporting the frost work; Callum McPherson for the sulphate testing; Steve Williams for technical team leadership). Transport of Moisture and Chlorides into Sprayed Concrete

Diego Aponte, Marilda Barra, Susanna Valls and Lucia Fernandez

Department of Civil and Environmental Engineering (DECA), Universitat Politècnica de Catalunya-BarcelonaTECH, Campus Nord UPC, 08034-Barcelona, Spain, diego.fernando.aponte@upc.edu

Abstract. *This contribution is a study of the durability and transport properties of sprayed concrete used in an actual construction site. It considers whether concrete spraying can generate different porosities as the thickness of the sprayed layer increases. The work consisted of a study of the properties of the interior and exterior concrete layers with a particular focus on chloride penetration. A few of the methodologies and techniques used are compressive strength at 28 days, depth of penetration of water under pressure UNE EN 12390-8, boiled absorption and volume of permeable voids ASTM C642, and accelerate chloride penetration NT BUILD 443. Calculated transport property values included absorption (A) and volume of permeable voids (VPV), porosity interconnection, and chloride diffusion coefficient (De). The conclusion obtained is that there are no significant differences between the physical microstructural properties of the interior and exterior sprayed concrete layers, they present a similar porosity, and behave in the same way under a chloride attack when test tubes are completely saturated.*

Keywords: *Sprayed Concrete, Moisture Movement, Chloride Penetration, Chloride Diffusion Coefficient, and Durability.*

1 Introduction

Sprayed concrete is typically used in the construction and stabilization of tunnels, underground structures, and other construction sites where the application of traditional cast-in-place concrete is particularly challenging (Wang *et al.*, 2015). Unlike conventional concrete, sprayed concrete has a short setting time as well as high mechanical properties due to the incorporation of set accelerating additives (Austin *et al.*, 2002; Galobardes, 2013). At the same time, sprayed concrete presents more porosity than cast-in-place concrete, which can affect its durability by making it more vulnerable to damages caused by moisture, chemicals, and other external agents (Galobardes *et al.*, 2014).

This study conducted a characterization of the physical, mechanic, and durability properties of sprayed concrete with two goals in mind. The first is to determine if, when studied by layers, sprayed concrete shows different transport properties depending on its proximity or direct contact with the projected surface. The second is to study the impact of the presence of chlorides introduced by moisture via the sprayed concrete's transport mechanisms to determine potential durability issues.

2 Methodology

This study was conducted with wet-mix sprayed concrete, using a CEM I 52.5 R, water/cement ratio 0,35 and 450 kg /m^3 of cement, a superplasticizer type

MASTERCLENIUM SKY 554-BASF, and the accelerating additive MasterRoc SA 172 (which is non-alkaline and presents no alkalis or chlorides). Table 1 shows the dosage used in the shotcrete.

Table 1. Sprayed concrete dosage.

Material	Quantity (kg/m^3)	Quantity (%)
Cement	450	19.4
Water	155	6.7
Sand 1 (0/2mm)	750	32.4
Sand 2 (0/6mm)	485	20.9
Medium Ag. (4/12mm)	435	18.8
Superplasticizer	4.5	0.2
Accellerator	38.2	1.7

The wet mix concrete was sprayed on 4 mm-thick metallic test panels located at an ongoing construction site, using 7-15 m^3 air pressure per minute at a 90° angle, and maintaining a 0.5 – 1.5m distance to ensure all samples would be sprayed with similar speed, compaction, and adherence.

After the spraying, the mixes were transported to the Construction Materials Laboratory of the Universitat Politècnica de Catalunya, and they were left outdoors for 28 days to simulate the environment to which they would have been exposed at the construction site. After the initial 28 days, the next step was to extract 7.5 cm diameter cores (cylindrical specimens) from the test panels (Figure 1a) and divide each sample into two equal parts of 5 cm each, which are called parts A and R (Figure 1b).

Part A is the first layer, which under real conditions would have been in contact with the terrain. Part R is the second layer, which is adhered to the first layer and has a surface that was used to simulate exposure to open air.

Three specimens of each type of sample (part A or part B) are used for density, water penetration, suction test and compressive strength . Two specimens of each type of sample are used for chloride penetration test.

Figure 1. Extraction of sprayed concrete specimens (a) and division of samples into part A and part B.

2.1 Density, Absorption, and Porosity

These specimens did not undergo any special preparations to test for density, absorption, or porosity. The test was conducted following the standard ASTM C642.

2.2 Moisture Penetration under Pressure

Epoxy paint was used to cover the lateral parts of the specimens, leaving only the two opposite faces of the cylinder exposed to ensure that the moisture flow would be vertical and ascending without lateral losses. This test used pressurized water under the surface of the hardened sprayed concrete for 72 hours, applying a 500±50 kPa pressure, as foreseen under norm UNE-EN-12390-8.

2.3 Capillary Cuction

The epoxy paint used to avoid moisture losses described above also prepared the specimens to undergo the capillary suction tests, which were conducted under the standards of norm ASTM C1585-04.

2.4 Chloride Determination

This test was based on the NT BUIL 443 method to determine the resistance of hardened concrete to chloride penetration. The specimens used for this test also received epoxy paint treatment to ensure the moisture would only flow in the desired direction and presented no visible cavities or cracks. Each specimen was cut through the layers of A and R, to study the penetration properties of each layer separately. Each sample tested was hence 50 mm high, in pairs originated from the same original sample.

An aqueous NaCl solution was prepared with a concentration of 165 ± 1g NaCl per dm3, which means that initially, the chloride concentration was 100,09 g Cl-/l ± 0,607 g Cl-/l. The samples were afterward inserted into the NaCl solution and underwent the following steps:

- Three type-A samples and three type-R samples were extracted, originating from three different specimens at 35, 60, and 90 days.
- After extracting the samples at 35 days, we replaced the aqueous solution with a new one with identical characteristics to the one used initially.
- Each time the samples were extracted, we conducted proceedings to determine the distance of penetration of the chlorides and the concentration of chlorides at each depth.

The results from the chloride penetration tests are presented as the average of two A samples and two R samples at 35, 60, and 90 days. This test did not consider the metallic test panels from which each sample originated. However, samples A and R came from the same specimen.

2.5 Compressive Strength

The samples were cut and polished at their extremes to obtain a 2 – 1 relation on the specimens that would be used to test the compressive strength, meaning that they were twice as high as the diameter of the cylinder. The norm used for this test was UNE 83-302.

3 Results

3.1 Physical Properties

Concerning the physical properties of the samples, the test shows only slight differences between the dry density and the apparent density. The average values of samples A and R are practically the same (Figure 2).

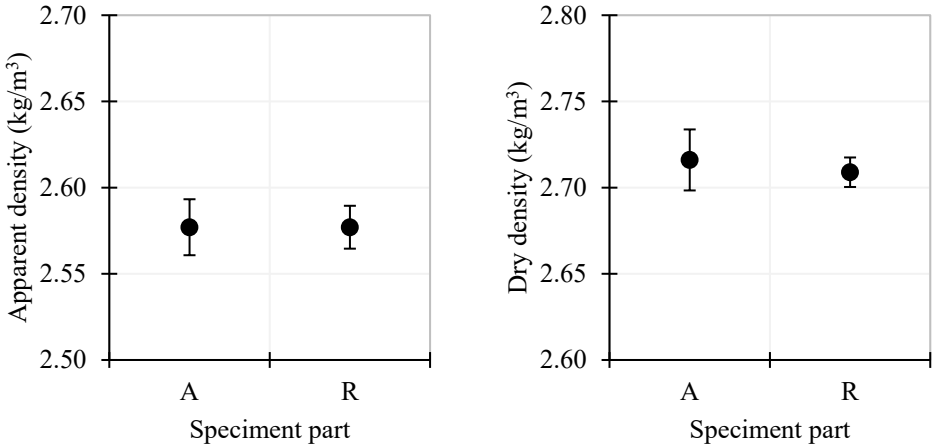

Figure 2. Apparent density and dry density of the samples.

Some differences were observed when it comes to the absorption capacity and porosity of the samples. R-type samples presented more porosity than A-type samples, and in consequence, a larger absorption capacity (Figure 3).

With regards to water penetration under pressure, we observed that there is a significant porous interconnection in both type-A and type-R samples. Throughout the 3-days test, moisture completely penetrated both samples.

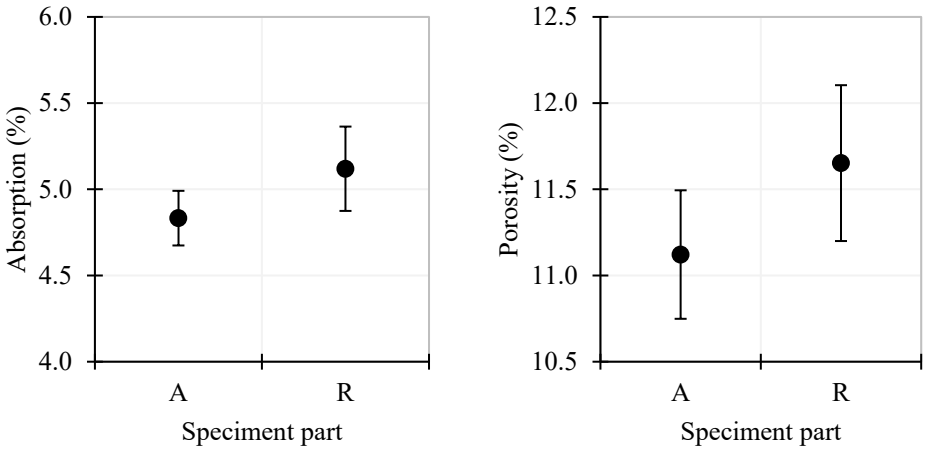

Figure 3. Absorption and porosity of the samples.

The capillary suction test confirmed the porous interconnectivity in both A and R samples, reaching almost a saturation level of 100% (Figure 4a). The only significant difference between the type-A and type-R samples performance is that during the first 6 hours of the test, the maximum free absorption was higher on type-A samples (Figure 4b). Forced absorption tests indicated that there were few isolated pores since, when dried, we observed very little water filling those pores.

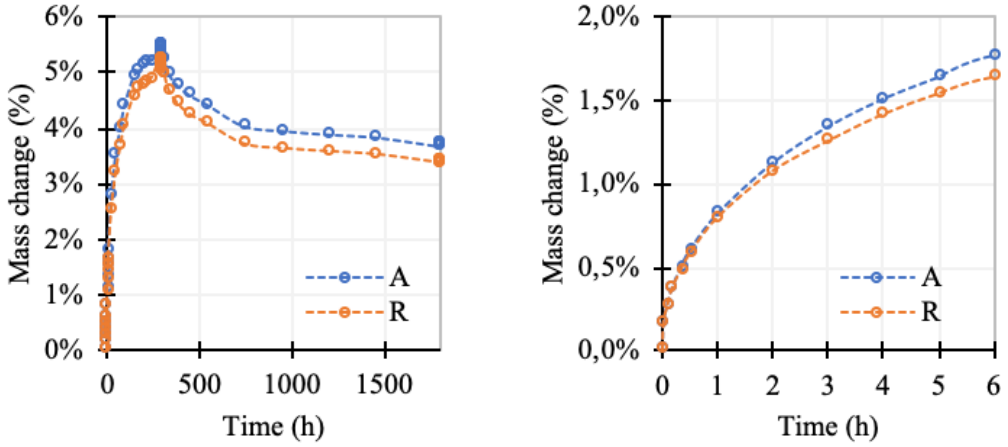

Figure 4. Capillary suction and drying of the samples (a). Capillary suction during the first 6 hours (b).

There is also no significant difference between the loss of water of samples A and R. This confirms that the porosity structure of both samples is very similar, being capable of retaining and losing the same quantity of moisture (Table 2).

Table 2. Mass of water absorbed during the free and forced absorption test.

Speciment part	Total water (g)	Free absorption (%)	Forced absorption (%)
A	29.59	5.1 (94.6%)	5.4
R	28.36	4.8 (93.0%)	5.2

3.2 Durability – Chloride Penetration

The test followed the directions of norm NT BUIL 443 to determine the chloride penetration profiles for samples type-A and type-R at immersion ages 35, 60, and 90 days. Figure 5 shows that there are no significant differences between the profiles determined on both types of samples at their different ages. The test shows that, as the exposure time increases, the concentration of chlorides on the surface increases significantly between 35 and 60 days, but from 60 to 90 days, the increase was not relevant.

It is important to notice that, according to the results of the penetration profiles, the diffusion coefficient decreases as the exposure time increases. Using the square minimums method as dictated by norm NT BUIL 443, the test determined the diffusion coefficients for all cases and showed that the differences are not relevant. (Table 3).

Table 3. Chloride coefficient of the samples at different ages ($x10^{-11}m^2/s$).

Specimen part	35 days	60 days	90 days
A	4.55	3.55	1.97
R	5.14	2.42	2.26

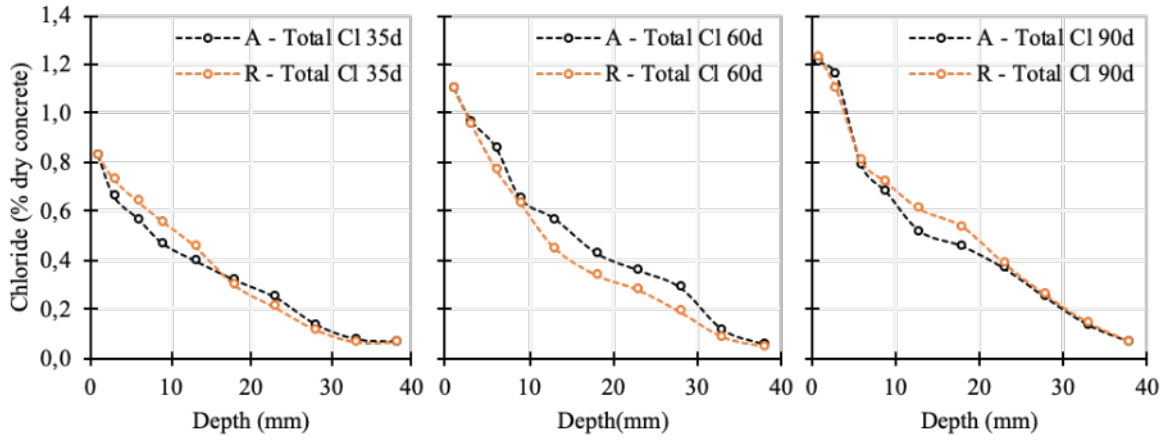

Figure 5. Chloride profiles at 35, 60, and 90 days fo the samples.

This data indicates that an increase of exposure time does not imply a higher accumulation of chlorides at the penetrated depths since, over time, the chloride ions in the solution accumulate at the walls of the sample's pores. The pores hence become progressively saturated, slowing down the aqueous solution's capacity of penetration.

3.3 Compressive Strength

For the mechanical tests, samples were obtained from three metallic test panels containing the

same type of sprayed concrete. Samples originated from the different test panels presented different results despite having used the same sprayed concrete at all of them (Table 4). This can be due to differences in the aggregate distribution during the spraying of the concrete, leading to differences in behavior. In order to verify the distribution of the aggregates in the different samples, a visual analysis was performed. Figure 6 shows that the specimens originated from test panel 2, the one where the aggregate distribution is most homogeneous, presented higher compressive strength.

Table 4. Compressive strength at 28 days of different test panels (MPa).

Sample	Test Panel 1	Test Panel 2	Test Panel 3
C. S	41.7	51.2	44.3

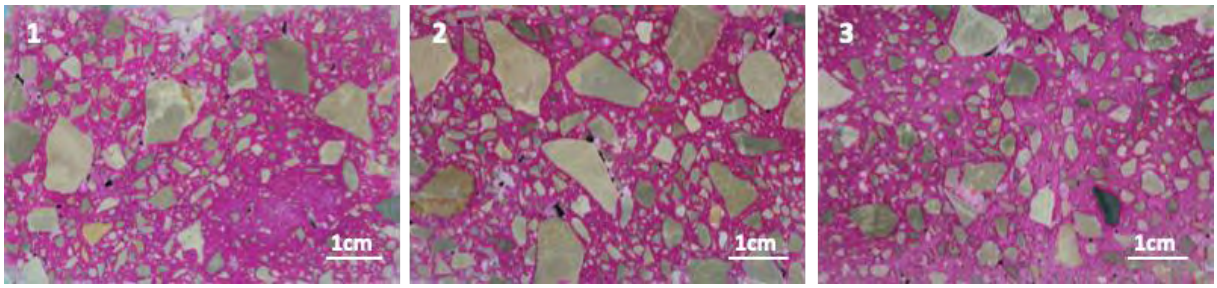

Figure 6. Visual analysis of the distribution of aggregates in the samples.

4 Conclusions

The experimental work carried out in this study presents the following conclusions:

- The samples used for the density tests show slightly different behavior compared to the ones used at the capillary suction tests. However, these differences are not relevant.
- The distribution of aggregates in concrete generates a difference in the mechanical properties of the different samples tested, but this difference does not show a significant impact on the moisture or chloride transport properties.
- On a microstructural level, there are no significant physical differences between shot concrete sample parts A and R. Both parts present a porosity network of similar characteristics.
- The samples of sprayed concrete analyzed in this study presented larger pore interconnectivity compared to regular concrete, which contributed to increase the speed of diffusion of chlorides. This indicates that sprayed concrete could be more vulnerable to chloride penetration than regular concrete.
- There are no noticeable performance differences in terms of chloride penetration between the concrete parts which were exposed to the surface, and the layers exposed to open air. Therefore, there is no proof that the chloride penetration is not homogeneous throughout all the shot concrete layers.
- The high level of concordance of the results obtained from different tests indicates that A and R behave similarly under a chloride attach when completely saturated.

Abstract. *The awareness of the environmental impact of buildings during their entire whole life cycle has seen a growing interest in recent years. In fact, as buildings become more energy-efficient, life cycle impacts become increasingly important. Investors in the building sector are becoming aware of the direct and indirect benefits of a design process that enables the control of the impact of the building, ensuring the higher quality, intrinsic value of materials under a circular economy point of view. The durability is, together with reusability and recyclability, one of the main characteristics of construction materials. In this framework, the purpose of this paper is to describe a BIM-based approach to life cycle assessment (LCA) from the initial stages of the design of the Socrates Building in Viladecans. For this scope, a digital model in the TCQi GMA software was created to assist in the evaluation, optimization, and comparison of different design and construction alternatives. An integrated project delivery contract was adopted. These aspects altogether showed the potential of increasing the real estate value and the profitability of the building. This paper discusses problems that emerged during the digital project management, assessing criticalities and opportunities.*

Keywords: *LCA, Circular Economy, Prefabricated Construction.*

1 Introduction

The Socrates Building is a mixed-use building that allows to explore the challenges of a new model of design and construction based on the circular economy. The building is located in Viladecans Business Park, close to Barcelona, a new business development area dedicated to emerging companies and new business models. The basis of achieving a building of circular economy was to ensure that the building could adapt to a wide range of uses that span from offices to tertiary. This goal was pursued with the following main directives: maximum spatial flexibility, structural durability, material disassembling and traceability and comfortable and healthy occupied spaces, followed an approach often only fully presented in theory (Berardi, 2015).

An industrialized and dry construction systemic approach was chosen as the best option to respond effectively to life cycle strategies and to reduce the negative impact of the operational phase and deconstruction phase. Construction materials were chosen according to their level of traceability, fostering the use of Cradle to Cradle materials, and the commitment of the contractor to select products with a material passport or Environmental Declaration of Product

(EPD). The decision-making during the design process was supported with a Life Cycle Assessment (LCA) developed with a digital BIM model and implemented with environmental impact data of the BEDEC database.

An important part of the process was dedicated to conceiving a building with an increased value during its operational phase, which is usually the highest impact in the life cycle (Asdrubali *et al.*, 2013). Therefore spaces were designed utilizing energy simulations to ensure optimal lighting and thermal comfort (Bernstein, 2011), and to give a direct benefit to energy conservation and a subsequent reduction in operating costs.

Another keystone in the design was to support direct access to nature and open spaces with vegetation, natural ventilation and direct access to daylight and views. Each floor plan possesses open space equipped with vegetation, irrigated with recovered rainwater. The LEED v.4 certification protocol was adopted to better structure all of the aspects related to sustainability, this decision was taken in accordance with an analysis of the office buildings market in Barcelona where the majority of buildings with environmental certifications have a higher real estate value and higher rental potential (Eje Prime, 2018). A final practical aspect of the design and construction phase was the implementation of an integrated delivery process (IDP) that aligned every stakeholder towards the common goal of conceiving a circular economy building.

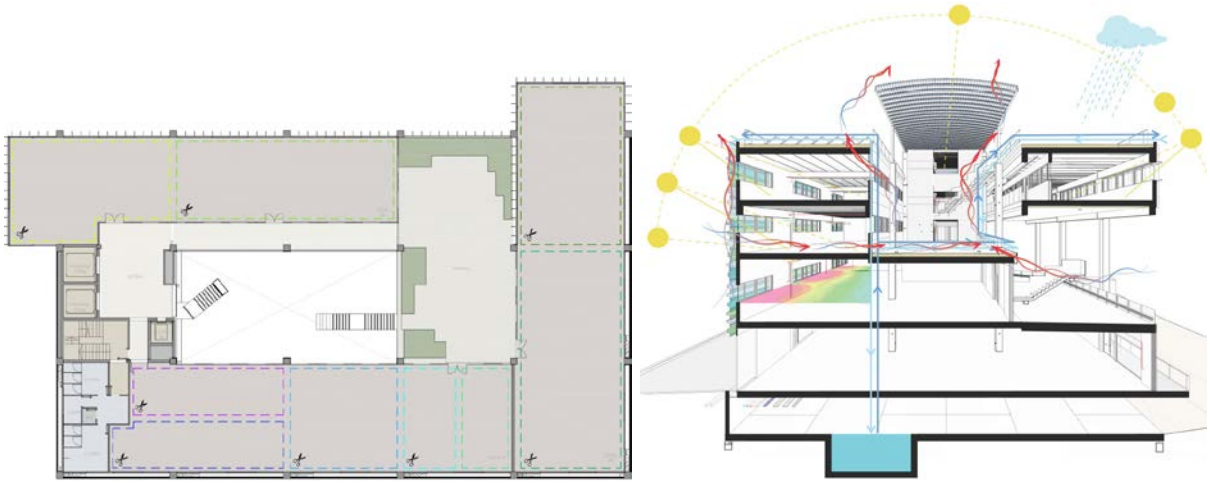

Figure 1. Type floor plan with interior subdivision schemes (left) and section (right) of the Socrates building.

2 Main Building Characteristics

The building comprises four levels: the first two stories are accessible to automated vehicles whereas the upper floors are designed according to office criteria. Open common spaces are provided on each floorplan and located to the core of the building, also serving as connection and circulation zones. The rooftop hosts a common terrace partially covered with a green substrate and an area dedicated to HVAC plant equipment and PV.

2.1 Construction Elements

Particular attention was dedicated to structural design as it is considered to be one of the most influential components of the building, remaining practically unchanged through the whole life cycle affecting its duration and the resulting building economy (Manganelli, 2014). The

building is designed to be fully industrialized and assembled onsite. This process guarantees a more effective construction process by reducing the construction time schedule, minimizing onsite waste production, facilitating the traceability of each material and its revalorization at the end of the lifecycle.

The structure is constructed from a prefabricated concrete frame composed of 0,60m x 0,80 m pillars that span the full height of the building as a single element without vertical interruption in addition to horizontal beams with a section of 60 x 80 cm that connects to the vertical structure. Pillars are distributed across a 10 x 10-meter grid, with a 100m^2 free areas that guarantee the highest spatial flexibility for any tertiary and light industrial use. Prefabricated hollow-core slabs complete the horizontal enclosure and give structural stability to the frame.

Figure 2. Prefabricated structure during the construction phase of the Socrates building.

2.2 Envelope

The façades are composed of a sandwich panel with 8 cm of mineral wool, held by a steel frame substructure and finished on the interior with plasterboard panels and an additional 4cm of insulation. The Eastern and Southern façades are covered by metallic perforated panels that leave sufficient space for natural ventilation and HVAC ducts and piping.

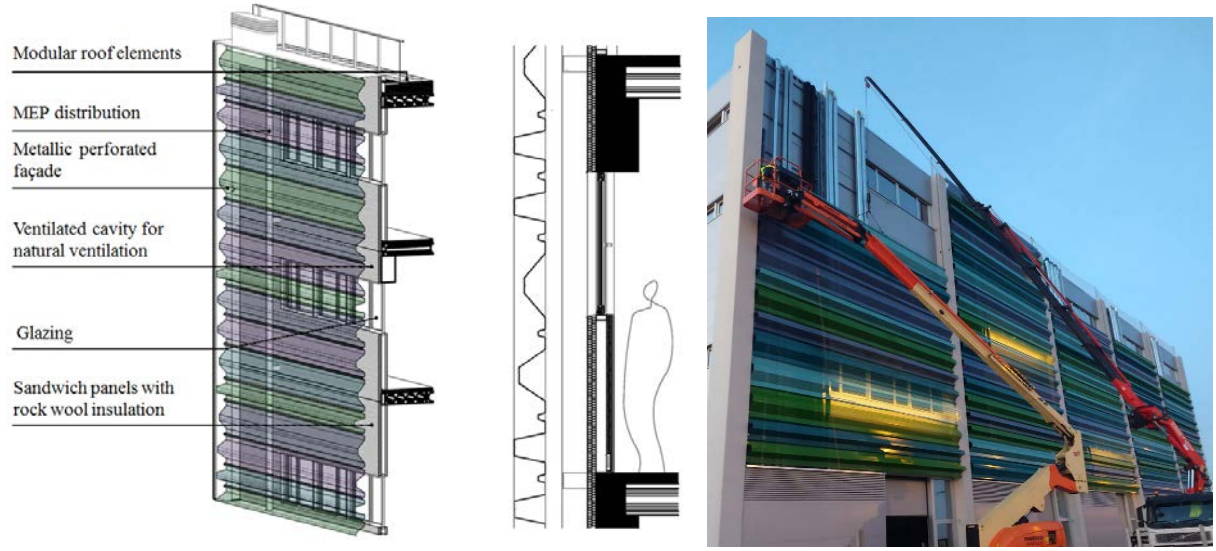

Figure 3. 3D of the façade (left), façade section (center) and construction phase (right) of the Socrates building.

All the horizontal enclosures in contact with occupied spaces present a waterproof layer covered by 10 cm of XPS thermal insulation. The roof garden consists of an industrialized green roof, modular elements that include the irrigation system. The remainder of the roof and terraces are covered with concrete floor tiles. Interior spaces are left without any additional finishing.

2.3 Mechanical, Electrical, and Plumbing

The HVAC system, linked with a geothermal heat pump of 303 kW, acts as the primary system and covers 80% of the demand for heating and cooling power. A water to air heat pump of 316kW supports the system during peak demand. The installation of 45 kWp of PV panels is estimated to produce 60.000 kWh, covering 38% of the expected energy consumption. The distribution systems run along the façade, connecting to the ventilation system of each interior space. This configuration was chosen to facilitate ease of maintenance and to improve internal spatial flexibility, offering multiple options of connection to services externally with no implication to the interior spaces.

3 Methodology

3.1 Application of an Integrated Process for the Building Life Cycle

Energy simulations with Energy plus were performed to optimize the building envelope for the thermal comfort. Daylight analysis determined the volumetric and spatial definition of the building, assisting with the interior design considerations that according to a different range of options in favor of maximum spatial flexibility. At the same time, an LCA was performed with the digital BIM model of the architectural proposal, then integrated with a personalized database of construction products, based on BEDEC (BEDEC), the Catalan online database of construction products with technical details, costs, and environmental information. The whole process took place within the TCQi-GMA software (TCQi-GMA).

3.1.1 Software TCQi-GMA, its development, and LCA

The TCQi-GMA (TCQi) is used for life cycle assessment and other applications of construction projects developed by IteC. It is based on TCQ2000 (TCQ), a software developer for the construction sector, formed by a set of applications to support the activities of the edition, contracting, planning and control of projects and construction sites. It includes indicators on time, cost, quality, security, waste generation and embodied energy. A specific methodology is used to calculate the environmental data, similar to the one used in eco-labels type III. The categorization of products and services for the construction sector, as defined by the European standard EN 15804 (EN 15804), is applied. Materials durability, joints disassemblability, and material positioning within a layer play a vital role in the process.

3.1.2 Application of the process in the Socrates building

The inputs for the LCA of the Socrates building were:

- The budget of the project in Excel, created by the construction contractor and;
- A set of 3D models converted to .IFC file format from various 3D modeling software. The 3D models provided consisted of b1) a foundations model, b2) a structural model,

created in Tecla by the provider of prefabricated structure b3) an HVAC model provided by the installation engineer, and of b4) an architectural model produced by the architects.

Eight chapters of LCA were defined for the project: demolition & groundworks, foundations, structure, building services, civil works, rainwater storage system, private urbanization, elevators, and extra modifications.

Each chapter was assigned a construction system as defined in the BEDEC database and given a specific code associated with detailed information about its construction process and the cost. During the next phase, the IFC models are associated with the TCQ2000 structure. Each of the four 3D models is integrated within the software. The different components were then manually selected and associated with the corresponding chapters of the created structure. The unit to import the BOQ is selected, and the BOQ is imported to the TCQ2000 structure. Some of the elements presented in the original budget file did not have representation in the 3D model, therefore the BOQ data comes from various sources: a) from the 3D model; b) from the Excel file, and c) calculated manually when incomplete in both inputs. Once the digital model has been defined, the LCA is performed, using the TCQi-GMA software. When uploading the structure from the TCQ2000 to TCQi, the software analyses the provided data and evaluates how complete the environmental data is, as defined by the structure.

In the Socrates Building, the information related to the waste generation is 100% complete, while the information referring to Energy and CO2 generation is missing in 9.09% (Gris and Alfaro, 2019). In order to complete the information, the incomplete chapters can be adapted, assimilated or completed manually. The last source is to integrate data coming from the material supplier, such as volume, mass, LoW (2014/955/EU) code, embodied energy and associated CO2 emission. Once all the data has been completed, the environmental impact of the construction phase is determined. Finally, the TCQi-GMA software allows the integration of data about the use phase, as well as the end-of-life phase, based on the existing database, as well as maintenance manuals, when specific information is not available.

4 Results

As a result of the implementation of energy simulation during the design process, the maximum depth of the volumes on the 2nd and 3rd floors was set to 10 meters, ensuring a 10-meter patio to the core. This strategically allowed openings towards an interior zone with better acoustic conditions. This choice guaranteed at least 2% of Daylight Factor (DF) across 75% of working areas and an efficient level of natural ventilation. The overall energy consumption of the proposal is reduced by 40% compared to the corresponding baseline model designed according to ASHRAE 90.1.

Concerning the LCA, detailed data related to the product, construction, use, and end of life phases have been studied. 8 chapters of the construction work divided into earth movement, foundations, structure, civil works, rainwater storage, private urbanization, elevators, and extra modifications. The BEDEC database was used for product and construction phases. Relationship with use and end of life future phases has been created, but not completed due to lack of information. At the current stage, the total LCA information for the foundations and structure phases has been created (Fig. 4).

The overall results considering the product and construction phase show the largest impact during the product phase (2.453.247 kg CO_2 eq). The construction phase impact is low (448.129 kg CO_2 eq). In the product phase the impact is distributed mostly between the foundations (542.000 kg CO_2 eq,), structure (846.885 kg CO_2 eq,) and civil works (883.000 kg CO_2 eq,). The civil works contain all the non-load bearing elements of the building envelope, interior partitions, and finishing. The rest of the construction categories in total count less than 181.000 kg CO_2 eq. The prefabricated concrete structure causes the largest impact during the construction phase, with 409.028 kg CO_2 eq compared to the second-largest impact by the earth moving with 25.000 kg CO_2 eq.

To achieve the total LCA, relations are being created between the different work items and the future items of works during the use phase and end of life phase. This process requires an important time dedication because each item that defines the construction work needs several works items to calculate the future impact. However, once the relationship has been created, it can be applied or adapted for future use in another project, becoming part of the company's own knowledge and future business. Unlike other LCA software that performs generic calculations in different scenarios, the methodology used in this paper identifies each material and associated construction processes, creating relationships reflecting the real construction work in detail, in order to conduct in-depth analysis, introduce the disassembly capacity or the material passport identification.

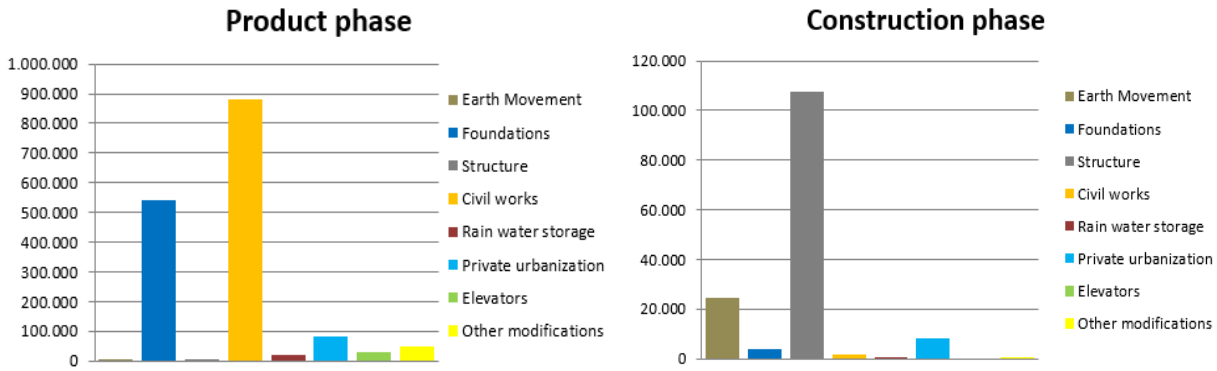

Figure 4 Global Warming potential in kg CO_2 eq: Product phase (left), and Construction phase (right).

Finally, in the Socrates Building, 88% of the construction materials have been identified and defined for its recyclability at the end of life, amounting to 7.800 tons. Moreover, 84%, accounted for its weight has a Cradle-2-Cradle certificate. The design and construction process has guaranteed a minimum waste production calculated for 25 tons of waste material, including excavation consisting of only 4 kg of waste per square meter of construction: 100% of this waste can be traced by a waste management protocol and 99,3 % is re-valorized.

5 Discussion and Conclusions

The new Socrates Building close to Barcelona was designed to be an example of the integration of circular economy in the construction sector. This experience has outlined some criticalities and opportunities, as discussed here.

As a first consideration, it is worth highlighting the importance of an integrative process during design and construction. The integration of all the stakeholders with an IDP was beneficial for technical and construction decisions, giving the opportunity to incorporate synergy to the whole value chain, allowing constant control on cost and quality. However, the IDP contract was introduced just before the construction works, causing initial maladjustment that produced an increase in technical costs. This could have been avoided by including this strategy from the start of the design phase.

As a general consideration of the circular economy, the Socrates Building is presented as a dynamic system of parts and functions attached to specific uses that can vary during its life cycle. The concept of the circular economy includes not only the life cycle of construction material but also the operational phase and the increased value derived from spatial flexibility, the health and comfort of occupants that can give greater performance, energy and economic savings during use and maintenance. This aspect is crucial for the generation of a different business model for tertiary buildings, moving the focus from only the environmental impact to include the quality of the service and the sub-sequential impact on occupant satisfaction and employee retention. In fact, employee cost is usually estimated to reach up to 90% of building cost (Attema *et al.*, 2018) and every improvement under this aspect can have much higher savings if properly quantified.

Concerning the lifecycle analysis, data availability is an important issue in the construction sector. In the Socrates project it was enhanced, as most of the products were Cradle-2-Cradle certified or had the Environmental Product Declaration (EPD). However, one of the main barriers in applying the LCA methodology in the design process is the lack of precise and consolidated data, especially considering the environmental impact of specific construction systems in the use phase. The availability of information about maintenance, repair, replacement, and refurbishment plays an important role in the development of this methodology. In order to overcome this barrier, ITeC is currently working on enabling the BEDEC users to create their own online database of construction systems, using the elements available in the existing database. The users will be able to share their database with one another and integrate them into their TCQi Software for LCA. This offers more flexibility in the exchange of information and in the acquisition of information for specifications, planning and construction tracking. Furthermore, with the increasing implementation of big data analysis and artificial intelligence, the statistical data will allow us to determine the most appropriate systems and installation methods for any geographical orientation or location, as well as being able to determine product needs or the capacity for growth based on existing resources in a specific area.

In order to consider the environmental impact of the construction beyond the system boundary, the reuse, recovery and recycling potential has to be considered in the life cycle assessment. Another issue identified in the process was the interoperability of software and the diverse needs of the LCA methodology on how to create the 3D model of the building.

Finally, the Socrates Building can be considered as one of the first real case studies for the integration of circular economy in the building sector. The next step required for a business model of the circular economy will be to consider each component of the life cycle in terms of intrinsic economic value in the real estate market so that buildings will increase its value beyond standard indicators and so enhancing the interest in sustainable buildings.

Development of 3D Printing Technology for Geopolymers

Kinga Korniejenko, Michał Łach, Janusz Mikuła, Maria Hebdowska-Krupa, Dariusz Mierzwiński, Szymon Gądek and Marek Hebda

Institute of Materials Engineering, Faculty of Materials Engineering and Physics, Cracow University of Technology, Jana Pawła II 37, 31-864 Cracow, Poland, michal.lach@pk.edu.pl

Abstract. *The article presents the first results of the project under the title: 'Development of 3D printing technology for construction and facade prefabricated elements made of concrete composites and geopolymers', grant no. POIR.04.01.04-00-0096/18, funded by the National Centre for Research and Development in Poland, within the framework of programme: 'Smart Growth Operational Programme 2014-2020, IV Increasing the research potential, 4.1.4: 'Application projects'. The main aim of the project is design and development of the innovative large-format printer using geopolymers for 3D printing for residential houses. It allows the development of a technology for the production of a universal residential building, with a construction that is easy to transport and fast to assemble, as well as with the possibility of simple and quick expansion depending on the needs of users. The article shows the main idea of the advanced large format 3D printing for geopolymers with using an ergonomic printing method as well as materials research in modern filaments in the form of geopolymers.*

Keywords: *Geopolymer, 3D Printing, Additive Manufacturing, Large-Format 3D Printer, 3D Printing in Civil Engineering.*

1 Introduction

Additive Manufacturing is a rapidly developing industrial sector and potentially a disruptive technology. It can provide new horizons in the construction sector, especially in terms of geometrical flexibility, reduction of labour costs, improvement of efficiency and safety, construction in harsh environments, and sustainability (Nematollahi *et al.*, 2019; Labonnote *et al.*, 2016; Panda and Tan, 2019; Soltan and Li, 2018). Unfortunately, the full exploitation of 3D printing processes is currently limited due to the in-process and in-service performance of the available materials' sets, especially in application in construction industry.

Nowadays, the using geopolymers for 3D printing in the large-format printer is a great challenge. It offers a new perspectives for the construction industry, but the development of this technology is slowed down by a lot of barriers. The article shows the possibility of development the 3D printing. The main idea of development the advanced large format 3D printing for geopolymers is using an ergonomic printing method as well as materials research in modern filaments in the form of geopolymers. The article is focused on problems that appear during the first trials of development 3D printing technology.

The first research were connected with basic properties of the materials – key factors of effectiveness 3D printing process, such as: viscosity and time of bonding (Labonnote *et al.*, 2016; Rahul *et al.*, 2019). This basic properties are related with the thixotropic, and allow to understood as high yield strength and low viscosity behavior of the materials, including (Labonnote *et al.*, 2016; Panda and Tan, 2019):

- pumpability - reliability with which material is moved through the delivery system,
- extrudability - depositing material through a deposition device,

- buildability - resistance of wet material to deformation under loads,
- and open time - period during which the aforementioned properties remain consistently within acceptable tolerance.

The basic challenge in 3D printing is received the material that is sufficiently fluid and at the same time has sufficient viscosity to retain its shape after the printing process (Panda and Tan, 2019; Panda *et al.*, 2018). Moreover, not only the material properties decided about the possibilities of effective process. The other elements associated with technology are also important. All of this factors happen that there is only a limited understanding of the material requirements for 3D printing technology (Labonnote *et al.*, 2016; Rahul *et al.*, 2019).

2 Materials

The samples for small scale prototyping were prepared with metakaolin with pigment addition. The samples for large scale were prepared as geopolymer concrete, based on:

- metakaolin and sand (ratio: 1:1),
- fly ash and sand (ratio: 1:1).

Both raw material, fly ash as well as metakaolin, were thoroughly investigated as a possible raw material for the production of the geopolymers. The chemical composition was determined by X-ray fluorescence (WD-XRF). They oxide composition is shown in Table 1.

Table 1. Oxide composition of fly ash and metakaolin.

	Oxide composition (wt.%)							
	SiO_2	TiO_2	Fe_2O_3	Al_2O_3	CaO	MgO	K_2O	Na_2O
Fly ash	55,9	1,09	5,92	23,49	2,72	2,61	3,55	0,59
Metakaolin	53,01	0,74	1,34	41,54	0,27	0,38	0,71	0,82

Geopolymers were made from fly ash from the metakaolin or fly ash and sand in ratio 1:1. The fly ash was delivered from the bituminous coal power plant 'Skawina'. This power plant is located in Skawina in Lesser Poland region on the south of Poland. The fly ash is obtained as combustion by-product through the electrostatic precipitation of fine particles from the exhaust gases from coal-fired furnaces. The chemical composition of this fly ash is relevant for the geopolymerization process – it is typical for class F (Łach et al., 2016). The detailed oxide composition is presented in Table1. This raw material contains less than 5% of unburned material and less than 10% of iron compounds. Additionally it has low amount calcium compounds. The amount of the reactive silica in the material is ca. 36%. Moreover, it has physical parameters relevant to geopolymers manufacturing, especially it contains a lot of spherical particles and has good workability (Łach et al., 2018) as well as large amount of amorphous phase (Łach et al., 2016). The process of activation has been made by 10M sodium hydroxide solution combined with the sodium silicate solution (the ratio of liquid glass - 1:2.5).

3 3D Printing of Small Scale Elements

Samples were prepared using sodium promoter for activation the metakaolin with some pigment addition. The trials has been made on the laboratory 3D printer for concrete – WASP 2040 with pneumatic feeder.

The samples some multilayers plate have been prepared using 3D printing method – Figure 1. The printed samples were characterized by different quality.

Figure 1. Page layout.

The most important problem was viscosity of the material. In the first trials the material was too solid and the process was impossible to print effectively (Figure 2b), but the layers in this case were created effectively. The samples had ratio between liquid and solid parts: c/s = 0.25. Because of the lack of possibility of printing the viscosity was regulated by ethanol addition. After receiving the required viscosity the main challenge was layer stability. The samples had ratio between liquid and solid parts: c/s = 0.3. This materials were very easy to printability, but the main problems was connected with lack of proper stiffness of the layers (Figure 2a), because of that the product loss they shape.

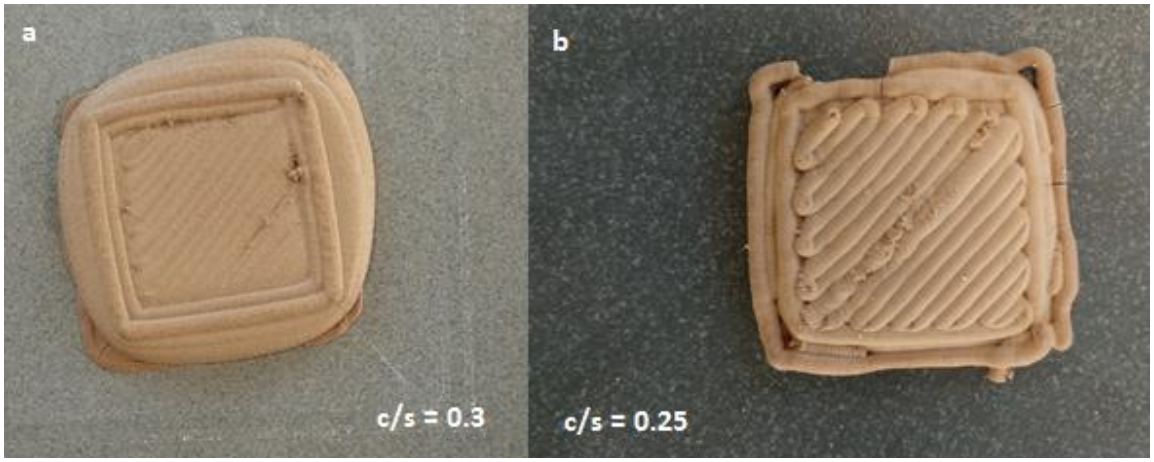

Figure 2. Samples after 3D printing with different liquid/solid ratio a) 0.3, b) 0.25.

The ratio between c/s required modification, but main problem is too long period for receiving the proper stiffness it must be analyzing once again and modify by proper addition on introducing some factors that accelerate the bonding such as additional sources of

temperature (Bong *et al.*, 2019; Nematollahi *et al.*, 2019).

The other challenge was brittle material behavior after the curing time and cracking during the drying process (Figure 3).

Figure 3. Samples after drying with visible cracks.

The problem of the cracks required introducing the additives to the geopolymer. It could be for example fibers addition that reduced the brittle material behavior (Korniejenko *et al.*, 2018; Nematollahi *et al.*, 2018; Silva *et al.*, 2020).

4 3D Printing for Large-Scale Elements – Manual Prototype for 3D Printing Process

The other trials was performed on large scale samples made on the self-produced manual 3D printing machine (Figure 4). The construction given material using a rotating screw (own design for determining the optimal consistency and speed of material reproduction).

The samples were prepared using metakaolin and fly ash mixed with sand in ratio 1:1.

Figure 4. Self- produced manual 3D printing machine.

The trials were conducted on the large form with using different ratio liquid and solid parts – Figure 5.

Figure 5. Samples after 3D printing with different liquid/solid ratio a) 0.3, b) 0.25.

The achieved results did not fulfil the requirements. The samples produced with different kind of ratio were too liquid to application for building elements. The material need further modification.

5 Conclusions

The article is focused on problems that appear during the first trials of development 3D printing technology, especially materials issues. It shows similar problems that appeared for small and large scale elements as well as for different raw materials used. The most important problem was viscosity the material. It was regulated by ratio between liquid and solid parts and additives such as ethanol. This problem was partly solved, but after receiving the required viscosity the main challenge was layer stability. There are planned further work on material stabilization.

The other challenge was brittle material behavior after the curing time and cracking during the drying process. The solving of this challenge required further works, especially connecting with design of proper curing process.

Abstract. *Temperature and humidity measurements provide useful information on multiple areas of civil engineering application such as Structural Health Monitoring (SHM), Structural System Identification (SSI) and structures rehabilitation. Majority of the existing commercial systems are so costly and also these measurement paradigms need many reference spots for a full-scale structure. The aforesaid paradigms are based on collecting data through smart devices, transferring information to each other and in the final stage processing the obtained information collaboratively through cloud computing or the others technologies. Taking into account the above information and obstacles, utilizing the Open Source Platforms (OSP) microcontrollers like Arduino as well as low cost sensors are attracting more and more attention. This paper gives a comprehensive information about the most determinant aspects of the aforementioned kits in terms of their pros and cons, installation procedure, communication protocol, number of the required connections and specific characteristics of the data acquisition system.*

Keywords: *Thermal Analysis, Low-Cost Sensors, Building Information Modeling, Open Source platforms, Structural Health Monitoring.*

1 Introduction

Climate change has drastically affected crops, wildlife and people's livelihoods. One of the main elements that can prevent this tragedy is to lessen the energy consumption since this incident could also be caused by burning of the fossil fuels for the human needs. In this way, one of the most efficient solution is to control the waste of energy in the buildings and public places. The development of economically viable Building Information Modelling (BIM) using different software and hardware has become increasingly popular in recent years. An economic Arduino-based embedded system can be defined as combination of Arduino open source platform and low-cost environmental sensors. Studies of the Arduino-based as well as

BIM-based controlling systems in different engineering fields were conducted by many scholars.

Barroca *et al.,* (2013) have designed and Arduino-based controlling system for concrete structures. They have prepared thermal and temperature sensors inside the concrete in order to measure temperature and humidity of the concrete at different levels. Different low-cost particle sensors were assessed by calibration methods adapted from the US EPA 2013 Air Sensor Workshop recommendations. The six different elements of the examinations were linearity response, precision of measurements, limit of detection, dependence on particle composition, dependence on particle size, relative humidity and temperature influences (Wang *et al.,* 2015). Bamodu *et al*., (2017) have used various types of humidity and temperature low cost sensors such as LM35 and DHT11 in order to control the indoor environment parameters of the buildings, heating, Ventilation, Air-Conditioning (HVACs).

Monitoring ventilation as well as thermal/humidity comfort level of the public places are vital issues since variation of the mentioned parameters might occur in different spaces. For instance, these variations may affect energy consumption and health of passengers in the subway. Marzouk and Abdelaty (2014) stablished Wireless Sensor Network (WSN) and BIM-based model in order to be able to monitor thermal condition in the different places of a subway. Kim *et al.* (2015) presented the development of Modelica Llibrry for BIM-based building energy simulation using an Object-Oriented Physical Modeling (OOPM) approach and Modelica, an equation-based OOPM language. Using the ModelicaBIM library they have prepared system interfaces between BIM and energy simulation, aiming to stablish semi-automatic translation from BIM to building Energy Modeling (BEM). Garcia and Kamsu-Foguem (2019) presented a new approach for automation of building construction when dealing with the energy efficiency for the purpose of predicting comfort levels elements such as heating, ventilating, air conditioning and etc. moreover they stablish BIM for thermal performance of prefabricated construction system (Mobaraki *et al.,* 2018).

As is evident from the aforementioned studies, the advantage of using the low-cost sensors for establishment of BIM in thermal performance of different structures has already proven. Along with the undertaken studies, it has to be mentioned that the accuracy of the low-cost sensors is a decisive parameter in reliability of the BIM. Therefore, in the section 2 of this article, a comprehensive information about the Arduino mechanism, types of smart connections and types of low-cost sensors will be presented. In the third section a detail explanation related to the performed experiments in terms of performance of low-cost sensors DHT22 will be explained.

2 Arduino Sensors

Arduino UNO is an open source software/hardware for making interactive electronic objects. The physical programable part is of 6.8 cm * 5.3 cm board which has 14 digital input/output pins, 6 analog inputs, 5 power pins (VIN, 5V, 3.3V and GND) with different performances, a 16 MHz crystal oscillator, a USB connection for compiling the data as well as using power supplied form the laptop/computer, a DC power jack (7 – 12V), a reset button for restarting the program/Arduino from the beginning and some small parts (Garin *et al.,* 2018). For talking to the sensors through Arduino as well as programing the board through compiling the sketches the open- source Arduino Integrated Development Environment (IDE) software has

been presented (Philips, 2019). This cross-platform application has written in Java, C and C^{++} and is compatible with all Windows, MacOS and Linux. The Arduino environment is extendable by utilizing the libraries. These libraries have written in C/ C^{++} and they increase functionality of the sketches for working with hardware as well as manipulating data. One of the main capabilities of microcontroller is to read sensors and capture the values. In other words, it can be express that sensors are sort of objects, capable of converting physical quantity (like temperature or humidity) into an electrical quantity. For measuring different parameters through Arduino various types of sensors exist. For instance, temperature, motion, humidity, vibration, displacement, pressure and etc. these measurements might be done for several purposes such as smartening systems of metering, retail, logistic, agriculture and security. For the connection of a sensor to the Arduino and observing the measured parameters, sensor's library which defines a canonical set of predefined sensors and control ability, should be used. The Arduino's sensors are categorized as digitals and analogs. Analog sensors observe the external changes such as temperature and humidity variations and yield analog voltage that represents the measured parameter. For instance, 2V might mean 23 degrees Fahrenheit. Normally this output voltage is between 0 to 5V. Analog signals might be influenced by the ambient noise which leads to produce errors in the output signals. However, the digital sensors generate discrete values like 0 and 1 which are so called digital/binary signals. They have lower range of calculation than the analog ones. Therefore, the analog sensors are more appropriate for wide range of measurements. As far as the analog outputs are liable to change rapidly and unpredictably, digital sensors are preferred over the analog ones.

3 Arduino-Based Thermal Controlling System

Temperature and humidity are one of the decisive factors measured in many projects. In order to evaluate the accuracy of the low-cost temperature sensors, it was decided to stablish an Arduino-based thermal controlling system. This system is going to measure variation of the temperature in an oven located in Universidad de Castilla-La Mancha (UCLM). The Arduino-based thermal measurement system is depicted in Fig.1.

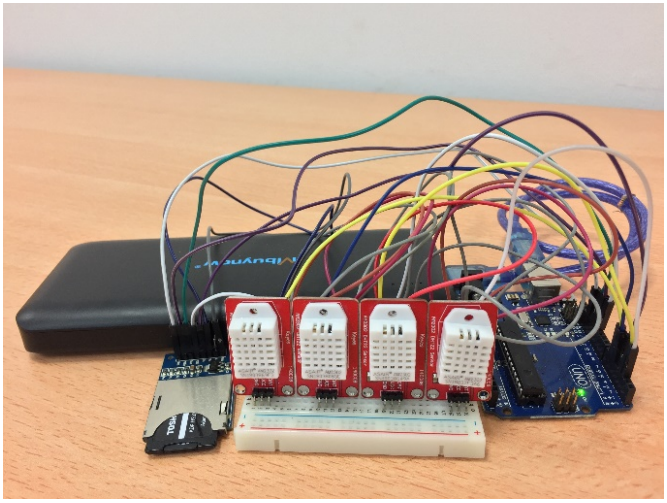

Figure 1. The Arduino-based thermal measurement system.

3.1 Hardware Description

Fig.2 shows all the used particles for establishment of this measurement system Arduino UNO, DHT22 sensor, breadboard and SD Card/Reader. The proposed system is based on the open source Arduino UNO platform and low-cost temperature/humidity sensor DHT22. The operating temperature of this sensor is between -40° C to 80° C with accuracy of 0.5° C. It is also capable of measuring humidity from 0-100% with resolution of 0.01 and accuracy of 2-5% RH. DHT22 sensor was chosen since it is one of the most employed and common low-cost humidity and temperature sensors in the engineering and environmental projects. The communication system of the sensor is a custom protocol which use a single wire/bus communication. Fig.2 illustrates the utilized oven for measuring the DHT22 accuracy (Sensor, 2019).

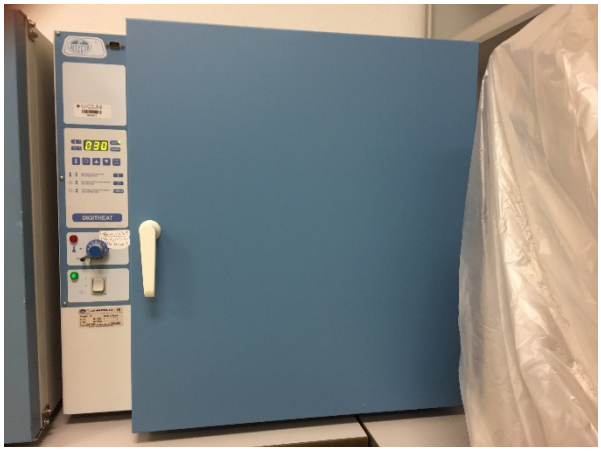

Figure 2. The utilized oven SELECTA-2001244 for the experiment.

3.2 Comparative Sensors Result

To estimate the responses of DHT22 sensor as well as their precision, variation of the temperature versus time related to the 4 sensors shown in the Fig.3. The sensors adjusted to record the temperature with frequency of 2 seconds. All of them have been registered to measure the temperature inside an oven in the laboratory of Universidad de Castilla-La Mancha (UCLM). Model of the oven is SELECTA-2001244, Capable of changing temperature from 10° C to 250° C with precision of 2% and resolution of 1° C. In order to figure out the precision of the sensors, the oven adjusted to reach to the temperature of 30° C and keep working for period of time. As shown in the Fig.3, variation of the temperature has been divided to two parts. The first part shows variation of the temperature for reaching to the adjusted temperature and the second part depicts behavior of the sensors at the fixed temperature of 30° C. In the second part the sensor number 1, number 2, number 3 and number 4 are showing constantly the temperature of 29.6° C, 29.4° C, 29.4° C and 29.6° C respectively. These observations indicate the discrepancy between the low-cost sensor DHT22 for recording the homogenous temperature in the oven. It has to be mentioned that in our measurements not only we are facing with error of the sensors, but also the oven has its own range of error, 2%, as mentioned in the above.

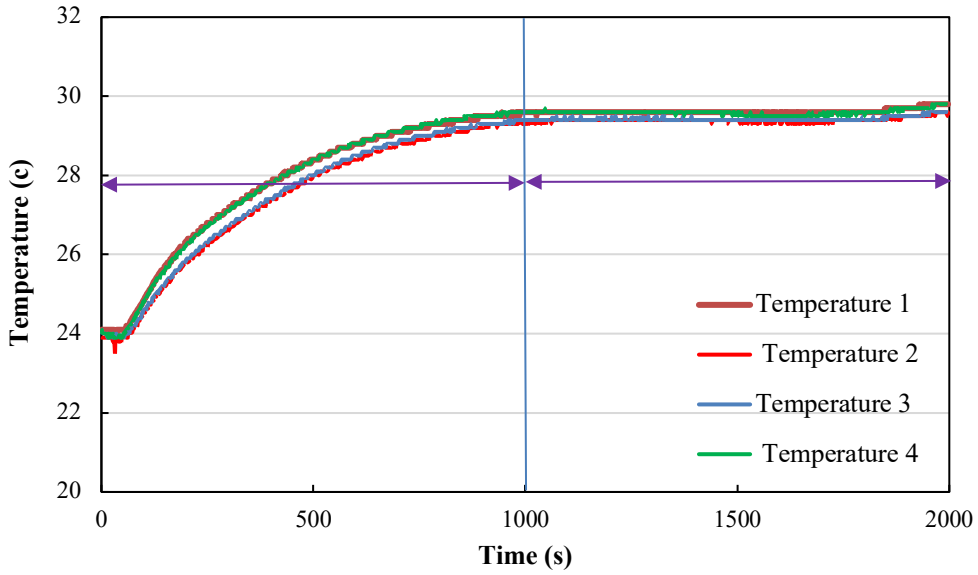

Figure. 3. Variation of the temperature related to the four DHT22 sensors.

By this graph it is clearly visible that the accuracy tolerance of the temperature sensor DHT22 is around 0.5° C. The obtained range of accuracy is almost as equal as the one indicated by the manufacturer in the DHT22 datasheet, 0.5° C (Zarnik and Papa, 2019). Low cost environmental sensors are so useful for determining the thermal parameters of buildings (Mobaraki and vaghefi, 2018). Moreover, they are applicable for determining characteristic of structures and inferring variation humidity and temperature of concrete during the construction procedure (Mobaraki *et al.,* 2020).

In order to have better recognition of the sensors' accuracy it is better to have a statistic view on the obtained results. In statistic standard deviation is defined as amount of dispersion of a data set. In this criterion, a low range of standard deviation shows that the values are tending to get close to the average/mean of the dataset however, the high range of that demonstrate that the set of data are dispersed and has a wider range. It can be seen from Fig. 4 that the derived standard deviation related to the four sensors vary from 0.04 to 0.13 which shows a good performance trend. These 1000 measured point are belong to the second part of the measurement when the homogenous temperature of 30° C starts in the oven.

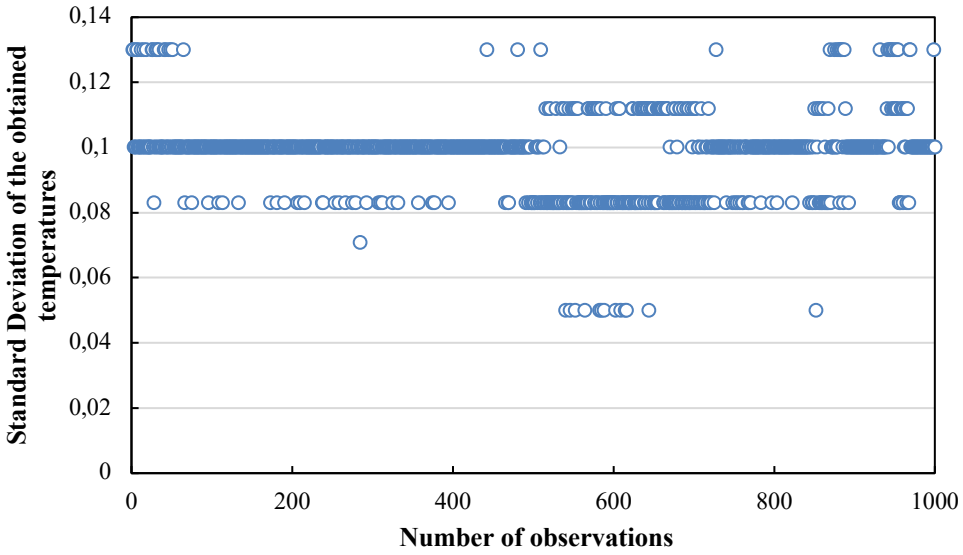

Figure 4. Variation of the standard deviation related to the 1000 measurements of temperature.

Fig.5 shows dispersion of standard deviation (in the case humidity) calculated for the four sensors by 1000 measurements at the third step of Fig. 5. Standard deviation is always positive number. Majority of the observations were extended above 1.25 close to 1.3 (1.25≤Standard deviation ≤1.3). A low range of standard deviation same as Fig.4 (related to temperature) shows that the observations tend to be close to the average temperature, however the higher one presents (Fig. 7) the wider range of observations discrepancy (Mobaraki and Vaghefi, 2016).

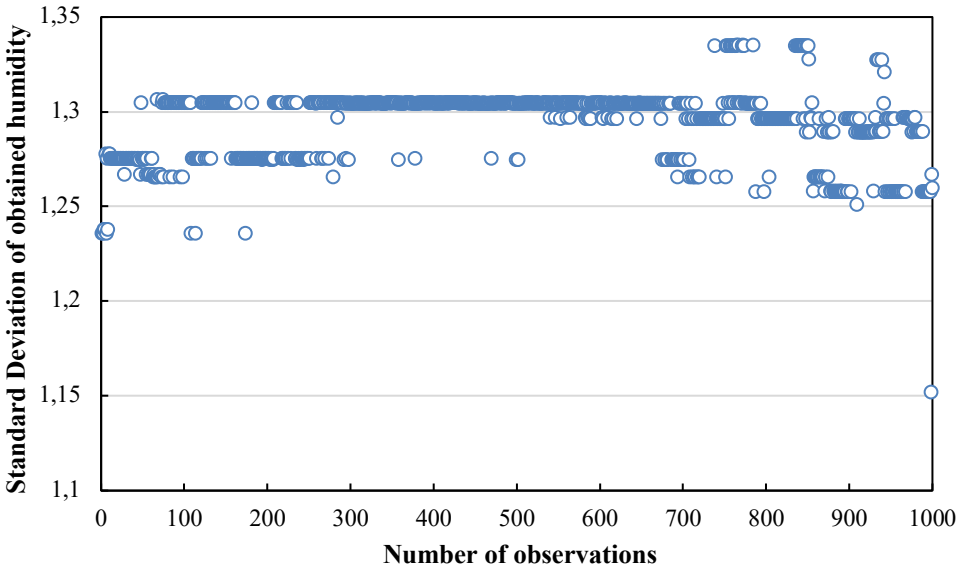

Figure 5. Variation of the standard deviation related to the 1000 measurements of humidity.

4 Conclusion

Low-cost environmental sensors are so practical in building rehabilitation projects for enhancing thermal resistance of buildings. Evaluation the accuracy of the low-cost temperature/humidity sensors through an Arduino-based system has been done for the environment sensor DHT22. Four sensors have hooked up to the digital ports 2, 3, 4 and 5 of the Arduino and variation of temperature and humidity related to the oven SELECTA were presented in this article. Lower range of standard deviation acquired for the temperature data set (0.04≤Standard deviation ≤0.13) rather than humidity (1.15≤Standard deviation ≤1.33). Which means that the sensor DHT22 is more accurate in terms of measuring temperature rather than humidity. From the obtained results it is clearly visible that the range of accuracy or in the other word the precision of the temperature sensor DHT22 is around 0.5° C which is almost equal to the one mentioned in the DHT22 datasheet, 0.5° C.

Abstract. *In the unavoidable way to achieve more sustainable buildings, it is essential to provide the architects with data on the environmental impact and the durability of the different components of the building, and make it available in the format they are using in the design phase. In this regard, the use of the building information modelling (BIM) tools has arisen as a new trend in the construction industry to improve the sustainable assessments of buildings in the design phase. In order to improve an existing tool developed by the Valencian Institute of Building in cooperation with the Valencian Regional Government, on providing the characteristics of the most common construction elements within a BIM-based environment, a database of durability and environmental impact data of construction elements and materials has been developed for integration within the tool. The reference service lives database has been created from a multicriteria study consisting in the analysis of sixty service life data bases published in recent decades. The work developed allows the architects working in Spain to have the durability required data of the construction elements from the design phase, for the integration and information exchange within a BIM-based environment to be able to use the existing BIM-based LCA/LCC.*

Keywords: *BIM-Based Software, Durability, Life Expectancy, Cost, Maintenance.*

1 Context

As it is considered to be a basic industry, the construction sector in Spain is one of the major sources of economic growth and development. So far, the most extended strategy among the construction companies applied to improve the efficiency and become more competitive has been to decrease the buildings construction costs without taking into account the life cycle of buildings. Trying to lower the initial construction costs had a negative impact on the quality of its processes and materials.

In this context, voices are being raised in the academic field that demand a change in the production model of the construction sector proposing solutions taking into account the whole life cycle of the building and the impact it has on the environment. The economic assessment of estate projects beyond the construction phase becomes an essential tool for cost optimization,

allowing realistic comparison between different investment options (García-Erviti, Armengot-Paradinas, and Ramírez-Pacheco, 2015).

The science of life cycle cost analysis is a fundamental tool to make changes in the Spanish construction sector. That is the reason why it is necessary to provide the stakeholders of the sector with the necessary tools to modify the decisions in the design stage based on the global cost. As an agent of the construction sector, The Valencian Institute of Building seeks to help technicians to apply the life cycle cost methodologies during the design phase by providing them with tools and data.

The Valencian Institute of Building (IVE), as a public interest incorporated foundation in the construction sector subjected to private law, constituted in 1986, promoted by the Second Vice Presidency of the Valencian Government and Regional Ministry of Housing and Bioclimatic Architecture and directed by a board committee, brings together a collective of professionals involved in the building and urban process. Its main interests, among others, lie in improving the processes linked to the edification and urban space, encouraging research and enhancing life quality, sustainability, safety, accessibility and durability standards through the smart development in the built environment.

2 Objective

During the last decades there has been rising concerns about the service life in terms of stability, safe functioning and appearance of the constructions already built and the ones to be built. The problem is not only to make the buildings and products last longer, which can be advantageous from the point of view of the scarcity of resources (MIT CSHub Cambridge, s.f.), but to know the reference service life of the systems mostly used (and therefore their global cost) to take knowledge based decisions.

The final purpose of the research is not to find out how to increase the durability of the products and systems, but to compile the maximum quantity of durability data available in order to have the ability to compare different constructive solutions. For this purpose, a reference service life database has been developed, not from tests, but from an analysis of different existing worldwide databases.

The developed database is due to be included in a BIM-based computer software so that architects and construction professionals can use it to predict how much their buildings will last and how much they will have cost at the end of their service life.

3 Methodology: Multiple-Criteria Decision-Making

Obtaining reliable data regarding the durability of building materials and systems was one of the difficulties in achieving the final goal. Instead of selecting a specific database, it was decided to rely on a multiple-criteria decision analysis applied to existing databases.

Multiple-criteria decision-making (MCDM) or multiple-criteria decision analysis (MCDA) studies, as part of the operational research linked to applying advanced analytical methods to provide a wide range of problem-solving techniques through applied mathematics methods, are a scientific method of obtaining information to aid in decision making by providing a comparative judgement between complex data. It is based in relating different indicators and giving each one of them certain degree of importance. (Mardani, 2011)

Even though it's a comprehensible and rational method which helps finding solutions in complex situations, it is difficult defining the comparison criteria, researching available data and, maybe the most important of all, the time factor.

Stage 1. Scope of application

To correctly evaluate the different sources, a taxonomy of the components of the constructive elements was developed, so the comparison can be as accurate as possible when compared to other sources under the same conditions.

Stage 2. Available databases

The next step was a thorough research to locate the most majority of available databases worldwide.

There were identified sixty service life databases published in the recent decades, from Spain, Germany, Portugal, UK, US, Canada, Australia, Italy, Sweden, Switzerland and Israel.

Stage 3. Indicators

Four indicators were defined to evaluate the weight each database should have when pondering the data: data affinity, which refers to the climate zone of the country were the study was made; data obsolescence depending on the publishing year; reliability of the source, depending on the authors and investigation center where the study was made and the level of expertise of the data base related to the different constructive elements. For each indicator 2 or 3 levels were created in order to rank the databases depending on the level achieved in each indicator, as seen in the tables below.

Table 1. Data Afinity.

Climate zone (country)	Score
Mediterranean climate zone (Spain, Portugal, Italy)	3
Temperate climate zone (Germany, UK, Sweden, Switzerland)	2
Cold and sunny climate zone (UK, Canada, Australia)	1

Table 2. Data Obsolescence.

Year	Score
2012 to present	3
2000-2005	2
Before 2000 or unknown	1

Table 3. Data Reliability.

Reliability	Score
High	3
Medium	2
Low	1

Table 4. Level of expertise.

Level of expertise	Score
High	2
Low	1

Stage 4. Multiple-criteria weigh

The analyzed databases were scored for each of the indicators mentioned above. As seen in the tables above, the maximum score that could be obtained was set in 11 points. Each database was scored a total number of points after evaluating the four indicators.

Stage 5. Multiple-criteria decision-making

After scoring the databases, to obtain a service life data for each construction element, a weighted average was applied to each durability data of every constructive element obtained from the different data bases. The weighted average was based on the weigh that each database obtained. Aberrant data was not taken into account.

For instance, considering a constructive element such as a wooden beam of which 3 different durability data were gathered, a weighted average was applied having more weight in the average the data gathered from sources closer to Spain, more reliable, more specialized and more recent.

Multiple-criteria decision-making results

The reference service life of the constructive materials database was a result of the multiple-criteria decision-making.

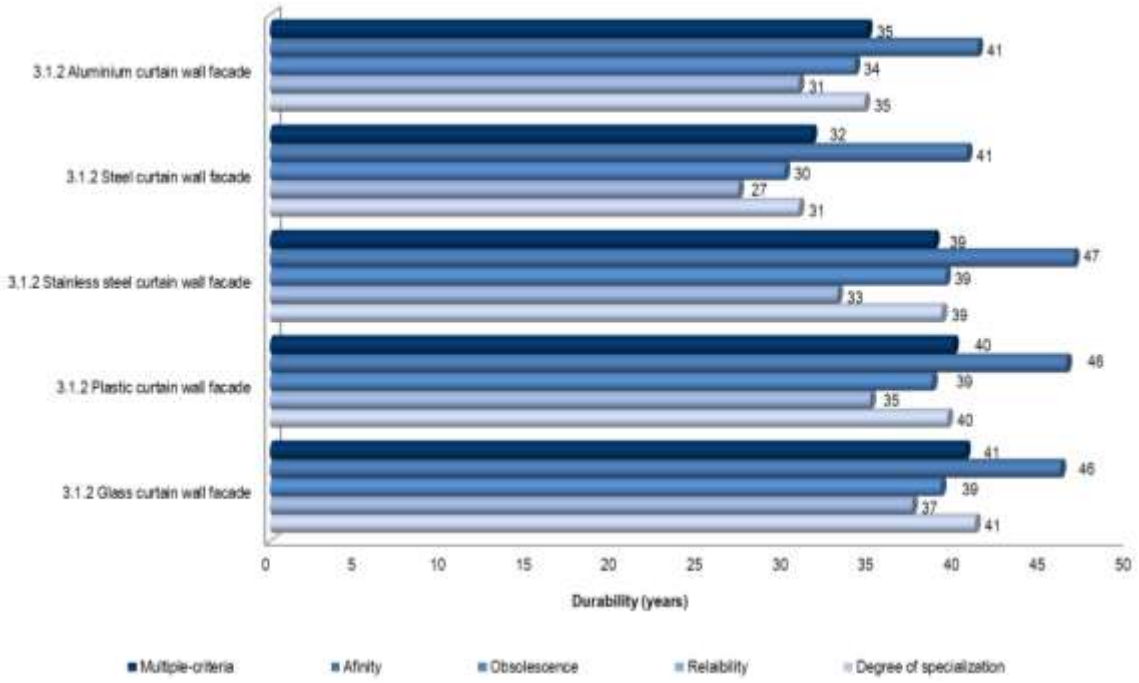
The service life data to be used with the objective of including it into a BIM-based environment tool was the one resulted from the process explained above. However, with research purposes, the results were also organized and sorted into a table including more complex information as the minimum and maximum service life or an average service life having considered only one of the four indicators or the critical value. The Image 1 below shows the results of the analyzed and processed data of the constructive elements of a brick wall façade. The data used for the BIM-based tool was the Multiple-criteria average service life column.

Image 1. Example. Durability data results.

Construction material: TAXONOMY			Construction material	Group										
03 Facade	3.1 Wall	3.1.1 Brick: cooked clay	Fabrica ladrillo cerámico	Brick clay pieces	23	High	40	150	79	90	77			
03 Facade	3.2 Exterior cladding	3.2.3 Plastered	Cement mortar reviewed	Plastering	15	Medium	5	60	32	40	32			
03 Facade	3.5 Others	3.5.2 Thermal insulation in 2-layer	Non-hidrofilic mineral w	Thermal insulation in two-layered facade	14	Medium	25	80	46	55	46			
03 Facade	4.2 Interior cladding	4.2.2 Plastered and trimmed	Plastered plaster	Plaster	14	Medium	5	62	38	48	38			

The database created allowed the extraction of a variety of relations between the analyzed elements. The Graphic 1 below shows an example of comparison between the durability of different types of curtain wall façade depending on the indicator taken into account. The first bar refers to the multiple-criteria, that is all the indicators, and the rest of them have into account just one indicator.

Graphic 1. Curtain wall façade durability comparison results.



4 Durability Into BIM-Based Computer Software

The Valencian Institute of Building in cooperation with the Valencian Regional Government, has been gathering information and created a database about the most common construction materials characteristics and put it together in the Catalogue of Construction Materials.

Complementary information such as materials durability, maintenance and costs are being added to the already existing Catalogue of Construction Materials in order to improve it and update it to nowadays needs.

It is well known that Building Information Modelling (BIM) as a method of developing architecture projects is as its peak and the big majority of architects and construction professionals are already using BIM-based computer software to efficiently plan, design, construct and manage buildings and infrastructure. The construction materials' information gathered and applied when planning buildings will allow knowing the service life of buildings and its cost from the design phase.

The current catalogue was released to the public as a software program tool in 2010 and it's being updated at the moment with the purpose of turning it into a web application. The catalogue provides tools for designing custom constructive solutions, calculate their properties and check them according to the Spanish law. The image 2 below is part of the Catalogue of Construction Materials being developed and it shows different façade types and its properties.

Table 5. Example. Façade types and properties. Catalogue of Construction Materials under development.

The Valencian Institute of Building has been working on integrating construction materials data, characteristics, durability data from the latest databases and information from other IVE tools in a BIM-based environment. Therefore, users will be able to know constructive information and characteristics from the design phase.

This web application will let users define and choose a bundle of constructive solutions for their project, downloading them in IFC and RFA formats with the properties of each solution, such as durability. It is currently in development and it is not released yet to the public, although it is expected to be available by the beginning of 2020.

Assessing the building over its life cycle (planning, construction, use and demolition phase) provides an insight into the real quality of the building (Federal Ministry for the Environment,

Nature Conservation and Nuclear Safety (BMUB), 2016). The application of the durability data into BIM software will allow professionals to previously assess buildings' life cycle.

The final input lies in the integration of the present research results and information gathered from other IVE tools into BIM software in order to be applied to projects from the design phase. A web application will let users define and choose a bundle of constructive solutions for projects, download them in IFC and RFA formats with the properties of each constructive element, such as durability. It is expected to be released to the public by the beginning of 2020.

5 Conclusions

The previous and numerous worldwide studies carried out in the field of predicting the construction materials service life and the latest research here displayed allowed us to carry out data extraction, process it and apply it to our nearby environment (Spain).

In these moments in which the construction sector needs to change the model that has been applied in the last decades, the progress achieved with the present research allows to take steps in order to improving quality and sustainability, encouraging a better understanding of the construction systems we use, as well as its components and materials. We cannot improve the functioning of the construction systems if we do not know their behavior.

The present study provides with data that architects and technicians need in order to be able to consider the reference service life of the buildings from the design phase, allowing the advance in multiple aspects that result in the improvement of the construction sector efficiency, such as maintenance plans, better forecast of life cycle costs, buildings and construction systems design, information given to clients accuracy... etc.

Nevertheless, in order to successfully carry out this process, it is necessary to raise awareness in the construction sector and to be supported by public policies. The Valencian Institute of Building works in parallel in this line together with the regional government for the improvement of quality and sustainability in the construction sector with a holistic and comprehensive vision of the entire construction process.

Abstract. *This study was developed at the Department of Architecture of Pescara and Department of Energy, Systems, Territory and Construction Engineering of the University of Pisa as part of an experimental thesis that led to the implementation of a Decision Support System. The objective of the work was to implement a tool capable of evaluating - in relation to the choices concerning the morphology of the building, the construction technologies, the materials and the design of the architectural elements - the levels of maintenance quality implemented in the various phases of the project, from the first phases, in which few relevant decisions are made, to the executive phase characterized by a multiplicity of choices. The aim was to construct a tool in which the reliability of the evaluations was related to the quantity and quality of the data that feeds the decision-making process, but which is also able to evaluate preliminary decisions based on the elements of choice that characterize the first phases of the project. The conceptual model has been defined through the construction and implementation of a Bayesian Network or a graphical system of probabilistic inference able to represent the set of stochastic variables and their conditional dependencies through the use of a direct acyclic graph. Through the interrogation of the network it is therefore possible to evaluate through the expression of a synthetic index, a real overall rating of the different aspects that contribute to define the maintenance quality. The use of Bayesian Networks, in the light of the analyses carried out on an experimental basis - exemplified here on the case study of ING Groupe headquarters - for the ability to control a multitude of factors linked to the durability of materials, the morphology of systems and ease of intervention, seems capable of generating useful, effective and expandable tools to support the design decision-making process.*

Keywords: *Design, Durability, Maintenability, SSD, Bayesian Networks.*

1 Introduction

The architectural design of buildings is increasingly characterized by a new morphological, functional and technological complexity that requires, from coordination to control, maintenance and management of the entire life cycle, new skills to effectively implement a process in which the act of conception and the moment of construction are continuously intertwined over time (Daniotti, 2007; Latouche, 2015; Di Sivo, 1994; Ladiana, 2009).

The use of Bayesian Networks is in this experimentation proposed for the construction of

an open model of a useful tool to manage uncertainty through the creation of conceptual maps of reality that aim to highlight the variables and links in a clear and rigorous way.

The study described in this paper has been developed at the Department of Architecture of Pescara with and the Department of Energy, Systems, Territory and Construction Engineering of the University of Pisa, starting from an experimental thesis that led to the implementation of a Decision Support System (SSD).

For the tool described, in addition to the purposes related to the operating mode and the possible implementation of databases, there is the structural purpose of being able to operate within an "open system" that can be progressively expanded, on which it would be possible, as the study and experimentation progresses, to graft new areas of evaluation, increasing its operations.

2 Research Objectives and Methodological Approach

The objective of the research developed was to implement a tool capable of evaluating - in relation to the choices concerning the morphology of the building, the construction technologies, the materials and the design of the architectural elements - the levels of maintenance quality implemented in the various phases of the project, from the first phases, in which few relevant decisions are made, to the executive phase characterized by a multiplicity of choices (Di Sivo, 1994).

It was intended to build a tool in which the reliability of the evaluations would be related to the quantity and quality of the data that feeds the decision-making process, but able to operate also in a preliminary way on the basis of the elements of choice that characterize the first phases of the project.

The fundamental aim was to achieve a design support tool capable of operating according to the logic of design optimization dictated by the criteria of maintainability consolidated in the scientific culture (D'Alessandro, 1994), while allowing, at the same time, to draw on databases, existing or gradually implementable, relating to: incompatibility of materials, forms of degradation resulting from the morphology of components and connections, size of maintenance equipment, ergonomic schemes related to maintenance operations, etc.

In order to be easy to use, the SSD was based on the evaluation and expression of maintenance quality through a rating index. From the methodological point of view, the work has been developed in the direction of the construction of a system capable of managing the large number of variables that distinguish maintenance-oriented architectural design from the initial phase.

The current reality of projects is in fact extremely complex, especially when analyzing problems related to maintainability, where the multitude of variables at stake and uncertainty factors characterize the entire life cycle of the project (Talamo, 2019). It is therefore necessary to be able to use a "interrogable" modelling tool capable of providing support for the automation of evaluation processes formalized on the basis of maintenance criteria that can be applied to the entire architectural organism or to a part of it, such as a façade system. A quantitative approach to integrate uncertainty and the multitude of variables in an objective and rigorous way into reasoning can be implemented through the use of the so-called Bayesian Networks.

The conceptual model for the decision support system has in fact been developed through

the construction and implementation of a Bayesian Network, a representation of a probabilistic inference model capable of describing the set of stochastic variables and their conditional dependencies through the use of a Direct Acyclic Graph (DAG) (Novi, 2018).

Following a "data driven" strategy, a space-time analysis tool has been developed to support decisions in order to reach a maintainability index. First of all, the knowledge network was built (directly through the Hugin Expert software) by defining a conceptual model consisting of nodes (variables) that represent the "maintainability criteria" defined, then linked together according to criteria of causal dependence (cause - effect).

In order to simplify the operational phase of compiling the values of the variables of the individual nodes - variables, a simple tabular interface has been created with the help of a spreadsheet that makes the input of data by the designer clear and simple and automates the numerical output with a compilation and update link directly to the nodes of the BN created in the Hugin Expert software.

Once the available values are propagated, the network allows to obtain through the expression of a synthetic index, a rating about the maintenance quality of the described project and to perform in real time multi-scenario simulations, diagnostic evaluations, sensitivity analysis, simply by directly modifying the values in the network or in the tabular interface. The tool thus obtained, even in the presence of partial or inhomogeneous data, allows to perform a multitude of simulations and obtain in real time functional results at the level of knowledge of the problem, guiding the designer in a conscious way in the evaluation and the necessary choices throughout the lifecycle design.

3 Implementation of the DSS on a Case Study: The Headquarters of ING Groupe

The method described has been tested through the application on case studies with different technologies and construction methods with the intent to test the flexibility and compliance of the project support tool developed to operate in cases of uncertainty and complexity.

Here is described the analysis carried out on a well-known existing building: the headquarters of ING Groupe in Amsterdam (Fig.1), built by Meyer and Van Schooten Architects (MVSA) in 2002; this building was chosen as a case study because it is characterized by a high design attention to the maintenance theme, in order to carry out the evaluation by simulating different possible scenarios related to different technical solutions as may happen in a possible design process. In the experimentation, the maintainability of the building has been tested in three areas: vertical closure - plant engineering system - upper closure but is exemplified here for exposure limits for the evaluations related to the facade.

ING Group is an example of sustainable, innovative and energy-efficient architecture.

The glass and aluminum structure of the building is raised on metal pillars whose height varies between 9 and 12m. The façade consists of two layers of glass spaced apart which contain a passage to allow both access for maintenance and natural ventilation.

The external glass is hooked through 6 fixing points that guarantee the support of the façade by means of glass elements (thickness 20mm), bound to the floor by stainless steel components. The sheets of 1800 x 3300mm size, are made of tempered or tempered - laminated glass 12 or 19mm thick.

Figure 1. Headquarters ING Group, Amsterdam. MVSA Architects.

The sheets are separated vertically by silicon joints of 12mm; horizontally by a glass opening element with a height of 410mm for the ventilation of the facade. The internal facade is made up of inward opening wooden frames 950mm wide and 2900mm high. The cleanability and periodic control of the facade cladding is also guaranteed thanks to the accessible roof on the tenth floor. A system of tracks that runs through the entire building is designed to ensure a high level of inspection and maintenance: thanks to the installation of mobile trolleys on the roof, the easy cleaning of all the windows has been ensured.

In the experimentation of the decision support system, the building was analyzed considering two possible configurations: in the first case, it was evaluated deprived of some of the solutions related to maintainability; in the second case, it was analyzed how it looks today, with the current technical characteristics related to maintainability.

The flexibility of the method, allows to perform multi-scenario analysis by intervening on probability distributions, i.e. to verify how simulations in real time, allow to take strategic decisions. Therefore, each case has been subjected to a double analysis: in the first one the method is tested as a tool for evaluating the building, while in the second one its potential as a support system for decision making has been verified.

The maintainability index of the building is obtained from the analysis of three guiding criteria:

- MATERIALS for assessing the durability not only of the intrinsic properties (quality of the component), but also in relation to the design and execution techniques and the environmental context to which it belongs (design quality - execution quality - environmental quality);

- the MORPHOLOGY OF SYSTEMS for the determination of the morphological quality through the analysis of the sub-requisites of maintainability such as: durability - not dirtiness - self-cleaning capacity - cleanability, in order to make more appropriate choices during the design phase to avoid possible pathologies;

- EASE OF INTERVENTION for the determination of accessibility and spatial ergonomics through the evaluation of the sub-requirements of maintainability such as: maintainability by the user - serviceability - serviceability - reparability - disassembly - replaceability.

3.1 Analysis of Cases and Evaluation of Alternatives

CASE 01 assumes the construction of the curtain wall using insulating glass on a single layer and without the equipment and access routes to the envelope.

Analysis 01: the first step consists in the realization of three tables on a spreadsheet (information database) in which the parameters of the sub-requirements related to the maintainability of the façade are analyzed, in order to determine the three criteria of the system (durability of the materials - morphology of the systems - ease of intervention) in relation to the materials and components used for the realization of the proposed case study.

The second step provides, in order to obtain the evaluation of the maintainability index, the use of Bayesian Networks. This consists in the realization of a second grid (Fig. 2) that allows to translate the parameters on Hugin (software for the use of Bayesian Networks).

In the third step, the saving of each parameter under examination and the subsequent export to Hugin, implements an automation process at the end of which you get a node for each parameter exported.

Figure 2. Database construction and data link.

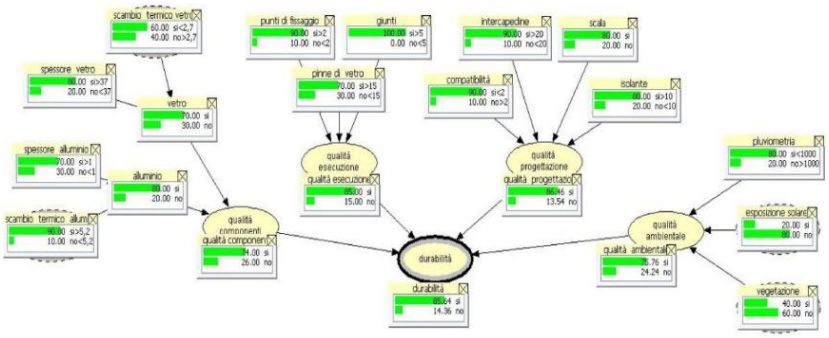

Figure 3. Each node-parameter is linked to a reference table with Boolean values.

The result is a relationship network (Fig.3) in which each node-parameter is linked to a reference table with values 1 or 0, indicating whether or not the requirement previously verified on the spreadsheet has been met. From the connection between the nodes it is possible to determine the maintainability of the facade under examination, which in this case expressed an index for maintainability of 48%.

The results obtained show that the main cause is to be attributed to the ease of intervention.

The system of vertical closures and the components integrated in it must be structured in such a way as to make their inspection easy. During the design, especially in relation to the surface conformation of the materials, dust and atmospheric pollution, it is necessary to provide easy access structures to facilitate cleaning operations.

In the *Analysis 02*, the implementation of a series of operations allows to verify the compliance of the instrument as a support to decision-making choices.

In intervention A the insertion of paths to overcome the difficulties connected to the periodic cleaning of the curtain wall was foreseen. The integration of this aspect has led to a 50% increase in inspectability, with an improvement also in terms of the cleanability of the facade.

Intervention B, consisted in the insertion of equipment (ladders - trolleys), particularly recommended for buildings with curtain walls, as they facilitate periodic cleaning and maintenance operations, avoiding the use of particularly expensive external means with consequent time savings. The integration of this aspect has led to reparability from 40 to 80%.

Finally, intervention C considered all ergonomic aspects with the aim of improving user satisfaction and the overall performance of the system. The intervention concerned the relationship between the dimensions and the geometry of the operating space, in order to take into account the body and limb positions of the operators and their movement in relation to the specific maintenance actions and the use of the required tools and utensils. The ergonomic aspect, therefore, allows to perform those periodic cleaning and maintenance operations without which the use of external means would be required.

The *Analysis 02*, through the progressive incorporation of the operations described above, has led to an increase in the sub-requisites of ease of intervention, which overall have led to an increase in terms of maintainability of 15% (from 48 to 63%).

In CASE 02, the insulating glass facade consisting of a transparent double skin was analyzed, with the presence of the inspectionable cavity, the accessible staircase and the tracks that allow the passage of the trolleys throughout the casing.

At the end of the process already described for the previous case here, the Evaluation 01 provided a rating index for maintainability of 71 %. Therefore, action was taken where the system had the lowest rating value, which in this case, among the three criteria examined, was the morphology of the systems.

During the design phase it is necessary to pay particular attention to the internal and external factors of the system in order to minimize the inconveniences due to the degradation caused by atmospheric agents on the walls. It was therefore considered, in this case, to provide a geometric configuration of the façade and a morphology of the components such as to allow a homogeneous washout of the surfaces while avoiding stagnation, accumulation, water absorption and the fixing of dust. Therefore, the 02 analysis simulated different conditions on some aspects related to the morphology of the system.

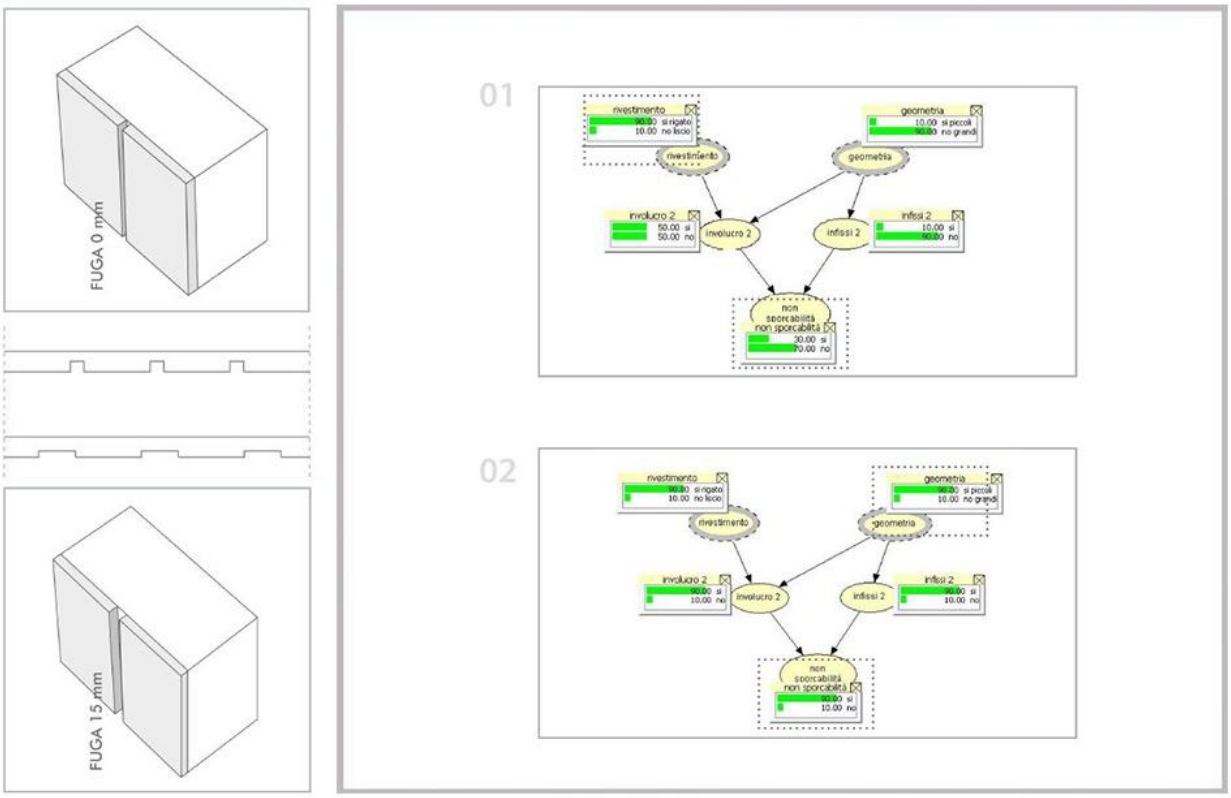

Figure 4. Evaluation of maintenance scenarios related to different forms of external panels.

Intervention D has provided for the use of smaller smooth panels in order to facilitate better washing of the facade and easier disassembly, with a 20% increase in non-dirtability.

Intervention E assumed the use of striped panels, with sufficiently wide and shallow joints to create preferential water flow paths; on the contrary, narrow and deep joints would lead to the deposit of debris and dirt with the need for specialized personnel for periodic cleaning operations. This intervention has led to 30 to 90% non-soiling.

The example described denotes how the Bayesian Networks offer the possibility to verify in real time how much each single intervention can affect, in percentage - probabilistic terms, the degree of maintainability of the project.

In the second analysis of Case 02 of ING, the progressive incorporation of the components led to an increase in the sub-requirements of the morphology of the systems, which on the whole led to an improvement in the maintainability of the system with an increase of 10% more (from 71 to 81%).

The results obtained from the proposed analyses show that certain choices, made during the design phase, can have a high impact on maintainability. Although it is a simple qualitative evaluation, the analysis highlights not only an objective comparison between the two scenarios, but also clarifies and makes explicit all the variables that significantly affect the results.

4 Conclusions

The use of Bayesian Networks, in the light of the analysis carried out on an experimental basis, for the ability to control a multitude of factors related to the durability of materials, the morphology of the systems and the ease of intervention, seems capable of generating a valuable tool not only useful as a support in decision-making ex-ante in the project phase of new construction but also ex-post for the identification of rehabilitation interventions in existing buildings. The system developed allows to determine the impact that determined variables, chosen from the point of view of maintainability, bring to the whole project allowing to establish what attention should be paid to the estimates of probability to obtain certain services of interest or at the same time what corrective actions are essential to be taken.

Future developments in the research of the SSD model are oriented in the direction of the integration of cost parameters for a more complete and effective evaluation and comparison of alternative intervention scenarios and the identification of implementable protocols for an objective comparison between contractors during the awarding of a contract.

Abstract. *In recent years, stochastic modeling has been increasingly applied to investigate the uncertainties of input parameters in hygrothermal simulation and the moisture damage risks of building envelopes. Generally, stochastic modeling requires hundreds or even thousands of simulations to take into account the uncertainties of input parameters, which is computationally intensive and time-consuming. This paper aims to apply polynomial and neural network metamodel as a substitute for the traditional hygrothermal model, to predict the hygrothermal performance of building envelopes. In the previous study carried out by the authors, stochastic simulations have been performed based on the traditional hygrothermal model, to investigate the hygrothermal performance of wood-frame walls under different rain leakage levels. The material properties and rain deposition factors were considered as stochastic variables, and stochastic simulations were performed under three rain leakage scenarios: 1%, 0.5% and 0.1% of wind-driven rain. In this paper, the stochastic inputs (the hygric material properties and rain deposition factor) and outputs (the maximum moisture content and mold growth index over a 5-year period of the simulation) of a conventional 2×6 wood-frame wall are used to develop the metamodels through polynomial regression and neural network methods. The metamodels are developed for each rain leakage scenario, and the stochastic data of the three rain leakage scenarios are aggregated together to train another metamodel. It is found that the metamodels generally perform well to predict the maximum moisture content and mold growth index. The metamodels for low rain leakage scenarios are better than those for high rain leakage scenarios and the neural network metamodel is more accurate than polynomial metamodel for high rain leakage scenarios, i.e. 1% of rain leakage.*

Keywords: *Neural Network Metamodel, Polynomial Metamodel, Hygrothermal Simulation, Wood-frame Wall, Rain Leakage.*

1 Introduction

In recent years, the stochastic modeling approach has been increasingly applied to investigate the uncertainties of input parameters in hygrothermal simulation and the moisture damage risks of building envelopes. Generally, stochastic modeling requires hundreds or even thousands of simulations to take into account the uncertainties of input parameters, which is computationally intensive and time-consuming. To improve computational efficiency, a statistical meta-model can be developed as a substitute for the traditional hygrothermal model, to predict the hygrothermal performance of building envelopes.

There are several comparative studies to investigate the performance of different metamodeling methods (Van Gelder *et al*., 2014; Janssen *et al*., 2015; Ostergard *et al*., 2018). And the hygrothermal performance of the building envelopes have been approximated by various metamodel methods, such as generalized additive model, polynomial regression and neural network (Zewdu Taffese and Sistonen, 2016; Zanetti Freire *et al*., 2017; Marincioni *et al*., 2018; Ostergard *et al.,* 2018; Tijskens *et al*., 2019). According to the comparison study by ANNEX 55, the best metamodeling techniques are polynomial regression (PR), multivariate adaptive regression splines (MARS), and sigmoidal transfer function neural networks, and it was suggested that the metamodel can only be used within the range of the training data values. (Janssen *et al*., 2015). On the contrary, the data set in different ranges may need different metamodels to ensure their reliability. Most of the previous studies have focused on the performance of different types of metamodels, however, there is a lack of studies investigating the reliability of the metamodels at different data ranges.

According to the stochastic analysis performed by Wang and Ge (2019), the rain leakage level significantly influences the moisture performance of building envelopes. This paper develops metamodels for predicting moisture performance of a conventional 2x6 wood-framed wall under different rain leakage scenarios. The polynomial regression and sigmoidal transfer function neural network methods are employed to develop the metamodels. Metamodels are developed for three rain leakage scenarios: 0.1%, 0.5% and 1% of wind-driven rain. Additionally, a metamodel representing all the three scenarios is developed by training the aggregated stochastic data. The performance indicators- Root Mean Square Error (RMSE) and Maximum Absolute Error (MAE) are used to evaluate the reliability of the developed metamodels.

2 Methods

2.1 Hygrothermal Model

The metamodels are developed based on a hygrothermal model of a conventional 2×6 wood-framed wall. Figure 1 shows the configuration of the investigated wall, and Table 1 shows the mean values of the material properties of each component in the wall.

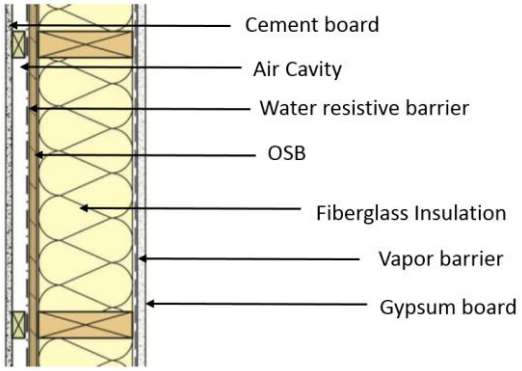

Figure 1. Configuration of 2x6 wood framed wall.

Table 1. Material properties.

	ρ (kg/m^3)	θ_{por} (m^3/m^3)	W_f (kg/m^3)	μ_{Dry} -	D_{ww} (m^2/s)	c (J/kg·K)	λ (W/m·K)
Cement Board	1130	0.479	152	905	2.16E-8	840	0.24
Air Gap	1.3	0.999	-	0.56	-	1000	0.13
Water Resistive Barrier	400	0.001	0.9	328	-	1500	2.4
OSB	650	0.9	377	994	1.29E-10	1880	0.1
Fiberglass	30	0.99	208	1.35	-	840	0.036
Vapor barrier	130	0.001	-	4E6	-	2300	2.3
Gypsum Board	625	0.706	430.625	172	3.47E-11	870	0.16

ρ- bulk density; θ_{por}- porosity; W_f – saturation water content; μ_{Dry} – vapor resistance factor at dry state; D_{ww}- moisture diffusivity at saturation wáter content; c- specific heat capacity; λ- termal conductivity

The boundary conditions are listed in Table 2. and the Canadian Weather Year for Energy Calculation (CWEC) data of Vancouver is used as weather data except for the rain data, which are extracted from the WUFI weather database. The wind-driven rain is calculated based on the semi-empirical model in ASHRAE 160 (2016). The equation of the semi-empirical model is presented as follows:

$$r_{bv} = F_E \cdot F_D \cdot F_L \cdot U \cdot \cos\theta \cdot r_h \quad (1)$$

where

F_E - rain exposure factor

F_D - rain deposition factor

F_L - empirical constant, 0.2 ($kg \cdot s/m^3 \cdot mm$)

U - hourly average wind speed at 10m (m/s)

θ - the angle between wind direction and normal to the wall

r_h - rainfall intensity, horizontal surface (mm/h)

Table 2. Boundary conditions.

α_{in} ($W/m^2 \cdot K$)	α_{ex} ($W/m^2 \cdot K$)	β_{in} (s/m)	β_{ex} (s/m)	α_s -	α_l -	F_E -	F_D -
8	17	5.6E-8	1.19E-7	0.6	0.9	1.0	0.35

To investigate the impact of rain leakage on the hygrothermal performance of the wall assembly, hygrothermal models are created for three rain leakage scenarios: 0.1%, 0.5%, and 1 % of wind-driven rain. The wall is assumed to face east orientation, which receives the highest amount of wind-driven rain. The penetrated rain wáter is assumed to be deposited on the exterior surface of OSB. The moisture content and mold growth index at the interior surface of OSB are used for performance evaluation. The details of the model setup can be found in Wang and Ge (2019).

2.2 Data Preparation

To evaluate the moisture problem and mold growth risks, stochastic simulations were performed for 5 years starting from Oct. 2012 based on DELPHIN and MATLAB (Wang and Ge, 2019). The stochastic input and output data are used for training the metamodels.

The input data includes stochastic hygric material properties of OSB and fiberglass and the rain deposition factor. The material properties are assumed to follow the normal distribution, the mean values and standard deviations are determined from literature (Kumaran *et al.*, 2003; Mukhopadhyaya *et al.*, 2007). The rain deposition factor is assumed to follow uniform distribution from 0.35 to 1.0 as prescribed in ASHRAE 160 (2016). The stochastic inputs are sampled by the Latin Hypercube Sampling technique, and the stochastic models are generated for the three rain leakage scenarios. For each scenario, 100 stochastic models are generated. In total, simulations are performed for 300 stochastic models. Table 3 shows the mean values and standard deviations of the stochastic inputs. Other parameters of the hygrothermal model are kept as deterministic values. The output data used for training the metamodel is the stochastic results of maximum moisture content and mold growth index for the 5-years' simulation.

Table 3. Stochastic inputs.

Material properties					Boundary condition
OSB			Fiberglass		Rain deposition factor
W_f	μ_{Dry}	A	W_f	μ_{Dry}	Fd
kg/m^3	-	$kg/m^2 \cdot s^{0.5}$	kg/m^3	-	
337 (54)	994 (38)	0.0022 (0.00055)	208 (14.5)	1.35 (0.034)	0.35 to 1

2.3 Metamodel Development

2.3.1 Polynomial Regression

The polynomial regression method is one of the most widely used meta-modeling methods. The metamodel is nth polynomial, which is fitted by input and output samples. The equation of the metamodel can be written as follows (Jin *et al.*, 2001):

$$\hat{y} = b_0 + \sum_{n=1}^{m}\sum_{i=1}^{p} b_{ni} x_i^n + \sum_{n=1}^{m}\sum_{k=1}^{m}\sum_{i=1}^{p}\sum_{j=1}^{p} b_{nkij} x_i^n x_j^k \quad (2)$$

where

$\hat{y}$- estimated output

x- input vectors

p- the number of inputs

m- the order of the polynomial

b- regression coefficients

In general, the regression coefficients can be determined based on the least square method. The accuracy of polynomial regression metamodel is influenced by sample size and order number. According to ANNEX 55 (Janssen *et al*., 2015), a third-order polynomial performs the best for approximating an original model with 14 parameters, while a second-order model significantly reduces the number of coefficients with only slightly worse performance than the third-order model. The Root Mean Square Error (RMSE), which measures the accuracy of the metamodel, has no significant reduction after the sample size is higher than 100. Therefore, in

this paper, the sample size is 100 for each rain leakage scenario, and the metamodel is developed based on the second-order polynomial. For the metamodel representing all the three rain leakage scenarios, there are 300 samples. The polynomial metamodels are developed using the Polyfitn toolbox in MATLAB (D'Errico, 2012).

2.3.2 Neural Network Metamodel

A neural network is composed of an input layer, an output layer, and one or more hidden layers in between. Figure 2 shows a typical architecture of the neural network. These layers are interconnected so that the information can be transferred from one layer to another through transfer function. At each hidden layer, there are several neurons that contain the transfer function. The number of neurons in the hidden layer is defined by the users and the transfer function can be radial basis function or sigmoidal transfer function. According to Van Gelder et al. (2014), the radial basis function network needs more training samples to obtain the same accuracy with a sigmoidal transfer function network. And the performance of one hidden layer neural network with 9 neurons could be better than that of two hidden layers with 17 and 19 neurons at each layer when predicting the number of hours with room temperature higher than 25 ℃ in a semi-detached dwelling model. Therefore, in this paper, the sigmoidal transfer function network is used to develop the metamodel, and there is only one hidden layer with 10 neurons. The number of neurons in the input layer and the output layer is equal to the number of input and output parameters. In this paper, there are six input parameters (the six stochastic variables shown in Table 3) and one output parameter (stochastic maximum moisture content or mold growth index). The training algorithm used in this paper is the Bayesian regularization, which shows a better performance than the Levenberg-Marquardt algorithm (Kayri, 2016). The neural network metamodels are developed using Neural Net Fitting APP in MATLAB.

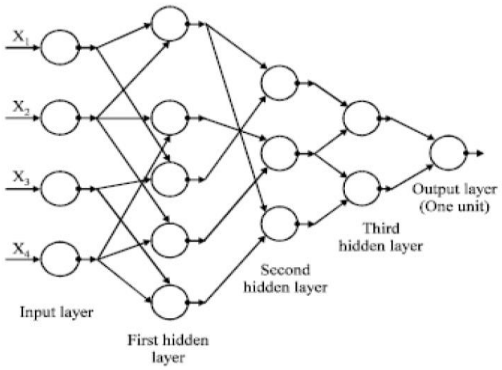

Figure 2. A typical neural network model (Galkin and Lawell, 2013).

3 Results and Discussion

3.1 Metamodels for Moisture Content

Figure 3 shows the comparison of maximum moisture content between metamodels and the originals model for the test data that are not participated in training the metamodels. In this paper, 85% of the sample data set are used for training, and 15% are used for testing. And Table 4 shows the RMSE and MAE of the two types of a metamodel for each scenario. It can be seen

from Figure 3 that the metamodels for 0.1% rain leakage scenario have the best performance.

All the metamodel outputs are almost on the 45-degree line, and the trendline of the outputs from metamodel is almost overlapping with the 45-degree line for both polynomial and neural

	Polynomial				Neural network			
	0.1%	0.5%	1%	0.1% to 1%	0.1%	0.5%	1%	0.1% to 1%
RMSE	0.05	1.49	3.29	2.05	0.06	1.50	2.11	1.12
MAE	0.11	4.93	5.99	5.31	0.12	5.49	3.80	4.91

network methods. Therefore, the predicted values from the metamodels are almost equal to those from original models and the metamodels perform very well for predicting the maximum moisture content. For the 0.5% and 1% rain leakage scenarios, the outputs from metamodels are distributed around the 45-degree lines, and the trendlines deviate from the 45-degree lines.

The outputs of 1% rain leakage scenario is more spreading than those of 0.5% rain leakage scenario, which means the accuracy of the 1% rain leakage metamodels is lower than that of 0.5% rain leakage metamodels. Figure 3 g and h show the metamodels representing the whole range of rain leakage from 0.1% to 1%. It can be observed the outputs of the neural network metamodel are closer to the 45-degree line than those of the polynomial metamodel, which means the neural network metamodel has a better performance than polynomial metamodel.

The performance of these metamodels can be verified by observing their RMSE and MAE as presented in Table 4. It can be seen that the 0.1% rain leakage scenario has the lowest RMSE and MAE, it is followed by 0.5% and 1% scenarios. The metamodels representing all the rain leakage scenarios have higher RMSE and MAE than the 0.1% and 0.5% rain leakage scenarios, but lower than the 1% scenario. For the 0.1% and 0.5% rain leakage scenarios, the RMSE and MAE of neural network metamodels are slightly higher than those of polynomial metamodels. While, for the 1% rain leakage scenario and the metamodels representing all the rain leakage scenarios, the neural network method has a lower RMSE and MAE than the polynomial regression method.

3.2 Metamodels for Mold Growth Index

Table 5. Comparison of the metamodel performance between polynomial method and neural network method for different rain leakage scenarios (maximum mold growth index).

	Polynomial				Neural network			
	0.1%	0.5%	1%	0.1% to 1%	0.1%	0.5%	1%	0.1% to 1%
RMSE	0.10	0.14	0.15	0.39	0.07	0.16	0.09	0.12
MAE	0.23	0.39	0.24	1.01	0.12	0.36	0.20	0.37

Table 5 shows the performance of the metamodels for predicting the maximum mold growth index. The conclusions that can be drawn from this table are similar to those for the maximum moisture content. The scenarios with higher rain leakage have higher RMSE and MAE, and the neural network method has lower RMSE and MAE than the polynomial method, particularly at higher rain leakage levels.

4 Conclusions

This paper developed polynomial and neural network metamodels to simulate the maximum

moisture content and mold growth index of a conventional 2x6 stud wall under different rain leakage levels. The main conclusions of this paper are: 1) In general, the developed metamodels are performing well to substitute the original hygrothermal models. 2) The metamodels for lower rain leakage levels (from 0.1% to 0.5% rain leakage) perform better than those with higher rain leakage levels (from 0.5% to 1% rain leakage). 3) Neural network metamodel performs better than polynomial metamodel, especially for the scenarios with higher rain leakage level.

Abstract. *Structural Health Monitoring (SHM) is essential to assess the accuracy of durability predictions of structures. Using low-cost sensors on structural evaluation has gained significant attention compare to high-cost sensors. Although these may not be as accurate and sensitive as the expensive electronic devices, with efficient code and right use, there is a possibility of getting useful information from them. These sensors can vary based on their functionality and the measurements they provide. For example, one is highly sensitive to the light of its environment while the other kind would give different results in different temperatures. In this paper, three different displacement measuring sensors have been studied. An ultrasonic sensor (HC-SR04) and two different types of laser sensors (VL53L0X and VL53L1X) are investigated in the paper. An Arduino Mega has captured their measured data, and a raspberry pi has made the acquisition. Not only issues regarding coding and placing of these sensors have been presented ultimately, but precise solutions for the aforementioned problems as well as an efficient way of assembling all the sensors are also presented in this paper. The data generated from these electronic devices can be used for Structural Health Monitoring applications.*

Keywords: *Low-Cost Sensors, Distance Measurement, Internet Of Things (IoT), Accuracy and Sensibility, Structural Health Monitoring.*

1 Introduction

Recently, the need for using sensors in structures for monitoring and inspection of their health state is growing. With this, the need for more economical means of doing SHM is getting very great attention. In this paper, a few models of static sensors have been presented. Moreover, the characteristics of each of them have been explained. Each type could be used in specific situations, and each one has advantages as well as disadvantages in different ambient (Komarizadehasl *et al.,* 2020a; Komarizadehasl *et al.,* 2020b). For being able to work with these sensors, first briefly, Arduino Uno (which is the central programable logic controller (PLC) in this project) would be introduced. Secondly, three different types of ranging sensors would be introduced along with their specifications. Each type of sensor may use a different way to send its data. Thirdly, different ways of communicating with this PLC will be presented. Finally, the results of these sensors against different situations, objects, and colors would be illustrated (Mobaraki *et al.,* 2020; Mobaraki and Vaghefi, 2016).

doi:10.23967/dbmc.2020.207

2 State of the Art

In this section, the sensors and a microcontroller that has been used in the project will be reviewed along with their technical descriptions.

2.1 Arduino Uno

Arduino (Figure 1) is an open-source electronics platform based on easy-to-use hardware and software. Arduino Uno is a microcontroller board based on the ATmega328P. It has 14 digital input/output pins, six analog inputs to measure and convert the voltage to a digital value. It facilitates numerous interfaces to communicate with other microcontrollers and computers such as Inter-Integrated Circuit (I2C), Serial Peripheral Interface (SPI), and Universal asynchronous receiver/transmitter (UARTA). The board can work on an external power supply via a USB port or a power jack. An integrated development environment (IDE) is available for writing, compiling, and developing the code. This IDE supports a dialect of C/C++ using specific regulation of code organizing (Pasha, 2016).

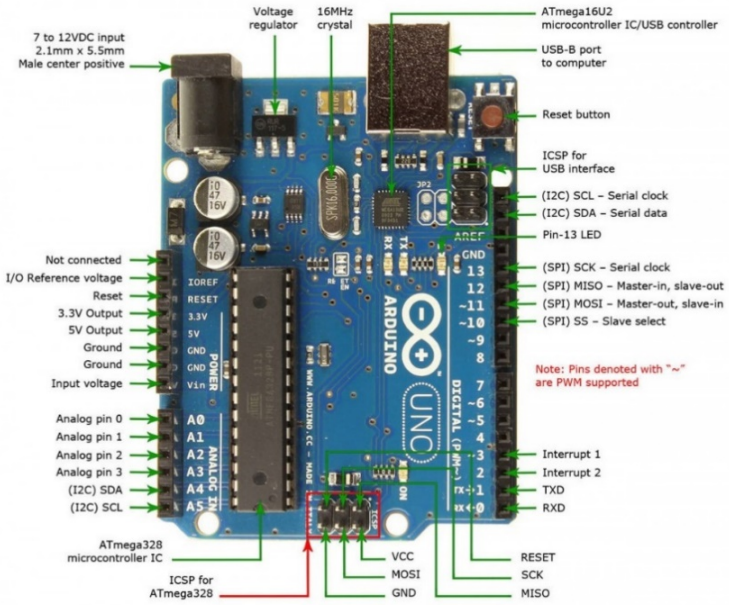

Figure 1. Schematic of the Arduino Uno.

2.2 Ultrasonic Sensors

Ultrasonic ranging module HC - SR04 (Figure 2) provides 2cm - 400cm non-contact measurement function, the ranging accuracy can reach to 3mm. The modules have transmitters, receivers, and processing circuits. The basic concept of work is: firstly, using the I\O trigger for at least 10uS (microsecond) high-level signal. Secondly, The Module automatically sends a frequency of 40 kHz and detects whether there is a pulse signal back. Finally, the range can be calculated through the time interval between sending trigger signals and receiving an echo signal. Test distance = (time × velocity of sound (340M/S)) (Kamal and Hemel, 2019). The technical specification of the use sensor is in Table 1.

Figure 2. Schematic of an Ultrasonic ranging module HC-SR04.

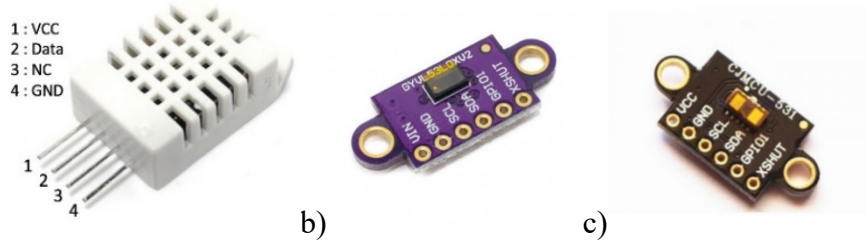
Table 1. Technical specification of the ultrasonic sensor.

Working Voltage	DC 5 V
Working Current	15mA
Working Frequency	20Hz
Max Range	4m
Min Range	2cm
Measuring Angle	15 degree
Trigger Input Signal	10uS TTL pulse
Echo Output Signal	Input TTL lever signal and the range in proportion
Dimension	45*20*15mm

The speed of sound can vary based on temperature and humidity. For calibrating the speed of sound, another kind of sensor had to be used.

2.2.2 Temperature and humidity sensor

As it has been written in section 2.2, for measuring the distance using that sensor, the speed of sound is needed. The sound travels at different speeds in different temperatures and humidity. DHT22 (Figure 3a) has already been calibrated during the production process and provides accurate information (Liu, 2013). The technical specification of the use sensor is in Table 2. Wire connecting illustration is as follows:



a) b) c)

Figure 3. a)Schematic of a DHT22, digital temperature, and humidity sensor, b) Schematic of a VL53L0X, c) Schematic of a VL53L1X.

Table 2. Technical specification of DHT22.

Working Voltage	3.3-6V DC
Working Current	0.3mA
Sensing element	Polymer capacitor
Operating range	Humidity: 0-100%RH Temperature: 40~80Celsius
Accuracy	Humidity: +-2%RH(Max+5%RH) Temperature: <+0.5Celsius
Resolution or sensitivity	Humidity: 0.1%RH Temperature: 0.1Celsius
Repeatability	Humidity: +-1%RH; Temperature: +-0.2Celsius
Humidity hysteresis	+-0.3%RH
Long-term Stability	+-0.5%RH/year
Sensing period	Average: 2s
Interchangeability	fully interchangeable
Dimensions	14*18*5.5mm

2.3 The VL53L0X

The VL53L0X (Figure 3b) is a new generation Time-of-Flight (ToF) laser-ranging module housed in the smallest package on the market today, providing accurate distance measurement whatever the target reflectance, unlike conventional technologies. The technical specification of the use sensor is in Table 3.

Table 3. Technical specification of VL530L0X.

Working Voltage	2.6-5.5V DC
Working Current	10mA up to 40mA
Working Frequency	50Hz
Output format (I^2C)	16-bit distance reading (in millimeters)
Distance measuring range	Up to 2m with a minimum range of 3cm
Weight without header pins	0.5 g
Dimension	13*18*2mm

It can measure absolute distances up to 2m, setting a new benchmark in ranging performance levels, opening the door to various new applications. The VL53L0X integrates a leading-edge SPAD array (Single Photon Avalanche Diodes) and embeds ST's second generation FlightSenseTM patented technology. The VL53L0X's 940 nm VCSEL emitter (Vertical-Cavity Surface-Emitting Laser), is invisible to the human eye, coupled with internal physical infrared filters, it enables longer ranging distances, higher immunity to ambient light, and better robustness to cover glass optical crosstalk (Adafruit, 2016).

2.4 The VL53L1X

The VL53L1X (Figure 3c) is a state-of-the-art, Time-of-Flight (ToF), laser-ranging sensor, enhancing the ST FlightSense™ product family. It is the fastest miniature ToF sensor on the market with accurate ranging up to 4 m and fast ranging frequency up to 50 Hz Housed in a miniature and reflowable package, it integrates a SPAD receiving array, a 940 nm invisible Class1 laser emitter, physical infrared filters, and optics to achieve the best ranging performance in various ambient lighting conditions with a range of cover window options. Unlike conventional IR sensors, the VL53L1X uses ST's latest generation ToF technology, which allows absolute distance measurement, whatever the target color and reflectance. It is also possible to program the size of the ROI on the receiving array, allowing the sensor FoV to be reduced. The technical specification of the use sensor is in Table 4.

Table 4. Technical specification of VL53L1X.

Working Voltage	2.6-5.5V DC
Working Current	10mA up to 40mA
Working Frequency 1-Short: up to ~130 cm 2-Medium: up to ~300 cm in the dark 3-Long: up to 400 cm in the dark	1-50 Hz max sampling rate (most immune to interference from ambient light) 2- 30 Hz max sampling rate 3- 30 Hz max sampling rate
Output format (I^2C)	16-bit distance reading (in millimeters)
Distance measuring range	Up to 2m with a minimum range of 4cm
Weight without header pins	0.5 g
Dimension	13*18*2mm

2.5 Price

In Table 5, information regarding prices of the introduced sensors has been given, VAT included.

Table 5. Price of used electronic gadgets.

Arduino Uno	10.99€
Ultrasonic Sensor	3.00€
VL53L0X	6.5€
VL53L1X	15.0€
DHT22	6.5€
16 GB SD card + Sd card module	5.56€+2.5€

3 Communication Ways

While many sensors use digital and analog ports for uploading the measured data to the microcontroller, some sensors use the inter-integrated circuit (I2C) protocol. This is a protocol that allows multiple "slave" digital integrated circuits (Sensors) to communicate with one or more "master" chips (Arduino). Like the Serial Peripheral Interface (SPI), which is only intended for short-distance communications within a single device. The ultrasonic sensor and DHT22 have been connected to the Arduino's digital ports. The laser ones had to be connected to I2C port (SCL, SDA) on the board. Since both of these laser sensors had the same board addresses, introducing them to the Arduino raised a problem. For solving this issue, the X shut pin of these two sensors has been used to change their circuit address. The code was written on the Arduino platform and uploaded to the board via a USB cable. For getting the main characteristics of these sensors, a few tests have been carried on. All the different types of ranging circuits have been connected and glued together like Figure 6, so data from all 3 of them would be measured almost the same and simultaneously.

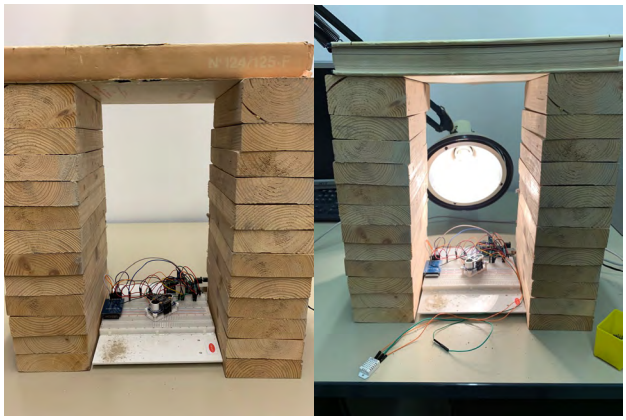


Figure 6. Experiment formation.

4 Experiments

The device was tested against the same measurement against different materials. In Figure 6, 2 tests with and without extreme ambient light have been done for getting the distance from the big book. For the one with the light bulb, the temperature sensor has been moved a bit far from the source of the light and heat. The reason was that the excruciating heat coming from the light bulb would not harm the sensor. The other tested objects were a white paper, a black paper, a clear and transparent plastic cover, and some thin tissues. In Table 6, standard deviations driven from the performed tests have been illustrated.

Table 6. Ranging results of the same experiment under different circumstances.

Tests / Sensors type	a thick book	a white paper	a black paper	a transparent plastic cover	a tissue	Extreme ambient light	Extreme ambient light*
Ultra	0.61	1.87	1	0.7	352	3.23	_
Laser1	2.5	2.67	7.18	5.46	4.66	3607	39.86
Laser2	1.5	1.48	1.87	3.12	1.62	21.94	_

On this table, the last column has been created to provide filtered data from the first laser sensor due to the extreme environmental light and heat test. The filter has deleted the ranging out-puts equal to 8190. When this sensor is not able to read, or the measurement distance is more than its capacity, it declares this number.

It should be mentioned that the ultrasonic sensor, which was the chipset sensor and the easiest one to install, had shown better performances compared to the laser ones. On the downside, this sensor needs 5v interaction digital ports and needs at least 4 volts for its full functionality. The only problem with this sensor could be its data providing speed. Although the laser has a faster rate (50Hz data production), this sensor has a frequency of only 20Hz. In other words, this sensor can provide up to 20 data each second. The biggest problem with the ultrasonic sensors would be their dependence on ambient temperature and humidity, since the speed of sound changes from an environment to another. This sensor needs an accurate speed of sound for its calculations. The proposition of this paper would be using the ultrasonic sensor with a laser sensor if there was the probability of changing temperature or of extreme ambient light. Using the first laser sensor or the second one is due to what range and circumstances the experiment may experience.

5 Conclusion

Notwithstanding that the laser sensors did not have as good results as the ultrasonic one, they can be useful as well. They are smaller, lighter, and faster than the ultrasonic sensors. Moreover, have noise-free technology (no noise can enter from the wires). Moreover, they work independently of the temperature of their testing situation. Best results will only appear if an ultrasonic sensor (attached to its temperature and humidity sensor) be used alongside a Laser sensor. They can cover the downsides of each other and provide an accurate, useful set of data. The selection of Laser type one or two depends on the circumstances of the experiment. If there is enough budget, Laser type 2 provides a way better set of data and is less sensitive to ambient light.

Abstract. *Serrat and Gibert (2011) introduced the use of survival analysis techniques for the study of time-to-failure in the facades of a building stock. Those techniques have been implemented in a predictive system that incorporates the inspection methodology together with the statistical methodology. The system proposes a network of urban laboratories for building research analysis and information with the aim of modelling the degradation time based on the information from all the cities participating in the project, from a multiscale perspective. The approach is population based, that is from the manager of the building stock point of view, in order to obtain information on the evolution of the stock across time, and to help the manager with decision making process on global maintenance strategies. However, for an efficient decision making it is crucial to determine those covariates -like materials, morphology and characteristics of the facade, orientation or environmental conditions- that play a significant role in the progression of different failures along the façade service life. The proposed platform also incorporates an open source GIS plugin that includes survival and test moduli that allow the investigator to model the time until a damage when taking into account the variables collected during the inspection process. The aim of the paper is to introduce the methodology and the modelling strategy for the deteriorating process of an urban front. The contribution will be illustrated with a case study located in the city of L'Hospitalet de Llobregat (Barcelona, Spain) in which more than 14,000 facades have been inspected and analyzed.*

Keywords: *Non-Parametric Modelling, GIS for Building Durability, Inspection Methodologies, Survival Analysis, Collaboratory.*

1 Introduction

In order to design a multiscale predictive platform for the analysis of the deterioration process of the facades in a building stock, we will focus on determining a reliable inspection method that fits to any urban laboratory. The system proposes a network of urban laboratories for building research analysis and information (BRAIN) with the aim of modeling the degradation time based on the information from all the cities participating in the project, from a multiscale perspective.

On the other hand, the methodology must study the morphology of the architectural elements and the states of the damages in the facades, from a general perspective. Basic fundamentals

and definitions on the methodological parts and preliminary works have been previously introduced by Serrat and Gibert (2011) and Gibert *et al*. (2014).

The manuscript is organized as follows. In Section 2 the main predictive and methodological issues will be presented. Section 3 will be devoted to the non-parametric estimation of the statistical model and Section 4 will fully illustrate with a case study the Geographic Information System tool as well as the results and interpretation of the significant variables acting on the deterioration of built facades. The paper ends with a summary and the main conclusions of the conducted research.

2 A Predictive System

In this section we will introduce, in a short manner, the four ingredients of the predictive system that we are proposing. That is a) the collaborative approach in order to join and analyze the information from the nodes in the network of urban labs, b) the inspection methodology to be applied to the urban lab, c) the survival analysis methodology as a statistical technique for the durability and modeling estimation and, d) the GIS platform as a tool for managing the information and the analyses. Details of these components can be found in Gibert (2016).

2.1 A Collaborative Perspective

The research focuses the prospecting campaign of the facades at a multiscale level. Indeed, it concentrates the interest within the concept of the urban laboratory that collects the envelope of the buildings and constitutes the urban front. This approach defines the urban canyon as the U-shape location where the facades are exposed and the time-to-event variables as well as the territorial and environmental covariates occur and determine the facades durability over time. Figure 1 shows the urban laboratory and the urban canyon (Gibert, 2016).

The project is a translatable study to any city in the world in a networking manner. The net has a neuronal analysis center, the Collaboratory, as a coordination unit, able to store and analyze the information from the cells in order to test for similarities and differences accros the participants (cities, *i.e.* urban labs). Right-hand part of the Figure 1 illustrates the network. The main goal is to join efforts into the predictive knowledge of the deterioration of the urban fronts and facilitate the design of common standards as well as protocols of follow-up and intervention strategy.

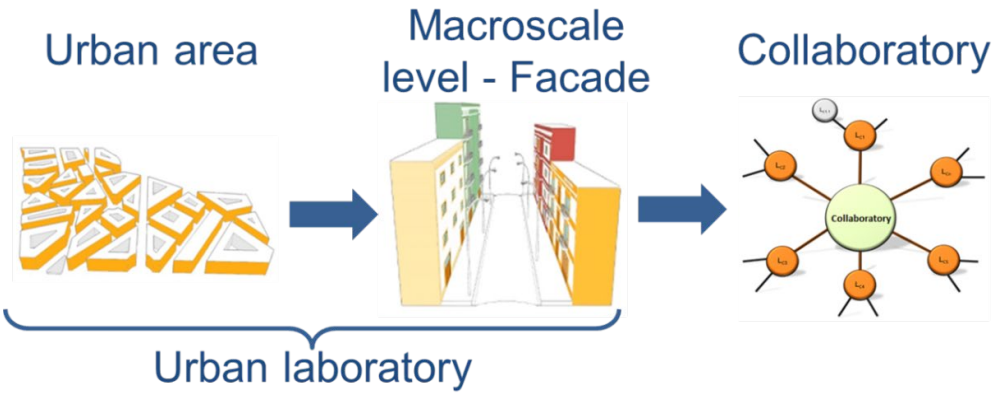

Figure 1. Urban laboratory network and Collaboratory for the BRAIN project.

2.2 Inspection Methodology

The main goal of the monitoring part is the follow-up of the facades in order to detect in which particular moment of the service life of the facade the damages occur and progress. From this perspective Gibert *et al.* (2014) designed the inspection protocol based on a list of requirements in order to apply a population approach and as a result an inspection document was derived. The document consists of two parts. Part a) allows to collect field data, cartographic data, cadastral data as well as plot/building/facade data and architectural characteristics. Part b) is made for collecting the existing elements and materials and the state of damages at the time of inspection.

2.3 Survival Analysis Methodology

Let T be the time from the beginning of the follow-up (time zero) until the failure (the event of interest) happens. T is our random variable of interest. Let $f(t)$ and $F(t)$ be the density and the cumulative distribution function of the random variable T. Based on f and F we can derive statistics of interest like, the quantiles of the distribution. This will allow us to estimate the time until a proportion of damaged buildings in the population or, in the reverse sense, the proportion of damaged buildings at certain time for a particular damage. In the service life setup, time zero will mean the date that the building is built and by failure we will understand the successive grades of gravity, or the successive grades of extent, of the damages. The survival (*i.e.* durability) function for the random variable T is the complement to one of the distribution function F, that is,

$$S(t) = 1 - F(t) = 1 - \mathrm{P}(T \leq t) = \mathrm{P}(T > t) \tag{1}$$

Our sample will be inspected at different inspection times (t_1, t_2, …) and the information on the failures times for the damages that the inspector collects will be interval censored, in the sense that the investigator only can ensure with probability one that the time to failure is in a time interval (l_i, r_i) (Serrat and Gibert, 2011).

In the context of our research on facades durability, since there are no references on the distribution functions that failure times follow, we will estimate the durability function and the hazard function in a non-parametric manner. That is, our estimates will be only based on the data and we will not suppose any hypothetical (and non-testable) distributions family for the unknown density f. We will use the Turnbull's estimator (Turnbull, 1976) based on an iterative algorithm that maximizes the non-parametric likelihood function

$$L = \prod_{i \in O} \big(F(o_i) - F(o_i^-)\big) \prod_{i \in R} \big(1 - F(r_i)\big) \prod_{i \in L} F(l_i) \prod_{i \in I} \big(F(r_i) - F(l_i)\big), \tag{2}$$

where O, R, L and I are the subsets of exact, right-censored, left-censored and interval-censored observations, respectively. From the resulting probabilities, durability and hazard functions can be derived. From the computational point of view, in order to obtain the proper estimates for the survival model, we will use the Turnbull's estimator implemented in the statistical environment R (R Core Team, 2014) in the Icens package (Gentleman and Vandal, 2016) available at Bioconductor website.

2.4 GIS Platform

In order to visualize and analyze, in a territorial and multiscale approach, the available information on the urban canyon, we have implemented a QGIS plugin for the Linux environment (QGIS Development Team, 2016). The application allows the manager the visual follow-up (*i.e.* location and characteristics at a multiscale level) of the ageing process of the urban laboratory. The language used to implement this application has been Python (van Rossum and the Python development team, 2016), open source language, object-oriented, which allows the use of other external programs, such as the case of R used for the statistical analysis. More details on the plugin and its development can be found in (Gibert, 2016).

3 A Modelling Strategy

As a first result the proposed platform allows the investigator to select a subsample of facades of interest, a particular failure in a particular element and to estimate and draw the durability functions for each level of severity and each level of extent, in a marginal way. This output allows to compute the percentiles distribution as well as the cumulative distribution function of the overall subsample. In a similar manner, the plugin offers the possibility of adding one specific covariate value (material, orientation, environmental condition…) and to derive the durability function for this specific value of that covariate. Based on these features it is possible to visually identify which variables could be significantly involved in the deterioration process.

In order to select the significant variables that take part in a non-parametric model for the deteriorating process we will use the extension of the Fleming-Harrington class of tests proposed for interval censored data by Oller and Langohr (2015). These tests allow to compare for equality of distribution functions and to check for ordered survival distributions among the categories of a covariate.

3.1 Proposed Selection Algorithm

The algorithm that we have designed to select, from a set of candidates, the sequence of covariates in the model for a given significance level, α, is:

- STEP 1: Perform an equality test for each one the covariates candidates to explain the failure of interest. Choose, if exists, the covariate that shows the minimum p-value lower than α. In case none of the candidates satisfies the constrain this would mean that none of the covariates would be significative enough to explain the deteriorating process.
- STEP 2: Branch the subsample according the selected covariate and compute the sample size of each one the categories. Explore and validate the possibility of recoding those values. In case of recodification, apply equality tests in order to ensure the significance of the just restratified covariate.
- STEP 3: Repeat steps 1 and 2 for each one of the resulting branches by considering the remaining candidate covariates, until none of them becomes significative.

Figure 2 illustrates, in a global manner, the three steps of the proposed algorithm. The final non-parametric model will identify a significantly different behavior in the aging process among the branches in the resulting classification tree.

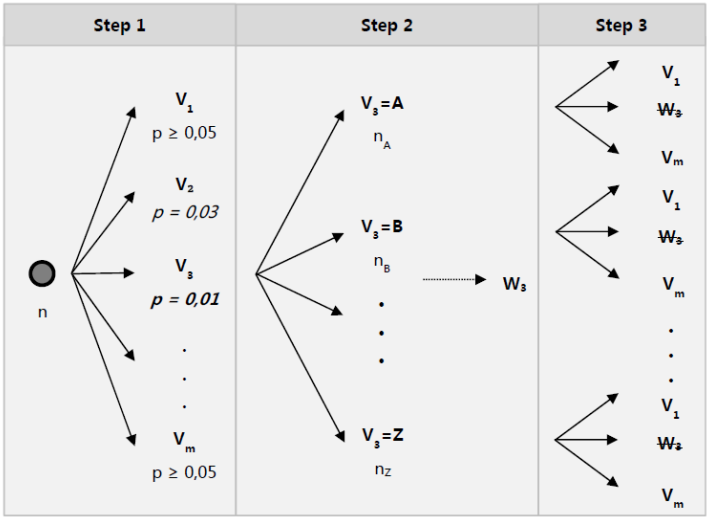

Figure 2. Algorithm for the selection of the covariates of interest from a given set V_1, V_2, … V_m of candidates (for a supposed significance level $\alpha = 0.05$, *i.e.* a 95% of confidence level).

4 A Case Study: L'Hospitalet de Llobregat

The collaborative strategy has been introduced in a variety of countries and cities, as a strategy for building stock management (Serrat and Gibert, 2011). As an illustration of the modelling strategy we will use the analysis of a particular failure in L'Hospitalet de Llobregat (hereafter L'Hospitalet) in the metropolitan area of Barcelona. L'Hospitalet is the city having the second largest population and is among the twenty most populated cities in Spain. The municipality covers an area of 12.5 square kilometers next to Barcelona, and it is divided in 12 neighborhoods.

A first group of 13,193 inspections were done by 2001 across all the city. Later on, by 2016, 1,308 facades have been reinspected. We will focus in the dwelling buildings located in the Centre, Collblanc and Santa Eulàlia neighborhoods as a statistical population of interest. The sample size is 814 and we are talking almost 150,000 square meters of exposed facades. Figure 3 shows the subsample of interest.

After computing the Weighted Severity Index (Gibert, 2016) for all the failures of interest in the selected sample we saw that the most relevant failure is the moisture in the deck railing plasters. The subsample at risk of suffering this failure is made by 512 facades. Figure 4 shows, numerically and graphically, the estimated survival functions for each one of the levels of extent (low, medium and high). We will focus now in obtaining a model non-parametric for the moisture in the deck railing plasters in a low level of extent (*i.e.* the dark green stepwise line in Figure 4).

The covariates that have been considered of interest to be in the model are: V_1: the morphology of the facade, V_2: the construction period, V_3: the material, V_4: the neighborhood and V_5: the orientation. After applying the selection algorithm described in the previous section we obtain the model

$$T \sim V_2 + W_1 + W_4 \tag{3}$$

Figure 3. QGIS map of the subsample of interest in L'Hospitalet de Llobregat (inspected facades in light blue, n = 814).

where V_2 stands for the construction period stratified in two groups (before and after 1960), W_1 describe the morphology of the facade (flat versus no flat) and W_4 indicates if the facade belongs to the Centre neighborhood. In Figure 5 we can see the characteristics of the resulting four groups, named G_1, G_2, G_3 and G_4.

	LC %	IC %	RC %	10%	25%	50%	75%	10.0	25.0	50.0	100.0
Low	56.2	14.6	29.1	0.1	17.8	33.7	73.2	22.4	36.3	69.3	95.7
Medium	43.0	11.5	45.5	0.2	20.6	48.2	98.7	14.5	26.4	53.4	87.4
High	29.7	6.8	63.5	0.2	29.7	80.3	98.8	12.5	19.5	36.0	78.0

Figure 4. Durability functions for moisture in the deck railing plasters, in our subsample of interest in L'Hospitalet de Llobregat (% of censoring –in pink–, quantiles –in blue– and cumulative of failures across time –in green–).

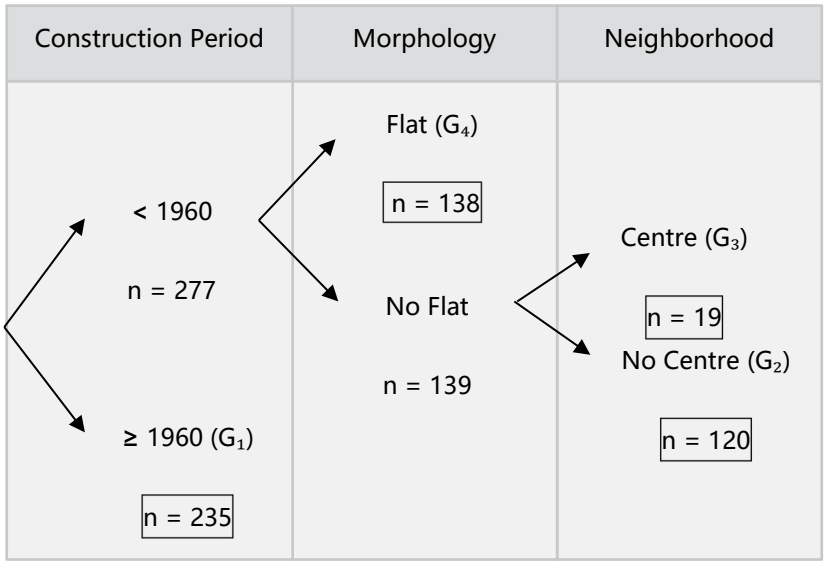

Figure 5. Classification tree for the time until the occurrence of puntual humidities in the plaster of the deck railing in the facades of residential buildings of L'Hospitalet de Llobregat.

By performing pairwise tests we can prove that the durability functions are ordered according to the groups in which the subsample has been split. In fact, the survival distributions follow the sequence

$$S_{G3} > S_{G2} > S_{G4} > S_{G1} \tag{4}$$

as it is shown in Figure 6.

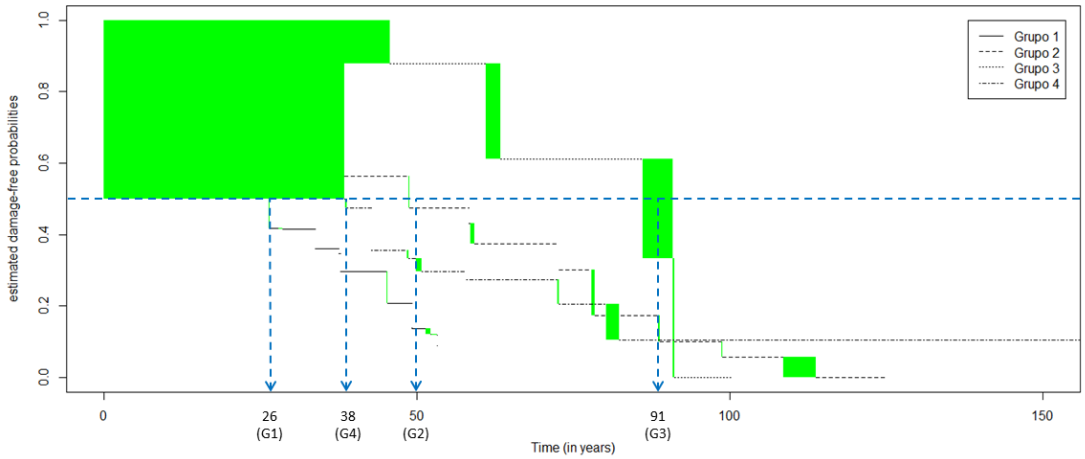

Figure 6. Stratified durability functions for puntual humidities in the plaster of the deck railing according the model defined by the construction period, the morphology and the neighborhood covariates, and estimated median time for each group.

It is interesting to highlight the improvement introduced in the predictive estimation from the proposed model with respect to the marginal estimation in Figure 4. For example, the estimation of the median time to injury is approximately 34 years in the marginal model, whereas, when the model is known, this median is estimated in about 26, 38, 50 and 91 years, for the facades of groups G_1, G_4, G_2 and G_3, respectively.

It can be observed that young facades (the ones in the group G_1) fails before than the others. In contrast, the facades with a better durability (the ones in the group G_3) are the older ones, located in the Centre neighborhood and with a no flat morphology (*i.e.* with other elements in the facade like balconies and tribunes). This fact poses a new and interesting debate on the constructive models and the associated building technology.

5 Conclusions

From a non-parametric approach it is really convenient to model how different covariates can play a significant role in the aging process of the elements of the facades. When data are interval censored this goal is actually more challenging due to the uncertainty in the data. The main benefit of the proposed algorithm is that it allows to build a model in which at every step the most significative covariate is chosen and validated, in a sequential manner. This is a powerful strategy in order to identify priorities and to guide the decision making. Through the case study it has been illustrated the advantages of the proposed modelling strategy overcoming the limitations of not being available a parametric alternative.

Abstract. *The negative effects of climate change are underway despite the global efforts to mitigate them and the future scenario are unsettling. Climate change poses critical challenges to urban environments and highlights the need for research its impacts on the built environment. One of the most significant effects of climate change on reinforced concrete structures is associated with the carbonation of these structures. The increase of parameters such as temperature and carbon dioxide jeopardise the degradation of such structures by carbonation-induced corrosion. This paper presents the results of the monitoring and analysis of a set of buildings that determine carbonation as the main degradation mechanism of structures in Paraguay. Through the application of a previously developed carbonation model, the worsening of the carbonation-induced degradation has been determined after considering the climate change effects in the coming 50 years. The outcomes of the study determined that the poor quality of the structures in Paraguay cause premature degradation in them. Furthermore, considering climate change effects, it has been determined that this phenomenon could accelerate corrosion failure times in reinforced concrete structures.*

Keywords: *Carbonation, Climate Change, Real Carbonation Data, Reinforcement Corrosion.*

1 Introduction

Nowadays, ensuring that structures can withstand the environmental factors that determine their degradation has become a big challenge for engineers, who often are subject to a limited budget when are designing their projects. The study of the degradation of structures caused by environmental phenomena did not reach a significant interest until a few decades ago when climate change became tangible as a critical problem that affects the daily integrity of human beings. Furthermore, such as the buildings built in earlier times (*e.g.*, bridges, cathedrals, castles, and so on), it is now possible to classify several of the 20th-century concrete structures as modern heritage, whose maintenance has cultural and historical value for each country.

Rehabilitation, maintenance and repair of buildings play an important role in ensuring its performance in the long term, so they have a significant impact on the adaptation of buildings to climate change. Recent studies have shown widespread concern regarding the regulations in the construction industry in relation to durability, which are based on historical climate data. Therefore, a comprehensive study of the climate change impacts on the degradation of the structure is necessary (de Wilde and Coley, 2012). Perhaps one of the most meaningful

conclusions of the Intergovernmental Panel on Climate Change (IPCC) in its fifth assessment report was that the climate change effect comprises a problem that cannot be removed immediately. That is, the concentrations of greenhouse gases in the world are so high that their reduction or stabilization could not be possible for several centuries (IPCC, 2013).

Although civil engineering historically has covered its knowledge based on physical and mechanical stresses to establish the durability conditions of a structure, the effect of climate change has forced to expand knowledge in a deeper way towards the environmental and chemical stresses that influence directly on the integrity of infrastructures worldwide. Therefore, a neglected area is the impact of climate change on RC structures, where it is necessary to adapt future designs to ensure that infrastructures have adequate capacity and have sufficient durability to deal with the consequences of climate change (Talukdar, 2013).

Under this context, the degradation of reinforced concrete (RC) structures could be significant considering carbonation-induced corrosion. Carbonation is a natural phenomenon produced by the chemical reaction between cement hydroxides and the atmospheric carbon dioxide (CO_2) (Broomfield, 2007). This degradation mechanism is directly influenced by three climatic parameters that are associated to the effects of climate change: CO_2 concentration, temperature and relative humidity. Therefore, the study of the carbonation phenomenon as a degradation mechanism of concrete structures has been a spotlight of engineers since the emergence of climate change.

2 Carbonation in RC Structures

Regarding carbonation-induced degradation, the interpretation of reinforcement corrosion requires a quantitative understanding of the environment, physical deterioration process, transport mechanism through the concrete, cracking process and the corrosion phenomenon (Taffese and Sistonen, 2013). Corrosion in the reinforcement causes cracking of the surface of the structure and subsequent the spalling of the cover due to the expansion of the corroded rebar. Then, the corrosion rate directly affects the extension of the service life of the RC structures (Ahmad, 2003).

2.1 Effects of Climate Change on Concrete Degradation

Several studies agree that climate change will cause new considerations and establish new conditions for the construction industry. Due to climate change, the risks of damage induced by carbonation in concrete can increase by more than 16% by the year 2100, which means that one in six structures will suffer additional and costly corrosion damage due to this phenomenon. It has also been found that, as a consequence of climate change, the corrosion rate could increase by 15% if the temperature increases by 2 °C (Stewart *et al.,* 2011, 2012).

Research developed for concrete infrastructures in China has determined, taking into account the same climatic parameters mentioned above, that the depth of carbonation could increase by 45% in reinforced concrete structures by the year 2100 (Peng and Stewart, 2016). On the other hand, Stewart *et al*. concluded that in some regions of Australia, the risks of damage induced by carbonation can increase even by more than 400% by the year 2100 (Stewart *et al.,* 2011). Later, other studies showed that global warming could advance the time of failure by 31% or decrease the service life up to 15 years for moderate levels of aggressiveness (Bastidas-Arteaga *et al*., 2013).

The long life of the buildings is perhaps the most palpable problem since most of the buildings built now must continue in service within the next 50-100 years. However, the most efficient way for adaptation is taken the proper actions before these buildings are built, i.e. during the design stage. Therefore, it is crucial to develop policies and strategies that reduce long-term risks for new buildings, encourage early adaptation where possible to existing buildings and, at least, adopt a precautionary approach to the uncertain risks of climate change (Camilleri *et al.,* 2001).

2.2 Carbonation-Induced Degradation in Paraguay

Carbonation is one of the most frequent phenomenon that leads to degradation problems in structures located in Paraguay. The index of relative humidity and the tropical temperature makes a propitious place for the carbonation to propagate in the structures and jeopardise its durability due to the reinforcement corrosion. In this paper, a database with 327 carbonation depth measurements in different structures of Paraguay has been analyzed in order to know the real carbonation rate in RC structures. The construction industry in Paraguay has had significant growth in the last decade. However, the first infrastructures built in the country lacked adequate control, whereby currently a poor quality in buildings is evidenced that compromises its durability.

The carbonation data of the case study corresponds to buildings located in urban area. Considering that the study was conducted in existing buildings, the carbonation depth was measured by applying the phenolphthalein test. Three measurements were taken for each structural element and the average of these values was computed. The year of construction of these structures was between 1986 and 1997, although some of them were built in the current century. On the other hand, the interventions were made between 2013 and 2019. As for their constructive characteristics, these buildings are constructed with Ordinary Portland Cement. It should be noted that in several cases, the concrete structure was completely exposed. These cases correspond to unfinished buildings, a very common case in the country when construction projects do not end (usually due to budget problems) and remain exposed to weathering in some cases for more than ten years even.

Through a statistical analysis of the real carbonation data, the mean value and the standard deviation for the cover thickness and the carbonation depth are shown in Table 1. These results suggest that can be expected a carbonation depth that has almost the same thickness than the cover. This result is quite important since the probability of corrosion onset is too high considering the loss of alkalinity of concrete due to carbonation. On the other hand, the results shown in Table 1 have been classified according to the structural elements of the building. After this classification, it has been seen that the slabs were the most compromised elements from the point of view of the corrosion initiation by carbonation. This is deduced since the mean cover thickness (12.30 mm) was practically equal to the mean of the carbonation depth (12.15 mm) in the structures.

Considering the carbonation tests results, an analysis was performed in order to determine the carbonation-induced corrosion risk. It was possible to classify three conditions of degradation for the analysed structures: with corrosion risk, without corrosion risk, and the condition of imminent corrosion initiation. For this purpose, a structure without corrosion risk has been considered when the cover of the structure is not yet carbonated or, at least, the

carbonation front is not in a critical zone that may induce corrosion. This consideration is specifically referred to that an immediate carbonation-induced corrosion is not expected. However, as has been studied in the literature, corrosion could be induced by other mechanisms and this study has focused only on carbonation.

Table 1. Results for carbonation depth and concrete cover of the case study.

Variable	Main Value	Standard Deviation
Carbonation Depth (mm)	18.0	7.13
Cover Thickness (mm)	18.1	8.32

Furthermore, the condition referring to structures with corrosion risk includes those where the carbonation front had exceeded the cover thickness. This implies that the reinforcement is wholly embedded in a carbonated concrete, leaving it vulnerable to corrosion due to the suppression of the passive protection layer. The last condition referred to imminent initiation of corrosion considers what has been established in Yoon *et al*. (2007), in which the corrosion begins when the carbonation front is located at least within 5 mm of the rebar surface, being necessary an immediate intervention.

Then, this analysis has shown that almost half of the cases analysed (49.91%) present a considerable corrosion risk or imminent corrosion initiation caused by carbonation. That means the carbonated thickness in the concrete is higher than the cover thickness, and that the durability of the structure is in a critical condition. Thereby, it can be said that almost 50% of the buildings analysed in the urban area of Asunción, whose were built no more than 30 years ago, can be considered as structures at the beginning of the last stage (corrosion propagation) of its corrosion degradation. Such degradation conditions correspond to the time in which the interventions were carried out in the structures of the case study. Hence, the structures without corrosion risk could also be considered under carbonation-induced corrosion risk in the next years if appropriate maintenance actions are not performed. Over the 327 real carbonation data, the result of the analysis is depicted in Figure 1.

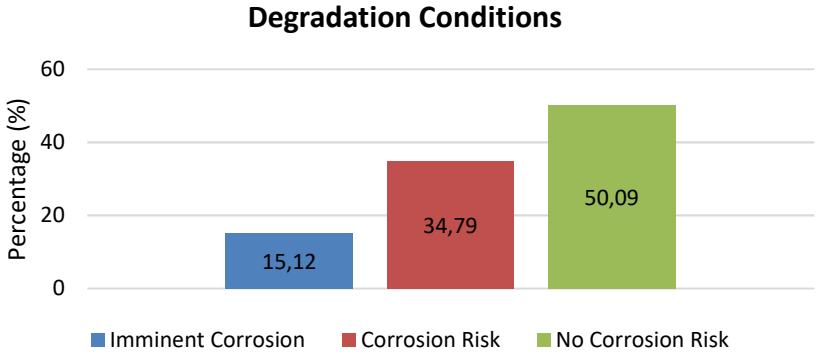

Figure 1. Degradations conditions considering inspection results.

In essence, through the case study shown in this section, it was possible to illustrate that carbonation is a common problem in the concrete structures of Paraguay. The lack of control

during the execution of the works often triggers in structures without the adequate conditions that guarantee their durability. Therefore, according to the study developed in this section, the cover thickness is referred to as the most influential parameter to reduce the time to corrosion initiation. In this way, a rigorous control is recommended during the elaboration of these structures that guarantee, not only the adequate thickness but a good cover quality through a low porosity.

3 Carbonation Modelling

Recently, many degradation models have sought to link the phenomenon of climate change and its influence on degradation parameters, which represents a significant advance. On the other hand, the estimation of the service life of structures under the influence of cracking or the system of loads to which a real structure is subjected is still insufficiently studied due to its complexity. The numerical degradation model applied in this paper to estimate the carbonation depth in structures due to the climate change effect was the model developed in (Talukdar *et al*., 2012). This model was considered suitable to represent the estimated carbonation-induced degradation over time since it is formulated as a function of a climatic scenario and concrete properties. This feature allows the model to predict the degradation of concrete structures under consideration of climate change, which is directly related to the context of this research.

The carbonation model applied in this research is a deterministic one-dimensional numerical diffusion model for a gaseous medium through a porous substrate based on Fick's Second Law. The model has been validated based on experimental results obtained in an accelerated carbonation chamber. Then, the model develops an extensive analysis of the carbonation phenomenon considering parameters such as porosity, relative humidity, temperature, diffusion and concentration of gases. Therefore, as it is considered parameters such as relative humidity, temperature and carbon dioxide concentration into the numerical model, the climate change effects can be included within the carbonation model. In this way, the model allows to determine the concentration of CO_2 and $Ca(OH)_2$ within the concrete as a function of time by applying the following equations:

$$\frac{\delta}{\delta t}\left[CO_{2(aq)}\right] = D\frac{\delta^2}{\delta x^2}\left[CO_{2(g)}\right]HRT - k\left[CO_{2(aq)}\right]\left[Ca(OH)_{2(aq)}\right] \quad (1)$$

$$\frac{\delta}{\delta t}\left[Ca(OH)_{2(aq)}\right] = D\frac{\delta^2}{\delta x^2}\left[Ca(OH)_{2(aq)}\right] - k\left[CO_{2(aq)}\right]\left[Ca(OH)_{2(aq)}\right] \quad (2)$$

Where $CO_{2(aq)}$ and $Ca(OH)_{2(aq)}$ are the aqueous concentration of CO_2 and $Ca(OH)_2$ respectively(mol/m^3), D is the effective diffusivity of the carbon dioxide into the concrete (m^2/s), *HR* is the relative humidity (%), *T* is the temperature (K), *k* is the reaction rate constant (m^3/mol/s), $CO_{2(g)}$ is the atmospheric concentration of carbon dioxide (mol/m^3). Therefore, by solving Equations (1) and (2) simultaneously, it is possible to obtain the concentrations of both solutions involved in the carbonation reaction using the "*Method of Lines*" proposed by Cutlip and Shacham (Cutlip and Shacham, 2007). Further details of the mathematical derivation of the model and the values of the parameters in both equations can be found on (Talukdar *et al*., 2012).

Equations (1) and (2) model the corrosion initiation stage. For the corrosion propagation stage, the model employs an analytical thick-walled uniform cylinder which assumes that the generation of a volume of corrosion products (rust) around the corroding steel causes an expansion in the diameter of the steel. Within the formulation of this stage of corrosion degradation, the model considers parameters such as the activation energy and the reference current flow density which are not generally taken as constants by other models. These parameters may depend on the interaction between the concrete resistivity, the saturation level and the cover thickness.

3.1 Carbonation Simulation Results

The carbonation model provides a valuable perspective on how the carbonation front advances over time through concrete structures under the influence of climate change. After running the carbonation model in MATLAB, the results are shown in Table 2 regarding the ultimate carbonation depth (UCD) for two typical RC structures of Paraguay (20 and 25 MPa) considering two different climatic scenarios of the IPCC (RCP 4.5 and RCP 8.5). The UCD represents the maximum depth reached by the carbonation front during the simulations.

Furthermore, a control scenario is considered to be able to monitor the expected increase in the carbonation depth caused by the climate change effect. This control scenario is a scenario where the relative humidity and the mean annual temperature were held to the current values for Paraguay as 75.1% and 23.7 °C, respectively. On the other hand, it is also possible to determine through the degradation model what are the times of corrosion initiation caused by carbonation, as well as the corrosion propagation time.

Table 2. Carbonation modelling - Simulation results.

Climatic Scenario	Corrosion Initiation (years)	Propagation Time (years)	Ultimate Carbonation Depth (mm)
Strength: 20 MPa – Cover thickness: 25 mm			
Control	20.15	2.32	35
RCP 4.5	19.27	2.95	35.6
RCP 8.5	18.24	2.88	40
Strength: 25 MPa – Cover thickness: 25 mm			
Control	26.65	2.66	30
RCP 4.5	23.69	2.69	30.8
RCP 8.5	22.57	2.76	35

After the application of the carbonation model, some conclusions can be drawn regarding the corrosion risk by carbonation in the concrete structures of Paraguay. Concrete structures would reach an UCD between 30 and 40 mm corresponding to a service life of 50 years, depending on the concrete quality and the climatic scenario predicted. Herein, the ultimate carbonation depth is considered as the maximum depth of carbonation front reached in the simulation and this parameter is subjected to the boundary conditions of the model. Moreover, it can be said that the RC structures in Paraguay would be under considerable corrosion risk considering the forecasting climate changes. Moreover, simulations have not shown alteration

regarding the UCD between the control scenario and the best scenario. The difference was concerning the time, where the UCD is reached in the best climate scenario between 12% and 20% earlier than in the control scenario. On the other hand, the carbonation depth could increase between 14% and 16% for the worst-case scenario.

On the other hand, it has been found that the higher the strength of the structure, the greater the carbonation resistance, which is reflected in the corrosion initiation times. The main reason for this behaviour is the porosity of the material. The concrete strength is directly related to the porosity of the material so that the diffusion of gases within the concrete is limited in the materials of greater resistance.The numerical model applied in this paper considers that before the expansive pressure of the oxide is generated, it is necessary that the porous zone of the concrete/steel interface be wholly filled with the corrosion products (rust). This porous zone has been initially considered in the numerical model with a value of 10 μm. However, many other studies consider different values for this parameter ranging from 50 μm to 100 μm (Siemes *et al*., 1985; Broomfield, 2007). If the porous zone is increased by 50%, the corrosion propagation time can be increased between 10 and 60%. Therefore, the limit pf rust generation to fill this zone is quite influential in the simulation results obtained. That is, the concrete quality will always be a critical factor regarding the durability of RC structures.

4 Conclusions

Although there are several investigations related to the corrosion of concrete reinforcements in countries such as China, the United States, Australia and European countries, at the Latin American level it was possible to confirm a lack of available research that can describe the same problems under the specific circumstances of the region. In the specific case of Paraguay, as it is a developing country, the accessibility to information and the low number of it does not allow to describe the state of degradation of the infrastructures scientifically.

It was found that quality control during the construction process is of utmost importance to ensure a minimum concrete cover, which is one of the most critical factors on the initiation of corrosion time. Furthermore, structures and infrastructures in Paraguay are not appropriately designed and executed according to the consideration of environmental effects. Regarding the degradation prediction models, one of the most significant handicaps is the difficulty in adopting the parameters in a precise and quantifiable way. It is true that these numerical models seek to describe, in an increasingly precise way, the natural behaviour of the degradation processes of structures. However, it is still necessary to carry out a lot of research in this area to achieve this objective entirely.

Concerning the carbonation model results for the structures of Paraguay, can be expected early degradation in the next years due to climate change effects. Thus, for the worst climate scenario, in the second half of this century is expected an average increase by 16 %, in the maximum carbonation depth regarding a control scenario for RC structures of 20 and 25 MPa. Meanwhile, the time to reach the same maximum carbonation depth of the control scenario can be reduced even in 8 years for the best climate scenario, depending on the quality of the concrete. After a sensitivity analysis through the carbonation model, it was found that the reduction of the concrete cover to a value of 10 mm provides a significant acceleration in the corrosion initiation time. Therefore, not only the concrete strength has to be monitored, but also the concrete cover. Perhaps one of the most concerning conclusions is given by the fact that the

carbon dioxide accumulated in the earth's atmosphere cannot be reduced to acceptable levels until within a few centuries, even considering that greenhouse gas emissions were entirely and immediately reduced. Then, this situation suggests that the best strategy to deal with this problem involves adaptation measures rather than mitigation measures. From the engineering and constructions approach, this strategy must be proposed dynamically considering the accelerated change in the expected climate according to the IPCC scenarios.

Abstract. *The inspection of the used house which is necessary to be evaluated is carried out without removal of the interior or exterior finishing materials. However, where the interior or exterior appearance was degraded, there was not always a bio-deterioration of the wooden structural member in the existing wood houses. Therefore, the interior or exterior appearance of the 103 used wood houses were inspected and the bio-deterioration of all wooden structural members were investigated after removal of the finishing materials. Then, the relationships between the appearance degradation and the actual bio-deterioration of the wooden structural members in the used wood houses were studied. The results were summarized as follows:*

1) *The bio-deterioration of the wooden structural members were found much on 1st story rather than 2nd story, in the elder building age, in case of short eaves and in case of low foundation. The issues known experience empirically were verified numerically.*
2) *The tendency of the appearance degradation occurrence were the same as the tendency of the bio-deterioration partially, but didn't match it entirely.*
3) *About 90 % of the portions whose interior or exterior appearance were degraded didn't have the bio-deterioration of the wooden structural member.*
4) *The ratio of the portion with the bio-deterioration of the wooden structural member without appearance degradation were only 1.6 %.*

Keywords: *Appearance Inspection, Degradation, Bio-Deterioration, Used Wood House.*

1 Introduction

It is not uncommon in Japan for wood houses to be scrapped after a family has finished using it and for a new house to be rebuilt for a new family. This makes the market for the used houses inactive and disturbs the growth of the sustainable society. Revitalizing the market for the used houses is one of the most important social issue in Japan (MLIT, 2015). One of the main factors disturbing the distribution of used wood houses is the difficulty in grasping whether structural components are decayed or damaged by termites (Cho *et al.*, 2013). Therefore, a visual inspection of the current state of more than 100 wooden houses was carried out, and after all the finishing materials and interior / exterior materials were removed, a biological deterioration survey of all structural members was carried out. Then, we analyzed the relationship between

appearance defects and biological deterioration of structural members.

2 Appearance Inspection and Bio-Deterioration Survey Methods

2.1 Attribution of Inspected and Surveyed Houses

Houses to be demolished for removing or renovated houses were selected (Tsuchimoto *et al.*, 2016). This was a necessary condition for exposing all structural members and surveying the state of bio-deterioration. Since the durability can be affected by the building age, the construction methods, and the site condition, we made an effort so that the attribution of the inspected and surveyed houses didn't have any bias. Most of the construction method of the inspected and surveyed houses were Japanese conventional post and beam construction. The wood frame construction and the prefabricated wood construction were only 4 and 2 houses, respectively. It was difficult to find the relatively new house for inspection and survey. The building age distribution of the inspected and surveyed houses are shown in Table 1. The minimum and maximum building ages were 14 and 63, respectively. As for the story of the houses, most were 2-story houses, excluding ten 1-story houses and a 3-story house. The distribution of the building locations of the inspected and surveyed houses are shown in Table 2. As mentioned above, though the houses needed to be chosen without bias, the houses built at the standard region were most and occupied about 73 %. Because most of the houses in Japan were built in the standard region including Tokyo and Osaka.

Table 1. Building age distribution of the inspected and surveyed houses.

Building age	20 years or less	21-30 years	31-40 years	41-50 years	51-60 years	61 years or more	Un-known	Total
Number of houses	4	26	36	25	7	1	4	103

Table 2. Building locations distribution of the inspected and surveyed houses.

Region	Cold region			Standard region		Hot and humid region		Total
Zone No.	1 & 2	3	4	5	6	7	8	
Example of place	Hokkaido	North Tohoku	South Tohoku	Cool area*	Warm area*	South Kyushu	Okinawa	
Number of houses	0	5	11	18	57	12	0	103

*: The cool area and the warm area respectively indicate the relatively cool and warm district of North Kyushu, Shikoku and the main island of Japan excluding Tohoku.

2.2 Method of Appearance Inspection

As the appearance inspection, the interior and exterior materials and the finishing material of the house, for example, shown in Photo 1(a) were observed (Photo 1(b)), and their degradation such as rain leak marks, cracks, discoloration and so on were grasped. The location and degree of these deteriorations were visually measured with reference to "Durability design and maintenance / deterioration diagnosis of wood houses" (2002) issued by the Japan Housing and

Wood Technology Center.

2.3 Method of Bio-Deterioration Survey of All Structural Members

The bio-deterioration survey were conducted to all structural members after the removal of all sheathings and finishing materials (Photo 1(c)). The visual and tactile inspection were conducted to survey all structural members for bio-deterioration. The bio-deterioration includes the decay and the termite damage. The position and degree of the deterioration were grasped and recorded with reference to the above-mentioned manual issued by HOWTEC.

Photo 1. Overview of (a) inspected house, (b) appearance inspection and (c) bio-deterioration survey.

3 Database of Inspection and Survey Results

3.1 Objective

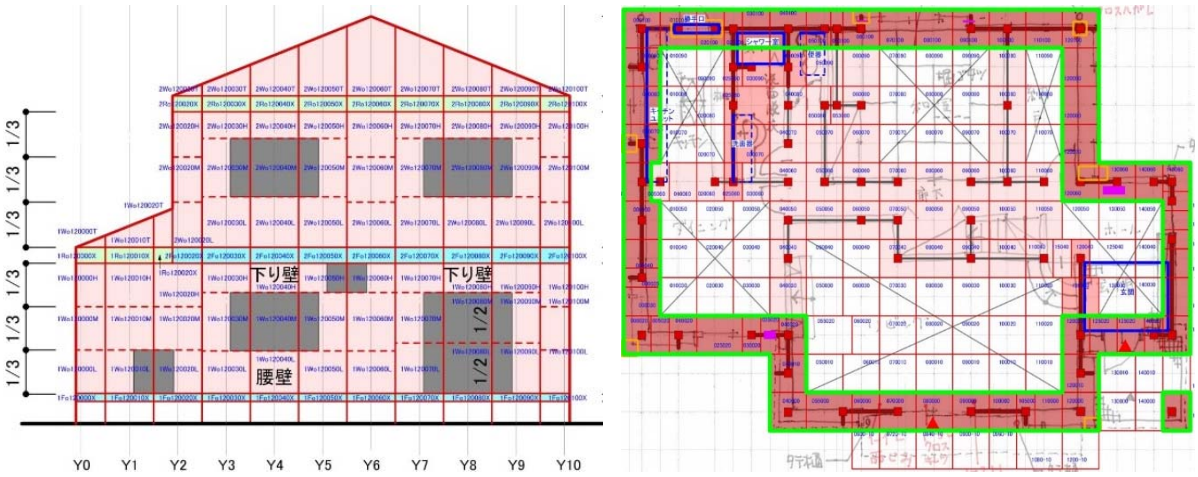
Although there are several factors that disturb the market distribution of the used wood houses, it is not too much to say that the largest factor among them is that they include degraded parts, or that the range and the degree of deterioration are unknown. Many studies of the degradation of old wood houses have revealed whether the house contains degraded components and the tendency for degradation to exist. But even if you know these things, the buyers cannot decide whether the used wood house needs to be repaired or whether they can live as it is, if they can endure. Therefore, it is necessary to evaluate not only whether or not the degradation has occurred but also in what range and how serious the bio-deterioration is.

Then, the inspected and surveyed houses were divided into square segments of approximately 900 mm, each linked to the results of appearance inspections and to the results of bio-deterioration survey of all structural members, including the degree of decay or termite damage. Each segment is not necessarily independent, but the number of segments indicates the range of degradation. In other words, minor deterioration is one segment, but widespread degradation is two or more segments. And, the relationship between the appearance defect and the bio-deterioration of the structural member was analyzed.

3.2 Compilation Method into Database

At first, the investigated houses were divided into roofs, walls, and floors of the 1st and 2nd story, respectively. The roof segment and the 2nd floor segment include the ceiling and the 1st story's ceiling, respectively. The wall segments included the interior sheathings and the exterior finishing material. Next, as shown in Figure 1, the wall, floor and roof were divided into approximately 900 mm square segments. The wall with the opening was divided into the

hanging wall and spandrel wall segments. As a result, 103 homes were divided into approximately 65,000 segments. Each segment linked to the attribution of the investigated houses and the information of the appearance degradation and the bio-deterioration of the structural members included in it.



(a) Wall divided into segments. (b) Floor divided into segments.

Figure 1. Dividing method of investigated house into segments.

4 Frequency of Appearance Degradation and Bio-Deterioration

All of the 103 houses had the degradation in appearance, and 97 houses had the bio-degradation. Out of 65,000 segments, the appearance degradation was found in 5,667 segments, corresponding to 8.7 %, and the bio-deterioration of the structural members was found in 1,421 segments, corresponding to 2.2 %. In other words, most existing wood houses have the bio-deterioration of structural members, but their range is generally limited. Figure 2 and 3 shows the frequency of the appearance degradation and the bio-deterioration of the structural members for each building age and each construction area, respectively. The incidence of the appearance degradation and the bio-deterioration increased with older building age, except for over 50 years whose sample was very few. The incidence of them was lowest in zone No. 7 with high temperature and humidity. In others, the incidence increased in warmer zone, except for zone No. 3 where the sample was very small.

Figure 4 shows the incidence of them for each building part. Both of the appearance degradation and the bio-deterioration of the structural member often occurred on the 1st story and outside rather than the 2nd story and inside, respectively.

Figure 5 shows the relationships between the construction method and height of the foundation and the bio-deterioration of the structural member in the 1st story. The incidence of the bio-deterioration was lower in the order of the concrete mat foundation with footing, only the footing with the moisture barrier concrete and the one without the moisture barrier concrete. The mat foundation and the moisture barrier concrete are effective in preventing the bio-deterioration of the structural member in the 1st story. Although there were some exceptions, the incidence of the bio-deterioration almost decreased as the foundation height raised.

Figure 6 shows the effect of the segment orientation on the incidence of the appearance degradation and the bio-deterioration of the structural members. The orientation of the segments

had no obvious effect on the incidence of them.

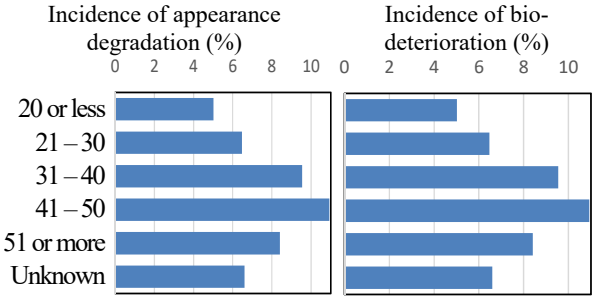


Figure 2. Incidence of the appearance degradation (left) and the bio-deterioration (right) for each building age.

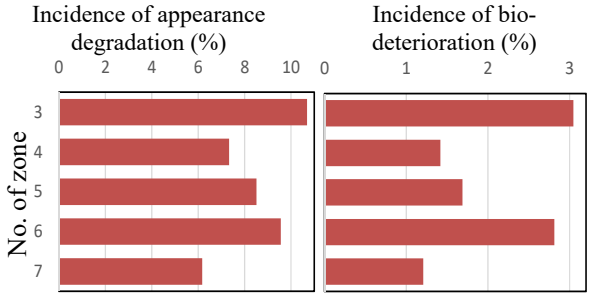

Figure 3. Incidence of the appearance degradation (left) and the bio-deterioration (right) for each building location.

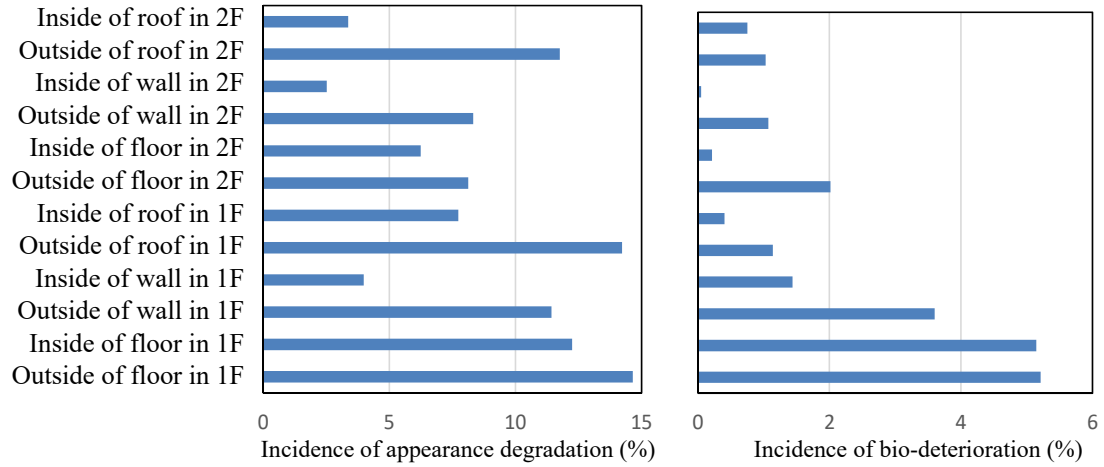

Figure 4. Incidence of the appearance degradation (left) and the bio-deterioration (right) for each building part.

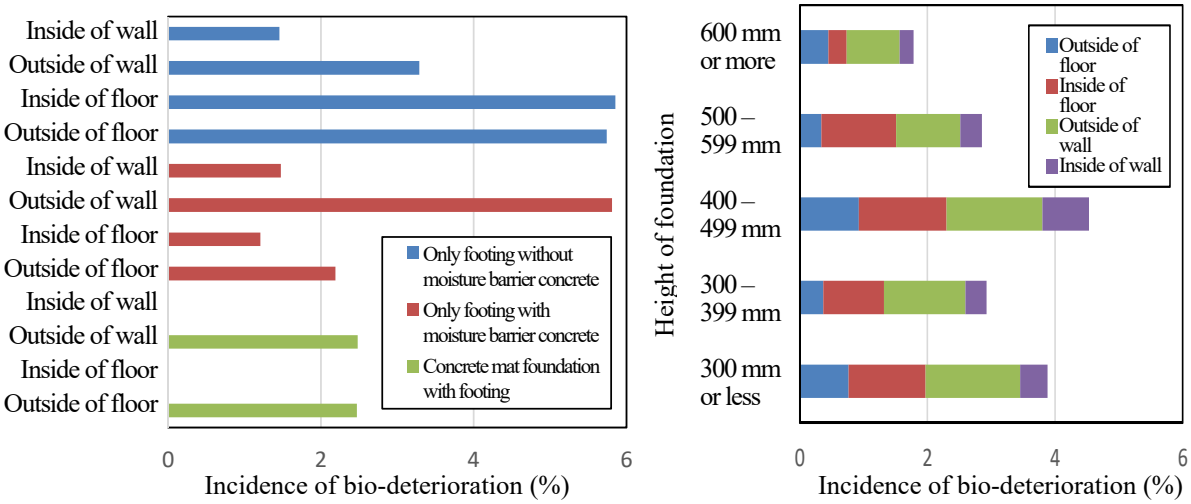

Figure 5. Relationships between the construction method (left) and height (right) of the foundation and the bio-deterioration of the structural member in the 1st story.

Figure 7 shows the effect of the eaves length on the incidence of the appearance degradation and the bio-deterioration of the structural members. The length of the eaves didn't clearly affect the incidence of the appearance degradation. However, as the length of the eaves increased, the incidence of the bio-deterioration almost decreased.

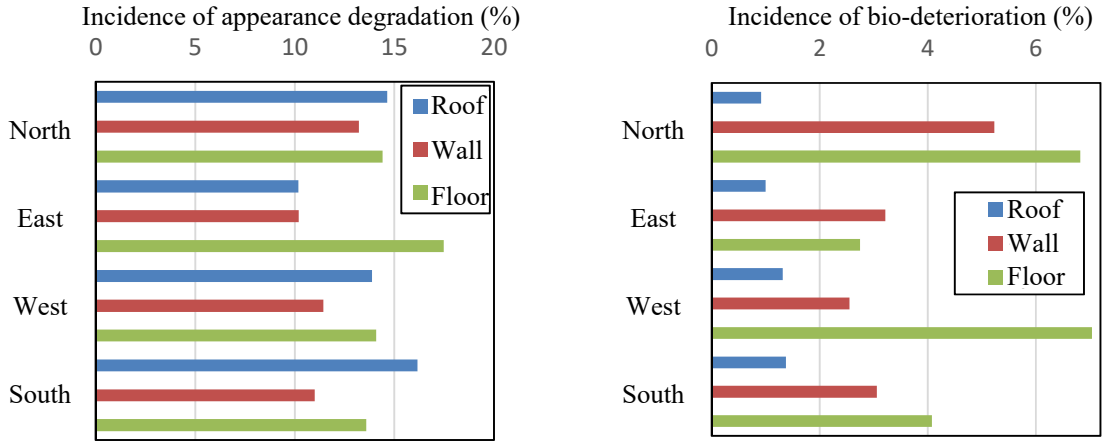

Figure 6. Relationships between the incidence of the appearance degradation (left) and the bio-deterioration (right) and the orientation of the segments.

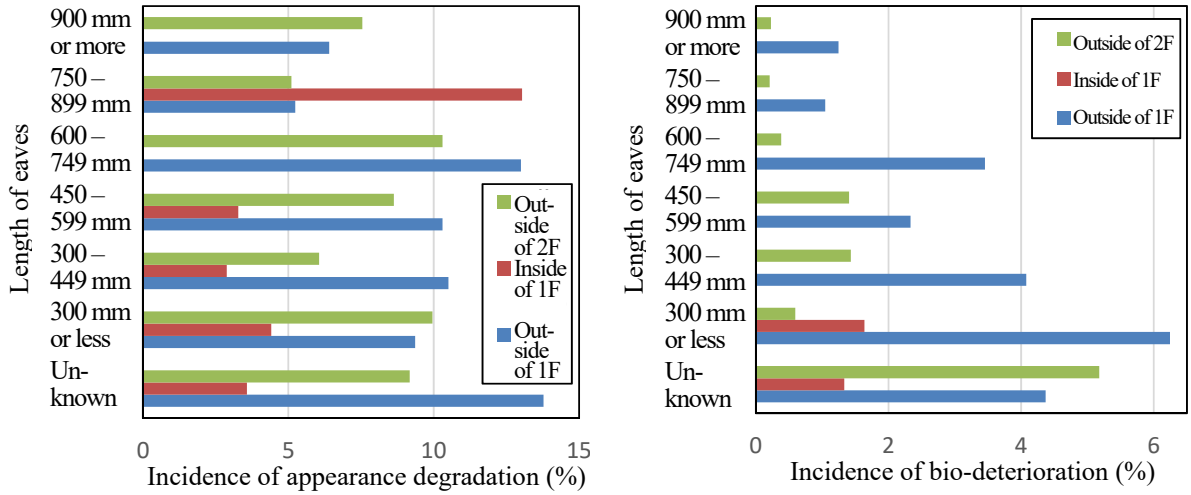

Figure 7. Relationships between the incidence of the appearance degradation (left) and the bio-deterioration (right) and the length of the eaves.

5 Difference between Appearance Degradation and Bio-Deterioration

On the most of the dealing with the used houses, only the appearance inspection is conducted. So, the result of the appearance inspection needs to match the position of the bio-deterioration. However, the occurrence of the appearance degradation and the bio-deterioration of structural members were not the same, as mentioned above. For example, there was no decayed member in the 2nd floor system near the position of the rain leak mark on the ceiling of the 1st story found by the appearance inspection, as shown in Figure 8. And, the bottom of the column decayed even though no degradation were found by the appearance inspection, as shown in Figure 9.

Figure 8. Not decayed structural member of floor system in 2F (right) in spite of the rain leak mark on the ceiling (left).

Figure 9. Decayed bottom of column (right) in spite of no degradation found by the appearance inspection.

Then, we analyzed the differences between the appearance degradation and the bio-deterioration of the structural members. The number of the segments with/without appearance degradation and those with/without the bio-deterioration of the structural member were subjected to the cross tabulation, as shown Table 3. It was clarified that there was no bio-deterioration in more than 90 % of segments out of all with the appearance degradation (*e.g.* Figure 8), and that there was the bio-deterioration in only 1.6 % of segments of all without the appearance degradation (*e.g.* Figure 9).

Table 3. Cross tabulation of the number of segments with/without the appearance degradation and those with/without the bio-deterioration of the structural members.

			Appearance degradation			
			Found		Not found	
			Number of segments	Ratio	Number of segments	Ratio
Bio-deterioration of structural member	Found	Total	484	8.5 %	**937**	**1.6 %**
		2F	88	5.1 %	**129**	**0.5 %**
		1F	396	10.0 %	**808**	**2.3 %**
	Not found	Total	**5,183**	**91.5 %**	58,416	98.4 %
		2F	**1,649**	**94.9 %**	23,698	99.5 %
		1F	**3,534**	**89.9 %**	34,718	97.7 %
Total			5,667	100 %	59,353	100 %
		2F	1,737	100 %	23,827	100 %
		1F	3,930	100 %	35,526	100 %

Next, the distribution of segments including those differences for each building part was studied, as shown in Figure 10. The incidence of the segments with the bio-deterioration in spite of the no appearance degradation in the 1st story was higher than that in the 2nd story and high in the order of the floor, the wall and the roof. From these, even if the occurrence rate of such differences depends on the incidence rate of biological deterioration, the appearance degradation, the structural members in the 1st story, especially in the floor, should be inspected or surveyed carefully, regardless of the appearance degradation. On the other hand, the distribution of the segments without the bio-deterioration in spite of the appearance degradation didn't have clear tendency for each building part and in each part the incidence was over 80%. One possible reason is that it takes time for the outside rain leak to penetrate the structural members, and the water evaporates before the water reaches the structural members.

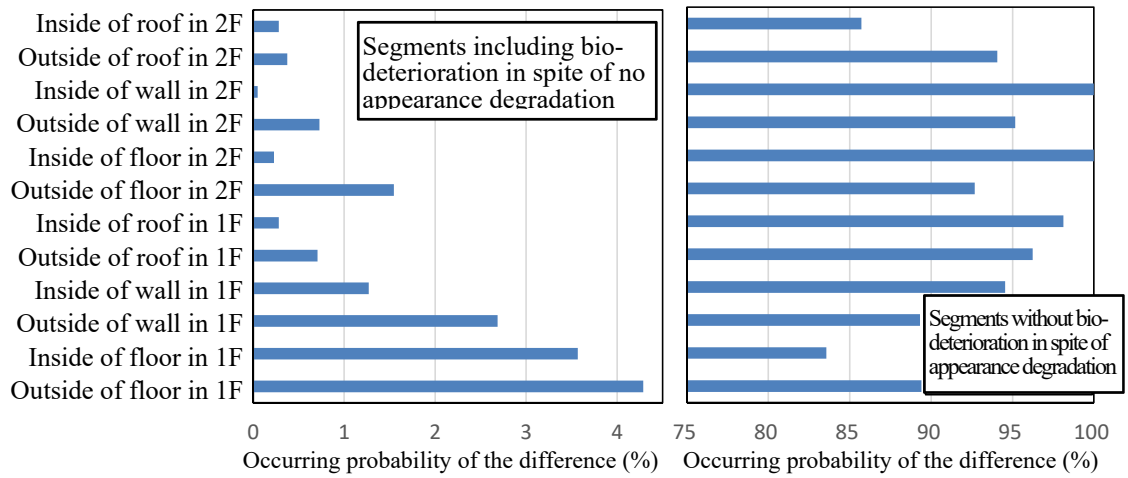

Figure 10. Distribution in each building part of the segments including the bio-deterioration in spite of no appearance degradation (left) and without the bio-deterioration in spite of appearance degradation (right).

6 Conclusions

The relationships between the appearance degradation and the actual bio-deterioration of the structural members obtained by the investigation for over 100 used wood houses were analyzed and concluded as follows:

- The bio-deterioration of the wooden structural members were found much on 1st story rather than 2nd story, in the elder building age, in case of short eaves and in case of low foundation. The issues known experience empirically were verified numerically.
- The tendency of the appearance degradation occurrence were the same as the tendency of the bio-deterioration partially, but didn't match it entirely.
- About 90 % of the portions whose interior or exterior appearance were degraded didn't have the bio-deterioration of the wooden structural member.
- The ratio of the portion with the bio-deterioration of the wooden structural member without appearance degradation were only 1.6 %.

Acknowledgements

The inspection and survey for over 100 used wood houses were conducted as a part of the R&D Project "Development on performance evaluation technologies for home inspection to reduce uncertainty of existing house" funded by The Ministry of Land, Infrastructure, Transport and Tourism (MLIT). The compilation of the inspection and survey results into the database was conducted as a part of the R&D Project of Building Research Institute "Development of durability evaluation method of buildings materials and components for strategic maintenances".

Abstract. *In a context of downturn of public investment after the financial crisis of 2007, an increase of social and economic inequality takes place in territories and cities. Socio-residential vulnerability is intensified in certain urban areas where processes of socioeconomic and socio-spatial regression are related with the resident population difficulties to access resources for the intervention and maintenance of an aging residential building stock that gradually decays. Mediterranean cities in Southern Europe and precisely the city of Barcelona face the added difficulty of counting with a residential built stock of mostly private property, accounting many situations of horizontal property in which each building is managed by a community of owners who are not necessary householders and users. The present study consists of an analysis of the relation between the state of maintenance of residential buildings and the property regime, tenancy and uses, based on the observation of common spaces and elements of a large sample of buildings located in the most vulnerable areas of the city of Barcelona. The provided results can contribute to foster improvements in future public rehabilitation programs and policies. Particularly according to local challenges to guarantee and promote durability of a mostly privately-owned residential built stock that is located in areas where socioeconomic difficulties hinder the residents' capacity to carry out rehabilitation or maintenance actions. Management of the maintenance of the residential built stock must take into account the repercussion of particularities in property regimes, tenancy and uses, especially when it refers to common spaces and elements of residential buildings.*

Keywords: *State of Maintenance, Property Regime, Form of Tenure, Building Pathology, Vulnerable Housing Stock.*

1 Introduction

In the current context of regression of public and private investment in the construction sector, the obsolescence of the existing residential building stock in areas of the city that are particularly vulnerable is a matter of high concern in the city of Barcelona (Ajuntament de Barcelona, 2016). A city where the design and provision of public policies to support maintenance and rehabilitation faces the challenge to address the predominance of a privately-owned residential building stock mostly characterized by a horizontal structure of ownership. This fact places the inhabitants, both users and owners, in a central role for the implementation of maintenance and rehabilitation actions of an aging housing stock (Cerezo, 2018).

In this context, current debates regarding the lack of maintenance and obsolescence of the existing urban fabric consider not only the decay of the built environment at different scales but also the increasing risk of social and residential exclusion affecting its inhabitants. The distinction between physical factors, related to the building stock material and technical processes, and behavioural factors, related to human actions, possibilities and struggles, is at the same time explanatory of the causes and descriptive of the effects of the progressive deprivation of the urban existing tissue. (Thomsen *et al*. 2015 and 2017).

The present paper provides a cross-analysis of quantitative and qualitative indicators of the state of maintenance of a large sample of residential buildings located in five of the most vulnerable neighbourhoods of the city of Barcelona, in relation to the property regime, tenancy and risk of residential exclusion as well as occupancy and uses within the building. This contribution can provide tools to consider the impact of this socioeconomic aspects on the issue of obsolescence and it aligns with the aim of the Council of Barcelona to foster the design of specific integral public rehabilitation programs that can support the most vulnerable tenants and householders to access maintenance and improvement actions at present and in long term. (Diari Oficial de la Generalitat, 2018).

2 Objectives

The main objectives of this research are:

- To describe the building stock in different vulnerable neighbourhoods according to the type of observed damages and the state of maintenance and conservation.
- To analyse and detect the impact of socioeconomic issues such as property regime, tenancy and risk of residential exclusion, forms of occupancy and uses in relation to the state of maintenance and conservation of the residential building stock.

3 Methodology

3.1 Sample of Study and Data Collection

The main sources for this paper are, firstly, a study on the detection of the most vulnerable areas of the city of Barcelona (Garcia-Almriall *et al*., 2017), and the following study on the prediagnosis of the state of conservation of the building stock in 16 vulnerable neighbourhoods (Cornadó *et al*., 2017).

This paper presents a cross-analysis of data of a total sample of 2434 buildings located in five of the previously studied vulnerable neighbourhoods that are selected for their very diverse characteristics. El Raval (1119/1685 analysed buildings) and La Barceloneta (737/1074 buildings) are central neighbourhoods with a historic urban tissue with mainly constructions of the XIX century. Ciutat Meridiana (54/78 buildings) and El Besòs (188/281 buildings) are peripheric neighbourhoods in the north and south of river Besòs and consist of a modern urban tissue with mainly open block and tower constructions built between 1950 and 1975. Trinitat Vella (345/592 buildings) is also a peripheric neighbourhood built in the same period, but its urban tissue consists of attached constructions between party walls conforming a closed urban block (Figure 1).

Figure 1. Different type of buildings of the five analysed neighbourhoods. From left to right: El Raval, La Barceloneta, Ciutat Meridiana, El Besòs and Trinitat Vella.

3.2 Data Analysis

3.2.1 Building pathology: type of observed damages

Firstly, this paper provides an analysis of a series of observed damages according to their relevance on the studied areas. The available data was obtained during a fieldwork campaign (Cornadó *et al*., 2017) (Figure 2). The described damages are: cracks in bearing walls, façade buckling, risk of material detachment in facades and roofs, dampness (rising damp, moisture and rainwater leaks), degraded windows and woodwork, rusty metal elements, cracks in the facing, stains and dirt.

Figure 2. Fieldwork images of observed damages.

3.2.2 State of maintenance and conservation in relation to property, tenancy and uses

Secondly, this paper presents qualitative and quantitative indicators to statistically analyse the state of maintenance and conservation of the building stock: a qualitative indicator that describes the need of rehabilitation of the building stock obtained in a campaign of fieldwork (Cornadó et al., 2017) (Figure 3), a quantitative indicator of the superposition of the previously described damages within one single building (Cornadó et al., 2017), and finally a quantitative indicator of the existence of administrative requirements and orders of conservation provided by the Council of Barcelona (Garcia-Almirall et al., 2017).

Figure 3. Fieldwork images of buildings with different results the need of rehabilitation indicator.

Results from the three indicators are classified according to four levels in relation to the state of maintenance and conservation of the building stock (Table 1), and they are further analysed according to socioeconomic variables related with property, tenancy and uses (Table 2):

Table 1. Qualitative and quantitative indicators of the state of maintenance and conservation.

Indicators	Level 1	Level 2	Level 3	Level 4
- Need of rehabilitation	High	Regular	Low	Very low
- Superposition of damages	7-9	4-6	1-3	0
- Administrative requirements	More than 2	2	1 (interior)	1 (façade)
Sate of maintenance	**Very low**	**Low**	**Regular**	**Adequate**

Table 2. Socioecnomic variables, data and sources.

Variables	Data	Source
- Property regime	· Horizontal Property · Vertical Property: legal entity or natural person	Garcia-Almirall, 2017 Statistical Database
- Risk of residential exclusion	· Application for public rental aid · Number of evictions	Garcia-Almirall, 2017 Statistical Database
- Tenancy and uses of the building	· Blocked and empty premises · Empty premises in ground floors · Private uses in ground floors · Public uses in ground floors	Cornadó *et al*., 2017 Fieldwork

4 Results

4.1 Observed Damages in Relation to the State of Maintenance of the Building Stock

The graphic in Figure 4 presents the distribution and relevance of the different observed damages in the total sample of studied buildings according to each neighbourhood:

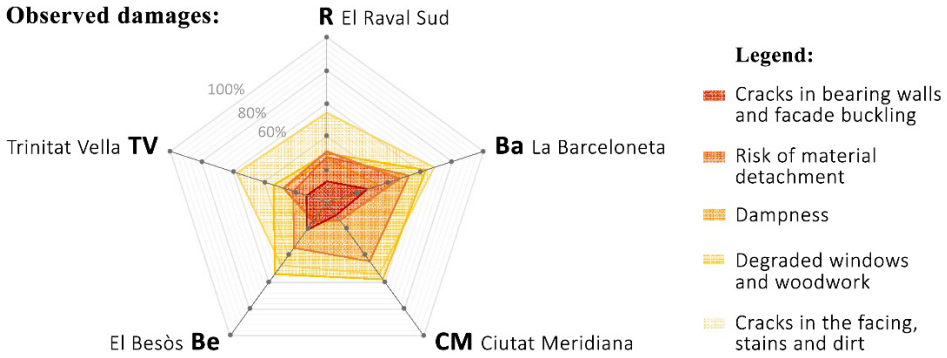

Figure 4. Proportion and distribution of observed damages.

The most abundant observed damages are those that are strictly related with a lack of ordinary and extraordinary maintenance actions: cracks in the facing, stains and dirt, as well as damages in windows and woodwork and carpentries. Their proportion according to neighbourhood varies between 55-68%. The proportion of cases with dampness is still quite relevant and a little bit more variable among neighbourhoods: between 50% in La Barceloneta

and Ciutat Meridiana, 30% in El Besòs and El Raval, and 20% in Trinitat Vella. There is a considerable number of cases with risk of material detachment, particularly in La Barceloneta (near the 50%), and still importantly in El Raval and Trinitat Vella (around the 30%), while it is very low in El Besòs and Ciutat Meridiana (15%). Finally, the proportion of cases presenting damages of mechanic structural origin such as cracks in the bearing walls is a lot lower and it presents high variability from La Barceloneta and el Besòs, the locations with a highest percentage (25%), to Ciutat Meridiana (10%). The graphic in Figure 5 presents the distribution of three groups of indicators that are classified in four levels in order to assess the state of maintenance of the whole sample:

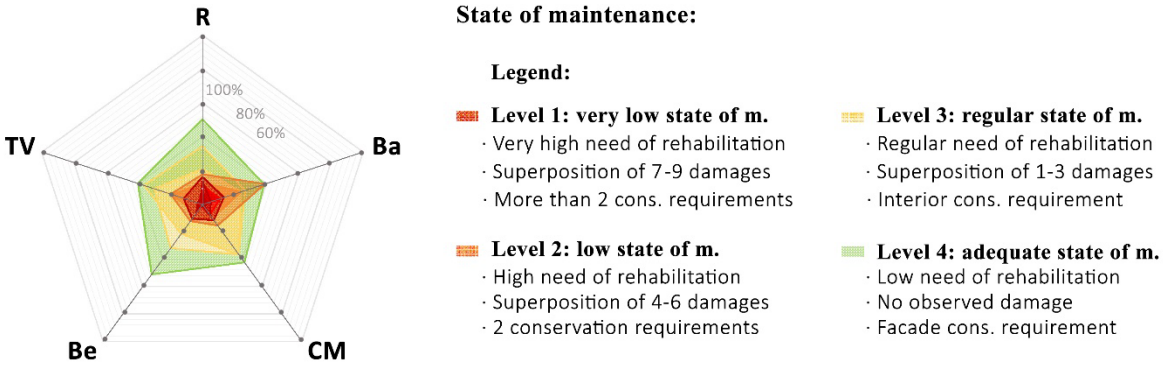

Figure 5. Proportion and distribution of four levels in relation to the state of maintenance.

The highest proportion of cases (between 40-50%) correspond to Level 4 and thus present an adequate state of maintenance and conservation, although this proportion is slightly lower in La Barceloneta, Ciutat Meridiana and Trinitat Vella. The proportion of cases included in Level 3, if we consider both the quantitative and qualitative indicators, is rather homogeneous around the 40% with slightly less cases in La Barceloneta. Instead, La Barceloneta presents a peak in the proportion of cases included in Level 2, with a 40% of cases that present a low state of maintenance according to the quantitative indicator. A proportion that is qualitatively less important but still accentuated: 25% of cases in Level 2 in La Barceloneta in comparison to a 18% in Trinitat Vella and between 7-13% in the rest of areas. Finally, the qualitative indicator provides an almost homogeneous distribution of cases included in Level 1 between 10% in El Besòs to 16% in El Raval, including cases with a very poor state of conservation. Even though the proportions of administrative requirements are very low (mostly under 10%), there is a 16% of cases with administrative requirements for interior conservation in El Raval.

4.2 Building Pathology and State of Maintenance in Relation to the Property Regimes

The cross-analysis of the distribution of damages and the indicators of the state of maintenance according to different property regimes is presented in Figure 6. The proportion of observed damages within cases of horizontal property is slightly higher if compared to the results of the full sample in Figure 4, and clearly higher if compared to the results for cases with a vertical property regime. Besides, there is a clear decrease of the proportion of cases presenting damages of mechanic structural origin as well as risk of material detachment for vertical properties. More particularly, vertical juridical properties clearly present lower percentages of all types of damages in comparison to vertical physical properties.

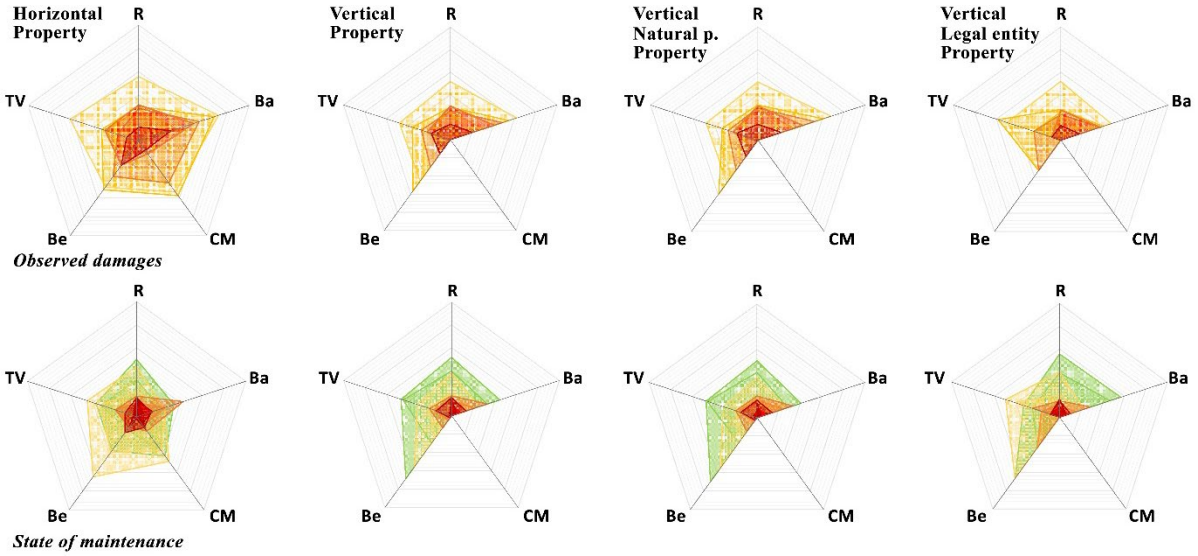

Figure 6. Proportion of observed damages and the state of maintenance in relation to property regimes.

Regarding quantitative and qualitative indicators of the state of maintenance and conservation of the building stock, similar results can be observed. The proportion of cases presenting an adequate state (Level 4) is clearly inferior for horizontal properties. Vertical properties include a much higher percentage of buildings in an adequate state, particularly in El Besòs, and most specifically in the case of vertical properties owned by of La Barceloneta. Instead, vertical properties owned by natural persons in Trinitat Vella concentrate the major number of cases with an adequate state. Regarding the poorest state of maintenance and conservation, the proportion of cases is more elevate for horizontal properties in all studied neighbourhoods and it is particularly lower in the case of vertical juridical properties in la Barceloneta and El Besòs.

4.3 Building Pathology and State of Maintenance in Relation to Tenancy and Risk of Residential Exclusion

In comparison to the results presented in Figures 4 and 5, Figure 7 clearly shows how the proportion of observed damages and the proportion of cases with a lower state of maintenance is much higher for those buildings in which the resident community has faced eviction processes in the last years. Results according to buildings in which many residents apply for rental social aid are very similar. This observation is particularly clear in La Barceloneta, El Besòs and Trinitat Vella, while it is also significant in El Raval and Ciutat Meridiana.

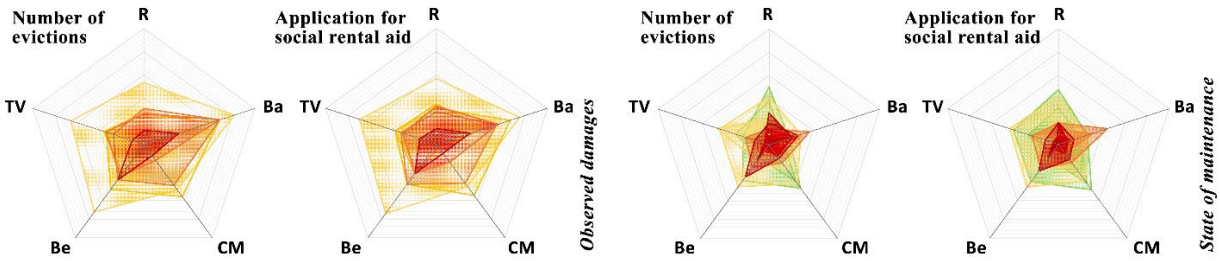

Figure 7. Proportion of observed damages and state of conservation according to risk of residential exclusion.

4.4 Building Pathology and State of Maintenance According to Occupancy and Uses of Residential and Ground Floors

The results presented in Figure 8 highlight the very high impact of the existence of blocked unused spaces both in residential and ground floors in relation to the observation of damages and the very poor state of conservation for all coincident cases. Remarkably, empty premises in ground floors present a similar correlation, particularly in Ciutat Meridiana and El Besòs.

Additionally, it is interesting to consider the impact of a different use of ground floors, be it of private access (housing, garage or storage) or of public access (commercial and services). In the case of El Raval, the percentage of cases with a very low state of maintenance is higher in buildings with housing or storage uses on the ground floor. Nevertheless, both the proportion of observed damages and of buildings with a very low state of maintenance tend to increase in buildings with commercial and services in the ground floor, with exceptions in El Besòs where the proportion of some types of damages decreases significantly while there is a higher proportion of buildings in an adequate state.

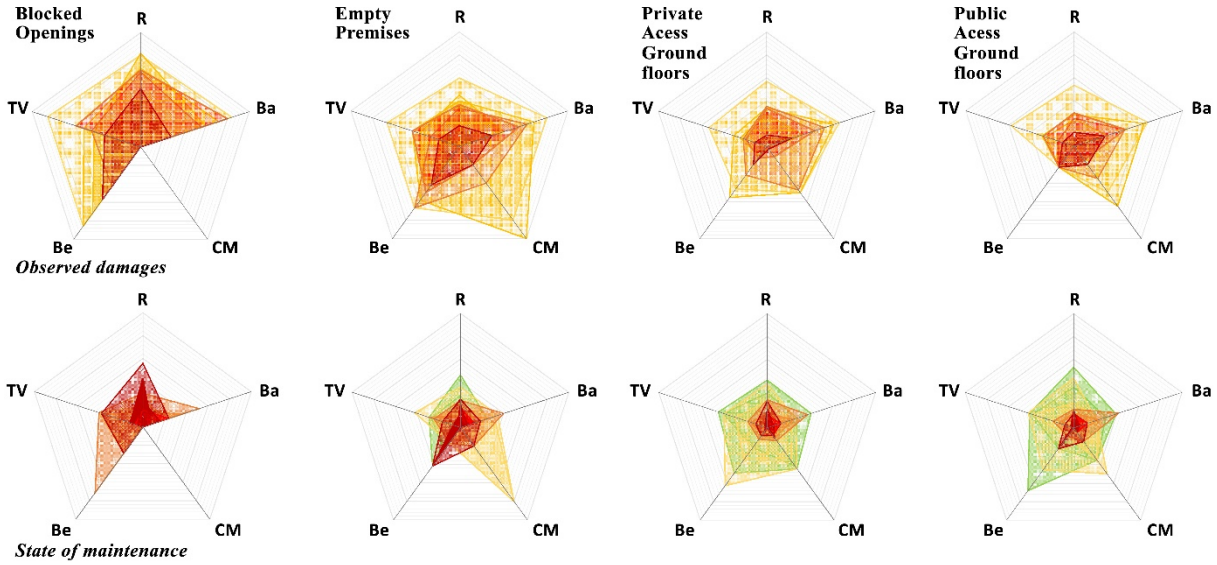

Figure 8. Proportion and distribution of observed damages and four levels of the state of conservation according to the occupancy and uses of residential and ground floors.

5 Conclusions

First of all, there is a clear relation between the abundance of most observed damages in common elements and spaces of buildings and lack of ordinary or extraordinary maintenance actions. Results regarding the qualitative indicators of the state of maintenance and conservation also confirm the existence of a low percentage of buildings that need an urgent intervention of rehabilitation, while they highlight a considerable proportion of cases in which the state of maintenance is not yet adequate.

In this context, the higher proportion of observed damages and lower state of maintenance of privately-owned buildings with a horizontal structure of property confirms the consequences of what can be pointed as an added difficulty hindering the implementation of maintenance

actions. The particularly lower proportions of damages and the increase of the adequate states of maintenance for the specific case of vertical juridical property in La Barceloneta and El Raval can be explained by the speculative pressure in the historic central areas, where the acquisition and renovation of entire buildings is frequent.

Secondly, the clear impact of socioeconomic variables that are closely related to the risk of residential exclusion in communities, confirms how socioeconomic difficulties and residential instability are also explanatory factors of the gradual decay of the residential building stock.

Finally, the high correlation between the existence of empty premises both in residential and ground floors and the accumulation of severe damages and a poor state of maintenance explains the high impact of a usually prolonged lack of activity. Besides, in most studied neighbourhoods where the common ground floor activity is housing, buildings with commercial ground floors present a lower state of maintenance. While in the case of El Raval, in which the common ground floor activity is commercial, the presence of other activities of private access such as housing, provides a sign of deprivation. The correlation between ground floor uses and state of maintenance must be interpreted according to the location and urban activities of each site.

Results from this paper confirm that the design and management of public programs aiming at improving the state of maintenance and conservation of the residential building stock must adapt and consider seriously socioeconomic aspects related with property, tenancy, occupancy and uses, particularly in contexts where the risks of socioresidential exclusion are high.

Statistical Analysis on Belgian Building Defects

Jasmijn De Vos, Anke Blommaert and Nathan Van Den Bossche

Ghent University, Faculty of Engineering and Architecture, Building Physics Group. Sint Pietersnieuwstraat 41 B4, 9000 Ghent, Belgium. *Nathan.vandenbossche@ugent.be

Abstract. *The lack of systematization in the collection of building defects leads to a wide range of data that is not used to its full potential. Unfortunately, this opportunity is missed since lessons could be drawn from analyzing this data by systematically mapping and investigating building defects. This paper presents the results of a statistical analysis on 27074 cases of building defects provided by a Belgian insurance company, ranging from 1991 up to 2019. This analysis focuses on the types of damage, the occurrence in relation to the construction time and the typology of the claims. Spearman correlation tests, X^2 tests, and Kruskal-Wallis tests are performed to assess the significance of correlations. Moisture problems constitute 49% of all technical defects, followed by structural issues (19%), and cracking (17%). Within the category of moisture problems, the roof is the dominant location for problems to occur, followed by basements, façades, windows, and rising damp. 50% of the judicial cases were closed after 3 years, whereas cases without lawsuit are typically settled after 1-2 years.*

Keywords: *Building Defects, Pathology, Catalogue, Statistical Analysis, Insurance Company.*

1 Introduction

Currently, an immense amount of information is available about building defects in the Belgian construction industry. Details about the causes, the damage caused by the defects, the associated repair cost, the liability, etc. can be found in reports of insurance companies, law offices and expertise bureaus, since they are appointed to deal with damage claims. However, the existing information is not fully used to prevent similar mistakes and to limit the number of damage claims in the future, since there is no harmonized data collection, no classification, no structure and no consent in processing the data.

In different countries, initiatives have been taken to create databases on building pathologies. 'Système de collecte des désordres' (France), 'Danish Building Defects Fund' (Denmark), 'Defect Action Sheet' (United Kingdom), 'Patorreb' (Portugal) and 'Learning from Mistakes' (Italy) are only a few initiatives where countries create databases on building pathologies. The CIB (International Council for Research and Innovation in Building and Construction) is a worldwide network concerned with the exchange of information to learn from past and current building pathologies. It achieves what the previously mentioned countries do at national level, on an international level.

Statistical analysis of these data may reveal unidentified patterns and provide insights on the dominant failures in terms of building component, type of damage, cause, time of occurrence, geographical location, building exposure, cost, and the like. Consequently, these insights may help in identifying aspects that need attention, additional guidelines, quality assurance protocols, or prevention, in order to reduce the failure cost in the building industry. This is of great importance since building defects often lead to discussions, and generate high costs, time

delay, reputation damage, litigations and decreased sustainability.

For property developers, architects and construction managers, the results of the analysis may provide a series of lessons on the critical aspects in order to minimize building defects. The insights derived from the analysis can be used by building professionals, leading to innovative ideas regarding materials, design concepts and construction methods. As a consequence, the quality of the buildings can be enhanced. Higher quality implies better durability, longer service life, lower life cycle cost, lower waste production, and higher sustainability.

2 Methodology

A qualitative and representative dataset is a prerequisite for statistical analysis to derive conclusions that can be extrapolated to the Belgian building industry. The analysis presented in this paper was based on the database of the largest Belgian insurance company in the building industry (containing 27 074 documented cases), representing the larger share of architects and engineering offices in that field.

Firstly, data are extracted from the insurance company's database, recoded and cleaned. The cleaning of the data is not discussed in this paper, but proved to be essential for the quality of the final dataset and analysis. Note that no statistical data-imputation for missing fields was done. A second step concerns the selection of the statistical tests and their graphical representation in the search for statistical correlations, associations and differences. Because of the size of the database (26 392 cases remaining after cleaning the database), it could be assumed that the variables are normally distributed and parametric tests can be performed (based on the Central Limit Theorem (CLT)). However, since the database contains a high number of outliers and extreme values and some combinations in the subdivisions contain a limited number of cases, the CLT cannot be applied for a more in-depth analysis. Therefore, non-parametric statistical testing is executed.

The following three tests are used: Spearman correlation, X^2 and Kruskal-Wallis. The focus is on the detection of correlations, trends and differences for the level of occurrence, cost and time. The trends and statistical differences are discussed and interpreted in chapter 4, Results. Finally, the last chapter provides some conclusions and future perspectives.

3 The Database

The database from the insurance company contains 27 074 documented cases, which have been processed and filed by either jurists or engineers between 1991 and 2019 working at the company. Since jurists are not trained in building science, there is perhaps a possibility that some damage cases are incorrectly diagnosed or documented in the database. However, for technical more complex cases a construction expert is always consulted, and given that this paper focusses mainly on the overall analysis, it is considered that this effect is negligible for the analysis presented here.

It must be considered that unconscious selection bias is present, as the insurance company mainly focuses on the insurance of the professional liability of architects and contractors. Hence, failures in which an insurance company is not involved (*e.g.* contractor makes a mistake

and repairs it) are not covered here. By consequence, the analysis does not provide insights into the complete overall fault cost or construction failures. Nonetheless, this database is a relevant sample of the real 'population' of construction failures, as it can be assumed that the more complex cases are covered, and as well the important failures in terms of associated costs.

4 Results

4.1 Damage Categories

Using descriptive statistics, the occurrence hierarchy of the nine categories of damage is shown in figure 1.

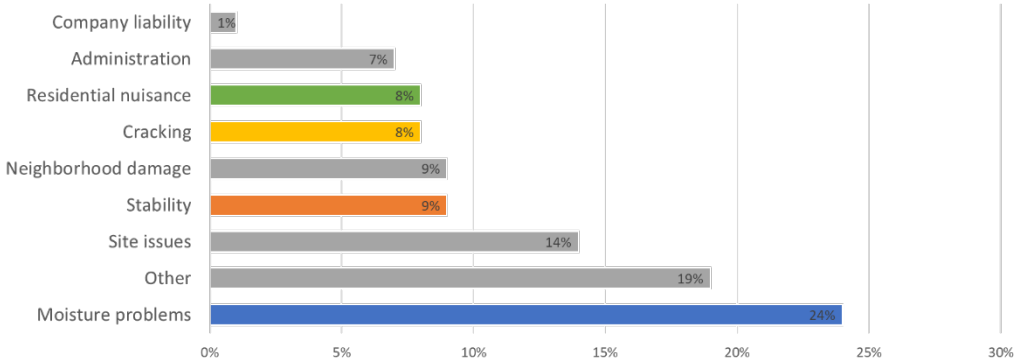

Figure 1. Distribution of the 9 categories of damage for 26 392 cases.

Five of the nine categories do not involve building defects and are therefore not further discussed. The category 'other' will not be taken into account even though this category also contains damages due to building defects. Due to the size of this category, we cannot analyze each case individually. Thus this category is eliminated to ensure homogeneity. Four categories remain: moisture problems, stability, cracking and residential nuisance (figure 2), containing 13 068 cases. Most building related damage claims are caused by moisture problems (49%). Cracking, residential nuisance and stability have a similarly smaller share of 16-19%.

The distribution of the damage types within the different categories is also shown in figure 2. For moisture problems, the two mayor problems are concerning water infiltration in the roof (24%) and the basement (21%), while all other problems only occur less than 10% of the time. It must be noted that the subcategories contain labels according to location and type. This makes it unclear how, for example, 'condensation problems in the roof' should be categorized.

For stability, the roof (27%) is the most affected apart from the 49% of cases which is categorized as "General stability problems". These general stability problems regard the general load-bearing structures like walls, beams and columns with the exclusion of the separate categories.

For cracking, the lack of a detailed categorization obstructs the opportunity for a more in-depth analysis. Cracks could have been formed due to stability or moisture problems.

For residential nuisance, the damage is the most often categorized as sewage problems (22%), defective material (12%), heating problems (11%) and finishing (11%).

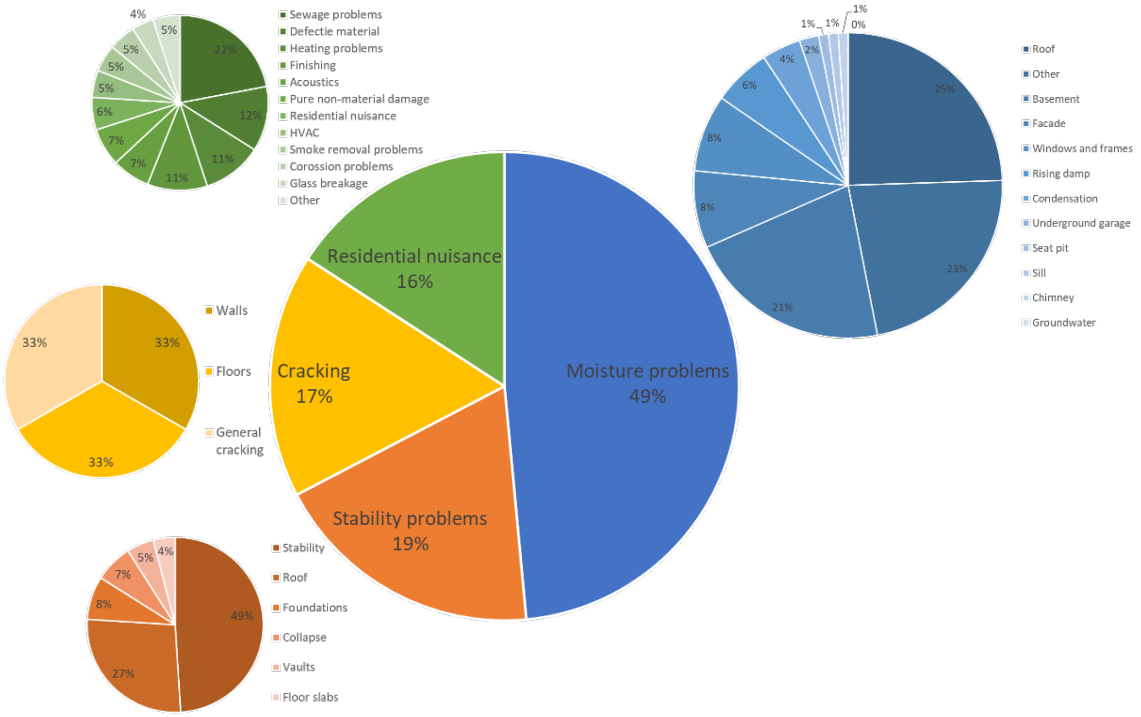

Figure 2. 4 categories of construction damage and their respective subdivisions for 13 068 cases.

4.2 Temporal Evolution of Claim Distribution

The number of claims evolves over time. Between 1991 and 2003, there is an almost constant number of claims, then the number starts to increase until 2010 when it slowly decreases again.

The reason why numbers start to increase in 2003 is that the insurance took over a competitor in that year. The decrease in claims starts a few years after the financial crisis in 2008, which of course had an impact on the construction market. In addition, in 2008, a new law was also introduced regarding the compensation of court costs: the losing party must pay the winning party a fee to compensate juridical costs. In 2010, the insurance company also decided to introduce prevention measures to cover contract initiations and contract problems and starts to provide advice and assistance to the insured professionals when a rise of the imminent defects can be noticed, which also might partially explain the decrease over the last decade. However, it can be concluded that the overall number of cases in the database is affected by the company structure, the variable market share over time, the work volume in the construction industry (business cycle), evolution of construction standards and guidelines, prevention measures, and the like. Although it is generally acknowledged that the introduction of the EPBD in 2006 has had a clear impact on the building sector and changed building component compositions drastically, it is yet unclear to what extent that change has resulted in an associated rise (learning curve for new methods) or decline (more quality control and larger buffers) in failures.

When we look at the distribution of the types of damage per year, it is observed that the percentages fluctuate over time. From 2001, an increase of ‘neighborhood damage’, is detected.

The latest ten years a small decrease in the number of 'site issues' (measurement and calculation errors, delivery problems, delays, budget exceedance,…) is noticed (figure 3).

When only the four main types of damage are considered (moisture problems, stability, cracking and residential nuisance), we see that 'moisture problems' remains the most occurring damage type.

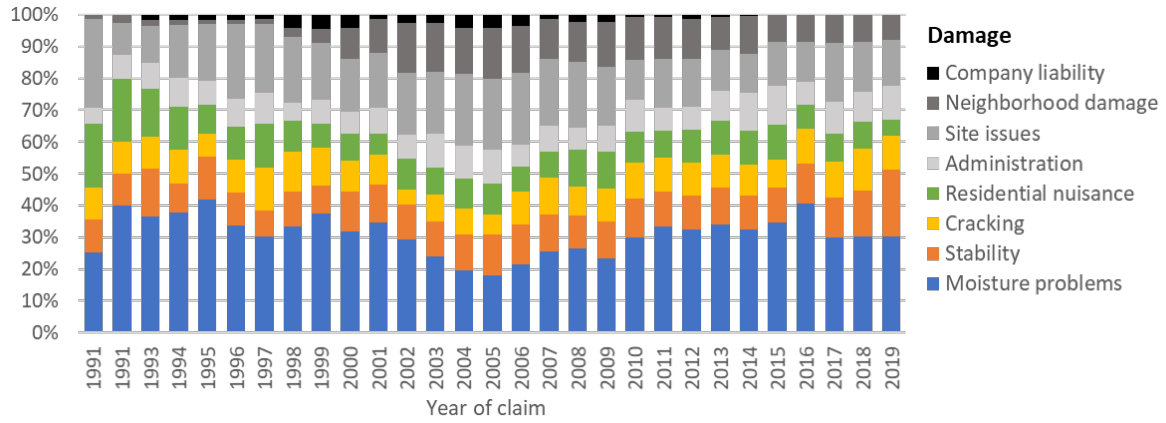

Figure 3. Evolution of the distribution of types of damage over time.

4.3 Moment of Occurrence in the Building Process

Damage claims can occur at different times. The milestones considered here are the provisional acceptance (PA), the final acceptance (FA), the fifth year after the final acceptance and the tenth year after the final acceptance (the end of the ten-year liability period).

In figure 4 it is observed that in 47% of the cases, damage occurs before the provisional acceptance and in 28% of the cases, damage occurs in the five years following the final acceptance. It makes sense that there are almost no damages found after more than 10 years. These cases are less relevant for the insurance company because there is only a 10 year liability. There is only a 1 year difference between PA and FA, explaining the lower percentage (13%) in this interval.

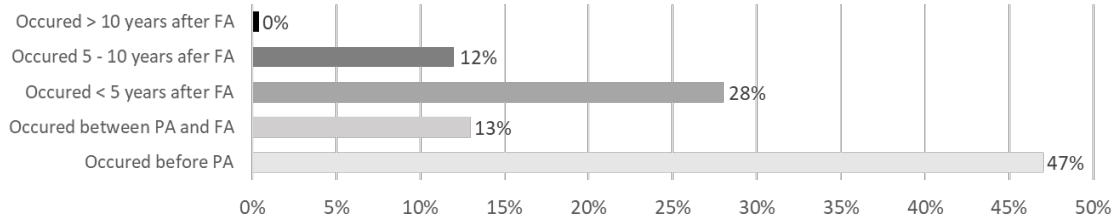

Figure 4. Bar chart: Distribution time (delivery).

The X^2 - test for 'Damage' and 'Time delivery' indicates various significances. Figure 5 shows that stability problems mainly arise even before the final acceptance has taken place and that moisture problems mainly occur within five years after the final acceptance. Only 15% - 25% of the cases are reported between five and ten years after the final acceptance. Therefore,

from these data, it can be concluded that stability problems occur early in the construction process and that cracking and moisture problems arise later.

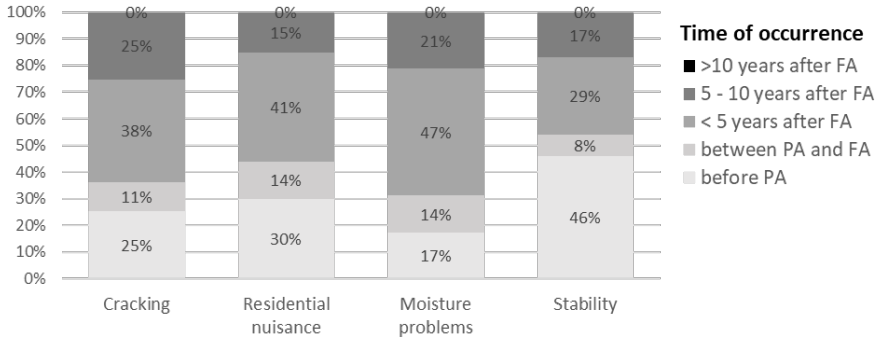

Figure 5. Analysis of time of occurrence in the building process (delivery) for the 4 main categories

Next, the four main categories are considered separately and conclusions are drawn for aspects for which relevant significances were found. No extreme exceptions are found for moisture problems. Water infiltration of roofs and basements occurs in more than 30% of the cases before the final acceptance. At first sight this appears to be in contrast to the general conclusion above on the occurrence of moisture problems. However, it should be noted that these building components typically adopt a perfect barrier watertightness concept: flat roofs and basements do not incorporate drainage or buffering systems which may result in a quick appearance of building defects. Next to that, both building components are subjected to water loads irrespective of co-occurrence of wind and rain events (resulting in wind driven rain loads on buildings). Although cathedral roofs typically include drainage systems, moisture mass buffering is not present. Rising damp occurs in 30% of the cases between five and ten years after delivery, while for the other moisture problems this is only around 20%-25%. Thus rising damp is a phenomenon that takes more time to develop, while water infiltration to roofs and basements occurs rather quickly.

For stability, it is observed that for the subcategories collapses, stability problems of foundations, and roofs, more than 50% occurs before final acceptance. On the other hand, for the stability of vaults and floor slabs this is between five and ten years after final acceptance. Collapses are probably mainly attributed to demolition and renovation works.

It seems remarkable that residential nuisance is already reported before the provisional acceptance (figure 5). However, this result can be explained by looking more in detail to the specifications of residential nuisance (figure 6). Damage related to finishing, color, aesthetics and pure non-material damage occur mainly before the provisional acceptance. These defects are detected when the material is supplied or when the construction is still in progress. As expected, corrosion and moss growth occur later in time.

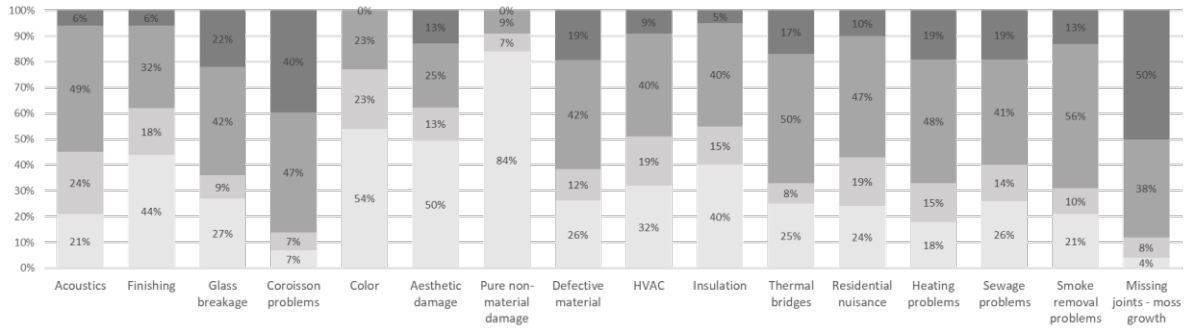

Figure 6. Specification residential nuisance versus time of occurrence (delivery)

4.4 Damage and Type of Settlement

The type of settlement reveals information on the complexity. There are three types of settlement: Amicable settlements without appointment of experts, amicable settlements with appointment of experts and juridical files with appointment of lawyers. An amicable settlement of a dispute is a settlement that satisfies both the parties. Juridical files are generally speaking more difficult. The different categories all have about the same amount of judicial files.

Therefore, the X^2 - test for 'Damage' and 'Type of settlement' indicates that specific types of damage are more complicated than others. Since stability is more complex, it is less classified as amicable settlements without the appointment of experts (only 18% of cases in this category) than residential nuisance (32%), moisture problems (27%) or cracking (23%).

4.5 Time of Occurrence and Type of Settlement

The X^2 - test between 'Time delivery' and 'Type of settlement' shows a significant difference. Damages occurring in the tenth year after the acceptance are mainly judicial files (56%) or amicable settlements without appointment of experts (38%). The type amicable settlements with appointment of experts is almost completely missing. This can be explained by the tight timeframe for lodging the complaint: the ten-year liability is coming to an end. Therefore, if necessary, it is classified as judicial, but if it can quickly be solved in an easy way, it is classified as amicable settlement without appointment of experts.

5 Conclusions

The database analyzed here comprises four main types of damage related to building defects: moisture problems, stability, cracking and residential nuisance. It was concluded that moisture problems, mainly water infiltration and rising damp, account for about half of the building defects. Even though the number of damage claims evolves over time, water infiltration remains the prominent claim. It must be noted that there are a lot of inconsistencies regarding the categorization of the cases. The subcategories, for instance, contain labels according to location and type. This makes it unclear how certain cases should be categorized.

Some types of damage are more complex than others. Stability is more complex since they are less classified as amicable settlements without the appointment of experts than residential

nuisance, moisture problems or cracking.

Most problems occur before the final acceptance. When we look at each type of damage individually, we notice that each type of damage occurs at different times. Moisture problems, cracking and residential nuisance occur later in time, compared to stability problems. Within the cases considering stability, especially collapses or damage arising at the foundations are the ones to occur before the provisional acceptance. For the cases considering moisture problems, rising damp occurs later than all other types of water damage.

For damages occurring in the tenth year after the acceptance, there are almost no amicable settlements with appointment of experts. This can be explained due to the tight timeframe for lodging the complaint, the ten-year liability is coming to an end. Therefore, if necessary, the complaint is classified as judicial, but if it can be easily solved, it is classified as amicable settlement without appointment of experts.

Acknowledgements

The authors would like to thank the insurance company for the access to the database, information and insights, and fruitful collaboration.

Abstract. *The significant growth of the building stock in the 20th century allied to the low rate of building retrofitting over the last years results in the current low conservation level of the Portuguese building stock. The building natural aging, associated with the lack of planned maintenance actions and the climate changes consequences contributed to accelerating the degradation of building materials in the existing buildings, leading to a poor conservation of Portuguese public building stock. So, to extend the service life of the materials, the application of appropriate maintenance actions is imperative. This work aims to assess the building performance and to prioritize the maintenance actions employing Key Performance Indicators using Building Information Modelling (BIM) as a supporting tool for building condition assessment and maintenance management. To achieve these goals the following methodology was applied to a case study: 1)Building Information Collection; 2) Building Life Cycle Cost Estimation, and 3) Automated calculation of Building Performance Indicator supported by BIM, using Revit software and Dynamo programming. The application of this maintenance management automated strategy shows the importance of BIM in Facility Management; permits the model's permanent update of information decreasing the probability of information loss and the consequent investment in data collection, and has high potential to prioritise the building maintenance actions, extending the materials service life and building durability.*

Keywords: *Building Condition Assessment (BCA), Key Performance Indicators (KPIs), Building Service Life, Durability, Dynamo, Building Information Modelling (BIM).*

1 Introduction

To slow down the buildings` degradation processes and consequently the increase of the materials lifetime is essential to implement suitable, cost-benefit maintenance actions through cost and time effective maintenance management systems. A consistent building performance evaluation taking advantages of quantifiable tools to evaluate Building Condition Assessment (BCA) is crucial to meet an efficient and sustainable maintenance strategy in the scope of the Facility Management (FM) (Abbot *et al.,* 2007; Marmo *et al.,* 2019).Therefore, the main objective of this work is to assess the building performance by the integration of KPIs in a BIM software - the Autodesk Revit - and through this software to prioritize the maintenance actions in a practical and automated way. These KPIs were applied to the building of the Civil

Engineering Department of the University of Aveiro to support FM systems and maintenance planning. For this purpose, the research pursued a methodology with the following steps: 1) Building information collection; 2) Building Life Cycle Cost estimation; 3) Automated calculation of BPI supported by BIM, using Revit software and Dynamo programming. This study contributes to optimize the maintenance management of the Aveiro's University campus and to provide an easy instrument to prioritize maintenance, based on existing and reliable performance metrics and leveraging new technologies like BIM. In the next sections, some important concepts are approached to understand the methodology applied that is presented and validated by applying them to a case study. In the end the results are presented and discussed.

2 Conceptual Review

According to Crawford (2011) and Ngwepe *et al.* (2015) there are six building life cycle stages, consuming the last three stages, namely the construction, operation and demolition, approximately 15% of world's freshwater resources, 36% of the world's energy; and produce about 40% of the world's greenhouse gas emissions (Ngwepe, 2015; Maslesa *et al.,* 2018; IEA, 2020). As almost all the buildings have a lifespan of over 50 years the operation stage is the longest, during which the performance of buildings relies on the proper operation and maintenance (O&M) (Lai *et al.*, 2007). For this purpose, the continuous monitoring at regular intervals is needed to identify indicators that precede failures and to perform necessary maintenance work at the right time. So, the so-called predictive maintenance starts with the BCA, which can be monitored by parameters that indicate the performance level, detecting early signs of failure leading to the beginning of maintenance procedures (Selcuk, 2017; Bortolini; *et al.*, 2016).

2.1 Building Condition Assessment

Building Condition Assessment (BCA) should be the basis for management and maintenance decisions in the built environment towards sustainable construction (Abbot *et al.,* 2007). BCA techniques have been studied and should be applied to measure assets performances during their service life, to consequently maintain them most effectively (CEN/ TS 17385:2019; Dejaco *et al.,* 2017; Wahida *et al*., 2012). According to Dejaco *et al.* (2017) and Marmo *et al.* (2019) to a BCA successfully oriented, the KPIs are the best way to measure the buildings' performance allowing to have accessible and useful information about buildings and their parts.

2.2 Key Performance Indicators (KPIs)

KPIs system aims to provide a measure of current performance and a clear statement of performance targets, as well as an evaluation of performance progress (Maslesa *et al*., 2018).

Building owners claim KPIs, mainly to understand the conditions of their assets and consequently, to allocate a suitable budget for maintenance or refurbishment and support their maintenance choices. Accordingly, the importance of measuring building performance through KPIs have been emphasized (Marmo *et al.,* 2019). Nevertheless, these methodologies mostly tend to evaluate the performance of the whole building and not the single components, mainly using analyses of users' satisfaction. For this reason, a Building Performance Indicator (BPI) was chosen for this study application, since it evaluates the performance of buildings and its systems.

2.2.1 Building Performance Indicator

The Building Performance Indicator (BPI) was developed by Shohet (a) *et al.* (2003); Shohet (c) (2003) Shohet (2006). A value between 0 and 100 defines this indicator, that expresses the building's state, by the performance evaluation of its various systems (Pn). The BPI is obtained by equation 1.

$$\text{BPI} = \sum_n P_n \times W_n \quad (1)$$

Where:

BPI - Building Performance Indicator (on a scale of 0-100):

Pn – Performance level for system n (on a scale of 0 to 100) as determined by equation 2.

Wn – Weight of each building system n, as determined by Life Cycle Costs (LCC).

The BPI value indicates the performance level of the building studied, according to the followed categories: BPI>80 indicates that the use of the building, and its subsequent performance, are good or better; 70<BPI<80 indicates that the state of the building is such that some of the systems are in marginal condition; 60<BPI≤70 reflects the deterioration of the building; BPI < 60 means that the building is run-down.

Each building's system is evaluated according to three criteria: actual physical performance of the systems (Cn); frequency of failures in building systems (Fn); and actual preventive maintenance carried out on the systems (PMn) and their correspondent weights $W(C)_n$, $W(F)_n$ and $W(pm)_n$. The combination of these three elements represents the performance level of the entire system (Pn) (Equation 2). This indicator has an economic component since it depends on the LCC.

$$P_n = C_n \times W(C)_n + F_n \times W(F)_n + PM_n \times W(pm)_n \quad (2)$$

For every system n, the sum $W(C)_n + W(F)_n + W(pm)_n = 1$.

Also, P_n and its components are graded according to performance scales between 0 and 100, like BPI. The weighting of each building system (Wn) is accomplished by weighting the contributions of the system's components to the total cost erection, maintenance, and replacement. The selection of this indicator is related to its reliability, and because it was previously validated by 6 experienced facility managers in maintenance (Lavy & Shohet, 2004).

2.3 KPIs integration within Building Information Modelling

According to ISO 29481-1(2014) BIM is a shared digital representation of the physical and functional characteristics of any built object, to facilitate design, construction and operation processes to form a reliable decision basis. In FM, BIM includes unified information base, consisting in a Big Data database, providing a building owner's manual, useful support for analysis, support for emergency response, security management and scenario planning (IFMA, 2013; Rodrigues et al., 2019). Revit is a BIM software offering a multi-disciplinary and collaborative approach to the design and construction process. To add extra functionalities to import/export data parameters from Revit to Excel, Dynamo tool can be used, as an add-in for extending Revit's parametric functionality and information retrieval (Autodesk Dynamo, 2020; Sadeghi *et al.*, 2019). Aboumoemen *et al.* (2017) verified that the linkage between BIM and KPIs to measure the building performance is an untimely task. So, in the present study, the potential of the linkage between BIM and KPIs to demonstrate the agility of the FM strategy researched is explored and verified.

3 Case Study

After the theoretical approach, the automated building performance indicator calculation and its extraction were applied to the Civil Engineering Department of Aveiro's University, built in 2004/2005, located in Aveiro, mainland Portugal.The methodology applied is described in the following points.

3.1 Building Information Collection

The Civil Department of Aveiro's University aims to provide an educational environment for its students and professors. With a plan area of 1613 m2, it is a building with four floors, one below the ground floor and three above the ground level, including the ground floor. Its main facade has a northeast orientation. Figure 1 is a plan of Aveiro's University Campus of Santiago representing in yellow the case study building location. The structural foundations are in reinforced concrete piles. The major part of the structure (columns and beams) are metallic, and the slabs are in reinforced concrete. The roof structure consists of steel columns and beams and tubular sections that support the metallic tile. The rainwater drainage system is characterized by galvanized zinc gutters and the dropp tubes in PVC-U. In terms of building interior finishing, the floors are in vinyl coating in the classrooms, and in the professors' offices the floor coating is in cork mosaic. The ceilings are mainly covered with plasterboard painted and in exposed concrete. The exterior doors and windows are in metallic profiles. In Figure 2, it is possible to observe a 3D model of the civil engineering department developed in Revit by Tavares (2019).

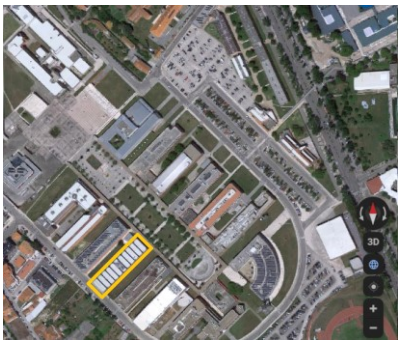

Figure 1. Building location in Aveiro's University Santiago Campus.

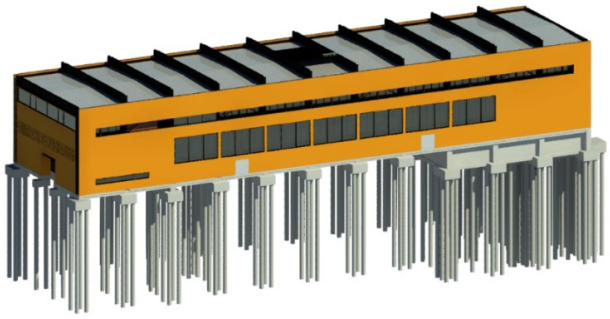

Figure 2. Revit model of the Civil Engineering Department of Aveiro's University (Tavares, 2019).

To understand the current periodicity of maintenance actions and to identify the main building anomalies, interviews with employees, lecturers and pivots in charge of management and maintenance of the building were carried out. The building plans, elevations, costs estimation and maintenance records were requested. Afterwards, a building inspection was accomplished and a report related to the assessment of buildings' deterioration state was done. Then, a set of building systems was selected to be evaluated by Pn's criteria such as windows, roofs, structural framing, structural columns, interior and exterior walls, mechanical and safety equipment, doors, drainage system, electric system, and lifts.

3.2 Building Life Cycle Cost Estimation

The economic contribution of each building system (Wn) selected to include in the BPI was

calculated by life cycle cost estimation. The contribution of each building system was given in percentage for the three alternative scales to include in BPI calculation: 1) Construction costs, 2) Maintenance Costs index, 3) Life Cycle Cost index. Despite being an essential step of this study, the results obtained in this step are not herein presented since it is out of this paper focus.

3.3 Automated Evaluation of BPI Supported by BIM

In this step, the integration of BPI into the Revit software with shared parameters and resourcing Dynamo to extract them as a final value to Microsoft Excel took place. In Revit software, the shared parameters are parameters attributed to the different object families with several types of information, which in this case allows associating the Cn, Fn, PMn, Wn(Cn), Wn(Fn) and Wn(Pmn) criteria and its contribution to each family objects. After the parameters attribution and based on the building inspection and the LCC calculated in the previous step of this methodology, it is possible to attribute to each system a quantifiable evaluation and contribution as depicted in the Revit schedule, automatically extracted, in Figure 3.

<KPI window>

A	B	C	D	E	F	G	H	I
EFM	Mark	Cn	Fn	PMn	Wn (Cn)	Wn (Fn)	Wn (PMn)	PN
Vão Envidraçado	F1	80	100	20	37.5	37.5	25	72.5
Vão Envidraçado	FX_2.1	60	80	20	37.5	37.5	25	57.5
Vão Envidraçado	FX_2.2	80	100	20	37.5	37.5	25	72.5
Vão Envidraçado	FX_2.3	60	80	20	37.5	37.5	25	57.5
Vão Envidracado	FX 2.4	60	80	20	37.5	37.5	25	57.5

Figure 3. Revit schedule with the parameters' values of the Building Performance Indicator.

The extraction of global values of each parameter for each building system to an Excel file is an essential task, after this one, to calculate the final value of the BPI. This task was accomplished through Dynamo programming tool.

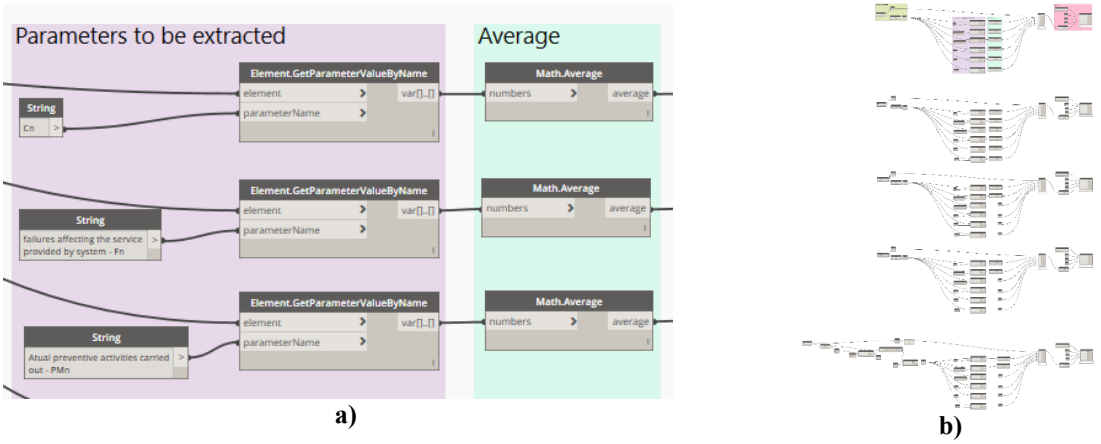

Figure 4 – **a)** Selection of parameters to be extracted and the calculation of the global value of each one. **b)** Piece of work from visual programming in Dynamo BIM to extract parameters from every category.

The interaction between the three software pretends to take advantage of its interoperability (Revit-Dynamo and Excel), to create an automated method that allows prioritizing maintenance actions. Thus, the Dynamo BIM allows selecting the category of elements and the parameters which is pretended to extract, generating the global value of each parameter correspondent to

each category of elements. Figure 4 shows part of the visual programming developed on the interface of Dynamo BIM software.

Then, the contribution of each element calculated for the total LCC in step 2 was included in the Excel sheet. After this, the BPI was calculated as presented in Figure 5.

Element	Cn	Fn	PMn	W(Cn)	W(Fn)	W(PMn)	Pn	Wn	BPI
Windows	73.78	79.49	21.54	37.50	37.50	25.00	62.86	7.86	4.94
Roofs	40.00	60.00	40.00	37.50	37.50	25.00	47.50	8.96	4.26
Structural Framing	78.39	100.00	20.00	45.00	45.00	10.00	82.28	9.85	8.10
Structural Columns	78.72	98.72	20.00	45.00	45.00	10.00	81.85	9.85	8.06
Walls Exterior	80.00	80.00	20.00	37.50	37.50	25.00	65.00	7.86	5.11
Walls Interior	80.00	80.00	20.00	35.00	35.00	30.00	62.00	17.49	10.84
Mechanical Equipment	20.00	20.00	20.00	20.00	20.00	50.00	18.00	2.45	0.44
Doors	79.62	80.00	40.19	35.00	35.00	30.00	67.92	17.49	11.88
Drainage system	80.00	80.00	50.00	37.50	37.50	25.00	72.50	3.18	2.31
Electric system	100.00	90.00	50.00	25.00	25.00	50.00	72.50	5.25	3.80
Elevators	100.00	100.00	80.00	30.00	30.00	40.00	92.00	8.28	7.62
Security (Fire, CTV)	100.00	100.00	60.00	37.50	37.50	25.00	90.00	1.49	1.34
							Total	100.0	68.70

Figure 5. Excel file with parameters and categories exported from Revit software by Dynamo software and BPI calculation.

3.4 Results Analysis

The value of the BPI obtained indicates the deterioration level of the building, meaning that preventive and break-down maintenance activities must be carried out since the value obtained is between $60<BPI\leq70$, according to the anomalies detection during the building inspection. Besides being a global performance indicator of the building, the BPI also allows defining the priorities of the maintenance actions about the building's systems. The Pn indicator should establish the intervention action priority of the systems. Through Figure 5, it is possible to observe that the HVAC system (Mechanical Equipment) has the lower Pn indicator, indicating that is the one that needs more urgent maintenance actions (preventive and corrective), followed in the second place by the roof system, and then by the windows framing, which is according to the building inspection done.

3.5 Application of "Color Splasher" to BIM Model

To simplify the maintenance management process, the values obtained in Figure 5 were categorized by colours, resourcing the color splasher BIM plug-in, which allows a quick recognition about building condition systems as it is presented in Figure 6.

The colour categorization to express the actual system's condition was done, in which red colour indicates urgency in system intervention and green colour indicates the satisfactory condition of the system.

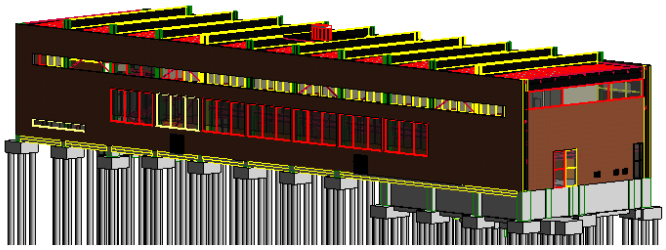

Figure 6. "Color splasher" application to 3D View of the building model.

With Figure 6, it is possible to observe easily and quickly that HVAC system, roof system, and windows framing are the ones that more urgently need maintenance actions, as mentioned above.

4 Final Conclusions

The methodology developed is innovative because it allows collecting and analyse the diversified information about building systems condition, permits calculating the systems' and the whole building`s performance in an automated way. This calculation is possible through shared parameters attributing the BPI parameters to Revit object families, and through interoperability Revit-Dynamo-Excel. Besides that, to facilitate the process of setting priorities of maintenance actions, the maintenance priorities were categorized by colours in the BIM model.

This methodology can be applied to any building typology and it is very relevant because its application allows prioritizing the maintenance actions in existing buildings, optimizes the building information sharing and facilitates building anomalies record and analysis. Moreover, its application leads to the easier building life cycle information retrieval, contributing to facility managers time and money-saving. The evaluation of systems performance leads facility managers in identifying anomalies early enough to minimize the impact of operational interruptions. So, faster maintenance processes and shorter periods of information disruption by using BIM was proved, and it motivates the FM implementation, which contributes to increasing the materials service life.

As a future study is proposed the development of an assessment approach, based on a set of KPIs, for measuring environmental building performance and green maintainability.

Assessment of Building Resistance to Accidental Actions in the Social Aspect of Sustainable Construction

Aleksandra Radziejowska[1] **and Anna Sobotka**[2]

[1] AGH University of Science and Technology in Cracow, Faculty of Mining and Geoengineering, Av. Mickiewicza 30, 30-059 Cracow, Poland, e-mail: aradziej@agh.edu.pl
[2] AGH University of Science and Technology in Cracow, Faculty of Mining and Geoengineering, Av. Mickiewicza 30, 30-059 Cracow, Poland, e-mail: sobotka@agh.edu.pl

Abstract. *In the article is considered one of the categories of social aspect of sustainable construction as specified in the standard EN 16309:2014 - namely: safety and security. The authors analyzed the component of the above-mentioned category with a subcategory called: resistance of buildings for accidental actions. The assessment criteria are: earthquake resistance, explosion resistance, fire performance and traffic impacts. A model of building's assessment of random interactions is presented, which will allow to make comparisons of the object's safety in the investigated ranges with other residential buildings, as well as with a reference building.*

Keywords: *Social Aspect, Security and Safety, Sustainable Construction, Accidental Actions.*

1 Introduction

Civil engineering is one of the main branches of the economy in which the goals of sustainable development are realized. According to (ISO 15392, 2008), three main aspects have been identified in sustainable construction: environmental, social and economic. Due to a number of studies and publications related to both the environmental and economic aspects, the authors focused on finding a model for assessing the social aspect, which is important for the user's comfort and health, especially in residential buildings (Yılmaz and Bakış, 2015).

Assessing the social aspect of a building is a difficult process. Only part of the assessed elements of the considered criteria can be quantified, compared with the parameters specified in legal acts and standards. On the other hand, such assessment allows to determine whether the object meets the examined criteria, thus allowing to obtain information about the facility's ability to meet the needs and expectations of users.

In this study, one of the subcategories of the sixth category (K_6) of social assessment regarding safety and security will be discussed and developed. Category K_6 Safety and security consists of four subcategories, which include: K_{61} *Resistance to climate change*, K_{62} *Safety and security against accidental actions*, K_{63} *Safety and security against intruders and vandalism* and K_{64} *Security against interruptions of utility supply* (EN 15643-1, 2011), (EN 15643-3, 2012). The subgroup that the authors presents concerns on K_{62} *Safety and security against accidental actions*, which consists of four criteria that will be included in the proposed assessment: K_{621} *Earthquake (rockburst mining),* K_{622} *Explosions,* K_{623} *Fire resistance* and K_{624} *Resistance to dynamic external actions* (Fig. 1). This publication is part of the work, which aims to present a comprehensive method of assessing the social aspect of sustainable construction.

2 Subcategory K_{62} Safety and Security Against Accidental Actions

The safety and security category is a measure of the building's ability to withstand current and future anticipated loads such as: rain, strong wind, snow, flood, fire, earthquake, explosion, landslide, etc., as well as protection against vandalism and crime and safety during use. It is a measure of the ability of buildings to provide safe shelter during exceptional events that may affect user safety.

In random impacts is assed building resistance (protection / forces / deformation / stability and safety) against accidental loads resulting from one-off events, e.g. earthquakes, explosions, fire and traffic, and their secondary effects (*e.g.* projectiles, toxic gases, crushed glass, etc.).

Figure 1 shows the division of the subcategory *Safety and security against accidental actions* (K_{62}), which is a component characterizing the *Safety and security* (K_6) category (EN 16309, 2014+A1). K_{62} is assessed by the criteria marked later in the article by the symbols $K_{621} \div K_{624}$. For the assessment of the criteria a discrete five-point scale was adopted, in which the most advantageous solution will assume the highest value equal to 5 (Radziejowska, 2018).

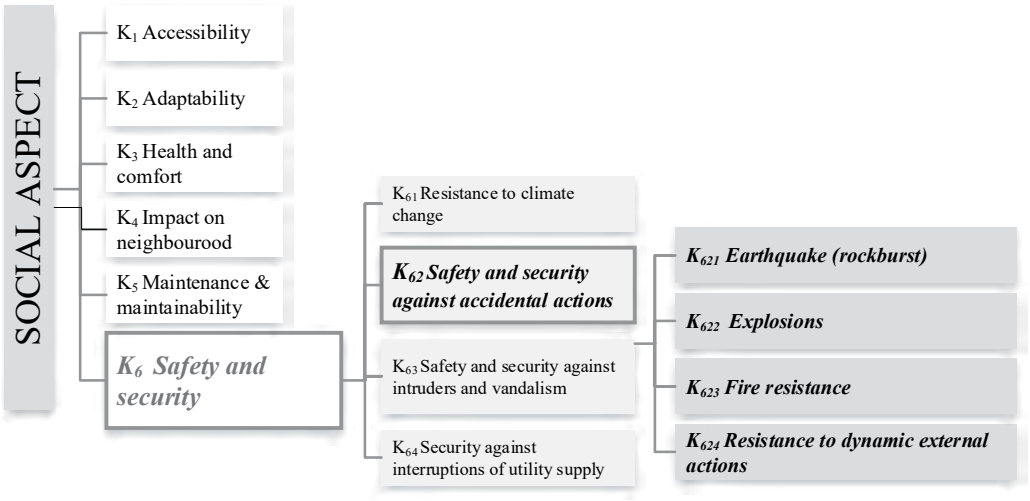

Figure 1. Fragment of the base structure of the criteria included in the proposed assessment (own elaboration).

3 Determining the Method of Evaluation of the Criteria

3.1 Determining the Scale of Parameter Values Characterizing the Criterion K_{621}

Criterion K_{621} *Earthquake resistance; rockburst mining* should be assessed through the use of protective measures in the building, which can be implemented by increasing structural stability, assembly of elements ensuring flexibility and shock resistance, resistant to breaking glass or alarm systems and gas and water shut-off valves.

Poland is located outside the areas of active tectonic plates, it is classified as aseismic zone. The specificity of our country, and more specifically the areas of mining basins, is the occurrence of paraseismic shocks, which are a consequence of underground mining operations. The phenomenon during which rapid destruction of the rock structure surrounding the excavation occurs as a result of exceeding their strength is called rockburst. The effect of such

a dynamic phenomenon in the rock mass (rapid rock relaxation) is the emission of vibrations, *i.e.* the seismic shock effect. Shock (seismic) waves propagate to the surface, which induce vibrations of buildings (Fig. 2 &3).

Figure 2. Cracks formed in a residential building in post-mining areas, around Bytom in Poland, 22/05/2011.

Figure 3. The uncontrolled dilatation of the building was created as a result of post-mining burst, around Bytom, 22/05/2011.

At the Central Mining Institute has been developed so-called Mining Scale of Intensity (Barański, 2014) for the area of the Upper Silesian Coalfield, based on the correlation of observed effects in buildings with the values of vibration parameters - so this is an empirical scale. The shock parameters necessary to assess the degree of vibration intensity on the surface for the GSIGZWKW-2012 scale are: the amplitude of the vibration speed and their duration.

Based on the existing GSIGZWKW-2012 scale, concerning the level of nuisance and related technical requirements necessary to be implemented shall be assessed the building's resistance to earthquakes (rock bursts) - criterion K_{621} - depending on the determined shocks according to a 5-point scale with levels with the following meaning: 5 - imperceptible nuisance, 4 - low nuisance, 3 - medium nuisance, 2 - high nuisance, 1 - very high nuisance (Table 1).

Table 1. Assessment of building resistance depending on the established level of nuisance and technical requirements for objects located in mining areas.

Scale of evaluation	Nuisance level					Technical requirements fulfilled
	Level 0	Level I	Level II	Level III	Level IV	
5	Fulfilled technical requirements for the considered level					
4		X				-
3			X			-
2				X		-
1					X	-

- not fulfilled technical requirements
+ technical requirements fulfilled

3.2 Determining the Scale of Parameter Values Characterizing the Criterion K_{622}

Criterion K_{622} *Explosions*, similarly to the previous one should be assessed by the applied protective measures or avoiding the use of explosive gases in buildings, installation of break-proof glass and separation of shelters inside

During the operation of residential buildings, there are two causes of disasters caused by explosions:

- gas explosion
- terrorist attack.

Construction disasters caused by an explosion are not common events, however, the consequences they carry are disproportionately high (Koccaz, Fatih Sutcu i Torunbalci, 2008).

In both causes of explosions in buildings, the method of protection should be similar and consist of the use of solutions that increase the building's resistance in this type of threat (Table 2).

Table 2. Assessment of residential buildings resistance to explosions.

Scale	Wired gas		Propane-butane gas		Gas detectors	Construction	
	with valve	without valve	with valve	without valve		resistant	no resistant
5	+				+	+	
4	+				+		+
			+		+	+	
3		+			+		
2			+				+
1				+			+

3.3 Determining the Scale of Parameter Values Characterizing the Criterion K_{623}

The next criterion for the assessed subcategory is K_{623} *Explosions*. In order to improve fire resistance, fire resistance of materials of higher classes than recommended can be used, which will improve the load-bearing capacity, integrity and / or insulation performance of building elements, improve access for fire brigades, make evacuation routes taking into account the needs of people with disabilities, install warning systems, smoke detectors, fire extinguishing systems in public areas, separate fire-cutting zones for the spread of fire, use fire-resistant products in places most exposed to fire (Fig. 4) (Phan, McAllister i Gross, 2010).

Figure 4. Fire extinguisher placed in the underground garage of a multi-family building 02/02/2016.

Figure 5. Entrance to the underground garage with a display informing about the concentration of carbon monoxide 12/06/2016.

Figure 6. Emergency exit from the underground garage in a residential building 11/10/2016.

An important element is also the users' awareness of the measures used in the event of

random events, which should be implemented by e.g. placing appropriate instructions in the common parts regarding evacuation or operating instructions for the use of fire-fighting equipment (Fig. 5&6).

For the assessment of *Fire safety* - criterion K_{623} - depending on the established safeguards, as in previous, a five-degree discrete scale was adopted, as is shown in Table 3.

Table 3. Fire safety assessment of buildings $\boldsymbol{K_{623}}$.

Scale	The degree of compliance with the requirements according to the Table 3				
	All 5 met	4 + 1 met to a limited extent	3 + 2 met to a limited extent	2 + 3 met to a limited extent	1+4 met to a limited extent
5	+				
4		+			
3			+		
2				+	
1					+

Where the requirements are:

1. *The proper load-bearing capacity of the structure in a timely manner after the fire*
2. *Limiting the spread of fire and smoke in the building*
3. *Limiting the spread of fire to neighboring buildings*
4. *The possibility of evacuating people*
5. *Ensuring the safety of rescue teams* (Infrastructure, 2002 and its subsequent amendments)

3.4 Determining the Scale of Parameter Values Characterizing the Criterion K_{624}

The last criterion in this subcategory is K_{624} *Resistance to dynamic external actions*, which can be implemented by applying measures for increased resistance to traffic influences, among which solutions such as: constructing barriers or strengthening the construction of building facilities located in areas at risk (Fig. 7&8).

Figure 7. Tram line running right next to multi-family buildings, Lisbon 31/12/2015.

Figure 8. Tram line and busy two-lane road in the Borek Fałęcki district in Krakow, 25/10/2016.

After consultation with an expert in the field of the impact of vibrations on people and buildings, it was assumed that the assessment of criterion K_{624} should be carried out separately

for both sub-criteria: *The impact of vibrations on people* (Table 4) i *Impact of vibration on buildings* (Table 5). It was determined that the final value less favorable from both grades obtained will be adopted.

Table 4. The impact of vibrations on people.

Scale	$a < a_{dop}$ *for direction x & y*	$a < a_{dop}$ *for direction z*	$a = a_{dop}$ *for direction x & y*	$a = a_{dop}$ *for direction z*	$a < a_{dop}$ *dla for direction x & y*	$a < a_{dop}$ *for direction z*

4 A Method Proposal for Assessing Building Resistance to Random Influences

The authors while developing the classes of standards in the assessed criteria for selected categories used, among others:

- national standards and regulations on technical conditions to be met by buildings and their location,
- expert research,
- direct surveys conducted among users,

– in situ research.

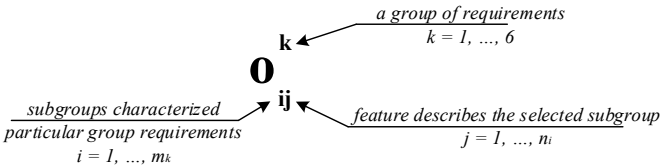
The proposed method assesses both quantitative and qualitative features. Qualitative features had to be processed into quantitative form by using the appropriate mathematical apparatus, e.g. fuzzy sets. Then all values were processed into non-denominated values, finally all criteria are evaluated using a discrete 5-point Likert scale, which allows comparison of features that were initially found in different physical measures. In addition, developing a method for quantifying grades required determining the weighting of the criteria. The final characteristics of the selected subcategory of the social aspect of the building is expressed in the form of a scalar function taking into account the weight of each criterion.

The vector below characterizes the subcategory (K_{62} *Safety and security against accidental actions*) of the social aspect together with the matrix of weights assigned to it.

$$O_{2j}^{6} = \left[o_{2,1}^{6} \quad o_{2,2}^{6} \quad o_{2,3}^{6} \quad o_{2,4}^{6}\right] \tag{1}$$

$$\Lambda_{2j}^{6} = \left[\lambda_{2,1}^{6} \quad \lambda_{2,2}^{6} \quad \lambda_{2,3}^{6} \quad \lambda_{2,4}^{6}\right] \tag{2}$$

where:



In the presented assessment it is proposed to use a corrected summation index (3), thanks to which a scalar function can be easily formulated, which allows the obtained result to be unequivocally interpreted.

$$O_i^k = \sum_{j=1}^{n_i} o_{ij}^k \ \lambda_{ij}^k = o_{i1}^k \ \lambda_{i1}^k + \cdots + o_{in_i}^k \ \lambda_{in_i}^k \tag{3}$$

where:

$o_{ij}^k = \left[o_{i1}^k, \ldots, o_{in_i}^k\right]$ – vector of the assessed features of the subgroup and,

$\lambda_{ij}^k = \left[\lambda_{i1}^k, \ldots, \lambda_{in_i}^k\right]^T$ – weight vector for features included in the assessment.

The above calculations should be made for the tested building as well as for the reference building. The reference building (reference building) will be treated as a hypothetical building designed in accordance with applicable standards and common practice and having the same technological, construction and functional parameters as the building being assessed. The reference building is to be used for carrying out comparative calculations with the analyzed object (Owczarek, 2006) .

The obtained values should be compared with the assessment obtained by the reference object, which will allow to assess how well the examined object is assessed in the scope of this subcategory. The information obtained from the calculations will indicate the weakest features that the analyzed building has, which will allow it to take appropriate action in the refurbishment policy in the future (Radziejowska, 2018).

5 Conclusions

The method of standardizing subcategory evaluations proposed in the work on the example of

K_{62} is a contribution to the unification of the assessment of social performance of sustainable construction. The established threshold values, the adopted scale of assessments for the considered criteria, as well as the weights assigned to individual criteria and subcategories are largely based on expert research.

The presented method of assessing the social aspect of sustainable construction based on the example of subcategory K_{62} allows to make a comparison regarding the building's resistance to random events between the tested building and the reference object, as well as between buildings made in different technologies. In the longer term, it will determine the scope of the planned refurbishment of the building, and may also be helpful in valuing the property.

Behaviors of Concrete with Recycled Clay Brick as Fine Aggregate

Wencui Yang, Xiaoping Cai and Duojie Jiangjiu

School of Transportation Science and Engineering, Harbin Institute of Technology, 73 Huanghe Road, Nangang District, 150090, Harbin, China, yangwencui@hit.edu.cn, caixiaoping@hit.edu.cn

Abstract. *Massive waste materials were produced by the construction and demolition industry every year. In residential constructions, clay bricks are a dominant material and they account for a large proportion of construction and demolition waste. Using crushed bricks in cement concrete is an effective way to preserve natural aggregate and to reduce construction and demolition waste. The mechanical properties, the permeability and the carbonation resistance of concrete with recycled clay brick as fine aggregate were studied in this paper. The results showed that the compressive strength, the flexural strength and the impermeability of concrete decreased with the increasing of the replacement percent of recycled clay brick. However, the permeability of concrete with the water to cement ratio of 0.35 was still at the "Low" level when the replacement percent was less than or equal to 75%. The carbonation resistance of concrete using recycled clay bricks as fine aggregate was degraded.*

Keywords: *Construction and Demolition Waste, Fine Recycled Aggregate, Clay Brick, Durability.*

1 Introduction

Vast amounts of waste materials are produced by the construction and demolition industry every year. The volume of these materials has reached an unacceptable level from an environmental, economic and social point of view (Vieira *et al*., 2016). In residential construction, clay bricks are a dominant material, so they account for a large proportion of construction and demolition waste (Crowther, 2000; Formoso *et al*., 2002). Since concrete is the most widely used construction materials in the world, using crushed bricks in concrete is an effective way to preserve natural aggregate and to reduce construction and demolition waste.

Several studies have been conducted to investigate the potential of using clay brick as aggregates. Poon and Chan (2006) investigated the possibility of using crushed clay brick as aggregates in sub-base materials. A study by Lan Zong showed the permeability of water, air and chloride ions increased when recycled coarse aggregates were used. Additionally, the recycled concrete containing clay brick waste had increased porosity and exhibited a loose paste matrix (Zong *et al*., 2014). Schackow used a powdered（<45μm）fired clay brick clean waste to replace Portland cement, and 28 and 90 days-compressive strength, water absorption, apparent porosity, absorption by capillarity, chloride retention, carbonation depth and sulphate resistance were evaluated. According to the results, they suggested that a moderate clay brick clean waste addition (up to 10 wt.%) is desirable if a comparable workability is desired (Schackow *et al*., 2015). Adamson's research (2015) showed that the natural coarse aggregates can be replaced by crushed bricks, without significant change in the durability of concrete when the steel is not present. However, when concrete is reinforced with steel, replacing natural aggregates with crushed brick is not recommended. Bektas's study (2009)

doi:10.23967/dbmc.2020.016

indicated that as the brick replacement level increased, the mortar flow ability reduced. The 10% and 20% brick replacements had no negative effect on the mortar compressive strength and very limited effect on the mortar shrinkage.

This paper reports a study with the aim to investigate the mechanical properties and durability of concrete with recycled clay brick as fine aggregate. By conducting a sort of laboratory experiments, the compressive strength, flexural strength, permeability and carbonation resistance of concrete with recycled clay brick were studied.

2 Experimental Program

2.1 Materials

Ordinary Portland Cement (P·O 42.5) was used in accordance with China National Standard GB/175-2009, and Table 1 summarized its properties.

Table 1. Chemical and physical properties of cement.

Initial setting time (min)	Final setting time (min)	Tensile strength (MPa)		Compressive strength (MPa)	
		3d	28d	3d	28d
190	250	4.2	7.1	22.9	43.8

Natural river sand was used as fine aggregate, the fineness modulus of river sand was 2.9. Crushed limestone was used as coarse aggregate, and the grading of coarse aggregate is given in Table 2. Recycled clay bricks were broken into pieces. And the grading of recycled clay brick was controlled as the requirements of Chinese National Standard GB/T 25176-2010. Table 3 and Table 4 show the properties and the gradation of the recycled clay bricks as fine aggregate. A super plasticizer was used to adjust the workability of concrete.

Table 2. The grading of coarse aggregate.

Sieve pore size (mm)	19.0-26.5	16.0-19.0	9.5-16.0	4.75-9.5
Percentage (%)	25	25	35	15

Table 3. The properties of recycled clay brick.

Apparent density (g/cm^3)	Packing density (kg/m^3)	Close packing density (kg/m^3)
2.34	899	994

Table 4. The grading of recycled clay brick as fine aggregate.

Sieve pore size (mm)	4.75	2.35	1.18	0.6	0.3	0.15	<0.15
Percentage (%)	2	7	10	30	36	13	2

2.2 Mix Proportions and Sample Preparation

The proportions of reference concrete with the water to cement ratio of 0.35 and 0.47 are given in Table 5. The recycled clay brick was introduced as volume percentage of the

concrete fine aggregate, and four levels of replacement, 25%, 50%, 75% and 100%, were investigated.

Due to the high water absorption of recycled clay brick, it is suggested to soak the brick aggregate in water prior to adding to concrete [Khalaf, 2005; Khalaf, 2006; Cachim, 2009]. Therefore, this procedure was adopted in this work for recycled clay brick. The recycled clay brick aggregate was soaked in water for 24h and added to concrete mixture in a saturated condition.

Table 5. Mixture proportions of reference concrete (kg/m^3).

W/C	Water	Cement	Sand	Gravel	Super plasticizer
0.35	175	500	629	1106	4.5
0.47	175	372	702	1151	4.5

2.3 Methods

2.3.1 Mechanical properties

The compressive strength and flexural strength of concrete were tested at 28d age. The compressive strength specimens with the size of 100mm×100mm×100mm and the flexural strength specimens with the size of 100mm×100mm×400mm were tested in accordance with the Chinese standard GB/T 50081-2002.

2.3.2 Carbonation resistance

The concrete cubes with the size of 100mm×100mm×100mm were casted, and the samples were demoulded after 24h and cured in the standard curing condition until 28 days, then the samples were placed in a carbonation chamber with the CO_2 concentration of 20%, the temperature of 20°C and the RH of 70%. The carbonation depth was determined at the start of exposure and after 3, 7, 14 and 21 days according to Chinese standard GB/T 50082-2009.

2.3.3 Permeability

The permeability of concrete was measured at 28d age according to the Chinese standard GB/T 50082-2009, and the size of specimen was φ100mm×50mm.

3 Test Results and Discussion

3.1 Mechanical Properties

Table 6 demonstrates the compressive strength and the flexural strength obtained from the concrete samples with different replacement of recycled clay bricks. Each data represents the average of three samples. It was observed that with the increasing of recycled clay brick content, both the compressive strength and the flexural strength decreased. When the water to cement ratio was 0.35, the compressive strength loss of approximately 20% at 28 days was observed in concrete produced with 25% recycled clay brick replacement ratio. The reduction in compressive strength was observed more significantly in concrete with 75% or more replacement ratio as it decreased over 30%. The compressive strength of concerte with the

water to cement ratio of 0.47 showed the similar change, and the decrease of compressive strength was more than 30% when 25% recycled clay brick was added. It was shown the replacement of recycled clay bricks had more influence on the concrete with higher water to cement ratio.

Table 6. Mechanical properties of concrete (28d).

W/C	Replacement percentage (%)	Compressive strength (MPa)	Flexural strength (MPa)
0.35	0	51.8	6.0
	25	42.3	4.8
	50	41.5	4.1
	75	35.2	3.8
	100	32.3	3.6
0.47	0	48.3	4.5
	25	33.2	4.1
	50	31.2	3.7
	75	26.8	3.4
	100	24.3	3.1

3.2 Permeability

The electric flux method was used to evaluate the permeability of concrete to chlorides, and the results was described in Figure 1. It can be found that with the increasing of the recycled clay brick content, the impermeability decreased. According to ASTM C1202, the permeability of concrete to chlorides could be divided into 5 classes by charge passed, which is shown in Table 7. When the water to cement ratio was 0.35 and the replacement percent of recycled clay brick was less than or equal to 75%, the permeability of concrete could be evaluated as “Low”. When the water to cement ratio was 0.47 and the replacement percent of recycled clay brick was less than or equal to 25%, the permeability of concrete could be evaluated as “Low”.

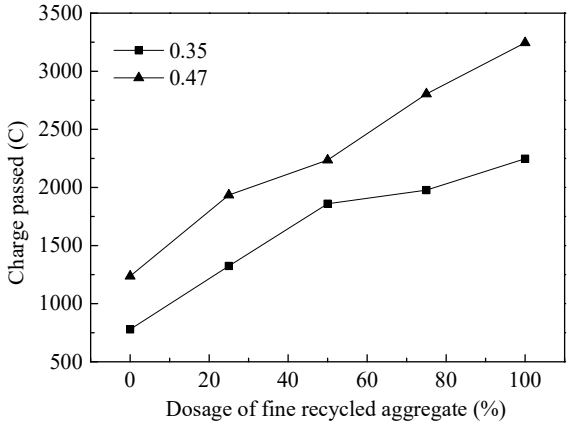

Figure 1. Effect of the dosage of fine recycled aggregate on the permeability of concrete.

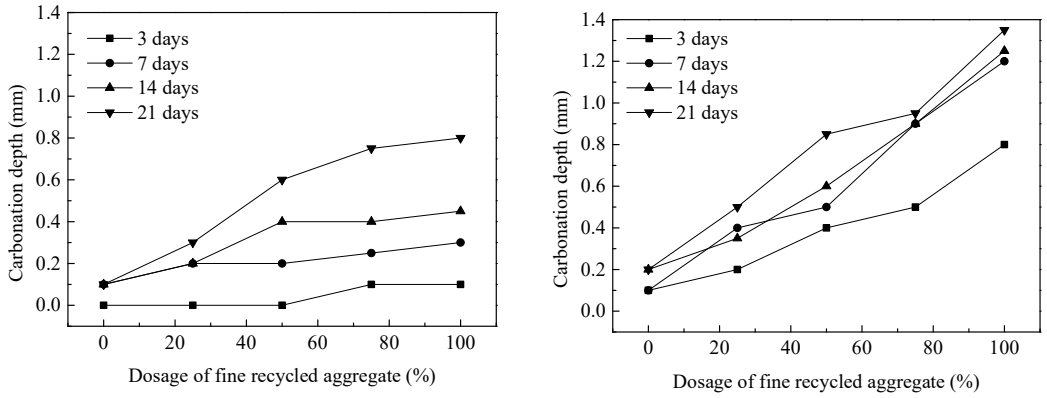
Table 7. Chloride ion penetrability based on charge passed.

Electric flux（6h, C）	Permeability
＞4000	High
2000-4000	Moderate
1000-2000	Low
100-1000	Very low
＜100	Negligible

3.3 Carbonation Resistance

The effect of the dosage of fine recycled aggregate on the carbonation depth of concrete is described in Figure 2. Generally, concrete with higher water to cement ratio has more pores, and CO_2 could get into concrete much easier through these pores. Consequently, the carbonation depth increased with the increasing of water to cement ratio for all test age. The carbonation depth also increased with the increasing of the test age and the replacement level of recycled clay brick. The porous recycled clay brick may carbonate considerably faster than the concrete with natural aggregate, causing a increase of the carbonation depth which was shown in Figure 3.



(a) *W*/*C*=0.35. (b) *W*/*C*=0.47.

Figure 2. Effect of the dosage of fine recycled aggregate on the carbonation depth of concrete.

Figure 3. Surface of split concrete cube with the replacement level of 100% used in the carbonation test after being sprayed with phenolphthalein at 21days (*W*/*C*=0.47).

4 Conclusions

Based on the above experimental results, some conclusions could be drawn below:

- Both the compressive strength and the flexural strength decreased with the increasing of the replacement percent of recycled clay brick.
- The impermeability of concrete decreased with the increasing of the replacement percent of recycled clay brick. But the permeability of concrete with the water to cement ratio of 0.35 was still kept at "Low" level when the replacement percent was less than or equal to 75%.
- The carbonation resistance of concrete using recycled clay bricks as fine aggregate was degraded.

Abstract. *The building sector is responsible for the introduction of about 40% of the waste in the environment (60 Mtons per year in Italy), with serious consequences for our future. Therefore, the statistics of the last few years have induced many researchers and many companies to investigate more sustainable products and technologies. Among these strategies, the re-use of waste materials has been widely encouraged. Many solutions have been proposed in the field of mortars for which the use of waste products such as ceramic materials, polystyrene, clay, concrete, has been tried out. The results have often been encouraging, especially for masonry mortars. Nevertheless, very few attempts have been made to place this type of products on the market. Moreover, the "younger" building materials such as Autoclaved Aerated Concrete have not been fully investigated in their potential use as recycled aggregates. The goal of this research was to evaluate the characteristics of mortars packaged with different percentages of production waste of Autoclaved Aerated Concrete components as aggregates, in order to assess the possible use of these conglomerates as masonry mortars or as plasters. The first campaign included tests for determining mechanical resistance, density, capillary water absorption, adherence to substrate, resistance to carbonation. The tested mortars had satisfactory mechanical characteristics and generally exhibited a good capacity to withstand the actions of atmospheric agents. Finally, the results highlighted the direct connection between Autoclaved Aerated Concrete percentage and mechanical and durability properties.*

Keywords: *Building Materials Production Waste, Carbonation, Lightweight Aggregates, Recycled Conglomerates, Sustainability.*

1 Introduction

The reuse of building waste materials in sustainable concretes or mortars has raised over the last years due to the environmental impact of building constructions. Building materials production waste is preferred rather than Construction and Demolition one due to its controlled chemical composition. The replacement of ordinary aggregates with production waste ones generally affects the mechanical performances of concretes or mortars owing to the low density of recycled aggregates (de Brito *et al.,* 2005; Ćosić *et al.*, 2015).

Nepomuceno, Isidoro and Catarino (2018) suggested a 30% threshold value of volume-replacement percentage of natural coarse aggregate with recycled ceramic in case of structural concrete. Actually, an increase of porosity and of average pore diameter is observed when the recycled aggregates are used (Anastasiou *et al.,*2018; Dang *et al.*, 2019). The accretion of

macropores and the reduction of micropores increases the resistance to external sulphate attack as a consequence of the lower capillary pores transport phenomena (Coppola *et al*., 2018). Moreover, the porosity improves the thermal insulation performances of mortars (Khan, 2002; Mendes *et al*., 2019).

Despite the raising interest on recycled lightweight aggregates, it is presently unclear whether the high porous structure of the recycled conglomerates affects their durability due to the microstructural changes induced by the aggregates. In particular, the relation between recycled mortars morphology and their carbonation resistance has not been fully investigated.

In order to analyze the effects of the use of a production waste lightweight material on the physical, the mechanical and the resistance to carbonation properties of conglomerates, five groups of mortars packaged with an increasing percentage by mass of Autoclaved Aerated Concrete (AAC) recycled aggregates were tested and compared. The changes in density, porosity, water adsorption, mechanical strengths and carbonation depths were measured.

The results of this study may be used to define the threshold of AAC aggregate percentage with the respect to the application of conglomerate as masonry mortars or as renderings and plasters.

2 Materials and Methods

2.1 Materials

The tested mortars were packaged with natural hydraulic lime (NHL 5 according to UNI EN 459-1:2010 standard) supplied by TSCcalce.

A natural siliceous sand and a recycled Autoclaved Aerated Concrete were used as aggregates. The natural sand was provided by Bacchi s.p.a and its apparent density, stated by the manufacturer, was 1460 kg/m^3. The recycled aggregate was supplied by Bacchi s.p.a, resulted from the production waste of Autoclaved Aerated Concrete (AAC) wall components. The particles size distribution of the recycled aggregate was measured through the dry sieving method according to UNI EN 933-1: 2012 and it is shown in Figure 1.

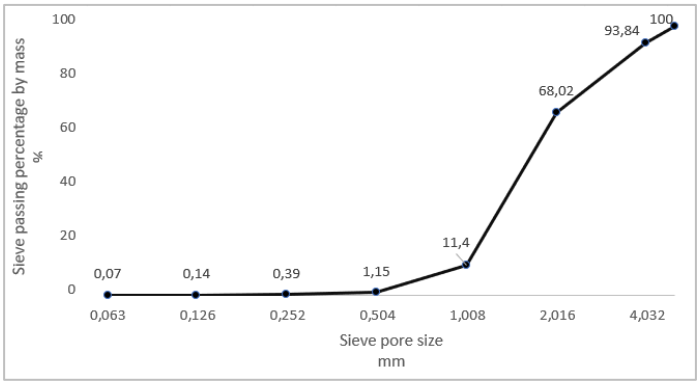

Figure 1. Particle size distribution of Autoclaved Aerated Concrete recycled aggregates according to the sieving test method.

The particle density and the water adsorption of AAC aggregates were analyzed according to UNI EN 1097-6:2013 pycnometer method for aggregate particles passing 4 mm test sieve and retained on the 0,063 mm test sieve. The outcomes are shown in Table 1.

Table 1. Particle density and water adsorption of Autoclaved Aerated Comcrete recycled aggregates.

M1 (g)	M2 (g)	M3 (g)	M4 (g)	ρ_{rd} (kg/m^3)	ρ_{ssd} (kg/m^3)	ρ_a (kg/m^3)	W (%)
77,93	477,73	452,29	45,11	860	1480	2290	72,76

M1, saturated and surface dried mass in air; M2, mass of pycnometer containing the saturated aggregate sample and the water; M3, mass of pycnometer filled with water only; ρ_{rd}, oven dried particle density; ρ_{ssd}, saturated and surface dried particle density; ρ_a, apparent particle density; W, water adsorption.

The chemical composition of the recycled aggregates was determined by a ThermoGravimetric Analysis (TGA) using a Netzsch- STA 409 PC Luxx apparatus. The mass losses of an AAC aggregate sample of 20 mg were monitored over time as the sample was heated in a controlled atmosphere. The temperature ranged from 23° to 1200° with a 10°/min heating rate. The mineralogical composition of AAC aggregates was analyzed by X-ray Diffraction (XRD) technique using a Philips X'pert PRO multipurpose powder diffractometer with X-ray wavelength of 1,54 Å. The outcomes were compared with the standard patterns of the International Centre for Diffraction Data database. The main mineralogical phases were Silicon Oxide, Calcium Carbonate, Calcium Hydroxide Hydrated Silicates and Calcium Sulfate Hydrated. A distilled water was used as kneading water.

Five groups of mortars with five specimens in each group were analyzed. All the tested specimens were packaged using the hydraulic lime and a binder-aggregate ratio of 1:3 by mass. The first group – noted 1 - was taken as reference and it was composed of mortars with 100% natural aggregate percentage. In the other four groups – noted 2,3,4,5 - the natural sand was gradually replaced with an increasing percentage by mass of recycled aggregate from 12,5% to 50%. The water – binder ratio of 2,3,4,5 was adjusted due to AAC aggregate water adsorption. Table 2 shows the compositions of the tested mortars.

Table 2. Compositions of tested mortars.

	HL (g)	SS (g)	AAC (g)	W (g)	W/B	RA (%)
1	450	1350	0	225	0,50	0
2	450	1181,25	168,75	337,5	0,75	12,5
3	450	1012,50	337,50	450	1,00	25
4	450	843,75	506,25	562,5	1,25	37,5
5	450	675	675	675	1,50	50

HL, hydraulic lime; SS, siliceous sand; AAC, Autoclaved Aerated Concrete recycled aggregates; W, kneading water; W/B, water/binder ratio; RA, AAC percentage by mass on the total aggregates.

2.2 Methods

2.2.1 Mixing procedure of mortars and testing program of physical, mechanical and resistance to carbonation properties

Physical, mechanical and resistance to carbonation tests were performed on prismatic specimens according to UNI EN 196-1:1996 specifications. The natural sand and the recycled

aggregates were dry premixed before they were blended with the hydraulic lime and the kneading water. The specimens were molded in prismatic casts (40x40x160 mm) and cured in a climatic chamber (MSL Humichamber EC 125) under controlled conditions according to UNI EN 1015-11:2007. Three specimens of each group were tested for density, porosity, water adsorption, compressive and flexural strength, two specimens of each group were tested for resistance to carbonation.

2.2.2 Apparent and bulk dry densities, open porosity and water adsorption

The tests were conducted according to UNI EN 1936:2007 specifications. The prismatic specimens were dried in an oven at 70±5° temperature until a constant mass was recorded.

As the mass was stabilized, the three specimens of each group were weighted and their dry mass M1 was recorded. Then the dry specimens were stored for 24h under vacuum in a vessel in which the pression was gradually lowered to 15±5 mmHg. After this period a volume of water was introduced in the vessel so that the specimens were immersed for at least 5 mm. The specimens were kept under vacuum and immersed in water for 24h with the same pression of 15±5 mmHg. Finally, the pression was returned to the atmospheric value and the specimens were left immersed for other 24h. After the 72h storage the immersed specimens were weighted and the M2 value was recorded. The mortars were then wiped with a cloth and the mass of the saturated specimens, noted M3, was measured.

The apparent (ρ_a) and the bulk (ρ_r) densities, the open porosity (p) and the water adsorption (W) were finally calculated using the UNI EN 1936:2007 equations.

2.3 Mechanical Properties

The compressive and the flexural resistance tests were performed according to UNI EN 1015-11:2007 procedure using the Alpha Technologies Tensometer 2020 machine. The compressive load cells were of three types: groups 3,4,5 were tested with 5kN, group 2 with 10kN and group 1 with 15kN. The flexural load cells were 5kN for groups 4,5 and 10kN for groups 1,2,3.

2.3.1 Adherence on substrates test

The adhesive strength of mortars on substrates was measured according to UNI EN 1015-12:2016 procedures. Three different substrates - brick, tuff and lapil-cement - were tested and their fracture patterns were compared.

2.3.2 Resistance to carbonation

The resistance to carbonation test and the analysis of the results were conducted according to UNI EN 13295:2005 indications. The carbonation depth was measured according to UNI EN 14630:2003 procedures. The measurement was repeated only two times - on 15th and on 30th day- because all the specimens were fully carbonated after thirty days.

3 Results

3.1 Apparent and Bulk Dry Densities, Open Porosity and Water Adsorption

The apparent and the bulk dry densities, the open porosity and the water adsorption of the tested

mortars are shown in Table 3. The mean values for the three specimens of each group are reported. The reference mortar -1- exhibited an apparent density 66% higher than the group 5.

The open porosity and the water adsorption of group 5 were respectively twice and three times as high as group 1.

Table 3. Apparent and bulk dry densities, open porosity and water adsorption. Mean values of the three specimens of each group are reported.

	ρ_a (g/cm^3)	ρ_r (g/cm^3)	*p* (%)	*W* (%)
1	1,75	2,24	22	12,58
2	1,51	2,13	29	19,35
3	1,27	1,95	35	27,12
4	1,20	1,91	37	31,07
5	1,05	1,87	44	41,53

ρ_a, apparent dry density; ρ_r, bulk dry density; p, open porosity; W, water adsorption

3.2 Mechanical Properties

The mean values of flexural and compressive strength are reported in Table 4. The flexural resistance of group 4 was tested only on two specimens due to the breakage of one sample during the curing period. The group 5 exhibited a flexural and a compressive resistance fifteen and ten times, respectively, as low as mortars of group 1.

Table 4. Flexural and compressive strength. Mean values of the three specimens of each group* are reported.

	σ_f (MPa)	σ_c (MPa)
1	2,62	6,93
2	1,54	4,53
3	0,67	1,49
4	0,13	0,90
5	0,17	0,57

* Except for flexural resistance of group 4 (mean values of two specimens); σ_f , flexural resistance; σ_c, compressive resistance.

The compressive strength values were compared to UNI EN 998-2:2016 and to UNI EN 998-1:2016 specifications with respect to the classes of masonry and rendering or plastering mortars, respectively. The classification of the tested mortars is reported in Table 5.

3.3 Adherence on Substrates Test

The adhesive strength of mortars on each of the tested substrates is shown in Table 6. Mean values of recorded resistance are reported along with UNI EN 1015-12:2016 fracture pattern classification. The A, B, C pattern types referred to an adhesion fracture at the interface between mortar and substrate, to a cohesion fracture in the mortar itself and to a cohesion fracture in the substrate material, respectively.

Table 5. Classification of the tested mortars according to UNI EN 998-1,2:2016.

3.4 Resistance to Carbonation

The results of the resistance to carbonation test are shown in Figure 2. On the 15th day the group five was carbonated twice as high as the reference mortar whereas all the specimens were fully carbonated on the 30th day.

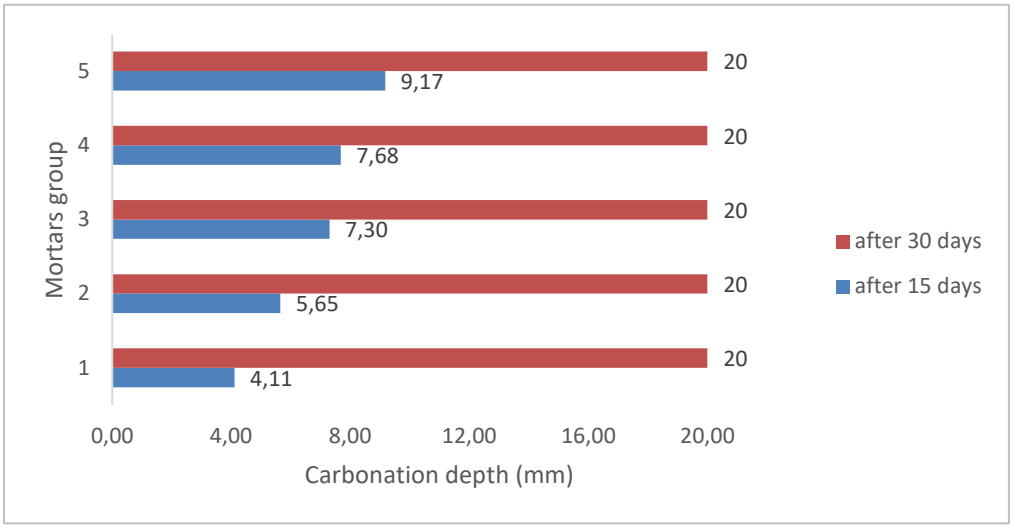

Figure 2. Resistance to carbonation test. Carbonation depth on 15th and 30th day are reported.

4 Discussions and Conclusions

The aim of the research was to investigate the influence of Autoclaved Aerated Concrete waste production aggregates on the mechanical and the durability properties of mortars, with specific respect to the resistance to carbonation. Results indicate that the replacement of the ordinary siliceous sand with AAC aggregate impacts on the hard-state properties of mortars.

The density and the mechanical properties – compressive and flexural strengths – and the adhesive strength to substrates decreased as the recycled aggregate percentage grew. Concerning the adhesive strength to substrate, the adherence to tuff rapidly lowered as the sand was replaced with AAC. Moreover, the open porosity and the water adsorption increased as AAC replaced the natural sand. Actually, the mortars with a higher percentage of AAC needed more kneading water due to the AAC adsorptive properties. Finally, the highest AAC mortar exhibited a short-term low resistance to carbonation, whereas the same value of carbonation depth was observed on 30^{th} day measurement for all the specimens.

Similar trends were reported by Blanco *et al.* (2000) who recorded a strong correlation between the use of lightweight aggregates and the physical and the mechanical properties of concretes. Moreover, the discussed results are consistent with Zhao *et al.* (2015) who measured the reduction of flexural and compressive strength of concretes due to the use of recycled aggregates. Tewar *et al.* (2017) also investigated the substitution of natural sand with AAC waste production aggregates and they reported the growing of kneading water mass and the lowering of compressive strength as AAC percentage was kept higher. Finally, the higher porosity of recycled-aggregates conglomerates was found responsible for a higher CO2 uptake, similar to Evangelista *et al.,*(2010); de Oliveira Andrade *et al.,*(2018).

However, the tested mortars were packaged with only one type of binder and one particle sizes distribution of aggregates, mainly ranged between 2 and 4 mm. Therefore, further studies are necessary to find if the type of binder and the packing of aggregates can modify the discussed results. The resistance to carbonation test needs to be repeated with a shorter time interval between the measures in order to better evaluate the evolution of the phenomenon. Finally, a mechanical test on the carbonated specimens has to be executed to investigate the effects of CO2 diffusion on the compressive and the flexural strength of the mortars.

In conclusions, the substitution of natural sand with AAC aggregates seems to be useful to package both masonry and rendering or plastering mortars. Moreover, the increased porosity and the reduced density of higher AAC percentage mortars suggest their potential thermal insulating properties. Conversely, a threshold for AAC percentage is necessary for masonry mortars packaged with hydraulic lime due to the reduction of mechanical performances and resistance to carbonation.

Effect of Supplementary Cementitious Material and Fine Recycled Aggregates on Shrinkage Properties of Self-Compacting Microconcrete

Miren Etxeberria and B.T. Purandhar Reddy

Department of Civil and Environmental Engineering (DECA), Universitat Politècnica de Catalunya-BarcelonaTECH, Campus Nord UPC, 08034-Barcelona, Spain, miren.etxeberria@upc.edu

Abstract. *An increase in the population has led to the progressive construction of infrastructures and buildings. This causes severe environmental problems, firstly high emissions of CO2 are caused in cement production; secondly, a high volume of construction and demolition waste is landfilled and thirdly, it is necessary to look for new, no natural resources for the production of construction materials. The objective of this work is to analyse the influence of fine recycled aggregates and high volumes of fly ash in the properties of high-performance self-compacting (SC) microconcrete. The experimental work presented in this paper was carried out in two phases. In phase 1, SC- microconcrete were produced with 100% of Portland cement, and natural sand was replaced by both mixed and ceramics recycled aggregates in 30% and 50%. In phase 2, SC- microconcretes were produced with the replacement of 50% of Portland cement by fly ash, and natural sand was replaced by both mixed and ceramics recycled aggregates in 30% and 50%. In each phase, the drying and autogenous shrinkage of all mortars was measured via their storage in a climate chamber after 24 hours of casting and the determining of properties during 90 days. In order to assess the influence of the shrinkage effect on the mechanical properties, the prismatic samples were also stored in a climatic chamber, and the compressive strength at several ages was determined in all of the SC mixtures. The results showed that the microconcretes produced employing mixed and ceramic fine aggregates achieved higher compressive strength and lower autogenous shrinkage. Although the C-N achieved the lowest drying shrinkage, the mixtures with 30% of CRA and MRA were found to have similar values. The employment of the CRA aggregates improved the drying shrinkage and compressive strength of the C-FA-N mixture.*

Keywords: *Self-Compacting Microconcrete, Fly Ash, Fine Recycled Aggregates, Shrinkage.*

1 Introduction

The portland cement (PC) industry is one of the major contributor to CO2 emissions. In recent years, Fly Ash (FA) has been widely used as supplementary cement material in replacement of part of PC in concrete construction. In addition, the mixtures employing FA require low water content in order to achieve good workability (Abdalhmid, Ashour, and Sheehan, 2019; Duran-Herrera, De-León-Esquivel, Bentz, and Valdez-Tamez, 2019; Kristiawan and Aditya, 2015; Matos, Foiato, and Prudêncio, 2019). Dinakar *et al.* (Dinakar, Kartik Reddy, and Sharma, 2013) described that about 30% -50% of FA content was ideal for the production of self-compacting concrete (SCC). It was determined that the replacement of 50 wt.% of PC by siliceous fly ash resulted in a low contribution to the hydration at early ages (up to 2 days of age). Between 12 h and 2 days after casting, the hydration is influenced by the so called "filler effect" of FA. Between 2 and 7 days, the fly ash reaction was detected by measuring the increase in chemical shrinkage, bound water and reduced portlandite contents (Deschner *et al.*, 2012). According to Matos *et al.* (Matos *et al.*, 2019), the compressive strength gains in SCC with FA were significant up to 180 days. According to certain researchers (Abdalhmid *et al.*, 2019; Duran-Herrera *et al.,* 2019; Kristiawan and Aditya, 2015) a higher cement replacement of FA tends to

decrease both drying and autogenous shrinkage. According to Altoubat *et al.* (Altoubat, Junaid, Leblouba, and Badran, 2017), the high strength SCC tested employing high degree of restraint (ASTMrings) showed that cement replacement of up to 35% of FA does not compromise the cracking resistance of the mix. The free shrinkage and thus the shrinkage potential of the SCC mixes decreases. It is also known that the employment of high absorption capacity recycled aggregates (RA) are able to reduce the autogenous shrinkage of high performance RA concrete (Etxeberria, Miren, Gonzalez-Corominas, 2018; Suzuki, Seddik Meddah, and Sato, 2009). The drying shrinkage of concrete increases when RA are employed. However, Behera *et al.* (Behera, Minocha, and Bhattacharyya, 2019) determined that in SCC concrete produced with fine RA and the ternary blend binder was more effective in controlling the shrinkage strain of concrete. Internal Curing can reduce autogenous shrinkage and improve concrete quality. Internal curing is necessary for designing HPC, and conventional concrete with low water–cement ratio, when RA have been employed (Al Saffar, Al Saad, and Tayeh, 2019).

In this research work the influence of the FA, supplementary cementitious material, as well as the employment of mixed and ceramic recycled aggregates (MRA and CRA, respectively) on the shrinkage and compressive strength of SC-microconcrete exposed to drying and sealing curing condition were analysed.

2 Materials

2.1 Binder

Portland cement (PC) CEM I 52.5 N-SR with a density of 3.22 kg/m^3 was employed for SC-microconcrete production. Class F Fly ash (FA) with a density of 2.21 kg/m^3 was also employed in up to 50% of replacement of cement volume.

2.2 Aggregates

Natural Silica sand (NA) with a fraction of 0/4 mm was employed for SC-microconcrete production. Its dry density and water absorption capacity at 24 hours were 2.47 kg/m^3 and 2.43%, respectively.

Fine MRA and CRA aggregates were employed in replacement of up to 50% of natural aggregates. The MRA aggregates were composed of approximately, 70% ceramic, 20% of concrete, 9.4% of raw aggregates, 0.5% of gypsum, and 0.1% of other components. The composition of the CRA aggregates was 100% ceramic material. The fraction of both RA was 0/4 mm, but their grading distribution was coarser than that of the NA aggregates, however they proved to have more particles finer than 63µm, which were 2%, 11% and 14.5% in the NA, MRA and CRA aggregates, respectively. The dry density (determined following UNE-EN 1097-6) of MRA and CRA were 1.92kg/dm^3 and 1.97kg/dm^3, respectively. The water absorption capacity of MRA and CRA was determined following UNE-EN 1097-6 specification proved to be 15.5% and 14.0%, respectively. The absorption capacity which was determined following the NY703-19 specification was 15.4% and 12.2%, respectively. Those last values were employed for concrete mixture design.

A superplasticizer based on PAE polymer technology was employed in all mixtures.

3 Mix Design and Production Process

Two series of the SC-microconcrete production were carried out, with five different mixtures produced in each of the series, see Table 1.

In Series 1 all the mixtures were produced employing 100% PC. In series 2, the same volume of binder employed in series 1 was used, but the binder was composed of 50% of PC and 50% of FA. In both series five SC-micrococrete mixtures were produced, one with 100% of natural sand and the other four mixtures employing MRA and CRA in 30% and 50%. In all mixtures the effective water-cement ratio of 0.27 was maintained. The RA was employed in saturated conditions (the value determined according to NY 703-19 standard).

A planetary mixer BE-20, in a low –medium speed was employed for SC-microconcrete production. The same production process was applied for all the SC-microconcretes. Firstly PC, FA and the 95% of effective water amount were mixed; secondly NA, the pre-saturated MRA/CRA were added to the mixer and mixing continued at a low speed. Thirdly, the chemical admixture was added together with the 5% of effective water amount. Finally, all the accumulated material was removed manually from the bottom and mixing continued for a few minutes. On finalizing the SC-microconcrete production, a slump flow test was performed according to EFNARC (Ankush, Rajeev, and Koshta, 2014; European Federation for Specialist Construction Chemicals and Concrete Systems (EFNARC), 2005). The spread diameter, D, of all the mixtures kept within the range of 250 ± 10 mm (see Table 3). The flow of the mixtures was adequate, and did not present bleeding and segregation. In series 2, the SC-microconcrete produced employing CRA needed a higher amount of admixture in order to achieve adequate fluidity. While following NY703-19 specifications which gave the CRA absorption capacity as 12.2% we believe it to be more advisable to follow UNE-EN-1097-6 which determined it to be 14%.

4 Test Procedure

All specimens were demoulded after 24 hours of casting and were exposed in a climatic chamber in drying condition (23 ±3ºC and 50%±3% of RH) and sealed condition (23 ±3ºC) in order to determine the drying and autogenous shrinkage after 24 hours of casting. The compressive strength of samples exposed to those curing condition was also determined.

4.1 Shrinkage (Autogenous-Sealed and Drying)

The shrinkage of the SC-microconcrete was determined following UNE-EN 12617-4 specifications. Six 25x25x287 mm specimens were produced for each type of SC-microconcrete. After casting, they were covered with plastic film, in order to avoid water evaporation, and place in the humidity room for 24 hours. After 24 hours of casting, all the specimens were demoulded. Half of the specimens were employed for autogenous (sealed) shrinkage determination and the other half for drying shrinkage (both shrinkage measurements were determined 24 hours after casting). A digital length comparator was employed for length measurements at different ages. According to their autogenous shrinkage values, the specimens were sealed with aluminium adhesive tape immediately after demoulding and placed in the climatic chamber at 23 ±3ºC. It was then that the first length (control length) measurement was carried out and periodically over 90 days. In order to determine the drying shrinkage value, after demoulding, the specimens were place in a climatic chamber at 23 ±3ºC and 50%±3% of

RH and the initial length was measured. The length measurements were carried out periodically for 90 days.

Table 1. Mix proportions of Series 1 and Series 2 microconcrete mixtures. The values are given of kg of component/m^3 of concrete production.

*Admixture is the % with respect to cement weight ** C-CRA50-ABS or C-FA-CRA50-ABS: the absorption capacity of RCA was considered of 14% determined following UNE-EN 1097-6

4.2 Compressive Strength

The compressive strength was determined following UNE-EN 12390-3 specifications (according to the dimensions and mechanical test procedure). Prismatic specimens of 40x40x160mm were produced for all mixtures. They were demoulded after 24 hours of casting and were exposed in a climatic chamber in identical conditions to those of the specimens employed for shrinkage testing. Four samples were employed for compressive strength determination.

5 Results

5.1 Autogenous (Sealed) Shrinkage and its Mechanical Properties

5.1.1 Shrinkage

The sealed- autogenous shrinkage in hardened state of each mixture produced in series 1 and series 2 are illustrated in Figure 1. According to the results of the autogenous shrinkage in S1 samples, it was clear that the C-MRA50 mixture achieved the lowest shrinkage. The 50% of MRA, which had the highest absorption capacity, was efficient reducing initial shrinkage. The C-N mixtures achieved the highest shrinkage during the first 2 days. In all probability this difference was higher during the first 24 hours after casting. In series 2, due to higher water and lower cement amount, the initial shrinkage values were lower than those in Series 1. After 28 days, the autogenous shrinkage of the C-MRA50 mixture was still found to be the lowest. However, the shrinkage caused by the hydration of the cementitious material was found to increase with time (see figure c) and d)). In all probability was due its to very high cementitious

material. The mixtures produced employing 30% of MRA and CRA, and 50% of CRA were not able to release enough water in order to reduce the shrinkage value in series 1. In series 2, the RA worked more efficiently probably due to the slightly higher water amount employed in this series and the presence of FA.

5.1.2 Compressive strength

Figure 2 illustrates the compressive strength at 2 and 28 days of the recycled aggregate microconcretes produced in series 1 and series 2 with respect to those of the conventional microconcrete. The compressive strength values of C-N and C-FA-N at 2 days (2D) and 28 days (28D) are also described in figure 3. In series 1, all the Sc-microconcretes produced with RA achieved more than 95% of the compressive strength achieved by the C-N mixture after 2 days (1 day in mould and 1 day in the chamber). At 28 days , all the RA microconcrete obtained higher strength than that of the C-N microconcrete. The C-MRA30 and C-CRA50 microconcretes achieved the highest strength. The internal curing capacity of the RA improved the compressive strength of the SC-microconcretes. However, the weak properties of the mortar present on the MRA reduced the strength of the SC-microconcrete when it was produced with 50% of MRA.

As expected the early strength value of SC-microconcretes was considerably reduced by using a high percentage of fly ash (Abdalhmid *et al.,* 2019). The samples produced in series S2 achieved 50% lower compressive strength than its corresponding sample in series S1 after 28 days. In series 2, the mixtures produced with RA achieved a lower early compressive strength than that of C-AF-N during the first 2 days. However, this increased after 28 days, and they achieved the same strength of the C-FA-N mixture.

In general, the SC-microconcrete produced employing MRA and CRA achieved a higher increase of strength from 2 to 28 days than that of C-N and C-FA-N mixtures.

5.2 Drying Shrinkage and its Compressive Strength

5.2.1 Drying shrinkage

Figure 3 a) and b) show the drying shrinkage values obtained by each mixture produced in series 1 and series 2, respectively, exposed to a climatic condition for 90days. In both series, the C-N and C-FA-N mixtures obtained the lowest drying shrinkage value. While in series 1 (100% of PC) the C-MRA50 and C-CRA50 mixtures achieved the highest shrinkage, in series 2 the SC-microconcrete produced with CRA achieved similar drying shrinkage to that of the C-FA-N mixture. The FA reduced the rate of hydration and thus the drying shrinkage of the microconcrete containing FA was considerably lower than that of the S1 mixtures (Abdalhmid *et al.*, 2019).

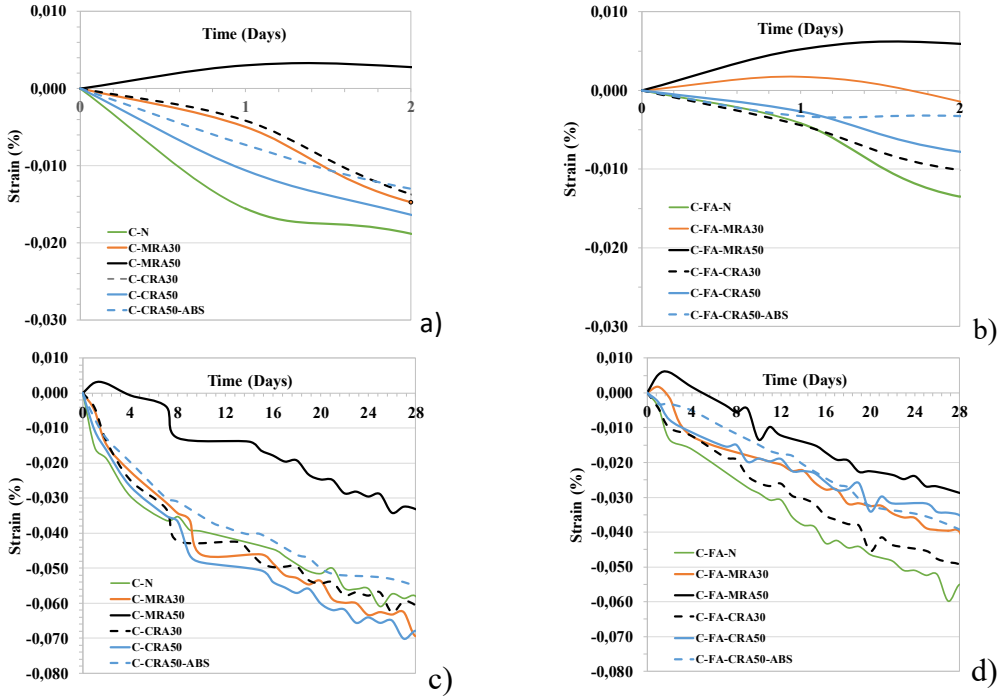

Figure 1. Autogenous (sealed) shrinkage values of Series 1 mixtures a) 2days, c) 28 days and Series 2 b) 2 days and d)28 days. (the time of 0 day is referring to 24hours after casting).

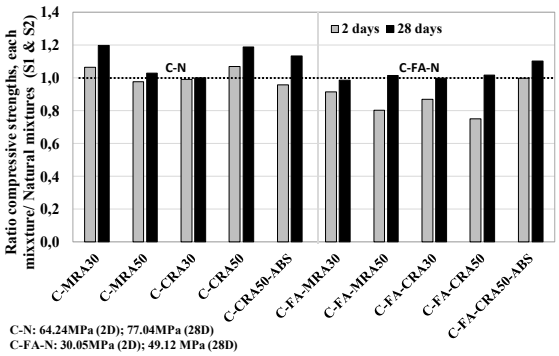

Figure 2. Ratio of compressive strength of recycled microconcretes with respect to conventional one at 2 days and 28 days after sealed condition at 23ºC.

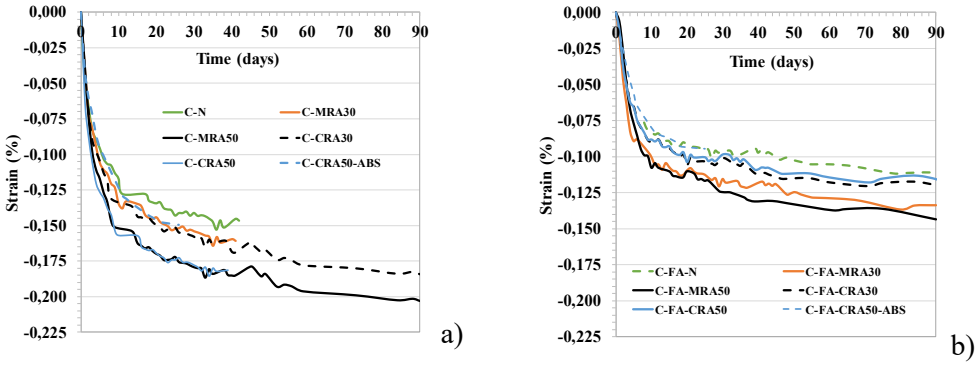

Figure 3. Drying shrinkage of the samples produced at series 1 (a) and series 2 (b).

5.2.2 Compressive strength

Figure 4 illustrates the compressive strength of SC-microconcretes produced with RA with respect to those of the conventional SC-microconcrete, series 1 and series 2, after 2 and 28 days. The compressive strength values of C-N and C-FA-N at 2 days (2D) and 28 days (28D) are also shown in figure 4. The SC-microconcretes produced in Series 1 achieved much higher strength than those produced in series 2, due to the fast drying process, in all probability the high volume of FA was not hydrated.

In series 1, the C-CRA mixtures achieved higher compressive strength than that of the C-N mixture at 2 and 28 days. However, the increase of compressive strength, from 2 to 28 days, was lower in all RA mixture than that of C-N, with the exception of the C-CRA30 mixture.

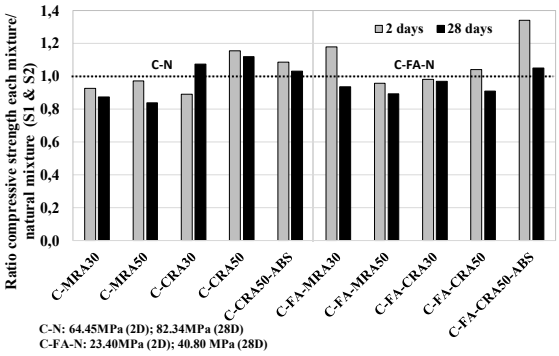

Figure 4. Ratio of compressive strength of recycled microconcretes with respect to conventional one at 2 days and 28 days (1days in mould and 27 days in drying condition).

In series 2, the mixture C-FA-CRA50-ABS achieved the highest compressive strength (the absorption capacity of 14% was the optimum). In general, the microconcrete produced with RA reached similar o higher strength values to that of C-FA-N after 2 days, all the RA microconcretes achieved lower strength values to those of the C-FA-N after 28 days.

6 Conclusions

The following conclusions can be drawn based on the results presented above:

- The autogenous shrinkage was effectively reduced by employing the MRA and CRA aggregates in SC-microconcrete mixtures made with 100% of PC, achieving also a higher compressive strength to the mixtures produced with NA. The C-MRA50 mixture achieved the lowest shrinkage value. However, due to the low mechanical properties of MRA aggregates, the C-MRA30 and C-CRA50 mixtures achieved a higher strength.
- The employment of 50% FA as a binder caused a reduction of up to 40-50% of the autogenous shrinkage value. The compressive strength was also reduced when compared to the mixtures produced with 100% of PC. The use of RA in FA mixtures also produced a favourable effect on lowering of the shrinkage value and the increasing of the strength value with respect to those SC-microconcrete produced employing NA and FA after 28 days.
- Although the C-N achieved the lowest drying shrinkage, the mixtures with 30% of CRA and MRA were found to have similar values. In addition, the mixtures made with CRA achieved the highest compressive strength when 100% of PC was employed.

- The employment of FA reduced the drying shrinkage as well as the compressive strength in up to 40-60% with respect to values obtained by mixtures produced with 100% of PC. The employment of the CRA aggregates improved the drying shrinkage and compressive strength of the C-FA-N mixture.

Abstract. *Cracks due to the service load in the reinforced concrete structures are controlled at the design stage, by limiting the calculated crack width. Widely used crack width calculation models (Eurocode 2 and Model code 2010), estimates the crack width by multiplying the crack spacing with the mean strain difference of concrete and reinforcement. Concrete cover thickness and the ratio of diameter to reinforcement area to effective tensile area of concrete ($Ø/\rho_{p,ef}$) are the two main crack spacing governing parameters in the aforementioned models. The existing models are mostly applicable when concrete cover thickness is within the specified limit. For example, Model Code 2010 model limits the concrete cover thickness to 75 mm. In order to identify the influence of aforementioned two governing parameters on crack spacing, the results of recent experiments have been considered. According to some recent studies, it is found that the concrete cover thickness has a significant influence and the $Ø/\rho_{p,ef}$ parameter has a negligible effect on crack spacing. To investigate the reasons why the $Ø/\rho_{p,ef}$ parameter has a negligible effect on crack spacing, the involvement of bond properties is needed to study. Some authors have specified that the large diameter bars consist of higher bond force per unit surface area than the small diameter bars, due to the high rib area. Due to this reason, the similar bond behavior could be identified, from low number of large bar diameters and high number of small diameter bars. A literature review has been carried out to study the bond behavior on specimens subjected to pure tension. With the facts and available data, it is further verified that the $Ø/\rho_{p,ef}$ parameter has a negligible influence and concrete cover thickness has a significant effect on crack spacing.*

Keywords: *Crack Spacing, Concrete Cover, Bond Stress-Slip, Axial Tension.*

1 Introduction

Cracks in the reinforced concrete (RC) structures create issues to the durability, aesthetic appearance and the liquid or gas tightness of the structure. Among the various types of cracks that can generate in a structure, the cracks due to service load is controlled at the design stage by limiting the calculated crack width. In the most widely used codes of practices (Ex. Eurocode 2, 2004; Model code 2010, 2013; etc.), the calculated crack width is governed by multiplying the crack spacing with the mean strain difference between reinforcement and concrete. Therefore, the crack spacing parameter can be identified as an important factor in crack controlling criteria. However, it has identified many limitations in the above-mentioned available crack controlling methods (Ex. limitation for the maximum value of concrete cover thickness). Further, there are many experimental evidences from previous literatures, that the experimental predictions do not match with the code prediction values.

In the aforementioned codes, the concrete cover thickness and $Ø/\rho_{p,ef}$ parameter (ratio of diameter to reinforcement area to effective tensile area of concrete) have identified as the two most governing factors of the crack spacing model. In order to improve the existing models, the authors have studied the behavior of aforementioned parameters with the help of available literatures. The crack width or crack spacing models developed in the mentioned codes are based on the axial tension experiments of an RC tie subjected to pure tension. Because a RC tie in pure tension can be represented the tensile region of a bending member with or without axial tension (Debernardi *et al.,* 2013). There are many previous experiments reported, which have

studied about the cracking behavior of RC members. Among them, it can be found various types of data to identify the crack width governing parameters. However, with the advancement of material and geometrical properties of concrete and reinforcement, the authors have selected two recent axial tensile experiments mentioned in (Tan *et al.,* 2018; Tan *et al.,*2019) and (Rimkus and Gribniak, 2017), to identify the crack spacing governing parameters. The selected experiments consist of the RC ties with multiple reinforcement bars, which are more similar to the RC members in practice.

The concrete cover parameter and $\emptyset/\rho_{p,ef}$ parameter is available in the existing crack governing models are due to the 'no-slip theory' and 'bond-slip theory' respectively (Saliger,1936; Broms, 1965). The 'no-slip theory' assumes a perfect bond between reinforcement and surrounding concrete. The 'bond-slip theory' considers that a slip occurs between the reinforcement-concrete interface. From the selected experimental data, it could identify that concrete cover thickness has a significant impact on crack spacing, and therefore to the crack width. When considering the effect of $\emptyset/\rho_{p,ef}$ parameter, it could identify that the parameter has a negligible effect on the crack spacing (Beeby, 2004; Rimkus and Gribniak, 2017). When trying to identify the reasons for this controversial conclusion, Ålander in (Beeby *et al.,* 2005) makes a statement, that when the bar diameter increases, the rib area also increases (even with similar rib pattern). This increased rib area in larger bar diameters cause to have a higher bond force per surface unit area, than the smaller bar diameters (Noghabai, 1995). This effect is not considered in the existing EC2 or MC 2010 models. The mentioned models assume the bond-stress is only a factor of tensile strength of concrete. For example, MC 2010 assumes that the mean bond stress between concrete and reinforcement is equal to 1.8 times the mean tensile strength of concrete in the stabilized cracking stage.

Balaz (1993), introduces a mathematical model to identify crack widths by using the well-known Ciampi-Eligehausen (Ciampi *et al.,* 1981; Eligehausen *et al.,* 1982) bond-slip model. Ciampi-Eligehausen, bond-slip model is based on Rilem-type pull-out test (RILEM, 1994) results. Therefore, at first this paper reviews literatures focusing on the effect of rebar size on bond properties in Rilem-type pull out tests. However, many existing literatures concluded that, bond strength and stiffness decrease with the increase of bar diameter (which is opposite to the expected results). Therefore, this paper investigates the actual bond-slip behavior of specimens subjected to 'axial tension'.

2 The Behavior of Concrete Cover and $\emptyset/\rho_{p,ef}$ Parameter on Crack Spacing from the Recent Experiments

Table 1 shows the test results of axial tensile experiments of RC ties mentioned in Tan *et al.,*(2018) and Tan *et al.,* (2019). Table 1 confirms that the increase of concrete cover, cause to increase crack spacing. When comparing the specimen 1 and 3, with the increase of concrete cover, the maximum crack spacing (Table 1) increases. Likewise, the crack spacing values and specimen 2 and 4 behaves similarly.

Table 1. Crack spacing values measured in stabilized cracking stage (Tan *et al.,* 2019).

Specimen No.	Width × height × length (m × m × m)	No. of bars	Diameter (mm)	Cover (mm)	$\emptyset/\rho_{p,ef}$	$S_{r,mean}$ (mm)	$S_{r,max}$ (mm)
1	0.4 × 0.4 × 3	8	32	40	796	178	240
2	0.4 × 0.4 × 3	8	20	40	1274	163	250
3	0.4 × 0.4 × 3	8	32	90	796	266	320
4	0.4 × 0.4 × 3	8	20	90	1274	217	290

Considering specimen 1 and 2 (likewise, 3 and 4) with the same concrete cover thickness, specimen size and material properties, the effect of $\emptyset/\rho_{p,ef}$ parameter on crack spacing cannot be compared, due to difference in steel areas (Specimen 1 and 2 have $8\times\pi\times16^2$ mm^2 and $8\times\pi\times10^2$ mm^2 steel areas respectively). The same steel area can be represented with different sizes of reinforcement. If small diameter bars are used, the circumference area of the rebar are higher than when the same steel area is replaced by large diameter bars. For example, if one 16 mm bar is replaced with four 8 mm bars (similar steel area), the circumference area is doubled [$(4\times\pi\times8) / (1\times\pi\times16) = 2$]. Therefore, the higher number of smaller diameter bars consist of higher concrete-reinforcement interface area than the few number of large diameter bars arrangement. When bond area becomes large, transfer length will be low. In theory, the RC specimens with similar cross-sectional area and similar steel area, the larger bar diameter has the higher $\emptyset/\rho_{p,ef}$ value. According to the EC2 and MC 2010 crack spacing models, this cause to predict larger crack spacing values than the specimens with smaller bar diameter.

Rimkus and Gribniak (2017) have studied the effect of $\emptyset/\rho_{p,ef}$ on crack spacing, by keeping the steel area and other previously mentioned crack spacing governing parameters constant. In the study, the different values for $\emptyset/\rho_{p,ef}$ has been obtained by changing the rebar diameters. This experiment had tested 21 number of specimens with 150 mm x 150 mm (Height x width) cross section size and 30 mm concrete cover thickness. The study have tested three different steel areas of 315 mm^2, 450 mm^2 and 607.5 mm^2 (Steel ratio ($\rho_{p,ef}$) of 1.4 %, 2.0 % and 2.7 % respectively) and used different deformed bar sizes of 5 mm, 6 mm, 8 mm, 10 mm, 12 mm and 14 mm diameters to change the $\emptyset/\rho_{p,ef}$ ratio. However, the final conclusion of the experiment is that, the crack spacing has a negligible influence from the $\emptyset/\rho_{p,ef}$ parameter.

The conclusions of the aforementioned results in Rimkus and Gribniak (2017), gives a good agreement with the statement of Beeby (2004). Moreover, Beeby (2004) compares previous experiment results of (Farra and Jaccoud, 1994; Haqqi, 1983) and concluded that the $\emptyset/\rho_{p,ef}$ parameter does not influence on crack width or crack spacing. However, when the experiments in (Farra and Jaccoud, 1994; Haqqi, 1983) have altered the $\emptyset/\rho_{p,ef}$ parameter for the comparison, the reinforcement ratios also differed unlike in the experiments of (Rimkus and Gribniak, 2017). Therefore, the statement of Beeby (2004) is further confirmed from the experimental results of (Rimkus and Gribniak, 2017).

3 The Involvement of The Bond-Properties to the Crack Spacing Models.

It is vital to investigate reasons why the previous experimental findings shows that $\emptyset/\rho_{p,ef}$ parameter, (which appears from the 'bond-slip approach') does not influence on crack spacing. Alander, who had studied the reinforcement rib geometry on crack widths in Alander (2002), have made a good explanation for this reason in the discussion paper Beeby *et al.* (2005). According to their findings, the bond per surface area of every reinforcement is not similar, due to the different rib geometry. Moreover, when the diameter of a bar increases, the bond strength increases, due to the increase in rib area and height relative to the smaller bar diameters (nominal bar diameter to rib height is generally used as 22). Therefore, the assumption made on developing the existing crack spacing models that the bond stress is similar among every bar diameter have to be reconsidered.

The rib pattern or height are considered as the governing factors of the bond-strength and bond-stiffness of a reinforcement. The ratio of the nominal bar diameter to rib height is generally used as 22 in reinforcement (Metelli and Plizzari, 2014). Bond-index parameter quantitatively represent the effect of rib-pattern and rib-height of a specific reinforcement. The

bond-index is identified as the most governing rib parameter that influences bond-strength and bond-stiffness and EC2 specifies to have a minimum bond index of 0.056 for a bar exceeding the diameter of 12 mm. To investigate the statement made by Alander in Beeby *et al.* (2005) discussion paper, a literature review has been studied on the size effect of the bars on the bond between concrete and reinforcement. The details and the conclusions of some existing literatures are listed in the Table 2.

Table 2. Summary of the previous studies on the bond behavior for size effect.

Publication	Experiment	Diameter (mm) - [Bond Index]	Results
Bažant *et al.* (1995)	Unconfined Pull-out test	3.175, 6.35, 12.7, 25.4 [smooth bars]	Size effect presents. Bond strength is low in large bars.
Noghabai (1995)	Confined (steel casing) Pull-out test.	8, 16, 32 [Deformed bars]	Bond strength increases with the diameter. The embedded length is short (2.5*diameter).
Bamonte and Gambarova (2007)	Confined (steel casing) Pull-out and push-in tests.	Machine Ribbed 5, 12, 16, 28 – [0.086]	Bond strength decreases with the increase of bar diameter
Metelli and Plizzari (2014)	Unconfined Pull-out test	Machine Ribbed 12, 16, 20 – [0.04-0.105] Commercial (hot-rolled) 12 - [0.095,0.105] 20 - [0.079, 0.089] 40 - [0.054, 0.072] 50 - [0.04, 0.063]	Bond strength increases with the increase of bond index (rib area). Bond strength and stiffness decreases with the increase of bar diameter.
Shima *et al.* (1987)	Confined Pull-out test for long embedded length (40 times diameter).	Ribbed Bars 19.1 25.4 31.8	Bar Diameter has a small effect and bond strength is proportional to 2/3 power of concrete compressive strength.
Morita (1994)	Confined (large covers (5.5*dia.)) Axial tensile test.	3, 7, 13, 19, 25, 51 [Deformed bars]	Size effect does not present in specimens subjected to axial tension with large covers.

According to the Table 2, except in Noghabai (1995), other experiments have concluded that the bond strength decreases with the increase of bar diameter. These results does not agree with the previously mentioned statement by Alander in Beeby *et al.* (2005) discussion paper. This can lead to another direction, whether the pull-out or push-in tests represents the bond-behavior of an RC tie subjected to axial tension or flexure. The authors in (Alander, 2002; Beconcini *et al.,* 2008; Mazzarolo *et al.,* 2012) explains that the traditional Rilem-type tests (RILEM, 1994) does not represent the bond condition of a member subjected to bending or axial tension. The main reasons for the discrepancy are identified as the short anchorage length (embedded length is five times the bar diameter), one-way loading method (the concrete parallel to the reinforcement is in compression), failure mode (splitting failure that occurs in unconfined tests) in the standard pull-out tests. The short embedded length is decided in the Rilem-type test is to ensure the uniform distribution of the bond stress along the bar (Mazzarolo *et al.,* 2012) and to reach the bond-failure before rebar yields (Bamonte and Gambarova, 2007; Mazzarolo *et al.,*

2012). In order to make the experimental conditions closer to the practical situation, Shima *et al.,* (1987) have used longer embedded lengths (40 times diameter) and studied the size effect on bond stress (Table 2).

It has observed that the reinforcement-concrete interface in axial tensile members does not subject to the range of slip value as observed in the Rilem-type tests. The experimental investigation of the crack widths at the level of reinforcement in (Borosnyói and Snóbli, 2010; Husain and Ferguson, 1968; Tammo and Thelandersson, 2009) have proved that the slip is in the range of hundredth of a millimeter (ex. 0.01 mm to 0.06 mm). These studies have observed the crack width propagation along the concrete cover thickness by sealing the crack, with a hardened epoxy and examining by cutting the specimen. (Borosnyói and Snóbli, 2010; Caldentey *et al.,* 2013) have explained the reason for the relatively small crack widths at the reinforcement face. They have considered that it is due to the accumulation of strains in secondary cracks, which are identified as Goto cracks in Goto (1971). These secondary cracks are developed around the primary cracks (Debernardi *et al.,* 2013; Debernardi and Taliano, 2016) and therefore the 'slip' is considered as spread at the vicinity of primary crack. However, Yannopoulos (1989) has conducted experiments to study the variation of crack widths along the concrete cover thickness. During, the experiment, the increase length of specimens was measured using gauges that were fixed at the both end-faces perpendicular to the reinforcement of the axial tensile tie. One measurement was obtained 2.2 mm away from the reinforcement and the other measurement was obtained at the edge (i.e. at a distance of concrete cover) of the specimen. The obtained average change in length were 0.06 mm and 0.13 mm respectively. The conclusion is that, even the internal cracks do exist, their accumulation does not equal with the crack widths at the concrete surface. Therefore, the internal cracks (spread around primary cracks) cannot be considered as a contributor to the slip.

The experiment mentioned in Beeby (2004), contributes to the fact that, slip does not occur between reinforcement and concrete interface in axial tensile members. A layer of grout is applied at the end faces of RC tie (faces perpendicular to reinforcement) and observed no cracks in the reinforcement-concrete interface after the tensile load is applied. Due to these facts, the slip between reinforcement and concrete can be expressed as negligible and the cracking is according to the 'no-slip theory'. However, to ensure this fact, the authors have studied through the aforementioned bond-slip experiments conducted for axial tensile experiments. The method of slip and bond-stress measurements in conducted axial tensile experiments are listed in Table 3. Except for the experiment mentioned in Doerr (1978), other listed experiments have not measured the concrete strain separately to obtain the slip. Either the researcher has neglected the concrete strain or calculated it from the force equilibrium using only the reinforcement strain. There is a possibility that these calculated concrete strain can be due to 'no-slip' conditions. The experiment mentioned in Doerr (1978), which had separately measured the 'concrete strain' with strain gauges, 16 mm away (one diameter length) from the reinforcement face. This measurement does not represent the slip at the reinforcement – concrete interface. Based on above reasons it is not clear whether the experiments given in Table 3 have measured the actual value of slip.

Table 3. Details of the axial tensile experiments focused on bond-slip.

Experiment	Details	Bond stress	Slip
Doerr (1978) Cylindrical specimen dia.= 150 mm. Length = 600 mm. Bar dia. = 16 mm Strain gauge on rebar and concrete. Spacing = 28 mm	Concrete strain gauges were placed 16 mm away from concrete, while casting. Electrical resistance wire strains were used. Specimen were sectioned to 28 mm size parts along the length.	Bond stress ($\tau_{(x)}$) along the bar $\tau(x) = -\frac{1}{\pi\varphi}.\frac{dP(x)}{dx}$ $P_{(x)}$- Force in reinforcement. Where P(x) can be identified by interpolating the steel strain at each segment.	Slip of the element 'a+1' ($s_{(a+1)}(x)$), $s_{(a+1)}(x) = \varepsilon_{s,a}.dx - \varepsilon_{c,a}.dx$ $\varepsilon_{s,a}$ – Strain in 6einforcement $\varepsilon_{c,a}$– Strain in concrete dx – spacing of strain guages
Morita (1994) Rectangle specimens Square c/s = 12*φ Length = 60*φ Strain gauge only on rebar. Spacing = 5* φ	Concrete strain is neglected when calculating the slip, assuming the domination contributor to the slip is the internal cracks.	Bond-slip model identified by (Muguruma, Morita, and Yoshida, 1967) $\frac{d^2y\ s(x)}{dx^2} = \frac{4\ (1+np)}{Es}.\tau(x)$ s(x) – Slip n – Modulus ratio p – Steel Ratio	Slip is identified from the steel strain, neglecting concrete strain. Slip of the element 'a+1', $s_{(a+1)}(x) = \varepsilon_{s,a}.dx$
Beconcini *et al.* (2008) Cylindrical specimen dia.= 132 mm. Length = 1000mm. Bar dia. = 16 mm Strain gauge only on rebar. Spacing = 25mm	Specimen were sectioned to 25 mm size parts along the length. Concrete and steel stresses and strains of each section were identified with a constitutive model based on Ramberg Osgood formation and with the force equilibrium F = Fs+ Fc.	Equilibrium of a rebar portion $d\sigma s\ .\frac{\pi\varphi^2}{4} = \pi\varphi\tau(x)$ σs – Steel stress calculated from steel strain	From the definition of slip $\frac{ds}{dx} = \varepsilon s - \varepsilon c$

When considering the bond-slip behavior of the specimens subjected to axial tension, it can be concluded that the 'bond-slip' theory can cause a negligible influence on crack spacing. Therefore the involvement of $\emptyset/\rho_{p,ef}$ parameter on crack spacing behavior have to be reconsidered. Further This description ends with agreeing the conclusion of Beeby (2004), that the $\emptyset/\rho_{p,ef}$ parameters has a negligible effect, while concrete cover thickness has a significant effect on crack spacing and therefore to the crack width.

4 Summary and Conclusions

Concrete cover thickness and $\emptyset/\rho_{p,ef}$ parameter have identified as governing parameters of crack spacing models in Eurocode 2 and Model code 2010. From the recent experimental results, it

could be identified that the concrete cover thickness has a significant effect on crack spacing. However, the $\emptyset/\rho_{p,ef}$ parameter, which present in the crack spacing model due to the 'bond-slip theory' has an negligible influence to the crack spacing. A possible reason for that can be the effect of different rib indexes of different bar sizes, which is not taken into account in the above-mentioned crack spacing models. Experimental results showed similar crack spacing values using low number of large bar diameters and high number of small bar diameters. Therefore, the bond per unit surface area have to be higher in large diameter bars than small diameter bars. A literature survey is carried out to identify the aforementioned effect and it is found that, the bond per unit surface area is getting lower with the increase of bar diameter. Moreover, it is vital to investigate the applicability of Rilem-type pull-out test results to study the bond behavior in a RC tie. The main contradiction is the, obtained slip value in axial tension is significantly smaller than Rilem-type pull-out tests. Further, there is an argument that the internal cracks contribute to the slip. However, the results of Yannopoulos (1989) have proved that the internal cracks do not have a significant contribution to the slip. Further, Beeby (2004) have experimentally proved that there is no slip occurred at the reinforcement-concrete interface of an RC tie in pure tension. Moreover, as mentioned in the available studies on bond-slip behavior subjected to axial tension, have not measured the concrete strain separately, to measure the slip value. Therefore, it can be concluded that the mentioned crack spacing models have overestimated the effect of bond-slip behavior.

Influence of High Volume Fly Ash and Recycled Aggregates in Chloride and Carbonation Resistance of Concrete

Miren Etxeberria and Fernando Álvarez

Departament of Civil and Environmental Engineering, Universitat Politècnica de Catalunya-BarcelonaTECH, Campus Nord UPC, 08034-Barcelona, Spain, miren.etxeberria@upc.edu

Abstract. *This paper deals with the evaluation of the influence of recycled concrete aggregate (RCA) and the employment of high volume of fly ash (FA) on the physical, mechanical and durability (chloride ion penetration and carbonation) properties of concretes. The obtained values of which, being compared to those of conventional concretes. Concrete was produced using 0%, 25% and 50% FA in replacement of Portland cement, and 0% and 50% of RCA in substitution of natural aggregates. All the concretes were produced employing an effective water-cement ratio of 0.50. The physical properties at 28 days and the compressive strength at 7, 28 and 90 days were determined in all the concretes produced as well as the assessment of durability (penetration of chlorides and depth of carbonation) on all concrete mixtures. The depth of the carbonation was determined after submitting every concrete sample to a series of accelerated tests at 20% of CO_2 concentration during 7, 14 and 28 days after the curing period in the humidity room and pre-condition in the laboratory. The chloride penetration was determined at 28 and 90 days of curing. It was concluded that the employment of 50% of un-carbonated RCA increased the early strength of concrete produced using FA, and at late ages, RCA concretes achieved similar strength when 25% of FA was employed. The concrete produced with 50% of FA achieved the highest resistance to chloride ion penetration also when RCA was employed. Although the use of FA increased the carbonation depth of the concrete samples, the employment of the un-carbonated RCA reduced that effect. The employment of RCA with CEM II or binder with 25% of FA caused the lowest carbonation depth.*

Keywords: *Fly Ash, Recycled Aggregates, Concrete, Carbonation, Chloride Resistance.*

1 Introduction

Concrete production has a high impact on our environment due to the abundant consumption of energy and a large amount of CO_2 emissions in cement production. In addition, the demolition of concrete structures causes a considerable volume of waste to end up in landfills. These problems may be reduced, achieving a green concrete, by employing fly ash (FA) as supplementary cementitious materials and recycled concrete aggregates (RCA) in replacement of cement and natural aggregates, respectively for concrete production (Marinković, Dragaš, Ignjatović, and Tošić, 2017).

It is known that the RCA is suitable for concrete production (Chen *et al.*, 2019), in addition the employment of recycled aggregate concrete (RAC) as structural material has been widely analysed and validated for many applications (Pedro, De Brito, and Evangelista, 2014). However, the durability of concrete produced with RCA is actively being studied in order to improve its qualities (Guo *et al.,* 2018). According to Guo *et al.* (Guo *et al.,* 2018) RAC has lower chloride ion diffusion resistance than conventional concretes due to the RCA's high porosity. According to the results of a carbonation resistance test, when the RAC were produced employing at least 70% of RCA, the resistance was found to be higher due to the larger amount of mortar in recycled concrete. In contrast, the results of studies by Silva *et al.* (Silva *et al.,*

2015) determined that the carbonation of concrete produced with 100% of RCA was 2.5 times higher than that produced with natural aggregates.

On the other hand, today the use of FA up to 15-20% (Chandra and Bendapudi, 2015) or up to 15-30% (Xu and Shi, 2018) in concrete production is considered usual and it has been determined that the employment of high amount of FA controlled the temperature of concrete and achieved adequate mechanical and durability properties. It is known that the concretes produced with FA have low strength at initial ages, this effect being more evident when higher percentages of FA are employed in concrete production and less evident when concrete are produced with a low water/cement ratio. However at later ages, the strength of concrete increases due to the reaction of its FA with Portlandite (Kocak and Nas, 2014; Xu and Shi, 2018). According to Lam *et al.* (L. Lam, Y.L. Wong, 1998) the chloride ion penetration resistance of concrete is higher when FA is employed. Dinakar *et al.* (Dinakar, Kartik Reddy, and Sharma, 2013) described that concretes achieve their highest strength and chloride ion resistance when up to 30% of FA is employed for concrete production. However, several other researchers (Kurda, De Brito, and Silvestre, 2019) determined that concrete produced with FA achieves lower carbonation resistance than the concrete produced employing 100% of Portland cement.

In this paper, the influence of RCA and the employment of high volumes of FA on the physical, mechanical and durability (chloride ion penetration and carbonation) properties of concretes have been evaluated, and those values were compared to those of conventional concretes. Concretes were produced using 0%, 25% and 50% FA in replacement of Portland cement, and 0% and 50% of RCA in substitution on natural aggregates

2 Materials

2.1 Binder

The cement types of CEM II A-L 42.5R (with 12% limestone, named CEMII) and CEM I 52.5R (high strength-rapid hardened, named CEMI) with the densities of 3.1 kg/dm^3 were employed. Class F fly ash (FA) with a density of 2.16 kg/dm^3 was also employed.

2.2 Aggregates

Three fractions of natural limestone aggregates were used for concrete production: fine (NS of 0/4mm,) and coarse aggregates (CA1 of 5/10mm and CA2 of 8/20 mm). The dry density of NS, CA1 and CA2 were 2.58kg/dm^3, 2.67kg/dm^3 and 2.67kg/dm^3, respectively. The absorption capacity was of 1.79%, 0.75% and 0.57%, respectively.

The recycled concrete aggregate (RCA) was produced via the crushing of a parent concrete, namely one-year-old waste, 30 MPa concrete specimens from a concrete company. The component of the parent concrete being CEM II A-L 42.5R cement and limestone aggregates. The RCA was used for concrete production immediately after the parent concrete was crushed, and the RCA aggregates were un-carbonated. The grading distribution was defined by the fraction 5/20mm. Its density was of 2.33 kg/dm^3 and an absorption capacity of 5.35%.

3 Mix Design and Production Process

Two stages of concrete productions were carried out. In stage 1, all the concretes were produced

employing 100% of natural aggregates. Four different concretes were produced in which different binders were employed. CC, 100% of CEMII; CFA25, 25% (in weight) of CEMII was replaced by FA; CFA50: 50% of CEMII was replaced by FA and CFA50.2: 50% of binder was CEMI and 50% of FA (see Table 1). In stage 2, all the mixtures were produced employing 50% of the aggregates volume defined in the CC mixtures replaced by RCA. Four different concrete mixtures were produced: CRA, 100% of CEMII; CRAFA25, 25% (in weight) of CEMII was replaced by FA; CRAFA50, 50% of CEMII was replaced by FA and CRAFA50.2, 50% of binder was CEMI and 50% of FA (see table 1).

The effective w/c ratio of 0.50 was maintained constant in all concretes. In stage 1, in order to determine the effective w/c ratio, the effective absorption capacity of 90%, 50% and 50% of the total absorption capacity of NS, CA1 and CA2, respectively were determined. In addition, in stage 2, the effective absorption capacity of RCA was determined as being 80% of its total absorption capacity. The RCA was used with high humidity, having 75-80% of water absorption capacity, and their moisture content was measured prior to their use.

The concrete specimens were produced and cured following UNE EN 12390-2:2001 regulations and were manually compacted using a steel rod. The concrete specimens were then covered with a plastic sheet and air-cured for the first 24 h. After 24 h of casting, the specimens were demoulded and then stored in a humidity room and kept at 21ªC and 95% of humidity until the test ages were reached for the physical, mechanical and chloride ion penetration test. The specimens taken from the humidity room after 28 days for carbonation resistance testing were sent to the laboratory to undergo pre-conditioning for 14 days at 400ppm, 24ºC and 55% humidity before being placed in the CO_2 chamber.

A superplasticizer based on modified polycarboxylates was employed in all mixtures. A 0.50% with respect to cement weight was needed in all the concrete mixtures in order to achieve a slump test of 17-19cm. The density at fresh state of all the concrete mixtures was also determined. Table 1 shows that the employment of FA increased the density of concrete due to its capacity to densify the cement paste, in contrast the employment of RCA decreased the density of concrete (Etxeberria *et al.*, 2007).

Table 1. Mix proportions of Stage 1 and Stage 2 concrete mixtures. The values are given of kg of component/m^3 of concrete production (W: water, Ad: admixture, Effect: Effective).

4 Test Procedure

4.1 Physical and Compressive Strength

Physical properties were measured according to ASTM C 642 ‘‘Standard Test Method for Density, Absorption and Voids in Hardened Concrete” at 28 days after casting. Three cubic specimens were used in this test for each concrete mixture produced.

The compressive strength of concretes at 7, 28 and 90 days were determined following UNE-EN 12390-3:2009 specifications. Three cylindrical specimens were used for each concrete mixtures.

4.2 Carbonation and Chloride Resistance

The concretes were submitted to accelerated carbonation test, following GB T50082-2009 standards, in order to assess the carbonation penetration resistance of each concrete produced employing different types of binders as well as the RCA. The concrete specimens were placed in a CO_2 chamber at 20% CO_2, 20ºC and 60% of RH for 7, 14 and 28 days after their curing process of 28 days and pre-conditioning period of 2 weeks. The concentration of the CO_2 employed was very high. It is known that the carbonation coefficient increases with an increase in carbon dioxide concentration (Shah and Bishnoi, 2018). In addition, at long test periods, the high concentrations of CO_2 cause a change of the cement paste microstructure compared to that of samples placed in natural exposure (Castellote *et al.,* 2009). However, the high concentration of CO_2 conditions, in short periods of testing, allow the concrete's resistance to carbonation to be characterized (Hyvert *et al.,* 2010). Two specimens of each concrete were employed for carbonation depth measurement. The compressive strength of each concrete was also determined.

The chloride penetrability of concrete was determined following the ASTM C1202 (1997) standard. The chloride ion penetration resistance of concrete is represented by the total charge passed in Coulombs during a test period of 6 h. In this study, the chloride ion penetrability test was carried out on the concrete specimens at the ages of 28 and 90 days and each result was the average of two measurements.

5 Results

5.1 Physical and Compressive Strength

Table 2 shows the physical properties obtained by all the concretes analysed. The employment of FA increased the density and decreased the absorption capacity of concrete due to its reaction with $Ca(OH)_2$ (Deschner *et al.,* 2012). The CFA50.2 produced with 50% of FA in substitution of CEMI achieved the lowest absorption capacity. The employment of RCA, in stage 2, decreased the density of its Stage 1 corresponding concrete. The CRA achieved 18% higher absorption capacity than that of CC concrete. Similar results were obtained by Kurda *et al.* (Kurda, de Brito, and Silvestre, 2019). The absorption capacity of recycled aggregate concrete was lower when FA was employed in its production. The CRAFA50.2, produced with CEMI, achieved the lowest absorption capacity. CRAFA50 and CRAFA50.2 achieved a higher density, lower absorption and porosity than that of the CC concrete.

Table 2 also shows the compressive strength at 7 days, 28 days and 90 days of all the

concretes produced. The CC mixture achieved the highest compressive strength at 7, 28 and 90 days. In addition, the concretes produced employing 25% of FA achieved the strength of CC concrete. Similar results were obtained by Nath and Sarker (2011) at 28 and 90 days. The concretes produced with 50% of FA achieved lower strength than the CC concrete in all the tested ages. Although the employment of CEMI improved the properties achieved by concrete produced using CEMII, the CFA50.2 proved to have 14.8% lower strength than that of CC after 90 days (see figure 1). This in all probability was due to a none reaction in some of its high volume of FA (Hemalatha and Ramaswamy, 2017; Xu and Shi, 2018). In stage 2, the concrete CRA achieved the highest strength at 7 and 28 days, and the CRAFA25 concrete after 90 days.

Table 2. Physical properties of concretes produced in Stage 1 and 2, Compressive strength of concretes at 7, 28 and 90 days.

	Physical properties			Compressive strength (MPa)		
	Absorption (%)	**Dry Density (kg/dm3)**	**Vol. of accesible porous (%)**	**7 days**	**28 days**	**90 days**
			STAGE 1			
CC	4.70	2.19	10.29	36.7	42.0	49.6
CFA25	3.98	2.28	9.09	29.0	39.3	49.4
CFA50	3.95	2.29	9.04	17.5	29.1	39.5

			STAGE 2			
CRA	5.56	2.16	12.04	34.5	41.3	47.5
CRAFA25	4.52	2.24	10.11	31.5	38.7	48.1
CRAFA50	4.16	2.24	9.32	19.2	26.9	37.8
CRAFA50.2	4.06	2.23	9.06	23.7	30.5	41.8

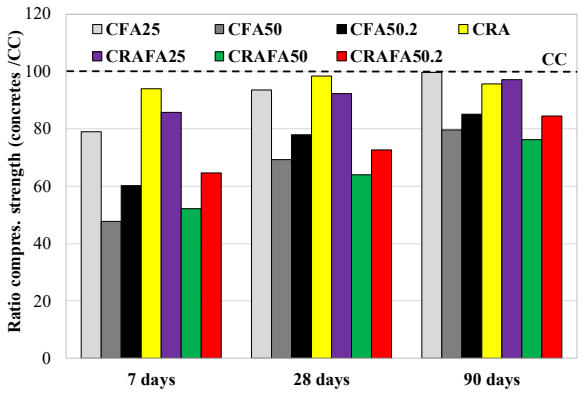

Figure 1. Ratio of the compressive strength of all the concrete with respect to that of CC concrete.

At 7 days of curing, the concretes produced employing RCA and FA achieved a higher strength than that of the concretes produced employing FA and NA (see Figure 1). The rough surface and attached un-carbonated mortar of the RCA caused adequate ITZ in CRA (Etxeberria *et al.,* 2007).

At 28 days and 90 days, the concrete produced with RCA achieved a slightly lower strength

to the concretes produced employing natural aggregates. In stage 2, the CRAFA25 achieved the highest strength at 90 days due to the pozzolanic effect of FA and its reaction with Ca(OH)2, similar behaviour was determined by Kou and Poon (2013).

In addition, the two concretes produced employing 25% of FA achieved the strength of the CC concrete. Cement type I 52.5R (CEMI) was required for concrete employing 50% of FA in order to avoid a high strength reduction at 90 days.

5.2 Carbonation and Chloride Resistance

Figure 2a shows the chloride penetration resistance of each concrete at 28 and 90 days, in accordance with the total charge passed value obtained, which are categorized as low, moderate and high corrosion risk.

At 28 days, almost all of the concretes were classified with moderate risk for corrosion, except the CC and CRA concretes, which were classified as high risk of corrosion. The employment of a higher percentage of FA reduced the corrosion risk. The concretes produced employing 50% of FA and RCA (CRAFA50 and CRAFA50.2) achieved the lowest value of the total charge passed. At 90 days, the concretes produced with 50% of FA, CFA50.2 and CRAFA50.2, achieved the lowest value. The CRA concrete was found to still have a high risk of corrosion after 90 days of curing.

In stage 1, the concretes produced with 50% FA and natural aggregates achieved the highest decrease of the total charge passed value from 28 days to 90 days. The reduction of the total charge passed of the CFA50.2, CFA50, CFA25 and CC concretes were 53%, 40%, 25% and 19% respectively. In stage 2, the reduction rate of CRAFA50.2, CRAFA50, CRAFA25 and CRA were 27%, 10%, 41% and 9%, respectively. The RCA was also found to have an influence on the chloride resistance.

The average carbonation depth of each concrete specimen after their exposure to 20% of CO_2 during 7 days, 14 days and 28 days is shown in Figure 2b. After 7 days of exposure, the concretes produced with 50% of FA and NA suffered the highest carbonation depth, the use of 50% of RCA reduced the CO_2 penetration.

It is clear that the employment of FA increased the depth of carbonation within the concrete samples. Several researchers have also determined this (Khunthongkeaw, Tangtermsirikul, and Leelawat 2006; Kurda, De Brito, *et al.,* 2019). The concretes produced with 100% of CEMII as well as employing 25% of FA achieved the highest resistance to carbonation at any time, being higher when RCA was employed for concrete production. In this research work un-carbonated RCA aggregate was employed, which was carbonated during their contact with CO_2, increasing the concretes carbonation resistance. Similar results were obtained by Thomas et al. (Thomas *et al*., 2013). Most of the research work carried out up to date define that concrete produced employing RCA achieved lower carbonation resistance due to its high porosity of RCA (Kurda, De Brito, *et al.,* 2019; Leemann and Loser 2019), however the carbonated or un-carbonated state of RCA could modify this behaviour. After 28 days of CO_2 exposure, the concretes produced with 50% of RCA and 50% of FA suffered a greater carbonation process. In all probability, the result was due to a higher presence of cement paste which became modified as a result of a high CO_2 concentration (Castellote *et al.*, 2009). However, this effect will be lower at natural exposure.

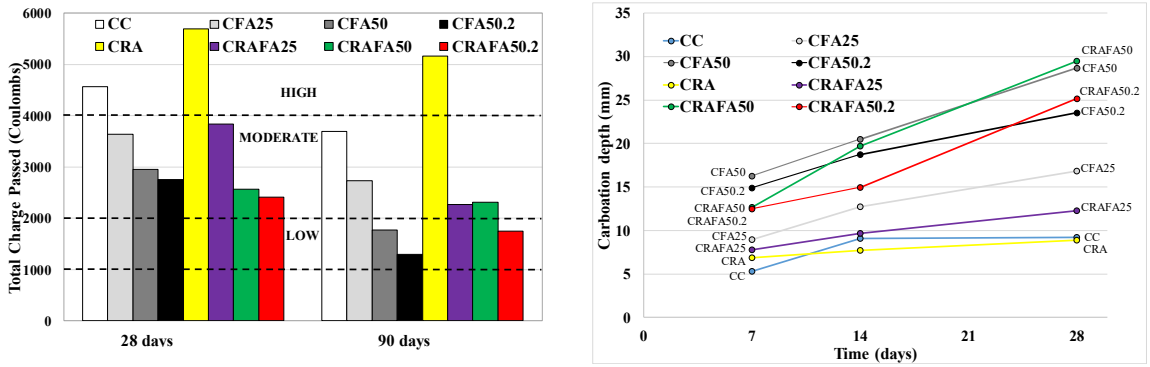

Figure 2 a) Chloride-ion penetration of concrete mixtures and ASTM corrosion ranges. b) carbonation depth of concrete mixtures.

6 Conclusions

The following conclusions can be drawn based on the results presented above:

- The effect of RCA in decreasing and increasing the density and absorption capacity, respectively, of concretes was lessened by employing FA. The CRAFA50 and CRAFA50.2 achieved a higher density, lower density and porosity than that of the CC concrete.
- The results of compressive strength test at 7 days determined that the concretes produced employing FA achieved higher strength when RCA was used than the concretes produced with NA. At 28 and 90 days. The concrete produced with 50% of RCA with or without employing 25% of FA achieved similar strength to that of the CC concrete. At 90 days, the concretes produced with CEM I and 50% FA achieved 14% lower strength than the CC concrete
- Chloride ion penetration was more influenced by the type of binder employed than the type of aggregates used. The concrete produced with 50% of FA achieved the highest resistance to chloride ion penetration. The concrete produced with 50% of RCA achieved high resistance to corrosion when 25% or 50% of FA was employed for concrete production. CRA (the concrete without FA) proved to achieve the lowest resistance to chloride ion penetration.
- The employment of FA increased the depth of the carbonation of the concrete samples. After 7 days of 20% CO_2 exposure, the use of RCA was shown to reduce the carbonation depth of the concretes produced with 50% FA and NA. The employment of RCA in concrete production with CEM II or employing 25% of FA caused the lowest carbonation depth.

Modernization of Housing Estates Towards Sustainable Development: What do Housing Estate Managers Provide, What do the Users See?

Anna Ostańska

Department of Architecture and Urban Planning, Faculty of Civil Engineering and Architecture, Lublin University of Technology, Nadbystrzycka 40, 20-618 Lublin, Poland, a.ostanska@pollub.pl

Abstract. *Modernizing multi-family residential estates in operation for about 40 years is a multifaceted and complex process. In Poland, these assets cannot be considered "degraded" yet, they are not an obvious object of deep retrofit actions. The literature on the subject and the author's own research confirm that the management of Polish housing estates is carried out with the focus on current repairs and improving energy efficiency by insulating the buildings' envelopes. Poland lacks long-term programs to implement retrofitting actions based on the analysis of both social and technical needs and aimed at improving the estate's sustainability parameters. The author puts forward an original approach to the programming of sustainable housing stock retrofit based on the PEARS model (People-Environment-Actions-Resources-Sociology). The paper focuses on the social research part of the model and presents the case-based analysis – the results of the recurring survey conducted to provide input for sustainable planning of the estate improvements. The paper is a summary of over ten years of research and studies on practices of maintenance of infrastructure and buildings, changing user needs, and user opinions on the possible directions towards sustainable housing.*

Keywords: *Housing Stock, Deep Retrofit, Sustainable Housing, Recurrent Survey.*

1 Introduction

Polish housing estates with prefabricated buildings, created between nineteen-sixties and -nineties, are still considered a valuable asset (Zyga, 2014). This is due to their generally satisfactory technical condition (Nowogońska, 2017), good location and presence of local amenities, as well as the shortage of affordable housing. However, the maintenance of these assets becomes a challenge because of the scale of the problem (Ostańska, 2019) (buildings of this type and age are present in practically all towns and cities, as shown in Fig. 1), complex ownership structure (obstacle in the decision-making process (Radziszewska-Zielina, 2006)), and changing regulations (promoting individual ownership of flats (Radziszewska-Zielina and Gleń, 2013, 2014). The growing expectations towards energy efficiency, user safety, and comfort, accompanied by growing requirements of the building codes, make the "prefab blocks" becoming obsolete. Therefore, keeping the buildings fit for purpose requires (Runkiewicz *et al*., 2014) not only repairs, but also investment (Yiu and Leung, 2005; Taczanowska and Ostańska, 2012; Radziszewska-Zielina and Gleń, 2013; Komar, 2014, Wójtowicz, 2014; Stevenson and Baborska-Narozny, 2017). She wrote about the types and needs of surveys in architecture, among others, about the types and needs of surveys in architecture Niezabitowska (2014).

The residents of the housing estates have the greatest knowledge on the functional deficiencies of the flats, the buildings, and the infrastructure and amenities of the estates. As flat owners, members of the housing cooperatives, or just clients-users, they have also the power

to oppose the investment plans proposed by the estate management as well as the power to affect them. As observed in practice, the residents rarely use the opportunity of the latter, so they rarely participate in the management of the estates in an active way.

The aim of the research presented in this paper was twofold: to collect input for planning improvement measures customized for a particular estate directly from the users, and to stimulate the interest of the residents in the possibilities of influencing the managers' decisions, especially regarding the current needs and corrective or improvement actions aimed at "reviving" the estates (Ostańska, 2009, 2015).

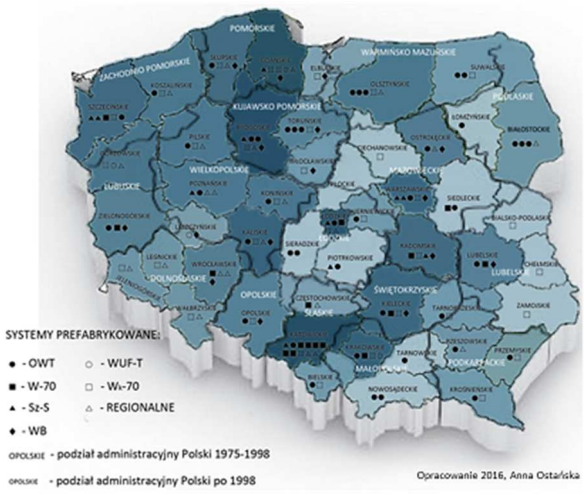

Figure 1. Distribution of prefabricated housing systems in Poland (1975-1985) according to location of prefabrication plants.

The author conducted a number of surveys in selected housing estates in three voivodships (Fig. 2). Most of them were carried out in Lubelskie Voivodship and repeated in regular intervals to juxtapose physical changes in the estate with changes of the residents' opinions on most urgent or most wanted improvements.

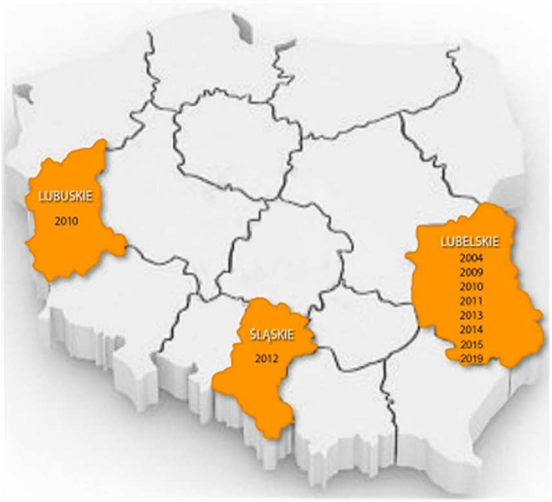

Figure 2. Location of surveys.

The paper presents the methodology behind the research and discusses results obtained in three particular housing estates in Lubartów (Ostańska, 2018). The surveys consisted in a questionnaire-based direct interview with the residents conducted first in 2010, and repeated in 2014.

2 Methods

The idea of the survey is presented in Figure 3. Its starting point was the selection of the object of research: an estate. After obtaining the estate management's consent to conduct the survey, a preliminary "in situ" assessment of the condition of the buildings and infrastructure was conducted and clusters of buildings representative for the estate were selected to serve as the sample. The residents of these buildings were then approached at home to provide answers to a set of questions on both renovation (*R*) and modernisation needs of the estate, the building and the flats. The modernisation comprises sustainability (*Me*) and functional (*Mf*) aspects.

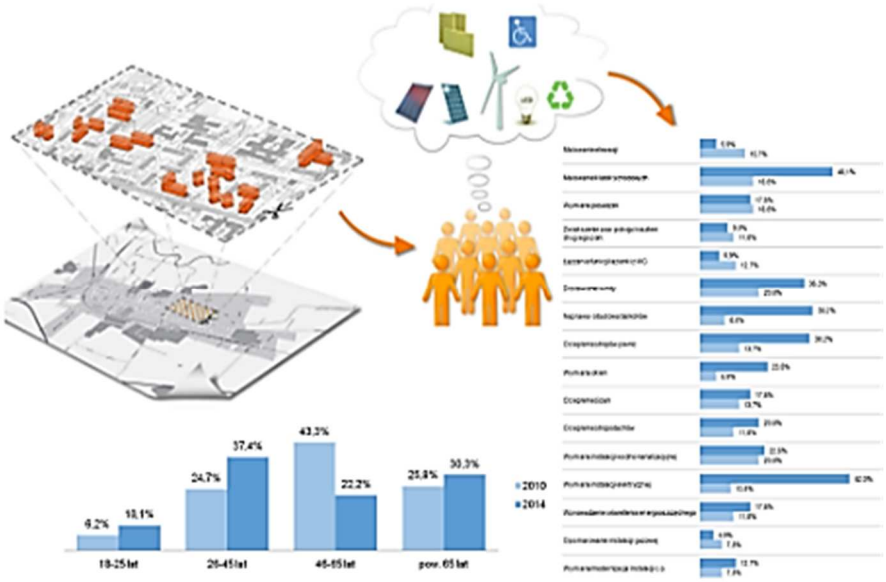

Figure 3. The idea of the survey on the opinions of the housing estate residents.

The interviews were intended to be repeated according to the same questionnaire in regular intervals. The purpose of repeating the survey was to update the insight into the modernization needs based on the opinion of the residents, and analyzing the perceived effects of the estate managers' activities.

The participants of the research were limited to adults living in the blocks of flats selected as the sample. Only one person per flat was asked to give answers.

The interviews were conducted on the basis of an original questionnaire: a standard form adjusted to the particularities of the housing estate in question. The questionnaire contained a total of 26 questions, including open-ended, closed-ended single-choice and closed-ended multiple-choice questions. Semi-open questions (logically open, technically closed) provided a list for multiple choice of feasible corrective actions, including measures for saving energy and improving functionality. Other semi-open questions concerned the list of common-use facilities

present in the estate to check if they are still in use. A single logically and technically open question concerned the works the residents conducted on their own in their flats. The classification and demographic questions concerned: age, education, migration and participation in the costs of renovation.

Thus, the full scope of the survey questions comprised:

- deficiencies in local amenities,
- condition of the estate's infrastructure,
- comfort of living (buildings and dwellings),
- opinion on the priorities for corrective actions.

The complete questionnaire form can be found in Ostańska (2018) (Appendix 3a, Questionnaire C/2010).

3 Results

In the particular case presented in this paper, the survey was conducted twice to answer the following questions:

1) Did the residents' priorities on "the most urgent needs" change over time and with the measures actually taken in the estate?
2) Did the preferences of the housing estate residents' needs change in terms of repair/renovation works (*R*), modernization measures aimed at environment protection (*Me*), and functional modernization (*Mf*)?
3) Did the housing cooperative's spending stay in proportion to the preferences of the residents?

The research conducted on three housing estates in Lubartów produced 102 filled questionnaires in 2010 and 102 questionnaires in 2014. Analysis of the results of three housing estates in Lubartów shows that the age structure of people surveyed in 2010 and 2014 is significantly different ($\chi 2[3, n = 196] = 10.46$; $p = 0.015$; $\phi = 0.231$). It should be noted that the number of people aged over 65 slightly increased (25.8% in 2010 vs. 30.3% in 2014). However, significant differences (decrease in 2014 compared to 2010) are observed in the age group 46-65. The remaining groups do not differ from each other in particular years (Figure 4).

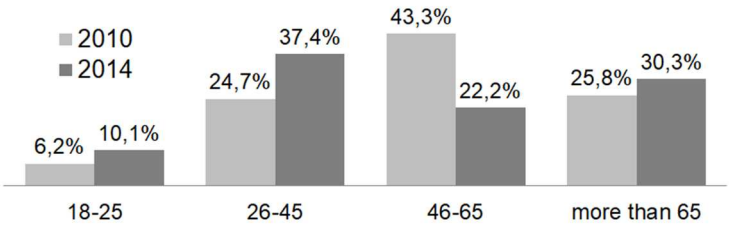

Figure 4. Age structure of the respondents: 2010 and 2014.

Considering the residents' responses to the perceived "most urgent needs" (Figure 5), it was observable that the average number of unsatisfied "most urgent needs" per respondent in 2014 (2.63) was lower than in 2010 (3.95) ($t(204) = 2.96$; $p = 0.003$). The detailed analyses confirmed differences in seven of the sixteen areas studied:

- Facade painting ($\chi 2[1, n = 204] = 5.10$; $p = 0.024$; $\phi = 0.158$) - increase from 5.9% to 15.7%,

- Painting staircases ($\chi 2[1, n = 204] = 19.02$; $p < 0.001$; $\phi = -0.305$) – a drop from 46.1% to 18.6%,
- Installing a lift ($\chi 2[1, n = 204] = 6.17$; $p = 0.013$; $\phi = -0.174$) – a drop from 36.3% to 20.6%,
- Repair or replacement of balconies ($\chi 2[1, n = 204] = 25.81$; $p < 0.001$; $\phi = -0.356$) – a drop from 39.2% to 20.6%,
- Basement ceiling insulation ($\chi 2[1, n = 204] = 15.93$; $p < 0.001$; $\phi = -0.279$) – a drop from 38.2% to 13.7%,
- Window replacement ($\chi 2[1, n = 204] = 12.66$; $p < 0.001$; $\phi = -0.249$) – a drop from 23.5% to 5.9%,
- Replacement of electrical installation ($\chi 2[1, n = 204] = 40.16$; $p < 0.001$; $\phi = -0.444$) – a drop from 52.0% to 10.8%.

No significant differences were noted in other aspects. Interestingly, only one aspect (facade painting) received a significant increase of residents' interest, almost by 10%, in relation to the results obtained in the first study.

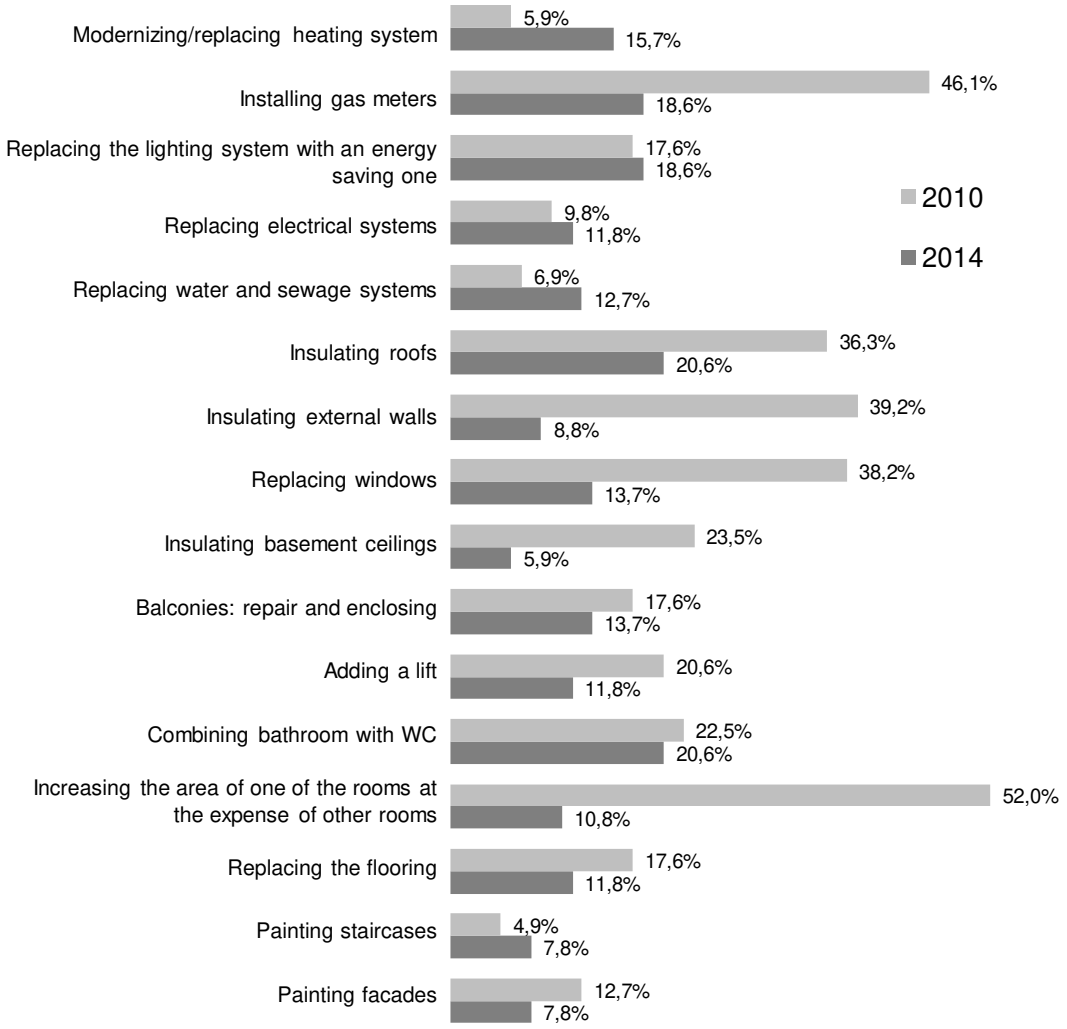

Figure 5. Priorities of improvements according to the respondents (share in the number of all indications).

Comparing the results of 2010 and 2014 (Figure 6), differences were observed in the category of "modernization measures aimed at environment protection" (*Me*) (decrease from 68.6% to 58.3%; $t(204) = 3.975$; $p < 0.001$) and functional modernization (*Mf*) (increase from 16.7% to 30.3%; $t(204) = -2.436$; $p = 0.016$).

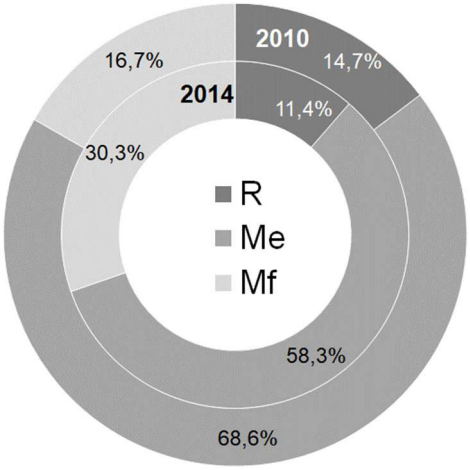

Figure 6. The residents' priorities of "most urgent" improvements according category and the year of the survey (description in the text).

The next step was to compare the priorities of the estate management with the priorities of the residents. This was done by juxtaposing the shares of actual spending on repair/renovation activities (*R*), modernization measures aimed at reducing the estate's environmental impact (*Me*), and functional modernization (*Mf*) with the proportions of the numbers of the residents' indications of the most urgent needs that belong to these categories (Figure 7). As expected, significant discrepancies were found.

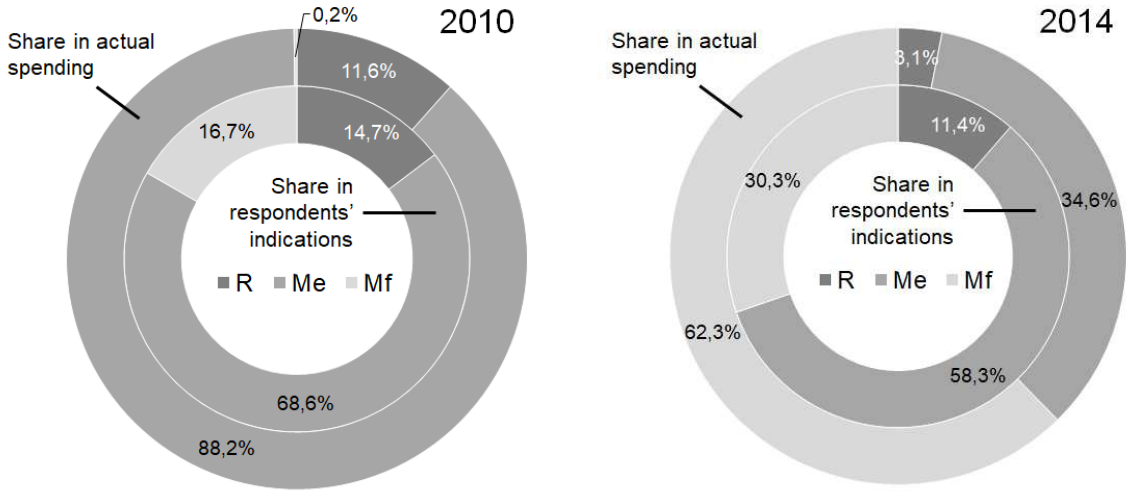

Figure 7. Users' perceived "most urgent" needs for improvements vs. actions taken by the estate managers expressed as the share in total spending (description in the text)

In 2010, 68.6% of all residents' indications on the "most urgent needs" concerned *Me*, whereas the housing cooperative spent 88.2% of its budget on actions within this category ($t(211) = -7.544$; $p < 0.001$). As for *Mf*, the cooperative spent practically nothing, while 16.7% of the inhabitants pointed to the urgency of actions from this category ($t(211) = 7.000$; $p < 0.001$).

In 2014, current repairs consumed only 3.1% of the cooperative's budget, though the residents' indications on actions from this category were 11.4% of all indications. The *Me*-related "most urgent" needs constituted 58.3% of all residents' indications, whereas the housing cooperative's spending on them constituted 34.6% of their total expenditures ($t(102) = 4.940$; $p < 0.001$). The "most urgent needs" in functional modernization had 30.3% of residents' indications, but the cooperative spent as much as 62.3% of the budget on this category ($t(102) = -6.666$; $p < 0.001$). This was possible due to extra funds from an EU-sponsored urban regeneration grant.

4 Summary and Conclusions

The residents' opinions on "urgent needs" related with maintenance and improvements to the fabric of their housing estates evolve over time (between the first survey in 2010 and the next one in 2014) and with the measures actually taken by the estate management. In particular, the repair/renovation needs seemed to be at least partly satisfied, as less people pointed to the items from this category in the second survey. A similar number of items from the list of "modernization measures aimed at environment protection" were selected as worth implementing in 2010 and in 2014. The need for "functional modernization" visibly increased, which may be related to the growing age of the residents and growing needs for comfort and accessibility.

The proportion between the housing cooperative's expenditures on maintenance and modernization measures does not correspond to the reported needs of the residents, especially in terms of functional modernization: in the case of the presented housing estate, no investment was done in functional modernization at all. Despite the passage of time, the actions taken by the estate management are not consistent with the expectations of the inhabitants.

The method of monitoring the residents' needs adopted in the presented research, so a direct interview, proved feasible. The results provide a valuable input on user expectations, and this input was successfully used in practice to define the scope of modernization projects in several housing estates in Lubartów. Keeping up to date with user needs, the housing estate managers are able to revise the action plans.

Though the face-to-face interview is a labor-intensive way of collecting input, both the cost and effort related with data collection and analysis proved acceptable. However, the surveys should be continued on a regular basis. To facilitate the dialog between the residents and the estate management and to streamline the data collection process in the future, it is advisable to construct an Internet platform. Its design is the current subject of the author's research.

Quality Evaluation of Granulated Blast Furnace Slag Sand Via Acid Immersion and Freeze-Thaw Tests

Takaya Kawato[1] **and Isao Kurashige**[2]

[1,2] Central Research Institute of Electric Power Industry, Civil Engineering Research Laboratory, Nuclear Fuel Cycle Backend Research Center, 1646 Abiko, Abiko-shi, Chiba, 270-1194 Japan.
[1] t-kawato@criepi.denken.or.jp [2] kurasige@criepi.denken.or.jp

Abstract. *In recent years, the use of granulated blast furnace slag (GBFS) sand as fine aggregate in concrete has been increasingly discussed from the viewpoint of environmental impact reduction and effective utilization of by-products in Japan. The various physical properties of concrete with GBFS sand, such as the compressive strength, drying shrinkage, and carbonation, were evaluated. Especially, it was demonstrated that GBFS sand can modify the hardened cement paste around it owing to the reaction of amorphous phase in the sand. Moreover, its resistance to sulfuric acid is considered to be as excellent as that of BFS powder. Therefore, in this study, we attempted to evaluate the performance of GBFS sand using a freeze-thaw (F-T) and acid immersion tests. Consequently, it was found that GBFS sand mortar had a significantly higher resistance to F-T and sulfuric acid than crushed sand mortar. In addition, it improved the resistance to freezing and thawing by prolonged curing. In our experiments, the resistance of GBFS sand mortar to sulfuric acid was measured to be approximately four times higher than that of crushed sand mortar. In contrast, in the case of nitric acid, the ratio was measured to be only two times higher. From the above results, it was concluded that the performance of GBFS sand can be easily judged by F-T and sulfuric acid immersion tests.*

1 Introduction

From the viewpoint of environmental protection and depletion of natural resources, the use of artificial aggregates and by-products are promoted for concrete aggregate. In Japan, the JIS standard for coarse aggregate for concrete of blast furnace slag was established in 1977 and the standard for blast furnace slag fine aggregate was added in 1981 (JIS A 5011-1). However, the use of blast furnace slag as aggregate remains at approximately 0.7% of the aggregate for concrete because blast furnace slag aggregate has a poor track record and its quality is not reliable enough.

If the utilization rate of GBFS sand is improved, the environmental footprint can be reduced and a high durability concrete structure can be constructed. Therefore, the reactivity of GBFS sand is appropriately evaluated and its performance is incorporated into the concrete performance design to improve reliability. When GBFS sand is used for concrete, it is known to improve the neutralization resistance, F-T resistance, and permeability resistance to chloride ion and sulfuric acid, and reduce the drying shrinkage (*e.g.*, Ayano *et al.*, 2014; Patra *et al.*, 2018; Takahashi *et al.*, 2018). The performance of GBFS sand is determined by the reactivity depending on the composition and manufacturing method.

In this study, to establish the method for evaluating the reactivity of GBFS sand, we

doi:10.23967/dbmc.2020.116

examined the GBFS sand quality evaluation test methods and test conditions. When GBFS sand is used for concrete, the interface between the aggregate and cement paste is modified. To measure the reactivity of interface between GBFS sand and cement paste, F-T test was conducted in salt-water. In addition, acid immersion test was performed to measure the reactivity of GBFS sand with acid. Crushed sand was used for the comparison with GBFS sand.

2 Experiments

2.1 F-T Test in Salt Water Using Small Mortar Pieces

2.1.1 F-T test process

- Using a diamond cutter, from a 40 * 40 * 160 mm mortar cured under water with a temperature of 20 °C until the age of seven days, quarry test specimens that is 10 ± 2 mm cube on all sides.
- Quarried specimens were cured in water up to the planned age.
- Test solution was prepared by adding 5 mass% sodium chloride.
- Moisture was wiped from the surface of the specimens cured until the planned age, the seven pieces were formed into a set, and the total mass (m_0) was measured.
- A set of specimens and 10 ± 0.05 times the test solution was placed in a 200–300 mL test container, its lid was capped, and it was left in the F-T apparatus (Figure 1.).
- The F-T cycle consisted of a 16 h freezing step and 8 h thawing step (Figure 1.).
- At the end of 28 cycles of F-T, the surfaces of the pieces that remain on the sieve (4.75 mm) were wiped off and the mass (m_t) was measured.
- Mass residual rate (R) was evaluated using the following formula.

$$R = \frac{m_t}{m_0} \times 100 \quad (1)$$

Where,

R: Mass residual rate after t cycle (%)

m_0: Initial mass (g)

m_t: Mass after t cycle (g)

2.1.2 F-T test conditions

Table 1. shows the conditions for the F-T test. We examined the effects of the curing period and test period on the F-T evaluation test in salt-water. Furthermore, to investigate leaching during the test, it was compared with a test system using a saturated aqueous solution of calcium hydroxide (CH) as a solvent.

Table 1. Conditions for the F-T test.

Symbol	Cement	Fine aggregate	W/C	S/C	Curing	Test period	Solution
14B	OPC	BFS	0.5	2.25	14d	(7cycles) 28cycles	5% NaCl
14S		S					
14B+CH		BFS					5% NaCl +CH sat.aq.

28S		S					
28B+CH		BFS					5% NaCl +CH sat.aq.
28S+CH		S					

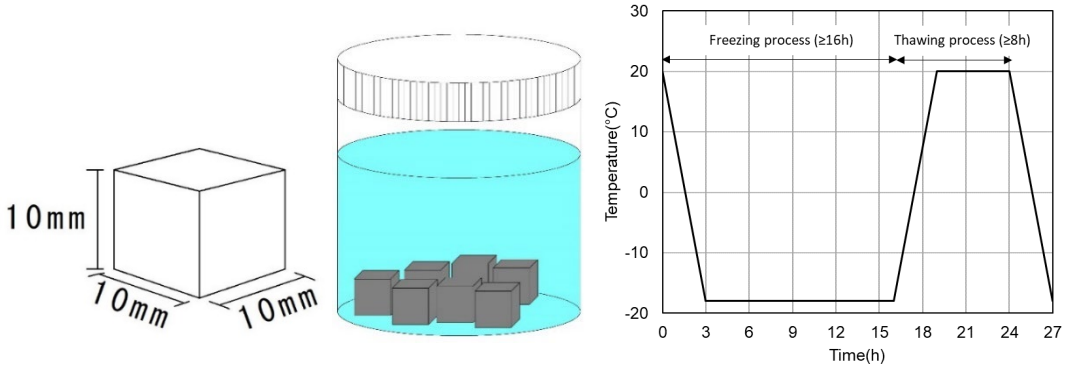

Figure 1. Conditions of F-T test.

2.2 Acid Immersion Test Using Mortar Cylinder

2.2.1 Acid immersion test process

- Cylinder specimens (diameter = 50 mm (D_0), height = 100mm) cured up to 28 days in water at 20 °C were immersed in 5 mass% acid, which is more than five times the specimen volume.
- Complete immersion of the specimen was confirmed, its container was covered, and left at 20 ± 2 °C. Figure 2. shows the conditions for the acid immersion test.
- In case of "with" exchange, all acid solutions were replaced every seven days, and the upper and lower sides of the specimen were inverted each time.
- After immersion for 56 days, a cut was made on the center of the remaining specimen height.
- Phenolphthalein solution was sprayed on the cut surface and the diameter of the colored part (D_{56}) was measured.
- Evaluation is based on the erosion depth (Ys) derived from the following equation.

$$\mathrm{Ys} = \frac{(D_0 - D_{56})}{2} \tag{2}$$

Where,

Ys: Erosion depth (mm)
D_0: Initial specimen diameter (mm)
D_{56}: Diameter of non-neutralization area after 56 days (mm)

2.2.2 Acid immersion test condition

For the acid immersion test, we investigated sulfuric acid and nitric acid. In addition, we investigated the possibility of reducing acid waste and the number of test processes by comparing the “with” and “without” test solution exchanges. Table 2. lists the conditions for the acid immersion test.

Table 2 Conditions for the acid immersion test.

Symbol	Cement	Fine aggregate	W/C	S/C	Curing	Test period	Solution	Solition exchange	Liquid-solid ratio

3 Results and Discussion

3.1 F-T Test Results and Discussion

Figure 3. shows the effect of curing days.
Figure 4. shows the effect of leaching.
Table 3. shows the pH of the solution after the F-T test.

3.1.1 Difference in number of curing days

Compared to crushed sand mortar, GBFS mortar clearly demonstrated the difference in mass residual rate for a curing period of 28 days. To evaluate the quality potential of GBFS, a longer curing period was considered necessary.

3.1.2 Difference in test period

GBFS with 28 days of curing could evaluate the quality even at the end of 28 cycles; however,

under other conditions, the mass residual rate was extremely low at the end of 14 cycles, making it impossible to evaluate the quality of the aggregate. When the residual mass of the mortar began to decrease, seven cycles were considered suitable for evaluation.

3.1.3 Effect of leaching

F-T using salt-water requires higher F-T resistance than when fresh water is used. Focusing on the difference in test solution during the seven cycles of 14-day curing, 5% NaCl showed a smaller value for 5% NaCl + CH sat.aq. (11% for GBFS, 13% for crushed sand). From these results, it is considered that 5% NaCl evaluates the quality of GBFS in the state of adding the influence of leaching as well as F-T. From Table 3., the initial value of 5% NaCl is pH = 7.22; however, after testing both GBFS and crushed sand, their pH exceeded a value of 12. In contrast, the initial value of 5% NaCl + CH sat.aq. was pH = 12.95 and 12 or more after the test. From the result, it was surmised that leaching is suppressed in 5% NaCl + CH sat.aq.

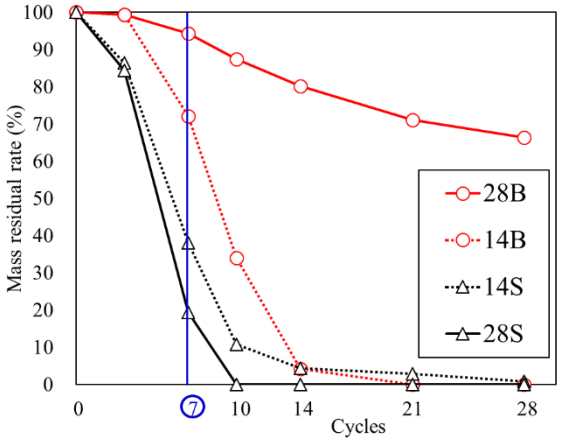

Figure 2. Effect of curing days.

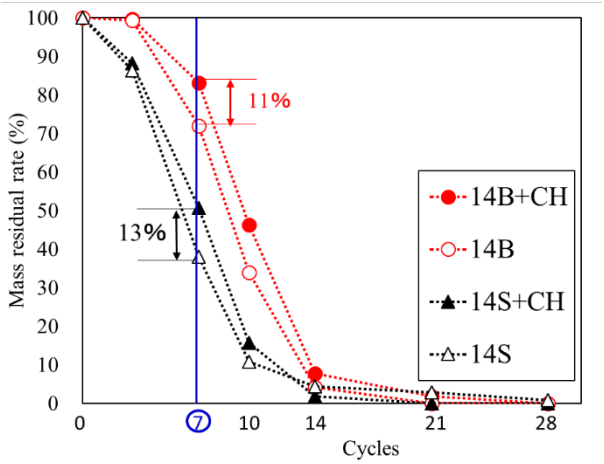

Figure 3. Effect of leaching.

Table 1. pH of the solution after the F-T test.

Symbol	5%NaCl	5%NaCl+CH sat.aq.
Initial	7.22	12.95
BFS-14	12.55	12.61
CS-14	12.45	12.54
BFS-28	12.87	12.95
CS-28	12.93	12.99

3.2 Acid Immersion Test Results and Discussion

Figure 5. shows the results of acid immersion test.
Figure 6. shows the state after the acid immersion test (no-exchange).
Figure 7. shows the shape of specimen after the acid immersion test about solution exchange.

3.2.1 Effect of liquid exchange

The depth of erosion in the sulfuric acid immersion test was reduced by 1.0 mm (28%) and

4.5 mm (34%) for GBFS and crushed sand, respectively, when the liquid was not changed because the total amount of solution in contact with the specimen during the test period was as small as 22.5 in "without replacement," as compared to 56 (7.0 times × 8 times) in "with replacement," per liquid-solid ratio. In addition, when the solution was changed, the difference in fine aggregate performance was more pronounced. The erosion depth in the nitric acid immersion test was also confirmed to decrease by 3.0 mm (48%) for GBFS and 3.2 mm (29%) for crushed sand. This is also thought to be due to the amount of solution in contact.

3.2.2 Difference between sulfuric acid and nitric acid

GBFS erosion depth in sulfuric acid immersion test decreased to 27% in comparison to crushed sand. In GBFS, calcium and magnesium were eluted by the reaction of sulfuric acid and aggregate; thus, the expansion force of the generated dihydrate gypsum was relaxed and deposited on the surface without peeling off, which is considered to suppress erosion (Jariyathitipong *et al.*, 2013). In this study as well, the suppression of peeling shown in Figure 6. was confirmed. In contrast, in the nitric acid immersion test, the erosion depth of GBFS only decreased to 58% in comparison to crushed sand. Unlike dihydrate gypsum, calcium nitrate is known to have very high solubility, which prevents the reactants from precipitating, and the calcium elution is excellent; thus, erosion proceeds (Tanaka *et al.*, 2008). This study also showed the melting of calcium and softening of the surface layer.

In nitric acid erosion, the density of the hardened body is dominant. However, in sulfuric acid, the influence of hydrate composition that affects the formation of dihydrate gypsum is also added. Therefore, it seems that the erosion depth during sulfuric acid erosion was further reduced.

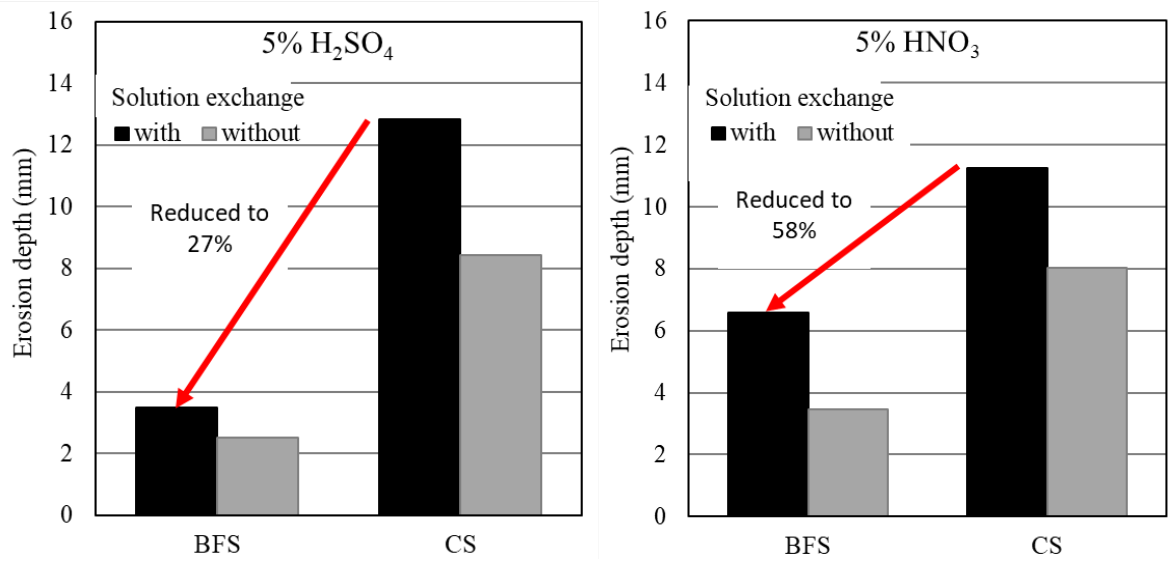

Figure 4. Results of the acid immersion test.

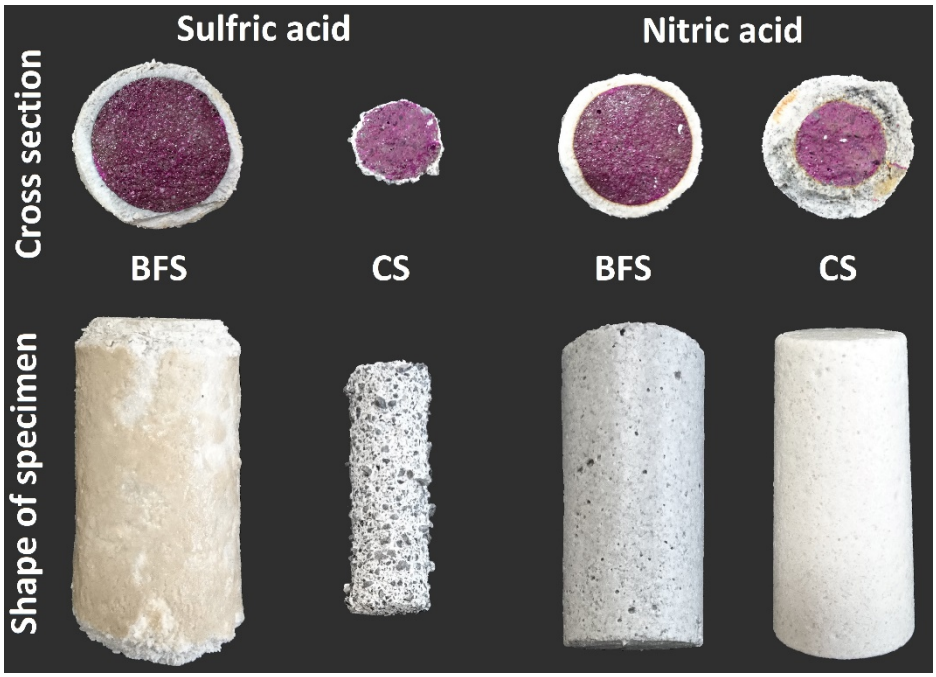

Figure 5. State after the acid immersion test (no-exchange).

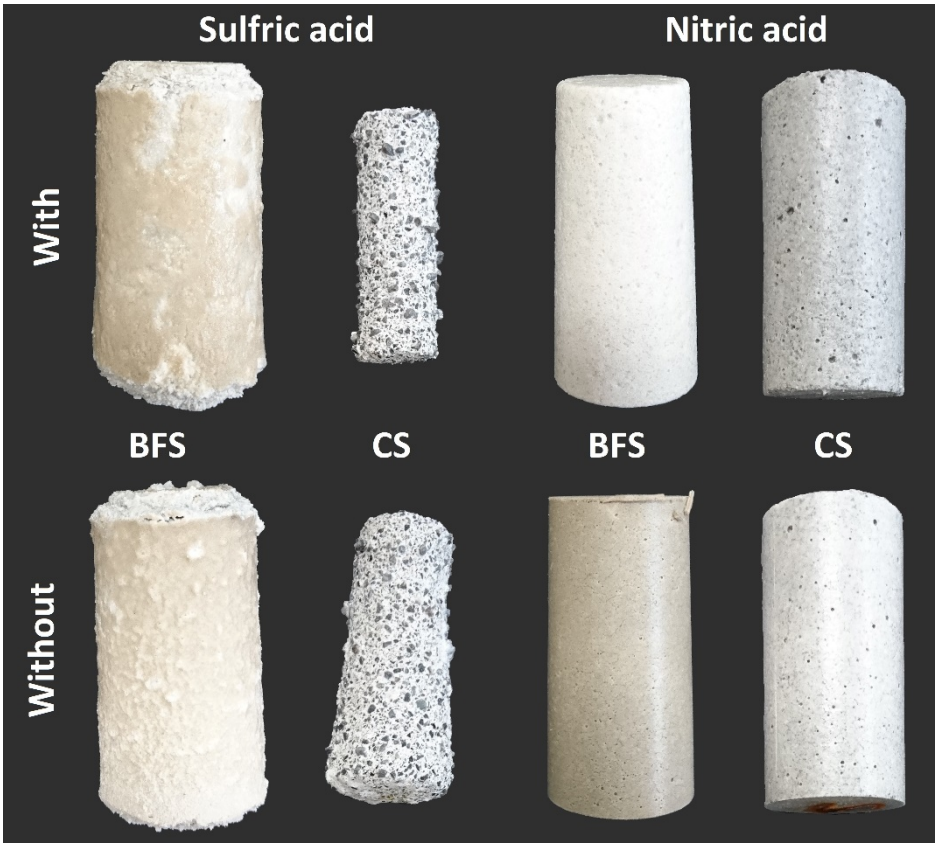

Figure 6. Shape of specimen after acid immersion test about solution exchange.

4 Conclusions

It is well known that GBFS has different performance depending on the raw iron ore and process of steel mill (Tobo *et al.*, 2015). However, few studies have evaluated the quality variation of GBFS. In this study, we examined a method that can easily determine the performance of GBFS. As a result, the following results were obtained from this study.

- The quality of GBFS sand as fine aggregate was evaluated by acid immersion test and F-T test in salt-water.
- The implementation of the F-T test evidently expressed the difference in durability depending on the reactivity of GBFS sand.
- Although leaching occurred during the F-T test by salt-water, it was found that destruction by F-T was superior to that by leaching. Or, even if leaching occurs, its effect is small when the liquid to solid ratio is 10.
- Long-cured GBFS mortar had a significantly improved resistance to F-T.
- The sulfuric acid immersion test enabled the evaluation of the resistance of GBFS sand to sulfuric acid.
- In the reaction with nitric acid, although GBFS sand mortar showed higher resistance than crushed sand mortar, it did not show special resistance like sulfuric acid immersion.

Risk-Based Approach for Improving Concrete Bridges' Inspection Planning

Sindre Tronsli, Samindi M.K Samarakoon and R.M Chandima Ratnayake

Department of Mechanical and Structural Engineering and Materials Science, University of Stavanger, Norway, www.uis.no

Abstract. *Visual inspection forms the basis of the inspection planning process for concrete bridges. The authority responsible for bridge inspection maintains a database to record past inspection results, in order to plan future inspections. It is a challenge to recognize and classify bridges that it is essential to inspect based on inherent requirements. This is further exacerbated by the limited budget available. This manuscript describes a methodology for classifying bridges based on risk of potential failure and distributing the annual inspection budget for carrying out inspections on bridges accordingly. The absence of such a methodology allocation of resources for bridge inspection without real need. For example, on some occasions it is not necessary to inspect certain bridges on a time basis. Hence, this study focuses on developing an inspection-planning approach based on the actual and predicted condition (i.e. based on the database of past inspection data). It enables the bridges to be classified into different categories, based on the risk of potential failures. This enables the effective distribution of annual budgets among the bridges, avoiding unnecessary inspection that incurs pointless inspection costs.*

Keywords: *Visual Inspection, Concrete Bridges, Group Technology.*

1 Introduction

Routine bridge inspections are essential for maintaining information, damage status and proper prioritization of bridge maintenance measures. In the Norwegian Public Road Administration (NPRA), bridge inspections are defined as follows: "Inspection is a visual control combined with surveying and testing of materials carried out to assess the bridges' condition and level of safety. The inspection shall reveal the need for operational measures and/or maintenance, as well as any need for reinforcement or rebuilding" (Vegdirektoratet, 2000). According to the available information on bridge maintenance and current inspection procedure at the NPRA, visual inspection has not been performed annually for over half the bridges in Norway. These are serious figures, highlighting troublesome issues with the Road Administration Inspection System. Following the disclosures, the NPRA estimated in 2017 that there is a lag in maintenance and improvements for bridges and quays, which has a cost of NOK 15 billion (Statens Vegvesen, 2017a). From 2017, the government increased funding for road and bridge maintenance in the national budget by NOK 2.9 billion, which corresponds to an increase of 7.7% (Regjeringen, 2017). But, even though the government has increased its support for bridge maintenance in recent years, it is not certain that this support will persist. The NPRA estimates that they have a huge backlog of NOK 15 billion in the maintenance of bridges and quays. At the same time, in 2013, an ambitious streamlining programme was established, which states that the NPRA must cut internal costs by 10-15% by 2023. This corresponds to cuts of around

doi:10.23967/dbmc.2020.120

NOK 1.4 billion (Statens Vegvesen, 2018). Therefore, it is vital to improve the existing inspection procedure, to optimize the available budget. This situation underlines the need for Risk Based Inspection procedures, which include optimal prioritization of inspections and the determination of optimal inspection interval. This paper proposes the use of Risk Based Inspection (RBI) for the planning of inspections, which will help to optimize and increase the efficiency of the inspection procedure carried out by the NPRA.

2 The Existing Inspection Procedure in NPRA

In the inspection programme, once a bridge needs to be inspected, visual inspection, combined with non-destructive/destructive testing, is performed to assess the condition and safety of the bridge. Then, any damage or deficiencies in the bridge's structural members (i.e. location) should be recorded in a database. Possible damage/deficiencies (i.e. corrosion, cracks, spalling, discolouring, etc.) in bridges are listed in the NPRA handbook (Vegdirektoratet, 2000) with a representing number. Moreover, the NPRA has established a bridge management system called 'Brutus' to input all the information about all bridges in Norway. Therefore, the Brutus (i.e. bridge inspection data base – BIDB) consists of the historical inspection data of the bridges. When assessing damage, it is vital to classify the type, level (use Table 1), cause and consequences of the damage to the entire bridge and/or the environment (use Tables 2 and 3). Then, to recommend the level of action required, a priority level is calculated using Equation (1). Furthermore, a higher priority level indicates a requirement for immediate action/measure (Ratnayake and Samarakoon, 2018). However, damage levels can be set based on quantitative parameters set by the NPRA, but only for cracks. Quantitative parameters for deciding the damage level for spalling/Reinforcement (RF) corrosion, leakage or other damage modes have not been set. This study will therefore develop quantitative measures to set damage levels accordingly.

According to the procedure, each bridge should initially have a General Visual Inspection (GVI) every year. Each bridge will initially have to carry out a Close Visual Inspection (CVI) every five years. A CVI is defined as a condition monitoring of the entire bridge, in order to verify that it fulfils its function, and is a more comprehensive type of inspection compared to a GVI. But the intervals of one and five years for GVI and CVI, respectively, do not always represent the optimal inspection interval. The procedure for changing the inspection interval starts with observation of serious damage during inspection, with the consequence level being set to a minimum of 3. Then, the inspection engineer evaluates the damage and the bridge as a whole, in respect of whether the inspection interval should be changed for that particular bridge. If the result of the evaluation indicates that the inspection interval should be changed, a Risk and Vulnerability Assessment (RVA) shall be carried out to determine a new inspection interval (Vegdirektoratet, 2018).

Table 1. Damage/defect level and rank. (Vegdirektoratet, 2000)

Rank	Damage/deficiency level	
1	Low (L)	
2	Medium (M)	
3	High (H)	
4	Very high (VH)	

Table 2. Consequence type and level. (Vegdirektoratet, 2000)

Consequence type	*Abb.
Damage/defect(s) threatening bearing capacity	B
Damage/defect(s) threatening road safety	RS
Damage/defect(s) that may increase maintenance costs	M/R
Damage/defect(s) that may affect the environment/ aesthetics	E/A

Consequence Level	Measures to be taken	Rank
L	No action required	1
M	Register the recommended measures in BIDB	2
H	• Register the recommended measures in BIDB, and • Inspection interval shall be recommended	3
VH	Immediate action is required	4

Abbreviation - B: Bearing capacity; RS: Road safety; M/R: Maintenance/Repair; E/A: Environment and aesthetic appearance

$P = 16$: Measures taken immediately

3 Group Technology Concept to Improve Inspection Planning

3.1 Bridge Families and Representative Bridges

In order to develop optimal inspection procedures, the concept of group technology has been used, as it has the potential to increase the efficiency of the inspection procedure (Rachman and Ratnayake, 2019). Group technology is widely used in the manufacturing industry to classify the system into subsystems and subdivide them into part families, based on design attributes and manufacturing similarities. According to the literature, the use of group technology in manufacturing processes helps to both improve the productivity and increase the efficiency of the process. However, there are limited applications of the concept in civil engineering applications. Group technology concepts are based on creating families of bridges with similar characteristics, such as building materials, degradation mechanisms and condition, and, for each bridge family, a representative bridge is designated. The representative bridge should have all the characteristics of the remaining bridges in each bridge family. The purpose of the representative bridges is that, on the basis of thorough inspections of the representative bridge, one should be able to predict future damage conditions on the remaining bridges in the bridge family. The representative bridge must undergo frequent inspections, and one should have good information about its condition. This information is used to map and predict the condition of the remaining bridges in the bridge family and should significantly reduce the number of GVIs needed.

Initially, based on building material, the bridges are grouped into primary families: reinforced concrete, pre-stressed concrete and steel. The secondary families group the bridges primarily by location and exposure. For example, they can be grouped as bridges close to the sea, inland bridges and high-risk bridges which need special attention. To classify the groups, information from the BIDB about previous inspections is used. Furthermore, a secondary family consisting of "high-risk bridges" includes bridges in poor condition and operates independently of exposure zone. The requirement for bridges in the high-risk family is a priority level > 9 on critical damage, as given in Equation (1), i.e. damage priority 12 or 16. Critical damage is damage with the highest priority level on the actual bridge. Bridges in the "High-risk" family will not have a representative bridge, because all the bridges in the bridge family are at high risk and therefore need thorough and frequent inspections on the same basis as the representative bridges. The different secondary families are as follows: bridges in coastal climates with priority level ≤ 9 on critical damage, bridges in inland climate with priority level ≤ 9 on critical damage, bridges with priority level > 9 on critical damage.

The study uses the bridges in the Rogaland, Norway, area to illustrate the method. Rogaland consists of 721 road bridges; concrete is the most typical building material, with 522 bridges. Furthermore, 133 bridges are built with pre-stressed concrete and 66 bridges with steel. Moreover, Rogaland is a region in Norway with an elongated coast, and this is evidenced by the high number of bridges located near/within the coastal area. In total, 359 of Rogaland's 720 bridges are in coastal areas, of which 48 qualify for the secondary family, "high-risk bridges". That leaves 311 bridges in the secondary family "bridges in coastal climate". Although Rogaland has an elongated coast, a large proportion of its bridges are located inland. A total of 361 bridges are located in inland areas, of which 51 are eligible for the secondary family, "high-risk bridges". That leaves 310 bridges in the secondary family, "bridges in coastal climate".

3.2 Selection of Representative Bridge

The representative bridges should have all the damage features (*i.e.* corrosion, leakage, spalling, etc.). To ensure this, the study compares the damage frequencies, as well as other characteristics like age, length and structural integrity for the individual bridges to the bridge family as a whole. This is information that is available in NPRA's database, Brutus. The study therefore involves a damage frequency analysis, and this is the decisive factor when appointing representative bridges. For this analysis, 90 bridges have been used, and the bridges are grouped. Then, damage vs frequency analysis has been carried out for each group which consists of at least 10 bridges. Figure 1 shows a Pareto chart of damage vs frequency for the reinforced concrete bridges in coastal areas, based on the registered inspections in the BIDB database until 2018. The dominant mechanisms of damage to reinforced concrete bridges in coastal areas is found to be corrosion of reinforcement and spalling (spalling/RF corrosion), leakage and cracks (80%). Based on the frequency of each type of damage, representative bridges have been assigned for each bridge group. For example, based on the damage and frequency analysis of reinforced concrete bridges in coastal areas, "Kongsbrua" has been chosen as the representative bridge for reinforced concrete bridges in coastal climate in Rogaland, Norway. It represents the remaining bridges, with an approximately equal frequency of damage to the rest of the bridging family, with damage rates of 45%, 27% and 27% for spalling/RF corrosion, leakage and cracks, respectively. An assessment of other characteristics like age, length and structural integrity also

has to be a significant factor in the process. In other words, the representative bridge should have similarities to the rest of the bridge family when it comes to damage frequencies, age, length and structural integrity.

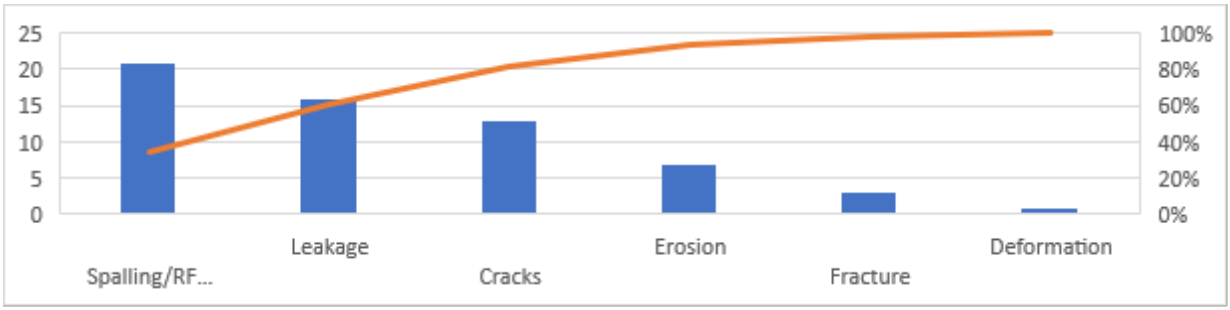

Figure 1. Different types of damage vs frequency in bridge group: reinforced concrete bridges in coastal areas.

The methodology based on the concept of group technology has great potential in inspection planning, and the use of representative bridges can significantly reduce the number of GVIs, without compromising safety. But there are several factors that determine the credibility of the method. Firstly, the bridges in the different families must be of a similar nature. This includes approximately similar damage frequencies, as well as similar characteristics like age, length and structural integrity. Secondly, the appointment of the representative bridge must be as correct as possible. In addition to having similar damage frequencies to the rest of the family, the representative bridge should both be older than and have greater damage than the majority of the bridges in the family. The process does not designate any representative bridges for the high-risk families. This is because bridges in the high-risk families are very different from each other in terms of climate, age and length. The only thing they have in common beyond common building material is one or more cases of serious damage (priority ≥ 12). It would be wrong to designate representative bridges for the high-risk families, as it is very difficult to predict future damage for serious damage whose development is already very advanced. Serious damage will often develop in an accelerating and unpredictable way, making the prediction of future condition uncertain (Vegdirektoratet, 2000). Therefore, all bridges in the high-risk families should be given priority, with frequent and thorough GVIs, on the same basis as the representative bridges. For bridges in families with a representative bridge, simple inspections can be given a lower priority, as long as inspections of the representative bridge have given satisfactory results.

3.3 Comparison of Repair Cost

In order to understand the severity of the damage in terms of repair costs, the cost of implemented measures in the most typical damage modes – crack, spalling/RF corrosion and leakage – have been studied. This was done by using the BIDB database, where both damage priority number (i.e. calculated as given in Equation (1)) and estimation of repair cost related to the damage have been recorded. The correlation between damage, damage priority number and cost of repair has been studied, to understand which damage should be prioritized in maintenance and inspection, from a cost-based perspective (Tronsli, 2019). It could be seen that spalling/RF corrosion is the most expensive to repair, followed by cracks and leakage. For

spalling/corrosion, the repair costs will, to a large extent, increase with increasing priority, compared to cracks and leakage. Therefore, from a cost-based perspective, it is beneficial to repair spalling/RF corrosion at an early phase of damage development.

3.4 Modification of the Existing Inspection Planning Process

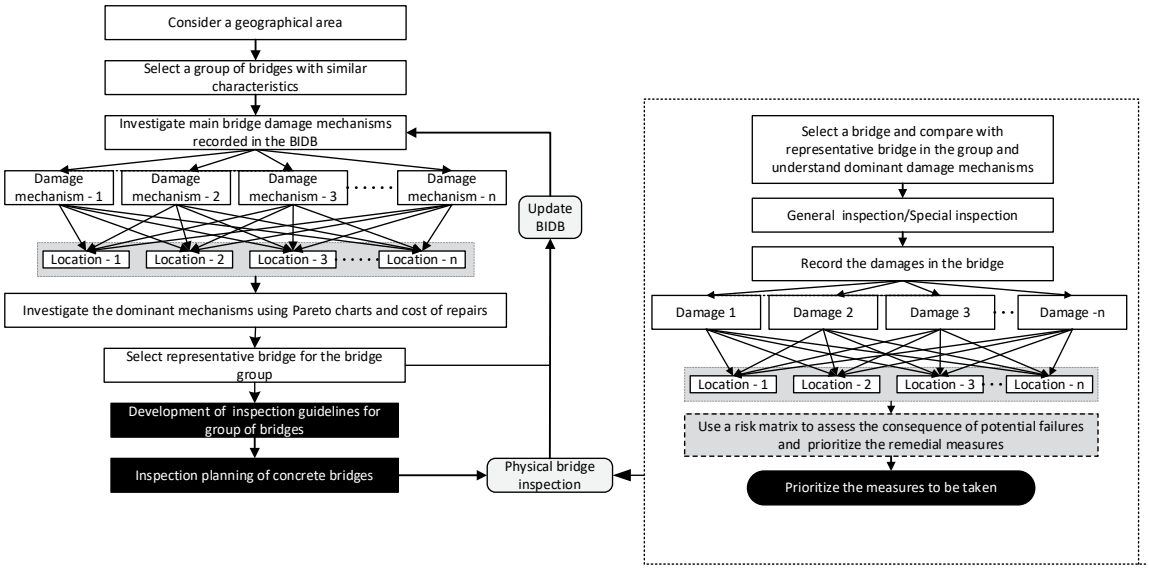

Figure 2. Modified inspection planning process.

The existing inspection procedure can be modified, as given in Figure 2, by implementing group technology and a risk-based inspection planning process. However, it is vital to develop risk matrices to assess the severity, considering consequences and repair costs. According to a repair cost comparison, the cost of repairing spalling/RF corrosion is very high. Therefore, the risk matrix has been developed to assess the severity of spalling/RF corrosion.

4 Development of Risk Matrix

To aid the inspection planning and to ensure an optimal inspection interval, the study developed risk matrices, which decide optimal interval time, based on the priority level (refer to Equation (1)) of the critical damage. The risk matrices developed are only in respect of the damage mode, spalling/RF corrosion, as the damage frequency analysis and cost analysis showed that spalling/RF corrosion are the most dominant and expensive of the damage modes. However, the method of developing risk matrices is applicable for other damage modes. Four matrices are applicable for the damage mode, spalling/RF corrosion, and they are based on the different consequence types the NPRA uses (bearing capacity, road safety, maintenance and aesthetics) when assessing damage. Table 4 shows the risk matrix developed for consequence type, “maintenance”. In order to correctly assess the level of spalling/RF corrosion damage, the study also developed a new scale, which evaluates the damage based on quantitative parameters. It assesses the damage level, based on the size of the area of damaged concrete, and is only applicable for reinforced and pre-stressed concrete bridges. The scale for consequence level is used as in the existing procedure. The exception is for the consequence type, “maintenance”,

where the consequence scale is replaced with a new scale, based on estimated cost for maintenance, worked out from the cost analysis. By adding quantitative parameters to the determination of damage and consequence levels, the accuracy of the assessment is increased, minimizing the possibility of human error or incompetence when assessing damage with consequence type, "maintenance".

Table 4. Risk matrix for assessing spalling/RF corrosion; consequence type: Maintenance.

			Consequence level for maintenance cost			
Maintenance		**Area of damaged concrete**	**1**	**2**	**3**	**4**
			<10,000 NOK	10,000-50,000 NOK	50,000-200,000 NOK	>200,000 NOK
Damage level / measure of probability of failure	**1**	Under 1m²	1	2	3	4
	2	1m²-5m²	2	4	6	8
	3	5m²-20m²	3	6	9	12
	4	Over 20m²	4	8	12	16

Priority	Risk and interval
1-2	Very low risk. Simple inspection can be abolished if the main inspection interval does not exceed 5 years.
3-4	Low risk. The range of simple inspection is 24-36 months.
5-8	Medium risk. The range of simple inspection intervals is 12-24 months.
9-12	High risk. The range of simple inspection intervals is 6-12 months.
16	Very high risk. Simple inspection should be performed as soon as possible. The maximum interval for simple inspections is 6 months.

5 Case Study: Illustrative Example

During the GVI, the bridge is checked for damage and defects according to the modified process given in Figure 2. When observing damage, damage and consequence levels shall be determined by finding the right matrix, based on the different consequence types (referring to Table 2). Then, the damage and consequence levels for the critical damage are entered into the risk matrix, and the matrix will propose a new inspection interval for future GVIs on that particular bridge. If the damage has consequence type M/R (maintenance/repair cost), a cost analysis must be performed. This is about finding the approximate cost of repairing the damage and must be done to find the consequence level, in order to find favourable inspection intervals for GVIs. Bridge 11-0307 Gyastøl, which is located in Rogaland, Norway, has been chosen. Built in 1945, it is a reinforced concrete bridge located in a coastal area. "Gyastøl" is compared with "Kongsbrua", which is the representative bridge for reinforced concrete bridges in coastal areas. Based on the representative bridge, critical damage to "Gyastøl" is spalling/RF corrosion on the bottom of the bridge slab, and the damage has been recorded with consequence level 2 and consequence type "maintenance". The damage description states that there is around 1.5m^2 of spalling, as given in Table 5, which corresponds to damage level 2. Using Table 4, a new inspection interval for future GVIs on the bridge can be estimated. The analysis shows that there is a low risk of failure, valued with priority 4 and consequence type "maintenance", and the matrix suggests a new inspection interval for upcoming GVIs of 24-36 months. Since the previous GVI on the bridge was carried out on 6.6.2018, the next GVI will be set to the period 6.6.2020-6.6.2021. The case shows that it is possible to increase the intervals of GVI using risk analysis and the risk matrix. This will ensure an optimal allocation of resources. Furthermore, this increase in efficiency will enable an increase in resources dedicated to those bridges with the greatest need for frequent inspections.

Table 5. Inspection registered in BIDB: Bridge 11-0307 Gyastøl.

Inspection								
Close visual inspection 12.09.2019 (Done)								
Damage mode				**Status**				
Spalling/RF corrosion				Open	Repaired		Expired	
Damage level				**Consequence level**				
1	2	3	4	**Bearing capacity**	1	2	3	4
Cause of damage				**Traffic safety**	1	2	3	4
Normal degradation of concrete				**Maintenance**	1	2	3	4
Damage description				**Aesthetics**	1	2	3	4
Around 1.5m^2 of spalling.								

6 Discussion and Conclusions

The existing NPRA inspection procedure shows how bridges in Norway prioritize inspections and utilize their budgets. It can be seen that the current inspection procedure does not utilize the allocated inspection budget efficiently. To improve the existing method, and to increase the efficiency of both the inspection procedure and the resource allocation in the NPRA, the concept of group technology is proposed. The proposal to group the bridges into families, according to different properties, and then to designate representative bridges for each bridge family is a new way of working that will increase both efficiency and safety. However, it must be considered that the sample size chosen in this study is small. Therefore, it is vital to carry out further work and a damage frequency analysis using a larger sample size of bridges. However, the application of the proposed improvements can contribute to a reduction in the number of simple inspections, without compromising on safety.

Structural Reliability of Bridges Made with EAF Concretes

Mariano A. Zanini

Dept. of Civil, Environmental and Architectural Engineering, University of Padua, Via Marzolo 9, 35131 Padua, Italy, marianoangelo.zanini@dicea.unipd.it

Abstract. *The development of sustainable concretes is becoming an emerging issue in civil construction sector. The use of Electric Arc Furnace (EAF) slag aggregates in the production of concretes is one way to fulfill sustainability goals. Past research demonstrated a significant increase of mechanical properties of EAF concretes when compared with ones made with natural aggregates (NA); however, at the same time, their use implies also an increase of self-weight loads. The present contribution aims to investigate the reliability of structural systems realized with EAF concretes, with special emphasis to bridge structures. Two different bridge types, considered as case-study examples, are designed considering ordinary concrete mixes, and subsequently, a reliability analysis is run for each EAF concrete class in order to investigate the variation of structural safety margins related to the use of the sustainable EAF concretes in replacement to the ordinary NA concrete mix.*

Keywords: *EAF Slag, Reinforced Concrete, Structural Reliability, Bridges.*

1 Introduction

Among the viable solutions to improve the environmental sustainability of cement-based materials, the use of recycled materials inside concrete mixes is acknowledged to be one of the most effective. Both non-conventional binders and aggregates can be successfully used to design concrete with satisfactorily high properties, both in terms of fresh properties, mechanical strength and durability. However, less research has been devoted both in laboratory and at field-scale about other manufactured aggregate types, even if the use of some of them in concrete has shown promising results. This is the case of electric arc furnace (EAF) slag, a stony, very hard, heavy-weight crushed material, which has been successfully employed to produce concrete (Geiseler, 1996; Motz, and Geiseler, 2001; Koros, 2003). Further, many other studies (*e.g.* Papayanni and Anastasiou, 2010; Pellegrino *et al.,* 2013; Faleschini *et al.,* 2015; Santamaria *et al.,* 2017) demonstrated how concrete with enhanced properties could be designed including EAF slag as partial or full aggregate replacement, significantly reducing the environmental impacts of the mix (Faleschini *et al.,* 2014). Following the positive results achieved in small-scale specimens, some research works have been carried out to study also the structural behavior of full-scale structural elements made of reinforced concrete (RC), including EAF slag at varying replacement ratio inside the mixes (*e.g.* Pellegrino and Faleschini 2013; Faleschini *et al.,* 2017a; Faleschini *et al.,* 2017b; Faleschini *et al.,* 2017c; De Domenico *et al.,* 2018). The above literature has evidenced that EAF slag concrete can be suitably applied in gravity structures, where its heavy-weight and high strength result as positive features. However, doubts might arise about its efficacy when applied in elevation RC structures, because the enhanced mechanical strength might not sufficiently balance the increased dead loads of the RC EAF concrete elements. Accordingly, this paper aims to solve this question, analyzing three classes of EAF concrete, characterized by increasing aggregates replacement ratio, through reliability-based analyses of the capacity of RC structural elements made with EAFconcretes.

Two different bridge types, *i.e.* a single-span simply supported prestressed reinforced concrete (PRC) bridge and a two- span continuous steel/concrete composite I-girder bridge, are designed according to the 2008- Italian Building Code prescriptions and considering a classic NA concrete mix. A reliability assessment is then performed for them, investigating the impact of full replacement of NA concrete with each of the three EAF concrete classes considered (*i.e.* C1, C2, A) on structural safety, thus quantifying the variation of structural safety margins related to the use of the sustainable EAF concretes in replacement to a classic NA concrete mix.

2 Structural Reliability Index Assessment

Figure 1 shows the general structural reliability workflow herein adopted in the following analyses: the workflow briefly presents key steps followed in assessing structural reliability index β. As regards the three EAF concrete classes, Table 1 lists main properties of the selected categories. More details can be found in Zanini (2019).

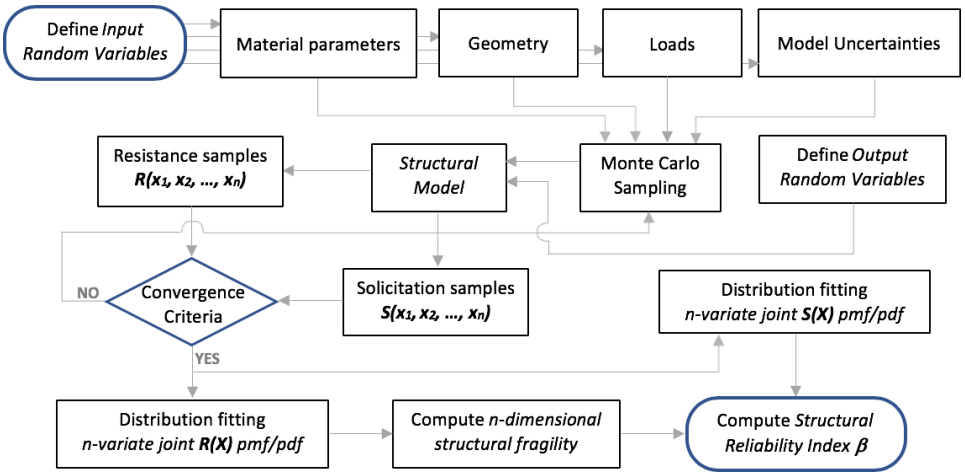

Figure 1. General structural reliability workflow.

Table 1. Properties of the selected EAF concrete categories ([a] concrete compressive strength ratio; [b] concrete specific weight ratio).

	EAF - C1	EAF - C2	EAF – A
EAF aggregates size	> 4 mm	> 4 mm	0 – 4 mm
w/c ratio	≤ 0.5	> 0.5	-
f_{c_EAF}/f_{c_NA} [a]	0.99 – 1.92	0.79 – 1.92	0.78 – 1.11
ρ_{c_EAF}/ρ_{c_NA} [b]	1.11 – 1.24	1.01 – 1.27	1.01 – 1.28

3 Application to Two Case-Study Bridges

The abovementioned structural reliability workflow was used to investigate how the use of EAF concretes can impact structural safety of two different common bridge configurations, namely a single-span simply supported PRC girder bridge (Bridge #1) and a two-span continuous steel/concrete composite I-girder bridge (Bridge #2). Both bridge types were first designed according to the 2008-Italian Building Code prescriptions (Italian Ministry for Constructions 2008), considering the use of ordinary NA concrete mixes. A reliability analysis was then carried out on the benchmark case (NA) and on the three hypothetical sustainable construction solutions (i.e. the same bridges in terms of sizing and reinforcement), realized with EAF-C1, EAF-C2 and EAF-A concrete mixes. Load analysis was conducted for both structures in accordance to Italian codes, accounting for self-weights of girders, dead loads of guard-rails and parapets, traffic loads, and in addition, taking into account wind actions and RC pier self-weight in Bridge #2.

3.1. Bridge #1: Single-Span Simply-Supported PRC Girder

The first case study is represented by a single-span simply supported PRC girder bridge. The span is 22 m-length and 13.5-m width and is composed by a RC slab of 30-cm thickness sustained by 7 PRC beams connected with transverse cast-in-situ RC beams (0.2-m x 0.9-m) located at the quarters. Each PRC beam is characterized by a double-T section of 1.3-m height h and 0.6-m width b, with wings t_f and web t_w thickness values of 0.13-m and 0.15-m, respectively. Figure 2 shows main geometrical features of Bridge #1.

For Bridge #1, the analysis was focused on the Ultimate Limit State (ULS) flexural strength of the PRC beams. PRC beams were first designed in compliance with Italian Ministry for Constructions (2008), considering a C30/37 NA concrete: acting ULS design girder bending moments were computed for self-weight of materials and load model LM1 with TS placed at mid-span, and subsequently distributed via the computation of Courbon's distribution coefficients in order to derive design acting bending moments Msd on each PRC beam. Hence, PRC beam design was performed considering a stress-block constitutive law for concrete and an elasto-perfectly plastic law for prestressing steel, assuming section wings of constant average thickness equal to 0.165 m, neglecting the contribution of ordinary steel reinforcing bars and considering a resultant prestressing cable ideally condensing all prestressing steel area Ap. Main materials parameters adopted in PRC beam design.

Once designed the most loaded PRC beam, reliability analysis was carried out in order to assess structural safety margin for the same bridge configuration realized both with NAC and the sustainable EAF concrete mixes. First, input random variables were fixed for material parameters, geometrical features, loads and model uncertainties: the type of distribution and coefficient of variation assumed for each random variable can be found in Zanini (2019). One output random variable x is here monitored, i.e. bending moment at mid-span. *MC* simulations were run sampling data from input distributions and deriving bending moment solicitation $M_S(x)$ and resistance $M_R(x)$ samples until the achievement of the convergence criterion. Hence, sampled $M_S(x)$ and $M_R(x)$ values were fitted in order to derive related pdfs parameters: Figure 3 shows bending moment M_S pdfs and M_R fragility curves for both NA and EAF concrete mixes, evidencing a lower fragility for EAF-C1 and EAF–C2 classes with respect to NA, whereas

EAF-A class shows a higher fragility, and this can be mainly attributed to the compressive strength reduction that characterizes EAF-A mix.

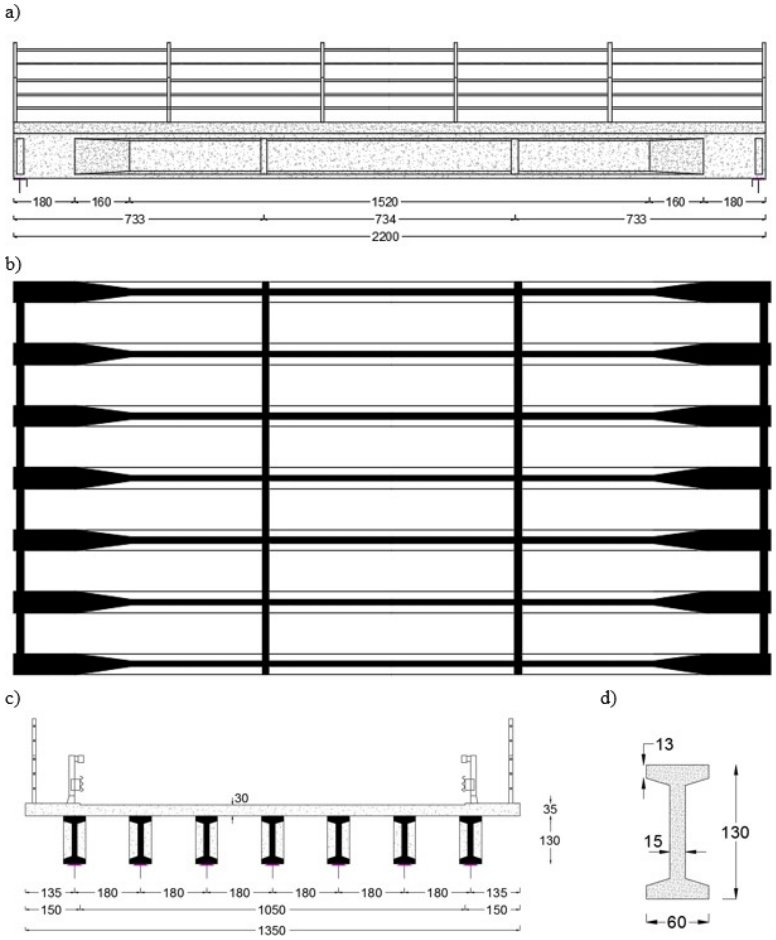

Figure 2. Bridge #1 main geometrical characteristics [in cm]: girder profile (a), girder plan (b), deck section (c) and PRC beam section (d).

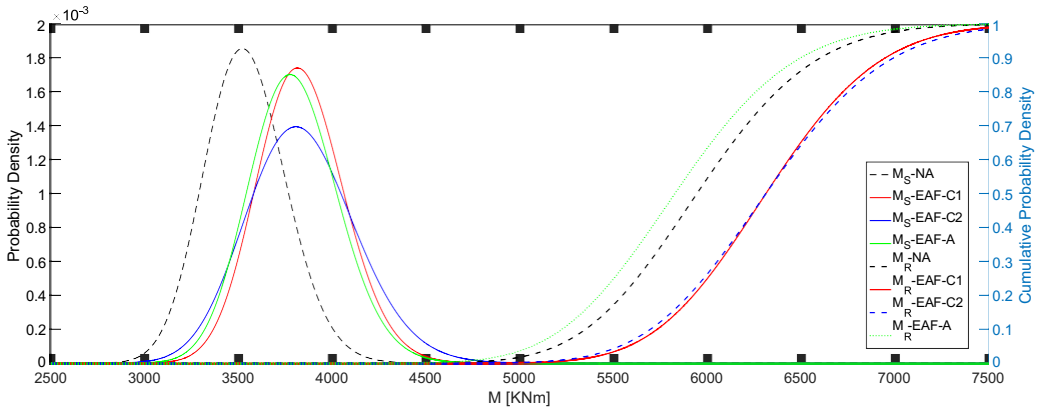

Figure 3. Bridge #1 bending moment M_S *pdf*s and M_R fragility curves for NA and EAF concretes.

In addition, slight differences can also be observed when comparing bending moment solicitations MS of the three EAF concrete classes, while their pdfs are higher with respect to the NA mix one, mainly due to their higher self-weight. Lastly, failure probabilities P_f and related Structural Reliability Index β were computed for each concrete mix, leading to P_f estimates of 1.98e-07, 7.24e-08, 3.48e-06, 2.28e-05 and β values 5.071, 5.259, 4.495, 4.077 for NA, EAF-C1, EAF-C2 and EAF-A concretes, respectively. Results highlighted how the use of EAF-C1 in this specific application leads to structural safety margins higher than NA concretes, whereas EAF-C2 and EAF-A are characterized by lower structural reliability levels.

3.2. Bridge #2: Two-Span Continuous Steel/Concrete Composite I-Girder

The second case study is represented by a two-span continuous steel/concrete composite I-girder bridge (Figure 4). Bridge #2 has two spans of 30-m length and 13.5-m width and is composed by a deck consisting in a RC slab of 30-cm thickness supported by 2 I steel profiles of variable height ranging from 1.7-m at abutments to 2.8-m at pier support, connected with open diaphragms made with coupled L steel profiles. I-steel profiles were sized according to the 2008-Italian Building Code prescriptions Italian Ministry for Constructions (2008), thus resulting in steel plates of 40-mm, 60-mm and 30-mm thickness for the upper wing, lower wing and web, with 0.9-m and 1.3-m width for upper and lower wings, respectively. The deck is supported by a 16-m height RC pier characterized by a rectangular hollow section with 2.5-m height, 1.5-m width and 30-cm thickness. In the upper part, pier has a variable section which joints with a beam cap of 1.3-height.

For Bridge #2, the analysis was focused on the Ultimate Limit State (ULS) combined axial force-bending moment of the RC rectangular hollow pier. Pier section was therefore first designed according to Italian Ministry for Constructions (2008), considering a C30/37 NA concrete and a B450C steel reinforcement. ULS design axial load-moment (P-M) solicitation points were computed considering two different load combinations (*i.e.* maximizing axial force or bending moment on pier base section) taking into account the self-weight of materials, load model LM1 with TSs placed at the most unfavorable section (*i.e.* in correspondence of pier support), and wind action computed with the following formula:

$$W = \frac{1}{2}\rho {v_b}^2 c_p c_e c_s A_{ref} \quad (1)$$

where ρ is the air mass density equal to 1.25 kg/m^3, v_b is the wind velocity measured at 10 m above the ground for open-country surface conditions, c_p, c_e and c_s stand for the pressure, exposure and shape coefficients, respectively, and A_{ref} is the surface area of the structural members impacted by wind. An equivalent rectangular $A_{ref,deck}$ area of 2.6-m height was considered for deck, also adding a 3-m height equivalent rectangular $A_{ref,traffic}$ area in order to take into account also vehicles profile, as specified in Italian Ministry for Constructions (2008). P-M solicitation points were derived for both analyzed load combinations and then reinforcing steel area was iteratively derived by computing the resistance P-M interaction diagram, adopting a stress-block constitutive law for concrete and an elasto-perfectly plastic law for reinforcing steel bars with main materials' mechanical properties listed in Zanini (2019).

Pier design process lead to identify the reinforcement solution able to equalize the worst P-M solicitation point, thus resulting in two layers of 20 mm diameter longitudinal reinforcement steel bars with 10 cm spacing (*i.e.* one inner and one outer surfaces, 28 bars in the shorter RC web and 40 bars in the longer one, see Figure 4d).

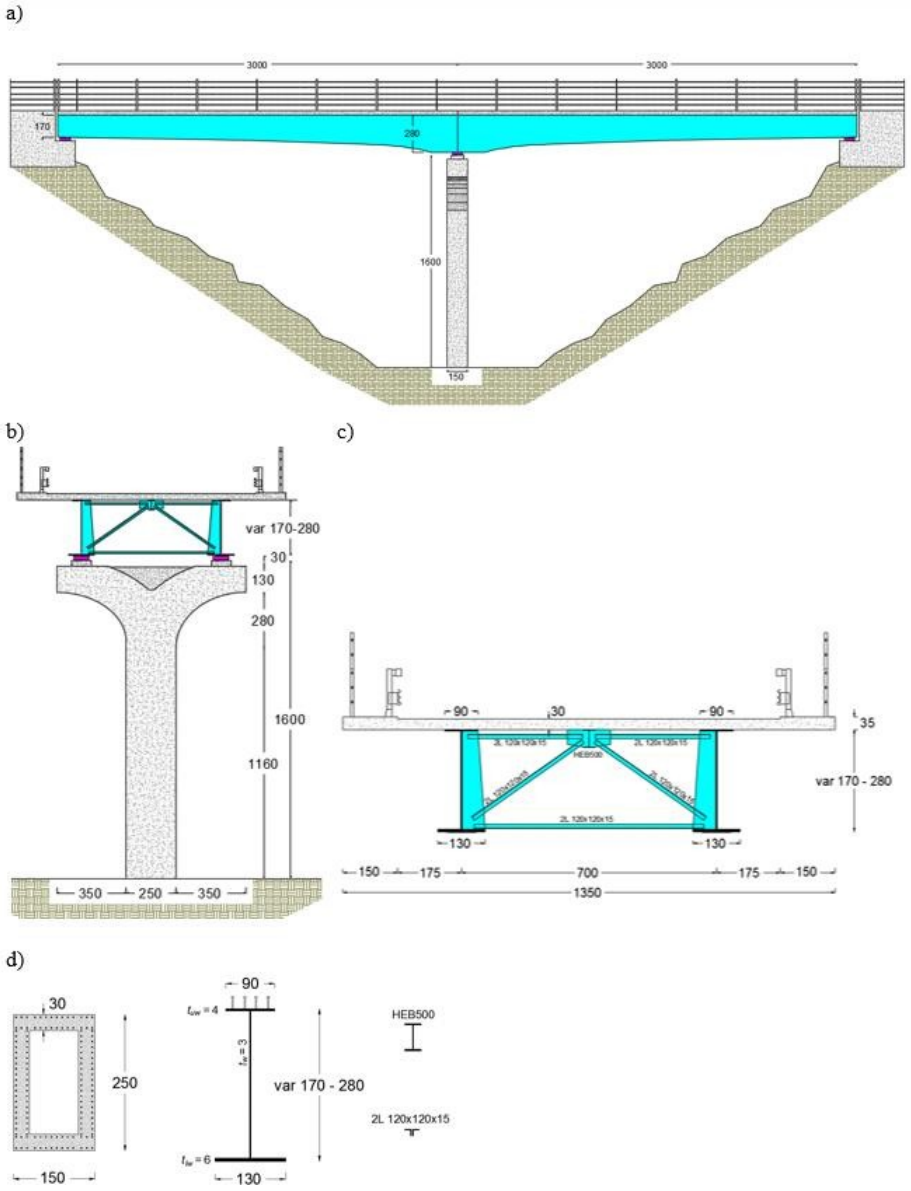

Figure 4. Bridge #2 main geometrical characteristics [in cm]: longitudinal profile (a), transversal section (b), deck section (c) and RC rectangular hollow pier and main steel profile sections (d).

Once designed the RC rectangular hollow pier, reliability analysis was carried out in order to assess structural safety margin for the same bridge configuration realized with sustainable EAF concrete mixes both in RC slab and pier elements. Input random variables were fixed, as listed

in Zanini (2019), whereas in this specific case, two output random variables x_1, x_2 were monitored, i.e. RC pier base section bending moment and axial force. MC simulations were run sampling data from input distributions, and deriving couples of bending moment-axial force solicitation $M_S(x_1)$-$N_S(x_2)$ and resistance P-M interaction diagram samples $M_R(x_1)$-$N_R(x_2)$ until the achievement of the adopted convergence criteria. Figure 5 represents fragility surfaces derived for both NA and EAF concrete mixes highlighting, as expected, a lower fragility for EAF-C1 and –C2 classes with respect to EAF-A and NA mixes.

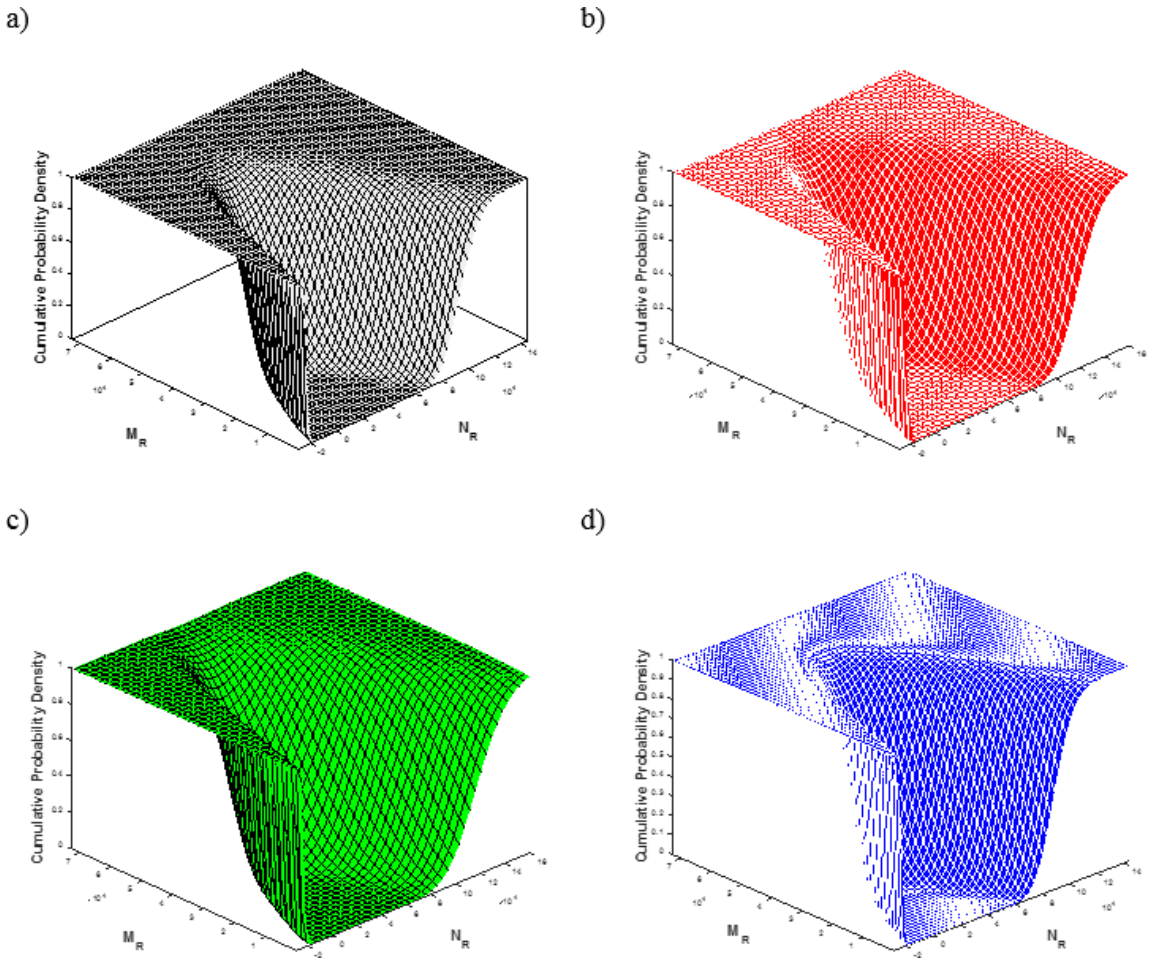

Figure 5. Bridge #2 joint bivariate fragility surfaces for NA (a), EAF-C1 (b), EAF-C2 (c) and EAF-A (d) concretes.

Failure probabilities P_f and related Structural Reliability Index β were then computed with Eqs. 1, 4 obtaining P_f estimates of 4.25e-05, 1.26e-05, 1.93e-05, 5.53e-05 and β values 3.930, 4.212, 4.116, 3.866 for NA, EAF-C1, EAF-C2 and EAF-A concretes, respectively. Results evidenced how the use of EAF-C1 and –C2 mixes in this specific application leads to structural safety margins higher than NAC, whereas EAF-A is characterized by lower structural reliability levels.

4 Conclusions

The present work investigated the influence on structural safety margins related to the replacement of common NAC mixes with EAF ones, with special emphasis to the field of the design of common bridge types. A general structural reliability workflow was proposed in order to formalize the methodology to be used in assessing the structural reliability index for a generic n-dimensional problem. Two bridge case studies were then analyzed, showing reliable outcomes when using EAF concretes for structural elements subject to compressional regimes, like bridge piers or PRC beams. Among future improvements of the present study, further efforts will also be required in order to investigate the impact of EAF concretes on seismic reliability of RC structural systems.

Abstract. *It is very important to improve and secure durability of reinforced concrete (RC) building and housing, in order to extend the service life of it. In this study, these were studied experimentally that the contribution ratio of blended cement to the carbonation resistance of concrete when a part of OPC replaced to FA or BFS much more were used for concrete, and the effect of carbonation suppression required for an effective finishing materials when these were applied for concrete surface. As a result, we were able to obtain the knowledge that the contribution ratio to the carbonation resistance of concrete using blended cement with different mixture replacement ratio, and the effect of carbonation suppression required for 4 types of finishing materials and its specifications, from the viewpoint of securing durability and extending the service life of RC structures. Therefore, these were considered to be able to sufficiently contribute to the review of the evaluation method or technical standards concerning about the durability of RC structures prescribed in "Housing Quality Assurance Act" in Japan.*

Keywords: *Blended Cement, Finishing Materials, Water-Cement Ratio, Depth (thickness) of Concrete Cover, Resistance or Suppression of Carbonation.*

1 Introduction

It is very important to improve and secure durability of reinforced concrete (RC) building and housing, in order to extend the service life of it. In Japan, the technical standards concerning about the durability of RC structures and quality of concrete are prescribed in "Housing Quality Assurance Act". In the notification No.1374 shown in Table 1 related to this laws, the subjects of "phenomenon of deterioration" are the rust of rebar caused by carbonation of concrete. This table means a necessary measures have been taken to extend the period of large-scale repair work is not required up to 3 generations (generally 75-90 years) under the general conditions of environment and maintenance that are normally assumed. And, as the evaluation standards of "reduction of deterioration" for concrete, the relationship between water-cement ratio (W/C) and depth (thickness) of concrete cover is prescribed depending on the required durability (carbonation resistance) of concrete. This is because the thickness of concrete cover in the RC structures directly affects the corrosion of the rebar due to the carbonation of the cover concrete. Therefore, in order to improve the durability performance and to extend service life of RC structures, it is necessary to increase the cover thickness or reduce the W/C of concrete.

In addition, this technical standard is specified assuming concrete using ordinary portland cement (OPC), and when using fly ash (FA) or ground granulated blast-furnace slag (BFS) for concrete, the mass of cement for calculating W/C must be excluding all (100%) of FA in this certification standards. Also, the mass of cement for calculating W/C must be excluding 30% of BFS, i.e. the "contribution ratio of carbonation resistance" of FA and BFS are defined as 0 and 0.7. This concept is determined in consideration of the contribution ratio of the mixture in blended cement to the carbonation resistance of concrete. This concept is determined by the replacement ratio of FA of about 15% and BFS of about 45%, which are equivalent to "Type B" in Japanese Industrial Standards (JIS), also based on many previous research and survey such as guidelines of Architectural Institute of Japan (AIJ).

Therefore, in case of using the blended cement and using FA or BFS much more for concrete, it is necessary to reduce the W/C of concrete much more, or to use the effective finishing material for durability, for examples, tiling, mortar coating, external insulation methods, etc. Table 1 shows that an effective finishing material for durability, and W/C of 5% are equivalent to a concrete cover of 1 cm (10mm). However, tiling, mortar coating, external insulation methods, and the like are exemplified as effective finishing material for durability, but required performance is not shown.

In this study, these were studied experimentally that the contribution ratio of blended cement to the carbonation resistance of concrete when a part of OPC replaced to FA or BFS much more were used for concrete, and the effect of carbonation suppression required for an effective finishing materials when these were applied for concrete surface. This study might be so useful to get the technical data for suggesting the new certification standards and to reduce environmental load in the construction sector, and to secure durability of RC structures.

Table 1. Certification standards of RC structures with long service life in the notification No.1374 related to Housing Quality Assurance Act in Japan.

Part or members of RC structures			≦W/C50%	≦W/C55%
not contacts directly with the ground	walls except bearing walls, slab of floors	inside	2cm	3cm
		outside*	3cm	4cm
	bearing walls, columns, beams	inside	3cm	4cm
		outside*	4cm	5cm
contacts directly with the ground	walls, columns, slab of floors, beams, rising part of continuous foundation		4cm	5cm
	foundation (except the rising part of continuous foundation, and leveling concrete)		6cm	7cm

Note *: It could be reduced by 1cm (10mm) on the outside, by using an effective finishing material for durability (ex: tiling, mortar coating, external insulation methods, etc.)

2 Carbonation Resistance of Concrete Using Blended Cement

An accelerated carbonation test was performed on specimens with changed water-binder ratio (W/B), the type and replacement ratio of mixture, and the ratio of each mixture contributing to the carbonation resistance was clarified experimentally. The goal is to provide useful and technical data for durability design of RC structures using blended cement.

2.1 Outline of Experiment

Table 2 shows the experimental factors and levels and their combinations. The W/B were 30, 40, 50, 60%, and the mixture replacement ratio is selected from 2 kinds of 15 and 25% for FA and 1 to 3 kinds selected for BFS of 30, 50, and 70%. It was set as the combination. In addition, when OPC was used, specimens with W/B80% and 100% were prepared in order to confirm the compressive strength and carbonation resistance of the specimen with a small amount of cement per unit volume of concrete. In addition, in order to ascertain the carbonation resistance of specimens using commercially available portland blast-furnace slag cement (Type B), W/B50% specimens (with a replacement ratio of 40-45%) were prepared and subjected to the same tests. The accelerated carbonation test conformed to JIS A 1153 (Method of accelerated carbonation test for concrete). The pre-curing was performed under standard curing until the age of 28 days, and then in-air curing at 20°C, 60% R.H. until the age of 56 days.

Table 2. Experimental factors and levels.

Type of mixture	W/B (%)	Mixture replacement ratio (%)	Curing before carbonation test
Non (only OPC)	40,50,60,80,100	-	1) Air curing up to age of 56 days (20℃, 60% RH) after sealed curing for 5 days 2) Air curing up to age of 56 days (20℃, 60% RH) after standard curing for 28 days
ground granulated Blast-furnace slag (BFS)	30	70***	
	40,50	30*,50**,70***	
	60	30*, 50**	
Portland blast-furnace slag cement (Type B)	50	40-45**	
Fly ash (FA)	40,50,60	15**,25***	

Note *: Type A, **:Type B, ***Type C, according to the classification of blended cement by JIS

2.2 Results of Experiment and Discussion

Figure 1 shows the relationship between the compressive strength and the carbonation rate coefficient. However, the modified carbonation depth subtracts the carbonation depth immediately before the start of the test (age of 0 week). The figure shows that the standard curing 28days compressive strength and the carbonation rate coefficient have a strong correlation, and the carbonation rate coefficient tends to decrease as the standard curing 28days compressive strength increases, regardless of the type of mixture and the replacement ratio.

Figure 2 shows the relationship between W/B and the carbonation rate coefficient, in case of using BFS. There was a strong linear correlation between W/B and the carbonation rate coefficient, which was similar when FA was used. Here, the ratio that the mixture contributes to carbonation resistance as a replacement of OPC was defined as “contribution ratio of carbonation resistance (α)”. Using the contribution ratio α, the amount of binder that contributes to carbonation resistance was determined as equation (1). In this equation, the “mixture” indicates mixtures (FA or BFS).

$$\text{Amount of Binder} = \text{Amount of OPC} + \alpha \times \text{Amount of mixture} \quad (1)$$

Figure 3 shows a trial calculation of the carbonation rate coefficient when α is changed by 0.2 from 0 to 1.0, in case of BFS50%. It was assumed that the ratio of mixture that could contribute to carbonation resistance as a replacement of cement could be estimated by back-

calculating α at the intersection where the trial calculation results of each α and the line of OPC (N, in Fig) intersect. Using this estimation method, the contribution ratio (α) of the carbonation resistance according to the mixture replacement ratio of FA and BFS were calculated and shown in Table 3. For α of fly ash, FA15 was 0.07 to 0.42, FA25 was 0 to 0.17. For α of ground granulated blast-furnace slag, BFS30 was 1.04 to 1.07, BFS50 was 0.83 to 0.84, BFS70 was 0.45 to 0.69. Among the mixtures, BFS had a higher contribution ratio of the carbonation than FA, and the greater the replacement ratio of mixture, the smaller the contribution ratio.

As the results, these were obtained that the ratio excluding BFS from the mass of cement for calculating W/C may be 0% for Type A, 20% for Type B and 30% to 60% for Type C. Also, in case of FA, it may be 60% to 100% for Type B and 90% to 100% for Type C. Therefore, it was found that the current standard (Table 1) could be mitigation in some cases.

Table 3. Calculation results of Contribution ratio for Carbonation Resistance.

Binder	Mixture replacement ratio (%)	Blended Cement (JIS)	Contribution ratio of Carbonation Resistance W/B (%)			
			30	40	50	60
OPC(N) +FA	15	Type B	-	0.42	0.21	0.07
	20	Type C	-	0.17	0.07	0.00
OPC(N) +BFS	30	Type A	-	1.04	1.06	1.07
	50	Type B	-	0.84	0.84	0.83
	70	Type C	0.45	0.59	0.69	-

3 Suppression Effect of Finishing Materials on Carbonation of Concrete

In RC structures, finishing materials that can suppress the intrusion of carbon dioxide, which causes carbonation, are often applied to the concrete surface. It is possible to use the effect of carbonation suppression of finishing materials. However, there were few experimental data that confirmed it such as tiling, mortar coating, and external insulation methods, and it was not clear how to select finishing materials that can be considered equivalent effect. Here, confirmation of the effect of suppression the carbonation of concrete of 4 types of finishing materials, which were tile, mortar, external insulation and coating materials for textured finishes, and the evaluation method of the suppression effect, were examined.

3.1 Outline of Experiment

Table 4 and Table 5 show type of finishing materials and mortar coating. Also, Figure 4 shows the experimental image. For concrete, W/C60% was used considering the upper limit of the technical standards prescribed in “Housing Quality Assurance Act”. Specimens were sealed at 20°C until the age of 4 weeks, then dried in a room with 60%R.H. and a temperature of 20°C until the age of 8 weeks, and then mortar was applied to one side of the mold surface. Thus, a specimen for the accelerated carbonation test was prepared. In each mortar, W/B was 40%, and the binder: fine aggregate = 1: 2.5 (mass ratio). The binder used for mortar was OPC, and high-early-strength portland cement (HPC), which could be expected to develop early strength, and silica fume (SF), which could be expected to be densify the concrete, 5% (mass ratio) of the binder was replaced. The type of aggregate was based on natural sand, and perlite artificial lightweight aggregate (standard weight 0.17kg/L) was also used.

The mortar coating was applied to concrete specimens, with the variable factors being the type of binder and aggregate, the amount of polymer (main component: ethylene vinyl acetate copolymer emulsion), the thickness of mortar and the curing method after mortar coating. The effect of carbonation suppression of mortar coating was confirmed.

The amount of polymer mixed in the mortar is based on B×3% as a general value in finished mortar, and B×6% with an increased amount of polymer was also examined. The thickness of mortar applied to the specimen was basically 10mm, and as shown in the Table 5, the mortar thickness was varied within the range of 5 to 30mm. The method of curing the specimens after mortar coating was based on air curing in a room at about 20°C, and examination was also made on those that were cured for 2 or 7 days after coating. The accelerated carbonation test started at concrete curing age of 12 weeks, in accordance with JIS A 1153. Also, the carbonation depth of concrete was measured at test age of 8, 13, 26 and 52 weeks.

Table 4. Type of Finishing Materials.

Type of finishing materials	Materials and symbols
Non	Concrete(C1)
Tile	Water absorption type 1(T1, T2(with M8), T3)、type 2(T4, T5(with M8))
Mortar	Primer(C-1(t=1mm(M1, M2)),C-2(t=2mm(M3, M4))), Primer(CM-1(t=10mm(M5, M6)), CM-2(t=10mm, M7, M8))) On-site mixing mortar(t=10mm,M9), (t=15mm,M10)
External insulation	Polystyrene type 4(t=30mm, IN1, IN2), Polystyrene type 3(t=30mm, IN3), Urethane foam typeA22(t=30mm, IN4)
Coating materials for textured finishes	Multi-layer coating materials for textured finishes(CM1,CM2), Coating materials for thick textured finishes(CM3,CM4), Coating materials for thin textured finishes(CM5)

Table 5. Type of Mortar Coating.

Binder (B)	Aggregate	Contents of polymer (B × wt%)	Curing after mortar coating	Thickness of mortar (mm)
-	-	-	In air without coating	0
OPC	Natural sand	3	In air after coating	5, 10, 20, 30
			2 days wet after coating, then air	10
			7 days wet after coating, then air	
		6	In air after coating	10, 30
			2 days wet after coating, then air	10
			7 days wet after coating, then air	
	Perlite ALA	3	In air after coating	10, 30
HPC	Natural sand	3	In air after coating	10, 30
			2 days wet after coating, then air	10
			7 days wet after coating, then air	
OPC+SF (95:5 wt)	Natural sand	3	In air after coating	10, 30

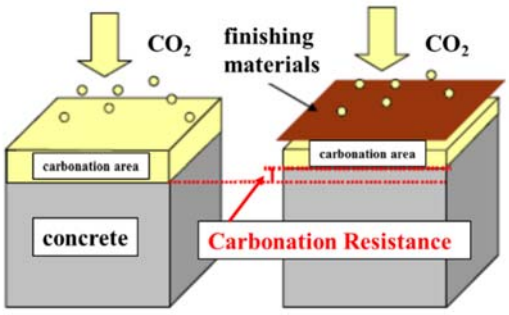

Figure 4. Outline of experiment.

3.2 Results of Experiment and Discussion

Figure 5 shows the carbonation depth of each specimen at the test age of 52 weeks. In this figure, the carbonation depth of the specimen that was not finished was also shown, and the value when the carbonation depth was 10 mm smaller than that was shown by the dotted line. As a result, it was found that the finishing material other than mortar has an effect of carbonation suppression of more than 10 mm compared to the specimen C1 (exposed concrete).

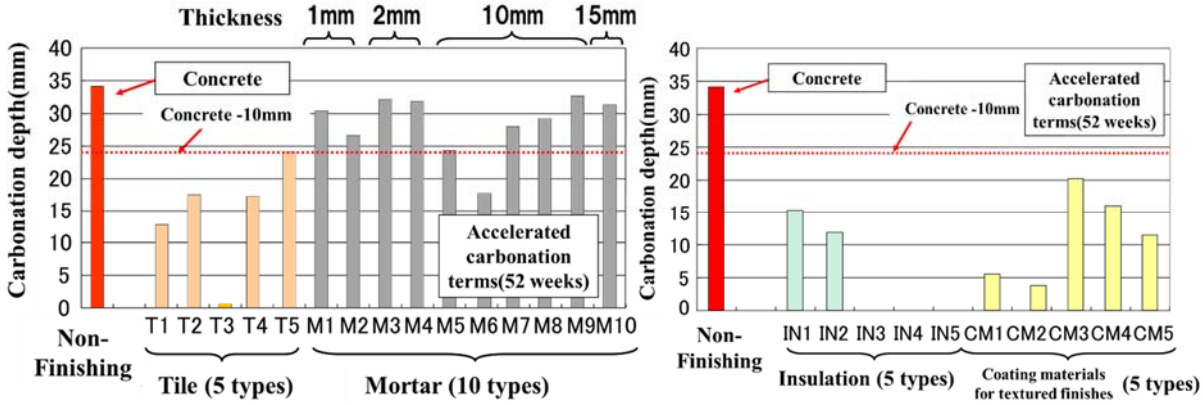

Figure 5. Carbonation depth of concrete with 4 types of finishing materials.

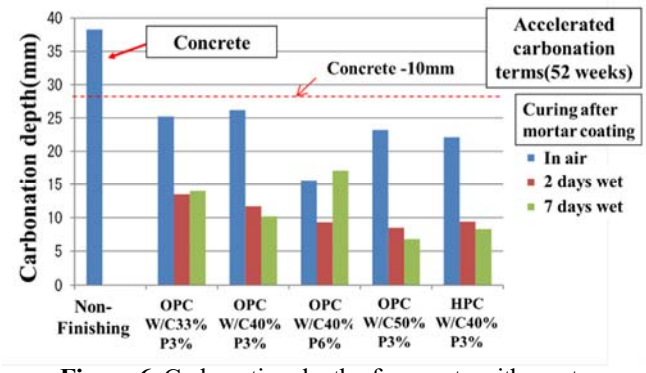

Figure 6. Carbonation depth of concrete with mortar changing curing condition.

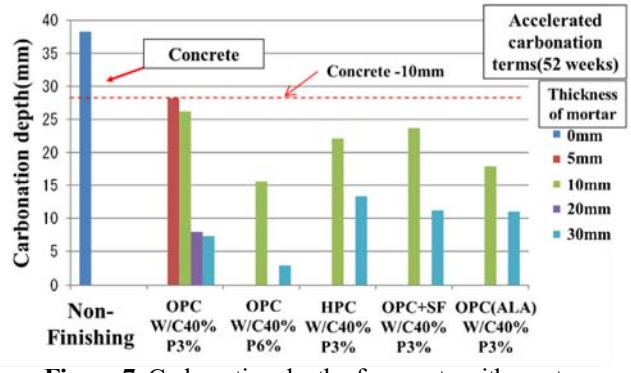

Figure 7. Carbonation depth of concrete with mortar changing thickness and materials used.

With regard to mortar coating, it was not possible to obtain a carbonation suppression effect of 10 mm or more with a primer of 1.0 to 2.0 mm, and an equivalent thickness of at least about 10 mm was required. However, not all M5 to M10 mortars with a thickness of 10 mm or more have a carbonation suppression effect.

Figure 6 shows the test results of the carbonation depth of concrete with a mortar thickness of 10 mm, at the test age of 52 weeks. The compressive strength of the mortar at the age of 28 days was greatly improved by the wet curing after mortar coating, and the carbonation suppression effect by the mortar was also greatly improved. In addition, in this experiment, it was suggested that by increasing the amount of polymer mixed in the mortar, the carbonation suppression effect equivalent to the case of wet curing can be obtained even if it was cured in the air. Figure 7 shows the test results of the carbonation depth of concrete cured in air after mortar coating at the test age of 52 weeks. As the thickness of mortar increased, the effect of suppressing carbonation increased. In this experiment, if the mortar thickness was 10 mm or more, the effect of suppressing carbonation was obtained equivalent 10 mm or more compared to the specimen C1 (exposed concrete) even if wet curing was performed. For mortar with HPC as the binder or mortar in which part of the binder was replaced with silica fume, the test results at test age of 13 weeks tended to slightly improve the carbonation suppression effect of mortar. However, the same trend was not clearly confirmed at the test age of 52 weeks. For the mortar using lightweight aggregate, the compressive strength was as low as about 40% when using natural sand, but the carbonation suppression effect was equivalent to that of mortar using

natural sand.

As the results, it was confirmed that the 4 types of finishing materials, which were tiling, mortar coating, and external insulation method and a finishing coating material, had the same carbonation suppression effect as the concrete cover thickness of 10 mm, *i.e.* W/C5%. In addition, these were obtained that the effect of carbonation suppression of mortar coating could be improved by initial curing, the amount of polymer increase and the mortar coating (thick coating) of about 30mm.

4 Conclusions

We were able to obtain the knowledge that the contribution ratio of blended cement to the carbonation resistance of concrete when a part of OPC replaced to FA or BFS much more were used for concrete, and the effect of carbonation suppression required for an effective finishing materials and its specifications when these were applied for concrete surface, from the viewpoint of securing durability of reinforced building and housing.

The results obtained were as follows:

- The ratio excluding FA from the mass of cement for calculating W/C may be 60% to 100% for Type B and 90% to 100% for Type C. Also, in case of BFS, it may be 0% for Type A, 20% for Type B and 30% to 60% for Type C.
- The 4 types of finishing materials, which were tiling, mortar coating, and external insulation method and a finishing coating material, had the same carbonation suppression effect as the concrete cover thickness of 10 mm, i.e. W/C5%.
- The effect of carbonation suppression of mortar coating could be improved by initial curing, the amount of polymer increase and the mortar coating (thick coating) of about 30mm.

As the results, these were considered to be able to sufficiently contribute to the review of the evaluation method or technical standards concerning about the durability of RC buildings and housing prescribed in “Housing Quality Assurance Act” in Japan.

Abstract. *This paper presents the results of a pathfinder project on re-usable buildings which was part funded by Climate- KIC, supported by the EIT, a body of the European Union. It places reusable buildings in the context of sustainability generally, and specifically within the general theme of circular economy transition. It includes a brief summary of the literature review undertaken, focussing on challenges and benefits to the business case for adoption of reusable buildings.*

Keywords: *Re-Usable, Sustainability, Circular Economy, Business Case, Literature Review.*

1 Introduction

This paper reports the initial results of a scoping study undertaken with partial funding from the Climate _KIC programme, which is supported by the EIT, a body of the European Union. The objective of the study was to test out the possibility of generating a critical mass of client support for re-usable buildings. Re-usable buildings for this study included those that could be adapted in use for same use or for different uses within a circular economy context. The work was undertaken by a consortium led by the London Waste and Recycling Board (LWARB), in partnership with the Sustainable Development Foundation (SDF), the Forum for the Future (FforF), the Alliance of Sustainable Building Products (ASBP) and Whole Life Ltd. (WLL).

The early part of the project involved a literature review. The later part of the project included workshops, which led to a sector routemap for the future development of the market, together with initial business models which might encourage and support the market for re-usable buildings and components. This paper is focussed on the challenges and benefits identified for the business case for re-usable buildings and components.

2 Literature Review Methodology and Scope

The literature review encompassed searches of academic papers, government and non-governmental organisation (NGO) publications and industry publications using Web of Science. A key word search was undertaken, using the term ‘reusable buildings’ in addition to sourcing works known to members of the consortium. The main aim of the literature review was to understand the outcomes of previous work in this area, and to identify the gaps with a focus on the business case.

3 Main Findings of the Literature Review

3.1 Overview

There is a perception that the application of circular economy principles to the built environment offers major opportunities, in environmental terms but also in terms of social and economic impacts. The reuse of buildings is gaining more interest; with evidence showing that conversion (from one function to another) is increasing in inner urban areas. The benefits and challenges for commercial re-usable buildings are well defined though not often quantified. There is a clear distinction in the motivations between the different development models (develop to sell, manage or occupy), with owner-occupancy driving a greater interest in adaptability. End-users preferences are for versatile and a refit-ready building that provides fewer disruptions, improved service and better quality of space.

3.2 Application of Circular Economy within the Building Sector

There are several industry studies that look at how a circular economy can be applied in the building sector, they mostly describe the different business models that could be applied, together with some of the challenges and opportunities, though they are lacking in actual costs. A few of these studies define what a circular economy in the built environment would look like and the macro-economic benefits (at a region or Country level). At the micro (business level), there is little economic information available within the literature on the financial benefits or costs for undertaking circular business models. Indeed, research by (Adams *et al.*, 2017) found that one of the largest challenges for adopting circularity in the built environment is the unclear financial case, particularly for the whole life of a product/building which ranked number one for the majority of stakeholders; having a clear business case was the most important enabler.

3.3 Re-Usable Buildings

Findings from the review of circular building case studies are limited, but some examples are shown below. They show that the client is instrumental in driving the circular building forward, along with establishing the benefits to the end user.

One of the key drivers identified within the literature is that of obsolescence which affects every building to some degree at some stage during its lifecycle (Douglas, 2006). As buildings age, the rate of decay increases and the decline in building condition escalates unless regular maintenance and upkeep is undertaken. There are 6 principal types of obsolescence; economic, functional, social, legal, physical and aesthetic (Barras and Clark, 1996). As such, when a certain level of obsolescence is reached, a building may require adaptation in some form.

Conversion (changing use or sometimes known as adaptive reuse), is a growing strategy for dealing with vacant buildings such as offices. A study in Liverpool showed that more than 60% of buildings have changed their original use during their life cycle and around 10% of them have changed their use frequently (every six years) during the last 20 years thereby signalling an increase in the rate of change (Manewa *et al*., 2016). However, the property market can be segregated and for example, office investors are not always keen on investing in the housing market. A study of 15 cases in the Netherlands displayed the following success factors: low purchase price, an adaptable floor plan, government subsidy, or clients with long- term

investment scenarios (housing associations) (Remöy and Voordt, 2014).

3.3.1 Re-use versus demolition

There is a debate of the costs of reuse verses demolition and new build, though studies tend to show that it usually lower for the former. For example, it is potentially cheaper to adapt than to demolish and rebuild, in as much as the structural components already exist and the cost of borrowing is reduced, as contract periods are typically shorter (Shipley *et al*., 2006). This is also likely to be the case if the building is designed for adaptation and re-use.

Buildings are generally demolished because they are perceived to no longer have any value (Kohler and Yang, 2007). In most cases, it is the market that sets this value, even though such an assessment may be based on incomplete information with no consideration given toward externalities. According to Ball (2002), it is generally preferable to repair a building than replace it because the value of the location and quality of a new building is not necessarily better than the old one. In contrast, O'Donnell (2004) suggests that an adapted building will not completely match a new building in terms of operational energy performance, but the shortfall should be balanced against gains in social value. Certainly, the life cycle expectancy of the materials in an older building may well fall short of those in a new building. The age of materials will also directly affect the on-going maintenance costs of an adapted building, which, as a result, may well be higher than those for a new building.

Bullen and Love, 2010 identified that there are a diverse set of issues that organisations need to consider when comparing the option to demolish or reuse a commercial building.

3.3.2 Stakeholders

In a survey of high profile UK property developers and agents, 94% saw the need for an adaptable building solution providing associated capital cost increases were minimised (Gregory, 2004). Workshops undertaken in the UK (Pinder, Schmidt and Saker, 2013) for adaptability suggested that more adaptable buildings might be suitable investment if they provide easier sales or command a price premium, but there are challenges for speculative developers (those procuring buildings to sell) as the purchaser obtains the benefits of adaptability, not the developer. Owner/occupiers may recoup the benefits through lower rates of depreciation of increased price at sale, but both funders and owners are risk-averse in respect of novel.

3.3.3 Costs of adaption of existing buildings

Cost is usually cited in the literature as the main obstacle to developing more adaptable (re-usable) buildings, with the assumption being that adaptability results in higher initial construction costs. For example, studies have shown that using solutions such as higher floor-to-ceiling heights, system walls and soundproof suspended ceilings, could increase initial construction costs by about 20–25% (Arge and Landstad, 2002). However, other adaptable design solutions, such as easily divisible building forms and floor plans, were found to be cost neutral (see Figure 2). Other studies found that on average, the design strategies employed resulted in a 1% increase in initial construction costs when compared with conventional (less adaptable) designs; one-third of the strategies resulted in longer initial construction times.

In the UK the notion that more adaptable (re-useable) buildings cost more to construct has,

to some extent, been fuelled by past attempts at 'future-proofing' buildings. Guy (1998) explains how, during the 1980s and 1990s, institutional investors' desire to reduce the risk of depreciation associated with changing occupier requirements led to the emergence of an institutional specification that involved over-specifying, among other things, floor loadings, small-power provision and comfort cooling services. Property agents insisted that all new office developments should incorporate these over-specified design features - a case of exchange value prevailing over use value.

Spending more on the initial construction costs of a building to make it more adaptable can only usually be justified if the adaptability is likely to generate some form of benefit or return on investment in the future. Slaughter (2001) estimated that all but one of the adaptable design solutions in her study would pay for themselves at the first adaptation cycle, generating, on average, a net saving equivalent to 2% of the initial construction cost. She found that three-quarters of the adaptable design strategies reduced the time required to adapt the building (thereby reducing disruption to users) and allowed for easier access when maintaining the building.

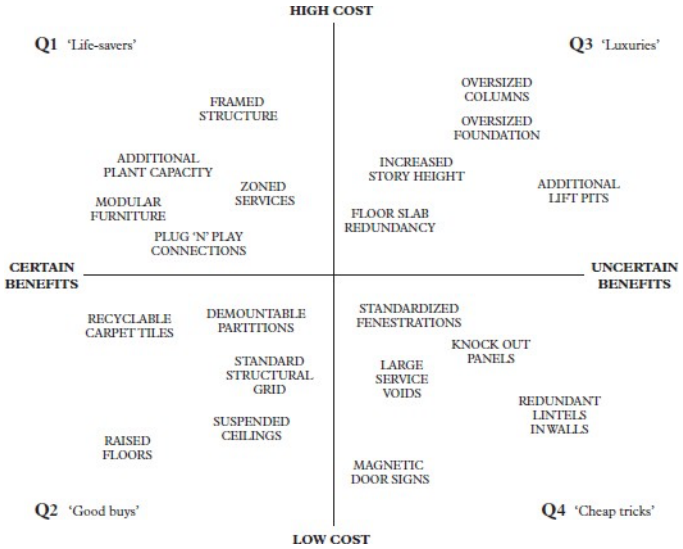

Figure 1. Cost and uncertainty in designing adaptable (re-usable) buildings (Pinder, Schmidt and Saker, 2013)

3.3.4 Whole life costs

A critical component to aid re-usable buildings is the use of whole-life costing (WLC), when all the costs and benefits (including incomes) are factored in over the projected lifecycle of the building which includes the cost of the demolished building. WLC can be used as a forecasting tool to evaluate alternative planned capital expenditures with the aim of ensuring the optimum value from capital assets considering all future costs and benefits in present day values.

An example is shown in Figure 2 of the difference in cash flow over the lifecycle of the building based on adaptable and standard design. However, the ultimate answer (for linear and circular buildings) depends on future assumptions which may involve high risk and uncertainty (which are likely to be less in the 'business as usual case' and the hidden costs/benefits associated with social and environmental issues remain untapped.

Discounting is commonly used in WLC and is based on the concept of time preference: the tendency for people to attach more value to a benefit received today than to the same benefit

received in the future. The choice of discount rate is important in the context of reuse as high discount rates give little weight to more distant entries in the cash flow and place great emphasis on the early years, thus favouring a short-term approach and the minimisation of capital investment. As such it is important to develop an economic model for circular buildings that allows the investor to benefit from day one.

BRE is also looking at how whole life cycle costing can be used within a circular building assessment methodology for the BAMB project. A number of modelling scenarios have been undertaken, and the key findings are that whilst the methodology can show benefits over one lifecycle (through adaptation), taking into account residual value within the current building is difficult, as is applying value from other building cycles. The model (similarly to life cycle assessment), is based on one building, and as such limits the opportunity to transfer value. Discounting as already recognised above, also presents issues (see Lowres and Hobbs, 2017).

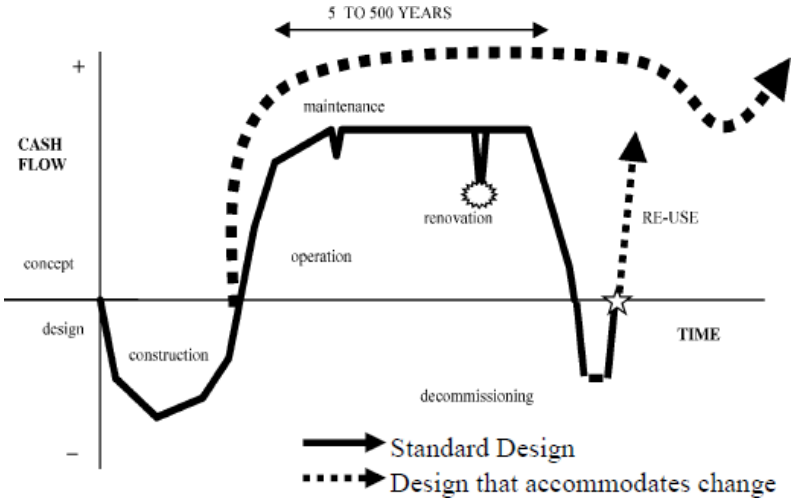

Figure 2. Illustrative whole life costs of standard design versus adaptable design (Manewa *et al.*, 2016)

3.3.5 Financing

Studies have shown that there is a fundamental shortcoming in the current financing of buildings (Circle Economy and ABN AMRO, 2017). Commonly, a bank issues a loan (mortgage) to buy a building, including the land on which it is built. However, the costs of demolition and recycling (as well as any residual value) at the end of its life are not part of the financing. The result is that it can be cheaper to leave a building vacant or not be incentivised to realise any value from the material within the building. The building and land are viewed as part of the same asset, if these were separated, financing may be easier or at least more flexible. There could be a benefit from having land that is easier to access as buildings can be dismantled quickly and reused elsewhere.

Moving towards circular buildings requires an alliance of parties that collaborate to deliver services. To do so, material reuse has to be the starting point, both during renovation (interior and exterior) and at the end of the lifecycle. This new chain is also based on an integrated

lifecycle approach to investment decisions and design. The producer or financer remains the owner of the resources and is responsible for the residual value. The residual value of materials remains on the balance sheet and can be estimated using resource model predictions.

Building in such a way that materials have a residual value instead of a negative value (disposal costs) makes investing in circular design useful. The customer pays for the performance of the building or a section of road, instead of the function. This shifts the responsibility for good maintenance and management from the customer to the owner of the materials. Investments in the adaptability of buildings generate value in the long term because the needs of (future) users are more easily met, as such there is value though utility, though there is little empirical evidence to support this within the literature.

Banks such as ABN Ambro are investigating how to allow for higher investment costs which justify lower running costs and a higher final value of the building elements. This therefore means a relatively higher loan-to-value ratio for a project, and a relatively smaller amount of equity capital relative to the loan capital. More (hybrid) financing products can further facilitate the financing. These could be equity, risk funds or other forms of financing besides bank financing. (Circle Economy and ABN AMRO, 2017)

3.3.6 Valuation

A building constructed according to a circular method has added value for investors. The value of real estate is currently linked mainly to the price of the location and the difference between rental income and operating costs. Often, the value of the raw materials in the building is of secondary importance. This view will change fundamentally in the transition from a linear to a circular economy. In addition, the purpose for which buildings are used changes with increasing regularity. A building that can be converted easily and inexpensively to another function has more potential future value than a one-purpose building. As a result, the investor knows that when the current tenant's lease is terminated, it will be relatively easy to re-let the building, possibly for a different use.

However, current investors' relatively short-term investment visions of between five and ten years and the highly limited or total absence of appreciation of this added value by surveyors often forms a barrier. Research by Ellison *et al*., (2007) suggested that only a very limited interpretation of adaptability, relating primarily to the flexibility of internal spaces, was currently factored into commercial property valuations. Consequently, valuations fail to reflect other forms of adaptability, such as the ability to accommodate changes of use.

McAllister (2009) suggests that property valuations play an important role in the property market by acting as a surrogate for prices, but he also argues that '… there is some anecdotal evidence to suggest that valuation can act as an impediment to innovation in property markets. This is because property values tend to be based on information from past transactions; in other words, if there is no evidence that a design attribute has added value to a building in the past, then valuers will not ascribe any additional value to those attributes in the present. This can result in a vicious circle, whereby developers will not include a particular design attribute in their buildings because valuers do not consider that it adds value, and valuers do not consider that it adds value because developers do not include it in their buildings.(Pinder, Schmidt and Saker, 2013).

One of the few empirical studies to (inadvertently) provide an insight into the relationship

between adaptability and rental values was undertaken by Baum (1994). Baum was interested in understanding why some buildings experience higher rates of depreciation than others, so he explored this by statistically analysing the relationship between building characteristics and rental values, using data from 125 office buildings in the City of London. He found that internal configuration (floor to ceiling height and floor layout) and internal specification (quality of finishes and services) were the most important determinants of depreciation in the sample buildings. Baum suggested that because demand for these characteristics would change over time (due to changes in working practices, fashions, etc.) property investors should look to purchase buildings that were flexible, in terms of their configuration and internal specification. He concluded that 'Flexibility reduces the risk of an irreversible and major reduction in the market value of a building'.

4 Summary of Results of the Literature Review

The reuse of buildings is gaining more interest; with evidence showing that conversion (from one function to another) is increasing in inner urban areas. The benefits and challenges for commercial Re-usable buildings are well defined though not often quantified. There is a clear distinction in the motivations between the different development models (develop to sell, manage or occupy), with owner-occupancy driving a greater interest in adaptability. The relative costs of re-use verses demolition and new build remains a matter of debate though studies tend to show that it usually lower for the former.

Where building have not been designed for reuse, then the cost of adaption of existing buildings can be greater than building them from scratch. As such building adaptation is a higher cost process, when adaptable features are not incorporated with the initial design. Cost is usually cited in the literature as the main obstacle to developing more adaptable (Re-usable) buildings, with the assumption being that adaptability results in higher initial construction costs. Though this is highly dependent on the solution adopted. Spending more on the initial construction costs of a building to make it more adaptable can only usually be justified if the adaptability is likely to generate some form of benefit or return on investment in the future.

Studies show that adaptable design solutions pay for themselves at the first adaptation cycle, generating, on average, a net saving equivalent to 2% of the initial construction cost. Investments in the adaptability of buildings generate value in the long term because the needs of (future) users are more easily met, as such there is value though utility, though there is little empirical evidence to support this within the literature.

Whole life costing is recommended to show payback, however there can be issues in its use from discounting. There is a fundamental shortcoming in the current financing of buildings with the costs of demolition and recycling (as well as any residual value) at the end of its life not factored into business case (a side effect partly of discounting but also reflecting different contractual parties at the end of life). The value of real estate is currently linked mainly to the price of the location and the difference between rental income and operating costs. Often, the value of the raw materials in the building is of secondary importance. It is unclear if property valuations consider any benefits from adaptability and 're-let ability' and how depreciation of assets is factored in.

Viability of Production and Application of Concrete with Addition of Fibers of Polyethylene Terephthalate (PET) Bottles for Construction

Edson C. Rodrigues

Estácio de Sá University (UNESA), Civil Engineering Undergraduate Course, e-mail: sonia.almeida@estacio.br, web page: www.portal.estacio.br Campus: Centro IV – Praça Onze Av Presidente Vargas, 2560 – Centro – Rio de Janeiro – 20210-031 Rio de Janeiro – Brazil

Abstract: *Concrete is the main material used in the construction industry not only for the ability to produce infinite variety of shapes for precast forms and for its characteristics of high resistance to compression, but primarily for their low manufacturing cost. Nonetheless, the production by mixing cement, fine aggregate, coarse aggregate and water, using natural raw materials such as stone, sand and water, despite being plentiful, represent the consumption of millions of tons of natural resources. Thus, the continuous search for new solutions is fundamental in order to not only further lower the manufacturing costs of this essential component in construction, but also to seek alternative materials, those of origin in processes of sustainability.*

Keywords: *Recycling, Polyethylene Terephthalate, Sustainability, Construction, Materials, Concrete, Cement, Fibers, Mixing, Production, Application.*

1 Objectives

A great amount of PET bottles that were once discarded damaging the environment are gaining a new function in the construction market, and their use as fibers in concrete, an alternative that hasn't been widely studied so far, can replace the use of glass fibers, polyethylene, polypropylene and even steel. Thus, this work aims to present an analysis on the sources of the recycling of PET (Polyethylene Terephthalate) to determine the possibilities for the production and availability of PET fibers that are appropriate for the concrete mixture of Portland cement, minimizing the use of sand in the civil construction industry; to review the physical mechanical behavior of the concrete with the addition of PET bottle fibers; and verify the best application of this concrete in the construction of buildings, aiming at reducing costs and ensuring the sustainability of the sector while maintaining the necessary quality. To achieve the desired goal, initially the possibilities of production and availability of PET fibers in the Brazilian market will be determined. Following, it will reviewed the mechanical and physical behavior of concrete with the addition of PET bottle fibers, analyzing the results of workability, its axial compression strength and diametral compression tensile strength. Finally, with all the foundation generated in the previous steps, it will be analyzed the possibilities of application in civil construction.

2 Methodology

The methodology used has included laboratory tests with the molding, curing, grinding and rupture of specimens to verify the behavior of the concrete with PET fibers in relation to its

axial compression strength and diametral compression tensile strength, when compared to the fiber-free concrete.

The theoretical and conceptual basis of this work was based on the analysis of the improvement of the concrete resistance properties with the addition of fibers. The study of the bibliographic material on concretes was based, mainly, on the Brazilian standards where the step by step of the execution of the experiments carried out in this work is illustrated, contributing also to the standardization of the tests.

3 Results

3.1 PET Recycling in Brazil

The recycling of PET in Brazil is one of the most developed in the world, presenting a high productivity rate. According with the Brazilian Census of Recycling of PET, Brazil in 2006 exceeded the score of 50% recycling rate and, in 2012, 331,000 tons of PET packaging were collected. Brazil also already have more than 90% of recycling companies with more than 5 years of activity.

With the help of the advanced taken by the Brazilian national solid waste policy, there has been a growth of cooperatives decreasing the difficulty of obtaining bottles to recycle. As indicated by Business Commitment for Recycling (CEMPRE), from 2004 to 2015 the level of recovery of materials increased by 29% and the volume of packages deposited in landfill was reduced by 21.3%. In addition, in relation to cooperatives and voluntary delivery points (VDP): 802 cooperatives were supported from 2012 to 2017, 4,487 cooperatives structuring actions carried out and 364 municipalities attended in 21 states; and 2,082 PEV were installed from 2012 to 2017; 7,826 PEV structuring actions carried out and 240 municipalities attended in 24 states.

3.2 PET fibers Brazilian Production

The Brazilian industry of PET flakes has a production capacity from 2,500 kg/h to 4,500kg/h including moderns grinding lines with optical separator systems, super washing and fines screening for the production of colorless PET flake, hot-wash PET recycling system covering all the production steps including label and lid removal and separation, grinding, hot-washing and drying. Also, the Brazilian industry of PET flakes developed a national technology for PET flake super washing, providing highest level of decontamination and final quality to the PET raw material marketed. This technology could also produces PET flakes with some specials specifications: standard colors: Crystal, Blue and Green; particle size between 8.0 and 12.0 mm; PVC contamination of less than 80 ppm; contamination by olefins and non-ferrous metals of less than 100 ppm; bulk density between 350 and 500 g/L; maximum humidity of 1,0%; and absence of PET powder.

3.3 Laboratory Tests

The cement agglomerate used was the CP II E32 of the MAUÁ brand and it was weighed on a WELMY mechanical scale. The sand used in the manufacturing process of the specimens was classified as the average sand of the MARQUES BROTHERS, sifted, whose maximum allowable granulometry is 1.41 mm and weighed on a WELMY mechanical scale. For the characterization of the sand, a specific mass test was performed based on the standard NBR NM 52 – 2009 – Fine aggregates, using a Chapman Vial. The unit mass test followed the standard NBR NM 45 – 2006 – Aggregates. The test on the sand's granulometry was performed as prescribed by NBR NM 248 – 2003. The coarse aggregate used was Gravel I of the brand IRMÃOS MARQUES and the sample was weighed on a WELMY mechanical scale.

The PET fibers used in this analysis were obtained from the recycling of soda bottles that were discarded in nature, then washed and cut with the aid of a ruler, scissors and guillotine in the dimensions of 30 mm x 3 mm. The fibers were weighed on a Bel electronic scale.

For the concrete dosage characteristics, the calculations were made according to the method of the Brazilian Association of Portland Cement (ABCP) by means of a technical study (ET-67), with the title "Concrete Dosing Parameters", authored by the public engineer Penna Firme Rodrigues (revised in 1995) that presents an eminently experimental feature.

The materials measurement was made from the mortar basic trace of 1: 1.5: 1.82: 0.47 a/c (cement, sand, gravel, water, respectively). It is worth noting that the basic trace represents a proportion of each material as is usually used in the civil construction.

For compression and diametral compression tests performance, cylindrical specimens were molded with dimensions of 100x200 mm, as well as, the procedures of density and healing were performed according to ABNT NBR 5738-2015.

The consistency of the fresh concrete was determined by the slump test of a concrete cone, according to NBR NM 67: 1998.

For the axial compression test, the I-3001-C 100 Tf digital hand press produced by Contenco was used. For the evaluation of the Axial Compression Strength test, the guidelines of ABNT NBR 5739: 2007 - Concrete - Compression test of cylindrical specimens were followed.

The test of determination of tensile strength by diametral compression was performed according to ABNT NBR 7222: 2011, considering the ages of 7 and 28 days. The press used in the test was the I-3001-C 100 Tf digital hand press produced by Contenco.

The fresh concrete test has showed the slump of the concrete cone specimen come was 90 mm for concrete without the addition of PET fibers, characterizing a rich concrete, while for the trait with 2% PET fiber, the slump was 20 mm indicating a poor concrete of very low workability, as shown in Figure 1.

Figure 1. Slump test of a concrete cone.

According to Mheta and Monteiro (1994), in concrete with fibers, compressive strength is not the most important contribution of reinforcement. Figures 2 and 3 present the results of axial compressive strength according to NBR 5739 (ABNT, 2007). It can be observed that there was not much difference in the deformation presented by concrete with addition of PET fiber to concrete without fiber. Both presented type of D - conical and sheared rupture, as specified in Annex A of NBR 5739.

Figure 2. Specimen with PET fibers after cracking under axial compression.

Figure 3. Specimen with no PET fibers after cracking under axial compression.

The axial compressive strength test has demonstrated that the mixture with addition of PET fibers (2% content) showed a small reduction in axial compressive strength in relation to concrete without fiber addition at the age of 28 (3.27% reduction). In contrast to what be observed at the age of 7 days, when fiber-reinforced concrete showed higher axial compressive strength results than fiber-free concrete (an increase of 1.18%), which can be seen in the comparison with the results in Figure 4.

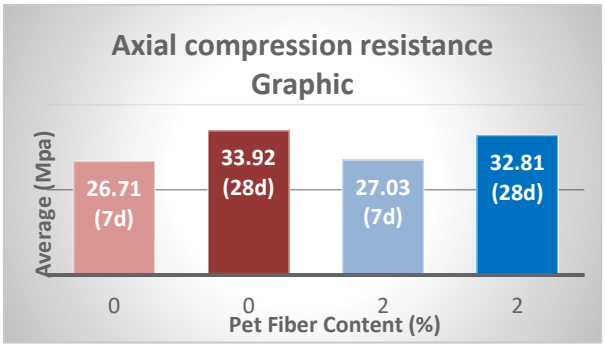

Figure 4. Comparative results of axial compression resistance tests.

The Figure 5 illustrates the specimen with PET fibers after the diametric compression test. According to NBR 7222 (ABNT, 1994), it can be observed that the crack propagated easily at the top and with some resistance at the bottom, holding the parts together. Thus, an excess load is required to break it completely. However, this is not the case with concrete without the addition of PET fiber, where the crack propagated throughout the body and abruptly breaking it, as shown in Figure 6.

Figure 5. Specimen with PET fibers after cracking under diametral compression.

Figure 6. Specimen with no PET fibers after cracking under diametral compression.

In the diametrical compression tensile strength test, we observed an increase in tensile strength by diametral compression with increasing control age (7 to 28 days), as expected. On the order hand, the results for axial compressive strength, PET fiber-reinforced concretes have presented a 18.38% increase in diametral tensile strength in relation to non-PET-reinforced concrete at both ages, which can be seen in the comparison of the results in Figure 7.

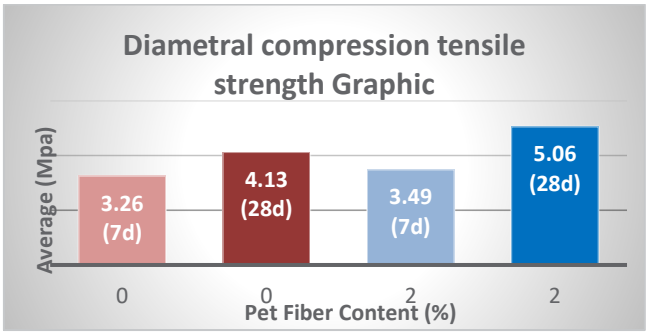

Figure 7. Comparative results of diametral compression tensile strength tests.

3.4 Application of Concrete with PET Fibers

The results have demonstrated that the greatest gains obtained with the use of fibers are associated with the increased strength of concrete to tensile stress. By adding PET fiber to concrete, it is no longer a fragile material. This is due to the increased bonding of the matrix to the concrete (transition zone), causing an increase in its mechanical characteristics, such as modulus of elasticity (Gpa), and tensile strength (MPa). Additionally, its filaments work as adhesion point of tensions between the cracks, preventing their propagation, thus making the concrete more resistant and ductile, with a post-fissure capacity.

With these results, important applications for concrete obtained from mixtures with PET fibers would be in pavement structures, hydroelectric plants, tunnel coverings, dams, slabs, which have a volumetric control of shrinkage, which would make it possible to reduce the possibilities of cracks, besides offering good protection.

In addition, there are other applications of PET fibers in construction that may be used more intensely in the future as repair materials (MRs) for degraded hydraulic surfaces, for example, to provide a satisfactory performance at lower cost compared to materials generally employed in these cases, with the advantage of an appropriate final disposal of these solid wastes.

4 Conclusions

From the analyzed aspects, the use of recycled PET fibers in concrete definitely provided considerable changes in the physical properties of the material.

- Regarding workability, the conventional concrete was workable and cohesive. It was noted a loss of rebate in the trait with 2% content of PET (20 mm slump), proving to be very consistent, a fact that, however, did not compromise the casting of the concrete;
- Regarding the axial compression strength, concrete with the addition of PET fibers at 7 days of age had a strength gain of 6.59% and a loss of 5.54% at 28 days of age. Regarding the mechanical test for axial compression at 28 days of age, there has been no significant difference for fiber-reinforced concrete compared to non-fiber concrete; and
- However, a significant increase in the results of tensile by diametral compression to 2% PET fiber concrete has been obtained with increasing control age (from 7 to 28 days), as expected. The result of increasing tensile strength was then successfully achieved. Thus, different to what has been observed in the axial strength results, the concrete with

addition of PET fiber presented a 18.38% increase in tensile strength compared to concrete with no fiber addition.

The results allow us to conclude that there is possibility of production and availability of PET fibers that are suitable for mixing in concrete, since the results of the mechanical physical behavior of the concrete were satisfactory for the performed mixing condition.

It is noteworthy that further studies are necessary to prove its applicability in structural use, aiming at a future revision of NBR 8953 (2015).

Thus, even though it has been well demonstrated academically that the tensile strength property of this technology proves superior to conventional concrete, the viability of its use at the industrial level will only occur with more government support and incentives through an infrastructure that can guarantee the stability of the production of PET fibers, establishing the necessary logistics to guarantee its offer for the civil construction, allowing construction companies to use this material for the preservation of our planet. As mentioned in the beginning of this study, the waste from PET bottles generates a major environmental problem, and any appropriate end we can find for this waste returns a great benefit to nature.

Abstract. *Concrete is a construction material that is well known for its durability. However, it is exposed to environmental attacks that lead to the penetration of aggressive agents such as water and chlorides, thus, threatening its durability and service life. Within this context and exploiting the sensitivity of the electromagnetic properties of concrete to its water content, the literature suggests determining water saturation profiles using non-destructive techniques. For instance, measuring the electrical resistivity at several points of the surface of the concrete structure can lead to an estimate of the resistivity depth profile. Then, after a calibration step, the water saturation depth profile can be obtained and the durability can be assessed. Similarly, the water depth profile can be assessed by dielectric permittivity measurements. In this paper, we propose a new inversion scheme based on the combination of both resistive and capacitive measurements: resistivity and permittivity measurements are inverted jointly to estimate the water saturation profile in concrete. Numerical experiments with simulated data show that information gathered from the two measurements enriches the inversion process, leading to the determination of more reliable water saturation profiles.*

Keywords: *Durability, Nondestructive Techniques, Capacitive and Resistive Measurements, Inversion Procedure.*

1 Introduction

Nondestructive (ND) methods are promising to assess the durability of concrete. They are non-intrusive and allow continuous structure monitoring (Balayssac, 2017). This study focuses on estimating the concrete saturation degree and handles two kinds of measurements: the DC-electrical resistivity and the dielectric permittivity. Both quantities are sensitive to the water content in concrete, and in a complementary way (Fares, 2018), and can, therefore, be used to evaluate the durability of concrete towards water ingress (Balayssac, 2017). The method consists of performing resistivity and permittivity measurements at the surface of the structure; then, an inversion procedure is required to retrieve the electromagnetic depth profiles. Finally, water saturation is obtained through calibration of the electromagnetic properties.

The inversion of measurements has been performed using either the resistivity or the permittivity data to obtain the water saturation with depth profile (Fares, 2016). However, inversion results may lack reliability, in particular, due to the small number of available data, the presence of noise in the measurements, and the lack of sensitivity of each data set to the

water saturation profile. Therefore, a possible solution to improve the inversion of ND measurements relies upon combining the two types of data, the electrical resistivity, and the dielectric permittivity, taking advantage of their complementarity (Tathed, 2018).

In Section 2, we introduce a brief description of both ND methods. Then, in Section 3, the searched saturation profile is modeled with a parametric curve, and both the forward model and the inverse problem are discussed. Our joint inversion procedure is described in Section 4. Finally, Section 5 presents numerical simulations evaluating the performance of the proposed methodology.

2 Electromagnetic Properties of Concrete

2.1 DC-Electrical Resistivity

The DC-electrical resistivity of concrete, noted ρ [Ω.m], expresses the ability of the material to oppose the flow of free electric charges when it is subjected to an electric field. In a homogeneous and isotropic material, it is expressed by the Ohm's law ratio of the measured voltage drop V [V] to the applied current intensity I [A], multiplied by a geometric factor G_r [m] :

$$\rho_a = G_r \frac{V}{I}. \tag{1}$$

The resistivity measurement principle consists of transmitting a direct current (DC) into the concrete using two electrodes and measuring the induced potential drops between one or several pairs of electrodes. Then, the 'apparent' resistivity can be calculated using Eq. (1). Since concrete is usually not a homogeneous material, the latter observable is not the 'true' resistivity of concrete but rather an integrating value over a volume depending on the electrode array configuration and size (Loke, 2004) (Presuel-Moreno, 2010) .

In this study, two electrode configurations are considered to measure apparent resistivities, the Wenner and the Schlumberger arrays (Loke, 2004). Our measuring device consists of a multi-electrode resistivity probe formed by 14-point electrodes equally spaced every 20 mm (Du Plooy, 2013). For all possible electrode combinations following the Wenner and Schlumberger configurations, a dataset consisting of about 100 apparent resistivities can be obtained.

2.2 Dielectric Permittivity

The dielectric permittivity, noted ε [F/m], is related to the phenomenon of electric polarization which results from the relative displacement of the bound charges in the material under the action of an external electric field. Due to the energy losses that accompany the polarization phenomenon, the permittivity can be expressed using a complex variable where the real part is the ability of the material to store electric energy. Consequently, the relative dielectric permittivity of concrete, ε (dimensionless), can be obtained from the system's capacitance, C [F], the vacuum permittivity, ε_0 [F/m] and the geometric factor, G_c [m]:

$$C = G_c . \varepsilon_0 . \varepsilon. \tag{2}$$

The measurement principle consists in applying an alternating current between two or more electrodes placed on the surface of the sample and measuring the resonance frequency of the

electrode-concrete system. The measuring device and consists of four different types of probes, each composed of metal plate electrodes and Plexiglas® support. The probes differ by their number of metal plates, their dimensions and the spacing between them (Fares 2016):

- electrode GE consisting of 2 plates (70xx40 mm^2) with a plate spacing of 40 mm,
- electrode ME+ consisting of 3 plates (70x15 mm^2) with a plate spacing of 15 mm,
- electrode ME consisting of 4 plates (70x10 mm^2) with a plate spacing of 10 mm,
- electrode PE consisting of 5 plates (70x5 mm^2) with a plate spacing of 5 mm.

Using this device, four apparent permittivity values can be collected for each measuring sequence, whose depth sensitivity increases with both the size and the spacing of the electrodes. Note that the measured apparent permittivity is equal to the 'true' permittivity of concrete in case of a semi-infinite homogeneous medium. Nonetheless, when the medium is of finite dimensions or is not homogeneous, the measured apparent permittivities must enter an inversion procedure to obtain the true permittivity distribution in the concrete medium.

3 Saturation Profile

In this section, a definition of the saturation degree is provided as well as the saturation profile chosen for this study. Then, the methodology for computing the forward model and solving the inverse problem for each ND electromagnetic method is briefly explained. Finally, our joint inversion approach is presented.

3.1 Definition

The saturation degree, noted S, represents the fraction occupied by water in the total pore volume. The saturation degree conditions the penetration of aggressive agents. For this, the determination of the saturation degree makes it possible to predict the degradation of concrete. Moreover, it is important to note that both resistive and capacitive properties of concrete are sensitive to saturation (Balayssac, 2017). The calibration of each of ρ and ε as functions of S is performed on the test specimen. The calibration of the electrical resistivity can be expressed by the model:

$$\rho = AS^{-B} \tag{3}$$

where A and B depend on the concrete specimen studied. Eq. (3) is consistent with Archie's empirical law (1942) proposed by geologists in the oil prospecting field for non-clayey rocks, and then for porous materials such as concrete (Fares, 2018). The calibration of the dielectric permittivity results is performed under the model (Fares, 2018):

$$\varepsilon = aS + b \tag{4}$$

where a and b depend also on the concrete specimen tested. This study aims to deal with the phenomena of drying and soaking in concrete, considered here as non-cyclic and unidirectional. As a result, the degree of saturation in concrete is assumed to evolve only in one direction, which is the depth z perpendicular to the concrete surface, and from a drier state to a wetter state or vice versa (monotonic curve). In addition to that, to better constrain the profile reconstruction, a parametric model is considered using a Weibull curve with the following expression:

$$S(z) = (\theta_1 - \theta_2)\exp(-(\frac{z}{\theta_3})^{\theta_4}) + \theta_2, \quad (5)$$

where θ_1 is the saturation ratio on the surface, θ_2 is the saturation ratio in the structure depth, θ_3 is the scale factor, and θ_4 is the shape factor. Eq. (5) provides a continuous parametric model, where the unknown saturation profile is expressed by the continuous function *S(z)* depending on the four parameters θ_i, i=1, …, 4. The inversion procedure then amounts to estimating the parameters θ_i from the apparent resistivities ρ_a or the apparent permittivities ε_a.

3.2 Forward Model

The forward model consists in the computation of the apparent observables corresponding to a given saturation profile *S(z)*. It has been implemented numerically using the commercial finite element (FE) modeling software COMSOL Multiphysics® (v.5.4). The 3D-concrete model is defined: geometry (700x900x150 mm^3 concrete block), FE mesh, electrode positions for both electrical and dielectric problems (Fig. 1). The FE mesh is finer near the electrodes with a maximum element size of 1 mm and coarser elsewhere with a maximum element size of 5 mm and consists of about 30000 elements. Then, the saturation profile is defined by the Weibull curve defined by Eq. (5). The electrode systems described in Section 2 are used for the measurement simulations.

For the DC-electric problem, 14-point electrodes (see Fig. 1a) represent the multi-electrode resistivity probe. Knowing the saturation profile in concrete depth, the imposed resistivity depth profile is obtained using Eq. (3). Then, the forward model resolution leads to the computation of the apparent resistivities using Eq. (1). For this, the module AC/DC - electric currents of COMSOL is used and positive current is injected in one electrode, negative current in another and an electric potential is simulated in the remaining electrodes. For the dielectric problem, the dielectric plates are represented by surface plates with an infinitely small thickness (Fig. 1b). Knowing the saturation depth profile in concrete, the corresponding permittivity depth profile is obtained using Eq. (4). Then, the forward model resolution leads to the computation of the apparent permittivities using Eq. (2) for each electrode set. For this, the module AC/DC - electrostatics of COMSOL is used and a potential difference is imposed on the electrode plates. For both DC-electric and dielectric models, the following conditions are considered: current conservation within the concrete block, electric insulation of the block boundaries and a null initial potential in the block.

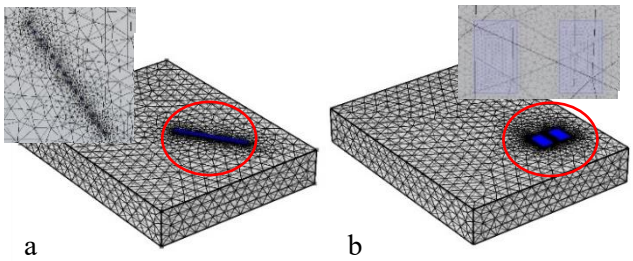

Figure 1. The meshing of the 3D model of a concrete slab (700x900x150 mm^3) with a) the resistivity probe and b) the capacitive electrodes.

3.3 Inverse Problem

The inversion procedure aims to retrieve the water saturation profile from the apparent measurements. This can be achieved by finding the parameters θ in Eq. (5) that best fit the data, by minimizing the least-squares mismatch between the measurements, say d_{mes}, and their prediction corresponding to a given saturation profile, say d_{mod}:

$$\psi = \sum_i (d_{mod_i} - d_{mes_i})^2 \tag{6}$$

In this work, we choose the Levenberg-Marquardt algorithm (Morrison, 1960), which is a standard method for non-linear least-squares optimization problems.

3.3.1 Separate inversion

In previous studies, apparent capacitive and resistive measurements were inverted separately to estimate the water profiles in concrete (Fares, 2016). A single type of measurement was considered (either the resistive or the capacitive ones) to estimate the saturation profile with depth. The method is similar for both types of measurements and is shown in Fig. 2. The goal is to minimize the cost function in Eq. (6), where:

$d_{mod} = \rho_{a_{mod}}$ and $d_{mes} = \rho_{a_{mes}}$ in the inversion of apparent resistivities,

$d_{mod} = \varepsilon_{a_{mod}}$, and $d_{mes} = \varepsilon_{a_{mes}}$ in the inversion of apparent permittivities.

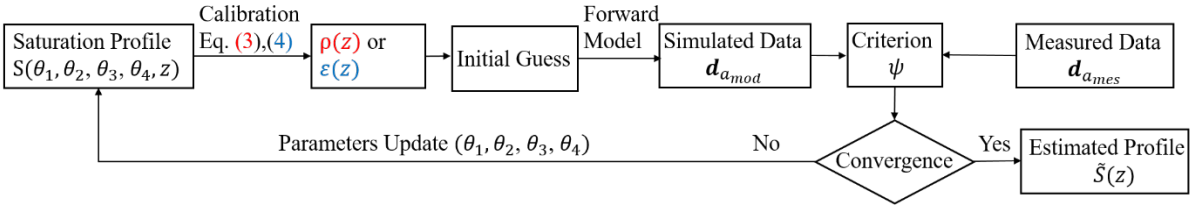

Figure 2. Scheme for the estimation of the saturation depth profile (parameters θ_i) from apparent resistivity or permittivity measurements.

3.3.2 Joint inversion

In this section, we consider a joint inversion approach. The calibration laws established by experimental studies (Eq. (3) and (4)) make it possible to connect each of the properties, electrical resistivity, and dielectric permittivity, to common property, the saturation degree. The joint inversion procedure is presented in Fig. 3. It is an iterative process, which starts with an initial saturation profile given by the initial parameters. Then the resistivity profile is obtained using Eq. (3) and the permittivity profile using Eq. (4). Afterward, the simulated data, that is, the apparent resistivities and permittivities, are computed and compared to the measured data in the joint least-squares criterion given in Eq. (7) ψ, where W_ρ and W_ε are weight parameters given to capacitive and resistive data respectively depending on the quality of these measurements.

$$\psi = W_\rho \sum_i (\rho_{a_{mod_i}} - \rho_{a_{mes_i}})^2 + W_\varepsilon \sum_j (\varepsilon_{a_{mod_j}} - \varepsilon_{a_{mes_j}})^2 \tag{7}$$

The main advantage of the joint inversion is that both measurements are sensitive to

saturation but in a complementary manner. Therefore, the information gathered may yield a better estimation of the saturation profile. Also, the joint inversion could have another advantage concerning the investigation depth of the measurements. Previous studies show that knowing the spacing between electrodes, the investigation depth of the corresponding measurements can be estimated (Loke, 2004) (Fares, 2016). The two ND methods sample differently the investigated volume concerning concrete slab thickness, therefore, combining the two methods makes it possible to better constrain the problem by information on the different regions of this volume of interest.

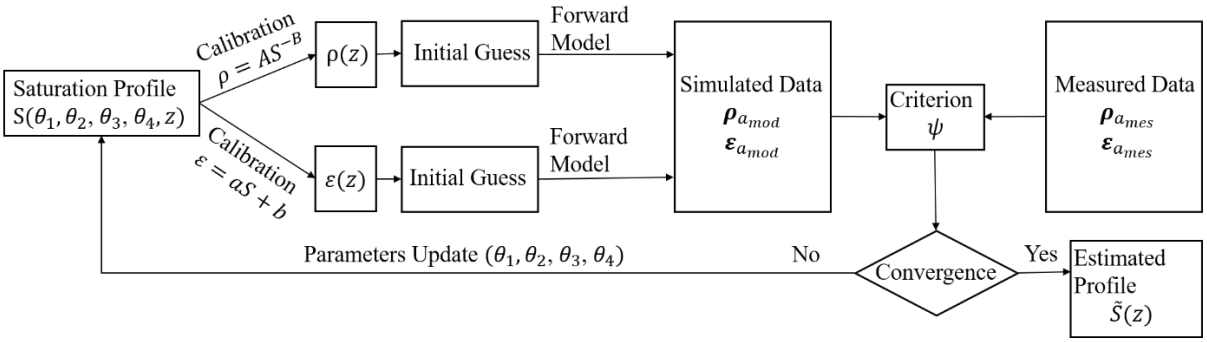

Figure 3. The joint inversion scheme to determine concrete saturation distribution in depth.

4 Numerical Experiments

In this section, numerical experiments are performed to validate the proposed joint inversion approach. Synthetic data are computed, where a saturation profile is generated according to Eq. (5) and represents the 'true' saturation profile (Table 1, column 1). The forward model is computed using the same numerical slab model and electrode simulation as presented in Section 3.2. In all simulations, the initial saturation profile in the optimization procedure is chosen such that the relative error compared to the true profile is equal to 10% (Table 1, column 2).

In the first numerical experiment, we consider noise-free data. The inversion procedure is run successively by considering only apparent resistivity data, only apparent permittivity data, and finally both data sets. The results are shown in Fig. 4. Profiles corresponding to the successive iterations of the Levenberg-Marquardt procedure are represented by the green curves. It is clear that the three inversion methods correctly converge toward the true profile. This result confirms that apparent resistivity and permittivity data, employing their corresponding calibration curves (Eq. (3) and Eq. (4)), can be jointly inverted into a unique saturation profile. In addition to that, the variability of the fitted profile between iterations is important in the inversion of apparent permittivity data (Fig. 4b); due to the smaller number of data, which is equal to the number of unknowns to be determined (the four parameters of the Weibull curve). This variability seems to disappear in the joint inversion (Fig. 4c) due to the additional number of resistivity data added to the permittivity data, which induces a faster convergence to the 'true' profile and a smaller number of iterations (15 for the joint inversion compared to 37 for the permittivity inversion alone). Note that inversion is stopped when the four following criteria are satisfied: the criterion ψ is less than 10^{-6}, the relative variation of estimated parameters between two consecutive iterations is less than 10^{-6}, the number of iterations is higher than 50 and the criterion gradient is less than 10^{-3}.

The second inversion test aims to study the influence of noise in the inversion. Referring to previous noise assessment studies done in the laboratory for capacitive and resistive data (Du Plooy, 2013), three additional sets of computations are carried out. The first one considers noisy resistivity data, such that the coefficient of variation (CV_r defined as the ratio between the standard deviation and the mean of the measurement) is 4%, and permittivity data remain noise-free. The second one considers noisy permittivity data, such that CV_p =2%, and noise-free resistivity data. Finally, the third data set considers noise on both resistivity and permittivity data (CV_r=4% and CV_p=2%, respectively). The results of this study are shown in Table 1, where the estimated profile parameters are given. For each test case, individual and joint inversions are performed. The relative error between the true profile parameters and the estimated one as well as the iteration number is given. In the first study, the two inversions have the same iteration number. However, the relative error is smaller for the joint inversion. For the second study, both the number of iterations and the relative error decrease significantly when the joint inversion is performed. Finally, in the last study, the relative error and the iteration number are the lowest for the joint inversion.

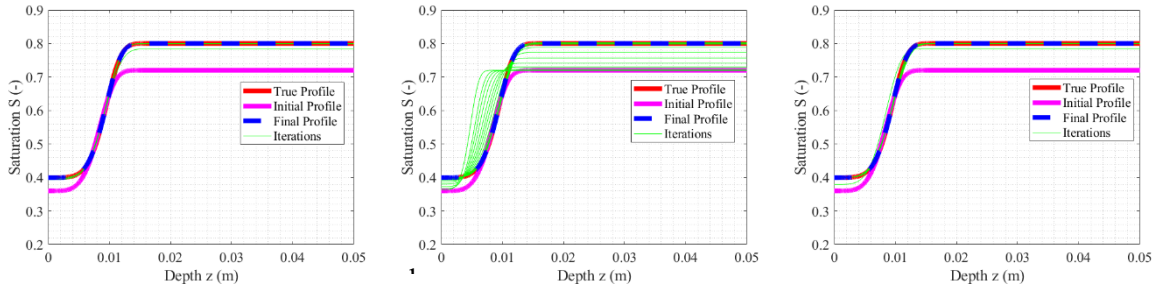

Figure 4. a) Inversion procedure using apparent resistivity data alone –b) Inversion of apparent permittivity data alone and c) Joint inversion of apparent resistivity and permittivity data.

Table 1. Separate and joint inversion results for noisy resistivity and permittivity data.

'True' Profile	Initial Profile	Noise Conditions	Resistivity	Permittivity	Joint

		Iteration Number	9	9	
		Relative Error	3.21 %	1.26%	
$\begin{bmatrix}0.4\\0.8\\0.01\\5\end{bmatrix}$	$\begin{bmatrix}0.36\\0.72\\0.009\\4.5\end{bmatrix}$	$CV_r = 0\%$ $CV_p = 2\%$		$\begin{bmatrix}0.4031\\0.9500\\0.0119\\10.85\end{bmatrix}$	$\begin{bmatrix}0.4030\\0.8000\\0.0100\\5.4910\end{bmatrix}$
		Iteration Number	50	9	
		Relative Error	38%	2.63%	
$\begin{bmatrix}0.4\\0.8\\0.01\\5\end{bmatrix}$	$\begin{bmatrix}0.36\\0.72\\0.009\\4.5\end{bmatrix}$	$CV_r = 4\%$ $CV_p = 2\%$	$\begin{bmatrix}0.3927\\0.8006\\0.0101\\4.4996\end{bmatrix}$	$\begin{bmatrix}0.4031\\0.9500\\0.0119\\10.85\end{bmatrix}$	$\begin{bmatrix}0.3991\\0.7967\\0.0100\\4.9811\end{bmatrix}$
		Iteration Number	9	50	6
		Relative Error	3.21%	38%	0.25%

5 Conclusion

In this study, we developed a new joint inversion approach for resistivity and permittivity data in concrete structures. Numerical experiments were carried out using synthetic data that showed that the joint inversion of DC-resistivity and dielectric permittivity data can produce a more accurate solution. Simulations using noise-free synthetic data showed good convergence to the 'true' considered saturation profile. Besides, when performing the inversion of synthetic noisy data, the profile estimation is improved by carrying out joint inversion as the relative error between the true and estimated parameters decreases as well as the iteration number compared to the separate inversions. For a complete validation of the joint inversion approach, more intensive simulation tests are required. Afterward, real lab data will be acquired to take into account furthermore the presence of noisy data and to validate the joint inversion approach.

A Risk-Based Approach for Quantifying Durability and Life-Expectancy of the Wall-Foundation Construction Detail in Timber Buildings

Andrea Gaspari, Ivan Giongo and Maurizio Piazza

Department of Civil, Environmental and Mechanical Engineering, University of Trento, via Mesiano, 77, 38123 Trento, Italy, andrea.gaspari.1@unitn.it, ivan.giongo@unitn.it, maurizio.piazza@unitn.it

Abstract. *Understanding and predicting the durability of timber structural components of buildings can lead to a more reliable and efficient use of this material in constructions. The work described herein presents a methodology to assess the life-expectancy of wall-foundation details in timber buildings based on the estimation of the durability of the timber structural element. Risk classes were defined starting from the inputs from the most relevant standards addressing the durability of timber available in Europe. The attribution of a risk class to the wall-foundation detail requires decision trees that consider the key aspects that affect the durability of this construction detail in the case of fungal attack. The methodology was then applied to three case studies and the results were compared to the observations from onsite inspections carried out on the decayed structural timber elements. The present work represents the first step towards the development of a tool capable of predicting the durability of timber components within the building structure. The work reported herein was carried out within the framework of the TSafe project.*

Keywords: *Timber Buildings, Wall-Foundation Detail, Durability, Risk-Based Approach, TSafe Project.*

1 Introduction

Understanding and predicting the durability of timber is of paramount importance for a more reliable, extensive and efficient use of this material in constructions. Furthermore, quantifying the durability will also allow for a more precise quantification of the carbon stocks stored into the wood products (Profft *et al.,* 2009).

Because decay caused by biotic attack is one of the most critical concerns in the long-term performance of wood, durability at the material level has been deeply investigated. In-ground and above-ground behaviour of wood has been studied through field and laboratory testing (*e.g.*: Meyer *et al.,* 2016; Meyer *et al.,* 2017). Prediction models have been also developed to predict decay caused by fungal attack or to predict mould grow (Brischke *et al.,* 2014).

The prediction of timber decay in building structural components has instead been investigated by only but a few researchers. The Australian project, reported in Leicester *et al.* (2008), is an interesting example of a comprehensive project that examines the decay of timber and the corrosion of the metal fasteners. Decay functions have been developed within the framework of the aforementioned project to predict the depth of the fungal attack on timber structural elements inside the building envelope.

The functions have been calibrated through an extensive field test campaign and on opinions of experts (Wang *et al.,* 2008c). Strong assumptions have been made by the researchers to keep these functions simple and straightforward. Moreover, a limited set of Australian structural typologies have been considered in the project.

Recently, the increasing availability of timber-based products for a diverse range of building solutions has stimulated researchers into approaching more sophisticated tools to map timber moisture distribution over time. The Heat, Air and Moisture (HAM) analysis is one of the tools adopted to predict timber moisture content with precision (*e.g.*: Carbonez *et al.*, 2015 and Chung *et al.*, 2019).

The Wall-Foundation Detail (WFD) in timber buildings can have quite different geometries, materials, wall stratigraphies and boundary conditions. The combination of these characteristics can create a very large number of possible configurations that escalates the effort of performing HAM analyses. With reference to the durability of this construction detail, finding the most critical combinations can be very important to approach this problem effectively. Another key issue to be solved when studying this detail is how to model water intrusion. Guidelines for modelling water intrusion in walls where the problem can be schematized as one-dimensional can be found in Lstiburek *et al.* (2016a-b). An equivalent of the above-mentioned guidelines for the two-dimensional problem is not available yet and because the WFD is essentially a two-dimensional problem, its study demands bigger efforts in order to run numerical analyses and perform experimental tests.

The paper presents a methodology to categorise the WFD of timber structures in relation with the durability of the timber structural element. This method permits to assign a risk class to the detail, based on decision trees that considers the most significant issues related to timber durability accounting for fungal attack. Risk classes are used both to identify the most critical configurations and to associate to them a decay estimation function that at this preliminary stage was taken from literature. Three case studies (Gaspari *et al.,* 2020) are then introduced to compare the results of this preliminary decay prediction.

The methodology proposed herein is part of the TSafe project where reliable strategies for the risk assessment of timber structures are used to create decision-making tools useful to every party involved in the construction of timber structures. The purpose of the TSafe project is to combine numerical simulations, such as HAM analyses, with artificial intelligence and machine learning algorithms to extract simple and applicable rules from complex problems solved numerically (see for example Glavind *et al.,* 2019 and Freire *et al.,* 2017).

Risk classes are defined in section 2. Then, the decision trees necessary to assign a risk class and the parameters for the quantification of the decay are presented in section 3. The results obtained are compared to three case studies in section 4. Finally, section 5 outlines the conclusions and future work.

2 Risk Classes

Risk classes were defined according to the provisions contained in the main European standards that deal with the durability of timber from the material point of view (*i.e.*: ÖNORM B 3802-1:2015, EN 335:2013 and DIN 68800-1:2019-06) and from that of a building detail (*i.e.*: ÖNORM B 2320:2017 and DIN 68800-2:2012-02). Risk classes identify a general behaviour of the construction detail in terms of protection against water intrusion, condensation, and water permanence and of timber drying performance. Moreover, the risk classes group together different building details that show similar behaviour. A definition of the risk classes for the WFD, considering the standards cited above, is reported in the following (Gaspari *et al.,* 2020).

- Risk class 1 (R1): timber is protected against outdoor weather (direct rain, bounce water,

wind-driven rain and external rain accumulation) and against rising damp. Moreover, presence of condensation is possible, but a rapid drying is ensured.

- Risk class 2 (R2): timber is protected against outdoor weather (direct rain, bounce water, wind-driven rain and external rain accumulation) and against rising damp. Presence and permanence of condensation is possible.
- Risk class 3 (R3.1 and R3.2): timber can get wet, due to outdoor weather (direct rain, bounce water, wind-driven rain and external rain accumulation) or to condensation caused by non-efficient airtightness. The class R3 is divided into the two subclasses R3.1 e R3.2 considering, respectively, the possibility of timber to dry or not.
- Risk class 4 (R4): timber can get wet due to outdoor weather (direct rain, bounce water, wind-driven rain and external rain accumulation) or to condensation. Timber is in direct contact with a porous material that can absorb water. Timber cannot dry rapidly.
- Risk class 5 (R5): timber can get wet due to outdoor weather (direct rain, bounce water, wind-driven rain and external rain accumulation) or to condensation. Timber is prevented from drying and water that comes in contact with timber cannot run out.

As a preliminary approach, a fast and straightforward evaluation of the decay is assessed through functions available in literature that estimate the depth of the fungal attack (Leicester *et al.,* 2008). According to Wang *et al.* (2008c), the decay depth d_t is evaluated through equation (1) as a function of the time *t* and the slope *r*

$$d_t = \begin{cases} 0 & , \quad t < lag \\ (t - lag)r, & t \geq lag \end{cases} \tag{1}$$

where $r = k_{wood} k_{geometry} k_{climate}$ and *lag* is a function of *r.* The parameters k_{wood} and $k_{geometry}$ are constant values that depend on the wood species, on the location of timber within the detail and on the interaction between timber and the other elements (as defined in Wang *et al.,* 2008c). The parameter $k_{climate}$ depends on the amount of water (from precipitation) penetrating the detail and on such water can dry off.

In order to consider the contribution of condensation, equation (2) is proposed, where the term $t_{wet,cond}$ is added to the equation proposed by Wang *et al.* (2008c).

$$k_{climate} = 0.03(t_{wet,rain} + t_{wet,cond})^{0.4} \tag{2}$$

$$\begin{cases} t_{wet,rain} = \sum_{i=1}^{12} (t_{rain} - t_{drying})_i \ , & (t_{rain} - t_{drying})_i \geq 0 \\ t_{wet,cond} = \sum_{i=1}^{12} (t_{cond} - t_{drying})_i \ , & (t_{cond} - t_{drying})_i \geq 0 \end{cases} \tag{3}$$

The "duration parameters" t_{cond}, t_{drying} and t_{rain} in equation (3), must be evaluated based on the assigned risk class. The relation between the risk classes and these parameters is reported in Table 1.

Table 1. Relations between the duration parameters and the risk classes.

R	$\boldsymbol{t_{rain}}$ [hour/month]	$\boldsymbol{t_{cond}}$ [hour/month]	$\boldsymbol{t_{drying}}$ [hour/month]
1	0	0	∞
2	0	To be evaluated	To be evaluated
3.1	To be evaluated	To be evaluated	To be evaluated
3.2	To be evaluated	To be evaluated	To be evaluated

4	720	To be evaluated	To be evaluated
5	720	To be evaluated	0

In the cases where t_{rain} and t_{drying} must be evaluated, suitable methods can be found in Wang *et al.* (2008c). The t_{cond} indicates the number of hours per month in which timber is wet because of condensation and it can be calculated by referring to well-established methods for the hygrothermal analysis of buildings. Leakage coming from the inside of a building was not considered in the present study for the sake of simplicity, but suitable approaches can be found in Wang *et al.* (2008c).

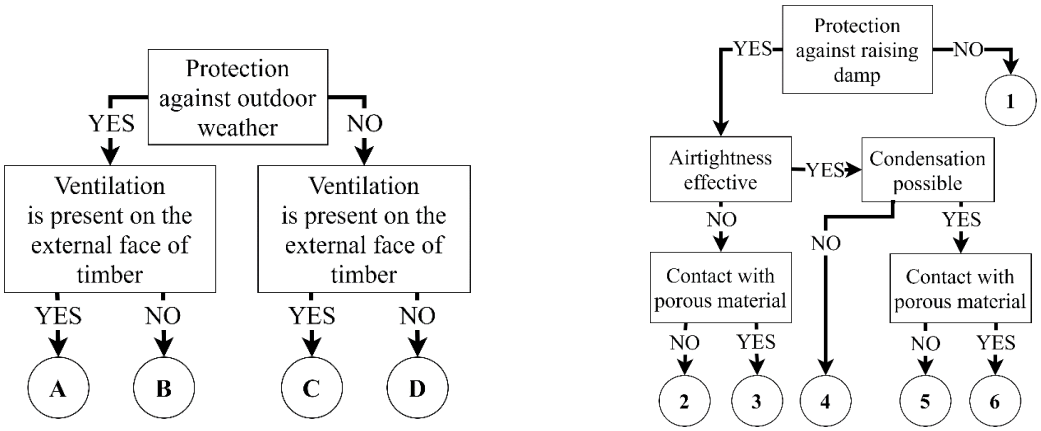
3 Decision Trees

The WFD in timber buildings can be classified through decision trees whose branches account for the various conditions which may occur and affect the durability of the timber structural components. For brevity, only the decision trees related to the three case studies selected to compare the results are presented.

The background material for developing the decision tree included prominent European standards in the field of durability of timber structures such as ÖNORM B 2320:2017 and DIN 68800-2:2012-02.

The most relevant parameter is the distance of the base-surface of the timber element from the ground surface. This distance *H* is positive when the position of the timber base-surface is higher than the ground surface, negative otherwise.

In the three case studies selected, *H* was always less than 10 centimetres, so two conditions were considered in the following: (a) *H* greater or equal to 0 cm, but lower than 10 cm, and (b) *H* lower than 0 cm. A decision tree was defined only for the first scenario since risk class R5 was always assigned to the second one. Figure 1 shows the two decision trees defined for the $0\ cm \leq H < 10\ cm$ (Gaspari *et al.,* 2020).



(a) (b)

Figure 1. Decision tree (a) DT1 and (b) DT2 for $\mathbf{0\ cm \leq H < 10\ cm}$.

The decision tree DT1 shown in Figure 1 (a) considers outdoor weather (direct rain, bounce water, wind-driven rain and external rain accumulation) and the possibility of timber drying off

due to ventilation. This tree results in 4 different conditions, from A to D. Decision tree DT2, reported in Figure 1 (b), takes into account the rising damp issue, the building airtightness and whether timber is in contact with porous material or not. This second tree leads to 6 conditions. These two trees are independent from one another, but both must be used for the evaluation of the detail. All combinations of the results from the two trees are shown in Table 2 (Gaspari *et al.,* 2020).

Table 2. Risk classes definition for the combination of DT1 and DT2.

	DT1			
DT2	**A**	**B**	**C**	**D**
1	4	4	4	5
2	3.1	3.2	3.1	5
3	4	4	4	5
4	1	4	3.1	5
5	2	2	3.1	5
6	4	4	4	5

In the preliminary procedure for the decay estimation, additional aspects must be specified in order to assess the decay estimation properly. In fact, decay estimation functions are typically defined for a single face of the timber element. However, depending on the geometry of the WFD and on the contact between timber and other materials, multiple faces can be affected by decay. These additional aspects are provided in Table 3.

Table 3. Additional aspects for the combination of DT1 and DT2.

	DT1			
DT2	**A**	**B**	**C**	**D**
1	A3	A4	A3	A3
2	A2	A4	A2	A3
3	A2	A4	A2	A3
4	A1	A4	A2	A3
5	A2	A4	A2	A3
6	A2	A4	A2	A3

The aspects reported in Table 3 are defined as follows, considering the internal and external faces of timber.

- A1: decay due to leakage must be evaluated solely on the internal face.
- A2: decay must be evaluated on the external face and eventually on the internal face due to leakage.
- A3: decay must be evaluated on both faces.
- A4: decay must be evaluated on the external face and eventually on the internal face due to leakage. Moreover, if the internal face of timber is in contact with a scarcely permeable material or $H_{int} < 0\ cm$, R5 risk class must be selected.

Considering a linear element (for example a post or a beam), if decay is present on both internal and external faces, the same depth of the fungal attack must be considered on the

lateral faces. The same must be done if decay is present on one face and a porous insulation is in contact with timber.

Finally, the leakage contribution must be considered only if $H_{int} \leq 5\ cm$.

4 Results

In this section the WFD of three case studies is analysed by applying the decision trees. Then, the preliminary procedure for the estimation of the decay is applied to the case studies and a final comparison is reported.

The case studies have been described in detail in Gaspari *et al.* (2020), while just a brief description is provided herein. Table 4 gives an overview on these case studies.

Table 4. Overview of the case studies.

Case study	Structural typology	Year of construction	Year of inspection	Element analysed	Dimensions [mm]	
					Thickness	Width
A	Light-frame	2007	2018	Post	140	80
B	Light-frame	2009	2018	Post	160	180
C	CLT	2015	2017	CLT	160	200

For case study C where the timber component is a CLT panel, a reference width of 200 mm corresponding to the width of a single wood-board of the CLT panel was selected.

In case study A, the distance of the base-surface of the post from the ground is set to *H = 0 cm*. In fact, in this case the base-surface of the timber element is at the same level of the ground surface. There are no waterproof membranes; protection against outdoor weather and ventilation are also absent. These conditions lead to path D in DT1 and to path 1 in DT2. The combination of paths D and 1 determines a risk class R5 with the additional condition A3. In case study A the element studied is a post and because both external and internal faces must be evaluated, then all four faces must be evaluated.

In case study C, the base of the post is set to *H = -23 cm* and consequently a risk class R5 was assigned to the detail. All faces of the post must be evaluated.

Case study C presents a CLT wall with *H = 0 cm.* The CLT wall is not properly protected against outdoor weather and ventilation is absent. Moreover, a hygro-thermal analysis verified the absence of accumulation of condensation. These conditions lead to path D in DT1 and path 4 in DT2. The combination of paths D and 1 results in assigning risk class R5 with the additional condition A3.

In order to evaluate correctly the decay of the CLT panel, the lateral faces of the board were considered. In fact, cracks and long-term effects on CLT boards usually lead to preferential paths for water to penetrate into the CLT.

Case studies A, B and C were inspected after 11, 9 and 3 years after construction, respectively. Case studies A and B showed 0 % of residual timber cross-section, where the residual cross-section is the ratio between the timber cross-section area in sound conditions at the time of the inspection and the original timber cross-section at the time of construction. Case study C showed a residual cross-section of approximately 60 %. The comparison between the outcomes of the inspections and the results of the model has been reported in Figure 2.

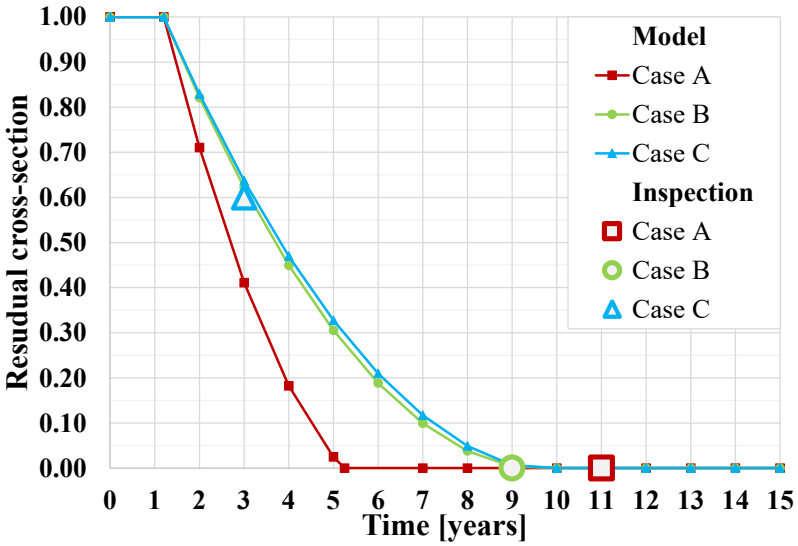


Figure 2. Comparison between the observations from the case-study inspections and the results of the analytical model.

5 Conclusions

This paper proposes a methodology to categorise the Wall-Foundation Detail (WFD) of timber structures in relation with the durability of the timber structural element. Risk classes were defined looking at the prominent standards that treat the topic of the durability of timber. The risk classes can be assigned to the WFD via decision trees designed to consider the main aspects that can affect the durability of this construction detail in relation with fungal attack. This was the first step to develop a reliable method capable of predicting the life-expectancy of timber construction details. Future research steps, as a part of the TSafe project, will involve more sophisticated tools such as Heat, Air and Moisture analysis, machine learning and a combination of both. For a preliminary validation of the overall analysis approach, three case studies were selected and studied using the methodology proposed herein. A good correspondence was observed from the comparison between the results of the proposed methodology and the onsite inspections.

Abstract. *Driving rain is one of the most critical sources of moisture affecting the hygrothermal and durability performance of building envelopes. The estimation of severity in terms of annual driving rain indices using annual and monthly weather data (aaDRI and maDRI respectively) aids towards contemplating potential moisture loads, and hence in the efficient design of buildings in the geographical area of interest. In this study, monthly and annual gridded datasets of wind and rainfall, pertaining to the thirty-year period of 1988-2017 have been used to design a spatially continuous driving rain map for India at 0.5°×0.5° (lat./long.) resolution. The observations reveal that the use of annually averaged data leads to underestimation of the driving rain severity thereby highlighting the inefficiency of a coarser temporal scale. A linear relationship has subsequently been developed to enable refinement of aaDRI into maDRI. The analysis of the monthly driving rain map reveals that the entire western coastal belt and a few regions in the north-eastern part of the country observe high to severe exposure conditions. Furthermore, a trend analysis of the yearly driving rain index values reveals statistically significant decreasing trends over the northern and eastern regions of the country, whereas increasing trends in the shielded regions surrounding central India is observed.*

Keywords: *Driving Rain Map, Gridded Data, Trend Analysis, India.*

1 Introduction

Durability performance of built facilities is a function of both the material characteristics and the environment to which they are exposed. The exposure conditions that primarily affect the durability include temperature and moisture conditions. The presence of moisture initiates and escalates numerous deterioration processes in building materials. Damage is often inflicted in the form of cracks and/or spalling of surface due to corrosion of reinforcement, and salt migration and crystallization (Broomfield, 2003; Charola, 2000; Neville, 1995). Prolonged dampness also leads to efflorescence and mold growth, which affects the aesthetics as well as the indoor air quality of buildings (Gaylarde *et al*., 2002; Bornehag *et al.*, 2001). Moisture accumulation in porous materials causes frost damage and a reduction in thermal insulation of the building envelope (Bhattacharjee, 2013; Jerman and Černý, 2012). The intricate and multifaceted impact of moisture on the performance of buildings invokes the need to realistically estimate the severity of moisture exposure.

Wind Driven Rain (WDR) is an important source of moisture affecting the hygrothermal performance and durability of building facades (Blocken *et al*., 2009). A significant development in the field of WDR research was associated with the field observations made

by Lacy (1965) and Hoppestad (1955), which established the proportionality of WDR intensity $\left(R_{wdr}\right)$, to horizontal rainfall $\left(R_h\right)$, and the wind speed (U). This proportionality relationship led to the development of WDR index $\left(R_h * U\right)$, and its application to map the driving rain severity in several countries (Narula *et al.*, 2017; Pérez-Bella *et al.*, 2012; Giarma, 2011; Chand and Bhargava, 2002). A schematic representation of WDR is depicted in Fig. 1.

The accuracy and reliability of such maps depend upon the spatial and temporal resolution of available meteorological data. The station records available in a country are often limited and lack temporal completeness. Gridded weather data poses a viable solution in this regard owing to their temporal and spatial consistency (Das *et al*., 2020). This study utilizes monthly average wind and rainfall gridded data to determine the *maDRI* and *aaDRI* at a spatial resolution of $0.5° \times 0.5°$ for the Indian subcontinent.

To the best of the authors' knowledge, the WDR map generated in this study offers the finest spatial resolution at which the *maDRI* and *aaDRI* have been mapped for Indian mainland. The numerical efficiency of the gridded data and the developed index is also verified by comparing the relationship between *maDRI* and *aaDRI* against previously reported studies by Chand and Bhargava (2002) and Narula *et al*. (2017). The results of this study are in close conformance with the previous studies. The study also extends to the trend analysis of driving rain index for the recent 30 years of weather records (1988-2017). Trend analysis of the WDR over India shows a receding trend of moisture loads over the country.

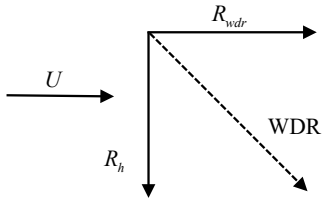

Figure 1. Components of wind-driven rain (WDR).

2 Gridded Data

Gridded datasets are interpolated products constituted using observations from sources like station observations, satellites, ships etc. and have the benefit of temporal continuity and spatial coverage. The present study uses gridded datasets of rainfall and wind for the determination of driving rain severity. The study uses thirty years of rainfall and wind data from 1988-2017.

2.1 Rainfall Data

Rainfall gridded dataset at a monthly scale has been obtained from the Climatic Research Unit (CRU) - version CRU TS v4.02. The data is based on station observations collected from reliable international agencies and covers all land masses excluding the Antarctica region at $0.5° \times 0.5°$ (lat./long.) resolution. The stations selected for the generation of data at individual grids is subjected to the criteria of minimum 75% data availability for the base period, 1961-1990 (Harris *et al.,* 2014). Out of the global dataset, rainfall data for 1179 grids pertaining to

the duration 1988-2017 have been extracted, which encompasses the geographical stretch of India lying within a rectangular region extending between 6.5°N - 37.5°N to 66.5°E - 101.5°E.

2.2 Wind Data

Monthly wind data have been obtained from the web repositories of the National Oceanic and Atmospheric Administration (NOAA). The dataset is available at a spatial resolution of $2.5° \times 2.5°$ between 90°N - 90°S and 0°E - 357.5°E (NOAA, 2019). Both horizontal and vertical components of wind records for India which comprises of 1179 grid values, have been extracted from the primary global dataset. The extracted records for the Indian region have been re-gridded to a resolution of $0.5° \times 0.5°$ for the purpose of this study using bilinear interpolation. The resultant wind vector was determined as: $\left(u^2 + v^2\right)^{0.5}$ where u and v are the horizontal and vertical wind components respectively.

3 Driving Rain Index

3.1 Calculation of *maDRI* and *aaDRI*

The procedure for determination of *maDRI* and *aaDRI* is adopted from previous studies (Chand and Bhargava, 2002; Giarma and Aravantinos, 2011). Firstly, the monthly driving rain index (*mDRI*) for each of the 12 months have been calculated using Eq. 1 and then the *maDRI* has been calculated using Eq. 2.

$$mDRI = \left(\sum_{i=1}^{N} W_{month,i} / N\right)\left(\sum_{i=1}^{N} R_{month,i} / N\right) \tag{1}$$

$$maDRI = \sum_{i=1}^{12} mDRI \tag{2}$$

where, *maDRI* is in m^2/s, W_{month} is the monthly average wind speed in *m/s*, R_{month} is the monthly total rainfall in *m*, *N* is the number of years under consideration. The estimation of *mDRI* can be carried out by including the cases for which rainfall is zero, or by excluding such instances for averaging of the rainfall. The latter approach is expected to provide a more realistic depiction. In this study, the *mDRI* values have been determined by both approaches to assess the differences in results obtained by the two approaches.

The *aaDRI* has been calculated as the product of average annual wind speed and average annual rainfall, as stated in Eq. 3.

$$aaDRI = \left(\sum_{i=1}^{N} W_{year,i} / N\right)\left(\sum_{i=1}^{N} R_{year,i} / N\right) \tag{3}$$

where *aaDRI* is in m^2/s, W_{year} is the annual average wind speed in *m/s*, R_{year} is the annual total rainfall in *m*, *N* is the number of years under consideration.

Based on the values of indices calculated using Eqs. 2 and 3, the exposure conditions have been categorized into four classes after Lacy (1977), namely, shielded, moderate, high, and severe for the ranges of [0,3), [3,7), [7,11), and [11, ∞), respectively. This classification has been subsequently used towards the development of *maDRI* and *aaDRI* maps for India.

Often meteorological data are not available at a monthly temporal scale. This study, therefore, establishes a relationship between *aaDRI* and *maDRI* to facilitate estimation of the latter from annual meteorological records which are often available.

3.2 Trend Analysis

A trend analysis of the yearly driving rain index (*yDRI*) has been carried out to ascertain the increasing or decreasing pattern of driving rain severity across the subcontinent. Mann-Kendall (MK) test is a non-parametric test commonly used to statistically assess any monotonic upward or downward trend in a time series data (Mann, 1945). The present study uses this test to identify the existence of trends in the manifestation of driving rain over the Indian mainland. In this test, the null hypothesis is that data comes from a sample of independent realizations, and hence there is no trend in the data, whereas the alternative hypothesis states that a monotonic trend exists. The MK test statistic is calculated using Eqs. 4 and 5:

$$S = \sum_{k=1}^{n-1} \sum_{j=k+1}^{n} \operatorname{sgn}\left(X_j - X_k\right) \tag{4}$$

such that,

$$\operatorname{sgn}(X_j - X_k) = \begin{cases} 1, \ if \ (X_j - X_k) > 0 \\ 0, \ if \ (X_j - X_k) = 0 \\ -1, \ if \ (X_j - X_k) < 0 \end{cases} \tag{5}$$

Here, $j \neq k$, and $j, k \leq n$, where n is the number of data points. The z-statistic is then computed as stated in Eq. 6:

$$Z_s = \begin{cases} \dfrac{S-1}{\sqrt{Var(S)}}, S > 0 \\ 0, \quad S = 0 \\ \dfrac{S+1}{\sqrt{Var(S)}}, S < 0 \end{cases} \tag{6}$$

If $|Z_s| > Z_{1-\alpha/2}$ ($Z_{1-\alpha/2}$ can be obtained from standard normal distribution level), then the null hypothesis is rejected. In the present study, the test is carried out at $\alpha = 0.05$ significance level. The trend analysis is also supported by the determination of Sen's slope. The Sens's slope (β) assists in the determination of direction of the existing trend. In the case of driving rain, the Sen's slope estimates if the driving rain severity is decreasing or increasing. This helps a designer to contemplate if a building will be exposed to a greater moisture load and thereby help towards efficient design of facade elements.

4 Results and Discussions

4.1 Driving Rain of India Based on *maDRI* and *aaDRI*

Figs. 2a and 2b represent the *maDRI* maps obtained respectively by including and excluding the cases for which rainfall is zero. It was observed that there is no significant difference between the *maDRI* maps developed using the two approaches. The plots reveal that the

shielded exposure region covers major area of northern part of the country, along with parts of central, western, and south-western India. The moderate exposure covers the entire eastern coastal belt and majority of north-eastern India, in addition to parts of western and central India. The high and severe exposure condition, is observed by the western coastal belt of India and parts of north-east. This observation is common for both the approaches adopted in the determination of *maDRI*. The percentage of land area covered by each of the exposure categories using the latter approach are 63.36%, 33.42%, 1.95%, and 1.27% respectively in increasing order of severity. This is in contrast with the observations made by Narula *et al.* (2017), in which most of the mainland of India was reported to observe moderate exposure condition. The present analysis using the most recent 30 years of data observes a shift in the severity level to the shielded conditions. This is indicative of the receding pattern of driving rain loads for the subcontinent.

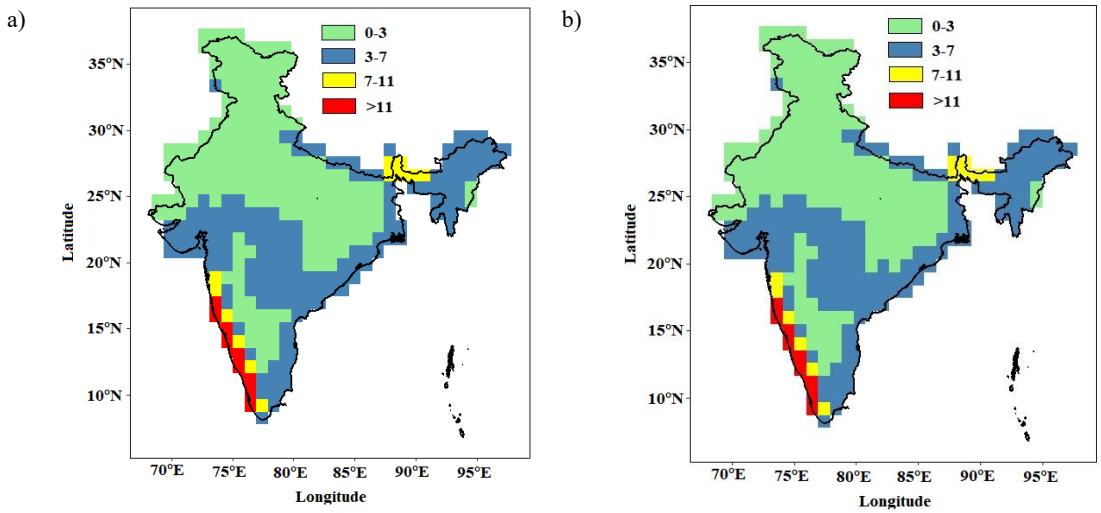

Figure 2. Driving rain map of India based on *maDRI* (a) including and (b) excluding months with no rainfall.

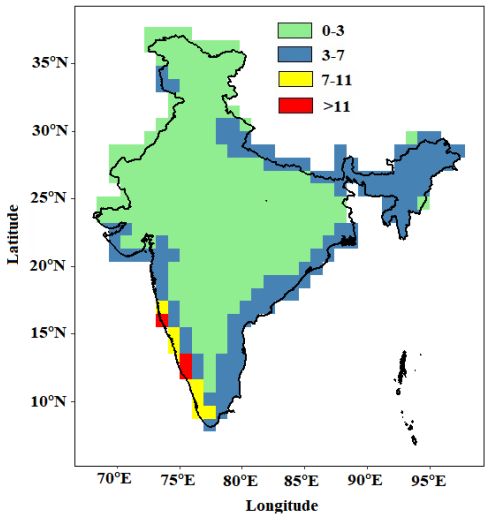

Figure 3. Driving rain map of India based on *aaDRI.*

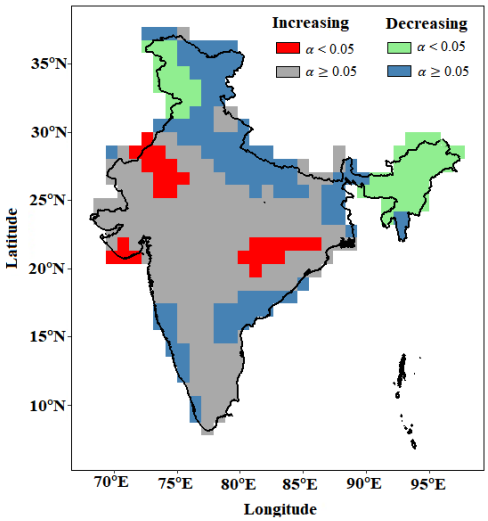

Figure 4. Trend analysis of WDR based on *yDRI.*

Fig. 3 shows the *aaDRI* map of India. Comparison of the *aaDRI* map with *maDRI* map shows a significant increase in the number of grids observing shielded exposure conditions. The percentage of area covered by each exposure category based on *aaDRI* is 77.01%, 21.37%, 1.36%, and 0.25%, respectively, in increasing order of severity. The observation suggests that implementation of *aaDRI* underestimates the driving rain severity at a given location. Therefore, *maDRI* is a more reliable choice for contemplating driving rain severity. For instances when meteorological records are not available at a finer temporal scale, the *aaDRI* can be used towards estimation of *maDRI*. In the following section, a relationship between *maDRI* and *aaDRI* has been established to facilitate the objective.

4.2 Relationship Between *maDRI* and *aaDRI*

The scatter plot between *maDRI* and *aaDRI* values presented in Fig. 5 indicates a fairly strong linear relationship between the two indices. This was also reported in previous studies for India. The relationship obtained between the two indices is given in Eq. 7 and those reported by Chand and Bhargava (2002) and Narula *et al.* (2017) are stated in Eqs. 8 and 9, respectively:

$$maDRI = 1.29 aaDRI - 0.28 \tag{7}$$

$$maDRI = 1.24 aaDRI - 0.18 \tag{8}$$

$$maDRI = 1.23 aaDRI - 0.32 \tag{9}$$

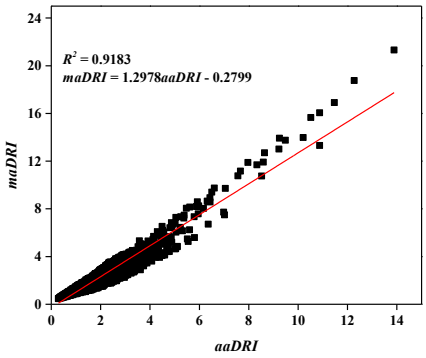

Figure 5. Relationship between *maDRI* and *aaDRI*.

A fair degree of match is observed between the expression reported in this study and those from the previous studies. This indicates the reliability of the indices determined using 0.5°×0.5° gridded data in the present study. The relationship would also aid towards the estimation of *maDRI* from *aaDRI* in instances wherein meteorological records of wind and rainfall are not available at a fine temporal resolution.

4.3 Trend Analysis Based on Yearly Driving Rain Index

This study extends to the determination of any existing trend between the driving rain index for the considered 30 years of data. This is facilitated by determination of yearly driving rain index (*yDRI)* for each year, calculated as stated in Eq. 10:

$$yDRI = (Total\ rainfall\ in\ a\ year) \times \left(Average\ rainfall\ in\ a\ year \right) \quad (10)$$

Rainfall in expressed in *m*, and the average wind speed is expressed in *m/s*. The objective is facilitated by conducting MK test and determination of Sen's slope for each of the grid as discussed in section 3.2. Fig. 4 shows the plot of trend analysis for each of the 1179 grids at 5% significance (α). It can be observed from Fig. 4 that, there exists significant negative trend in northern and north-eastern part of the country, where as significant positive trend is observed by parts of western and south-western India which observe shielded exposure condition. The value of β ranged between [-0.10, 0.04] which is fairly similar to the range of [-0.12, 0.03] as was reported by Narula *et al*. (2017). Out of the total number of grids exhibiting significant trend, 61.53% observe a negative trend in severity.

5 Summary and Conclusion

The present study assesses the severity of prevailing moisture loads on buildings in India at a spatial resolution of 0.5° × 0.5° using gridded records of wind and rainfall data. This assessment has been facilitated by the computation of *maDRI* and *aaDRI.* Trend analysis of yearly driving rain index has also been carried out at a 5% significance level to determine the temporal evolution of the relative severity of moisture loads. The major findings and contributions of this study are as follows:

- *aaDRI* and *maDRI* maps for India at 0.5°×0.5° spatial resolution have been developed.
- The *maDRI* map developed is apt for the assessment of relative severity of moisture loads for India. Zones of shielded, moderate, high, and severe exposure condition correspond to 63.36%, 33.42%, 1.95%, and 1.27% respectively of the total land area.
- There has been a decline in moisture loads manifesting on buildings. Majority of the area has been observed to be under shielded exposure condition, in comparison to a previous study wherein maximum area was reported to be under moderate exposure condition.
- *maDRI* and *aaDRI* exhibit strong linear relationship which is in compliance with previous studies, thus indicating the reliability of the equation developed (Eq. 7) for the determination of *maDRI.*
- Trend analysis of the *yDRI* values reveals statistically significant decreasing trends over the northern and eastern regions of the country whereas increasing trends in the shielded regions surrounding central India.
- The limitation of the reported results lies in the unavailability of fine resolution gridded wind data from ground observations and the lack of grid-to-point comparison of gridded datasets with respect to station data in order to assess the reliability of the gridded weather datasets.

The study can be further be extended towards the determination of daily driving rain index for the same spatial resolution subjected to the availability of data. This is expected to provide a better representation of the prevailing moisture loads on building envelopes in India.

Development of a Service Life Database of Building Elements Based on an International Data Collection

Kyriaki Goulouti, Morgane Giorgi, Didier Favre and Sébastien Lasvaux

Laboratory of Solar Energetics and Building Physics (IGT-LESBAT), HEIG-VD, University of Applied Sciences of Western Switzerland (HES-SO), Yverdon-les-Bains, Switzerland,
sebastien.lasvaux@hes-so.ch

Abstract. *This paper presents a new service life database (DUREE database) for building elements, based on international service life data. The database includes 7'000 service life data, for more than 2'000 building elements. In addition, the fitting of the data to a lognormal distribution is presented. The study contributes to the increasing demand of probabilistic building LCA and LCC and provides the possibility to define statistical distributions, with a systematic way, for a large number of building elements and different levels of details (LOD), appropriate for BIM-based assessments.*

Keywords: *Service Life, LCA, LCC, Lognormal Distribution, Probabilistic Analysis.*

1 Introduction

Reliability issues in life cycle studies, *i.e.* Life Cycle Assessment (LCA) or Life Cycle Cost (LCC) analysis have been long discussed (Björklund, 2002; Huijbregts, 1998). Different methods have been proposed to enhance the confidence in the LCA results, *i.e*. uncertainty and sensitivity analyses, as summarized in Pannier (2018) for the building sector. Reducing the variability and uncertainty of the input parameters, increase the accuracy of the LCA or LCC result. Among the different parameters that present significant uncertainty and influence the building LCA accuracy is the service life of the building elements, as it has been shown by different studies, *e.g.* (Grant and Ries, 2013). The service life mainly influences the use phase through the replacement of the building elements. For instance, in rescent LCA studies, the replacement stage can account for up to 36% of the greenhouse gas emissions (GHG) of a multifamily house (Goulouti *et al.*, 2019).

The term *'service life'* (or lifetime) can be understood and defined in various ways, depending on the scope of the final user *e.g.* building designer, owner, LCA or LCC expert (Lasvaux *et al.*, 2019). According to Thiebat (2019), the service life of a building can be classified into physical, functional or economic service life. The physical service life corresponds to the lifetime allowed by physical degradation procedures, contrary to the functional one that additionally takes into account the *'performance/requirements ratio'*, while the economic service life corresponds to the residual economic value. Furthermore, the international standard ISO 15686, (ISO 15686:2011), distinguishes among the service life, the reference service life, the estimated service life, the predicted service life and the service life during the design. In the Swiss context, the Swiss Society of Architects and Engineers (SIA) differentiates the technical service life (SIA 2047, 2015; SIA 480, 2016), from the useful life (SIA 2047, 2015; SIA 260, 2003; SIA 480, 2016) or the amortization period (SIA 2032, 2010), used for LCA calculations.

doi:10.23967/dbmc.2020.035

There are multiple studies, as summarized in Silvestre *et al.*, (2015) that discuss the ways the service life is estimated, mainly through the deterministic, the probabilistic and engineering method. However, in practice, the attribution of the building elements service life is based on standardized values, from technical standards, as for example in Switzerland, in the SIA 2032 technical book (SIA 2032, 2010). Apart from the technical parameters that affect the duration of service life, different scientific studies, as summarized in (Goulouti *et al.*, 2019; Volland *et al.*, 2019) have identified a variety of non-technical, socio-economic parameters that additionally affect the service lives of building elements.

Hence, there is a variability linked to the definition and the corresponding estimation of service life and there is no general agreement about the service life data, among the studies, as it is also stated in Dixit (2017). Furthermore, in the literature, there are different ways of decomposing buildings and attributing the service life, *i.e.* either at the functional or at the construction material level. Previous studies with service life data for specific materials have been conducted by Hoxha *et al.* (Hoxha *et al.,* 2014) and Dixit (2019), who additionally reported their variability through statistical distributions. Looking at more functional oriented databases, the Swiss eBKP-H – SN506511 (CRB, 2012) standard of construction costs provides a structured way to decompose the building into elements and sub-elements. Similar decomposition exists in Germany, too. In France, the INIES database that was developed to gather product-specific LCA studies of manufacturers (*i.e.* the "Environmental Product Declarations", EPDs), includes a hybrid building decomposition, combining both a function-oriented classification and a material orientation (*e.g.* firstly the Insulation product category, which is then decomposed into different materials like EPS, glass wool, etc.). The main limitations of the previous studies and databases are either that they are not complete, in terms of material variety (Dixit, 2019; Hoxha *et al.*, 2014) or that they report deterministic service life values and no statistical distributions can be derived (CRB, 2012; HQE, 2004).

In the context of increasing the reliability in LCA and LCC calculations, by integrating the inherent uncertainties of the different parameters, there is a necessity of providing a systematic way to take into account the service lives of building elements in LCA calculations, within a probabilistic framework. Thus, the aim of this paper is to present the development of a service life database that gathers service life data from 67 international sources. The database uses a hybrid decomposition (functional decomposition according to eBKP-H – SN506511 and material decomposition, as well) and it is thus compatible to the BIM-based LCA context, allowing calculations in different level of details (LOD), as stated in Cavalliere *et al.* (Cavalliere *et al*., 2018). Furthermore, statistical distributions are determined using the collected data, through a straightforward method.

2 Development of the DUREE Service Life Database

The literature search for service lives was conducted in English, French and German via Google, Google Scholar and Science Direct. The research of the service life data concerned data for the structural system, the technical installations, the façade elements and coatings, the roof elements, as well as for the interior layout. In total, 67 sources were identified, coming from energy standards, LCA and LCC standards, the public sector, scientific reports, private associations, banks, building management and insurance companies. Furthermore, the partners of the IEA EBC Annex 72 contributed to this research, by providing additional service life data

through a survey, conducted on national LCA methodologies, in the beginning of 2019 (Lasvaux *et al.*, 2019). Depending on the scope of the final user, the service life values were then classified in three main categories, *i.e.* LCA, LCC and Real – Estate Management. The 67 sources resulted in 95 entries and their allocation is presented in Table 1. Some documents did not only provide a single average service life but also a range of values *e.g.* min – mean – max. These values were treated as individual sources. Moreover, some service lives can be used in more than one category (*e.g.* LCA and LCC). In that case, the values were attributed to both LCA and LCC categories. This explains why the total number of sources in Table 1 is above 67. More details about the sources can be found in (Lasvaux et *al.*, 2019).

Table 1. Type and number of identified sources and service life values.

Type of sources	Total sources	Total values
LCA documentations	39	50
LCC analysis	14	23
Real – Estate Management domain	23	36

The service life data were organized in a database and formed the DUREE Database in an Excel spreadsheet, according to the eBKP-H – SN506511 that it is appropriate for different LOD calculations, in BIM-based LCA and LCC analyses. The five main groups of building elements, extracted from this functional nomenclature, include the structural work (main group C), the technical installations (main group D), the façade elements and coatings (main group E), the roof elements (main group F) and interior layout (main group G), see Figure 1. These main categories are further decomposed into two sub-categories, according to the SN 506511 nomenclature (*e.g.* the intermediate element level and the detailed element level). Five more sub-categories were added to this decomposition, in order to cover lower levels for more detailed components. Figure 1 presents an example of the database structure, for the SIA 2032 LCA perimeter. The names of the eBKP-H – SN506511 codes of the building elements are shown in Figure 2.

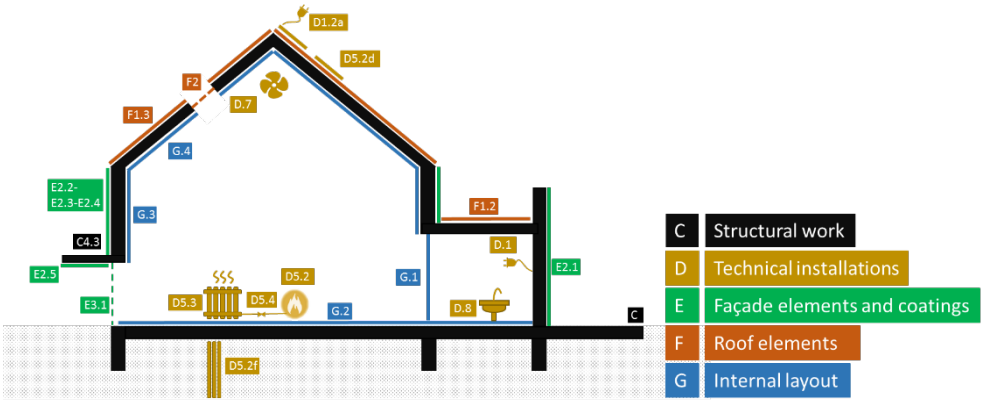

Figure 1. Main groups and intermediate element levels from the eBKP-H - SN 506511 nomenclature, for the 24 building elements, according to SIA 2032.

Each one of the 67 sources provides service life data for different components. Some sources offer data only for the main and intermediate categories, while others provide values at a lower

material level. Hence, an Excel function was created in order to calculate the statistic mean for each source for the main and intermediate categories, in case that service live data were provided at the material level. This function adds a flexibility to the database and allows calculations for the different stages of the design process, *i.e.*, for a screening analysis by taking values from the main categories (*e.g.* D Technical installations), or for a detailed analysis, by taking values from lower levels of details (*e.g*. heat producer, D5.2).

3 Descriptive Statistics

The database includes approximately 7'000 service lives data, for more than 2000 building elements. From these data, approximately 79% came from LCA and LCC sources. In addition, approximately 28% came from Switzerland and the rest were international data, mostly from European countries. The majority of Switzerland's data came from the management sector, while the majority of the international data belonged to the LCA domain.

Figure 2 presents the boxplots of the service lives for all the building elements included in the LCA perimeter of the Swiss SIA 2032 (see Figure 1). The descriptive statistics are presented for the total sample, as well as for the three sub-samples that correspond to service lives coming from LCA, LCC or Management sources. For some components such as photovoltaics, solar collectors or geothermal probes, some sub-samples (*e.g.* service life data for PVs in the LCC literature) are quite small, since there is a limited number of data found in the literature. The boxes correspond to the central 50% of the data, while the whiskers represent 80% of the data.

In general, there is a considerable variability for the most of the building elements and the different sources do not agree, as also stated in Dixit (2019). For each building element, the service life data exhibit a similar trend among the three sub-samples, regarding the variability. As far as the median values are concerned, two of the three sub-samples are relatively in accordance, but they are not systematically the same. In other words, there is no sub-sample that presents systematically lower or higher values. Hence, it is recommended to use the total sample, in order to determine a statistical distribution for the building elements' service life. Furthermore, the boxplots show that the service lives are positively or negatively skewed. The building elements exhibiting the highest variability are the technical installations (main group D), while the smallest variability is exhibited by the roof elements, (main group F). Furthermore, it should be noted that the variability of the sources diminishes, when moving towards lower levels of the database and more detailed materials, *e.g.* from D1 (electrical installations) to D1.2a (PV). The descriptive statistics for additional building elements can be found in (Goulouti *et al.*, 2019).

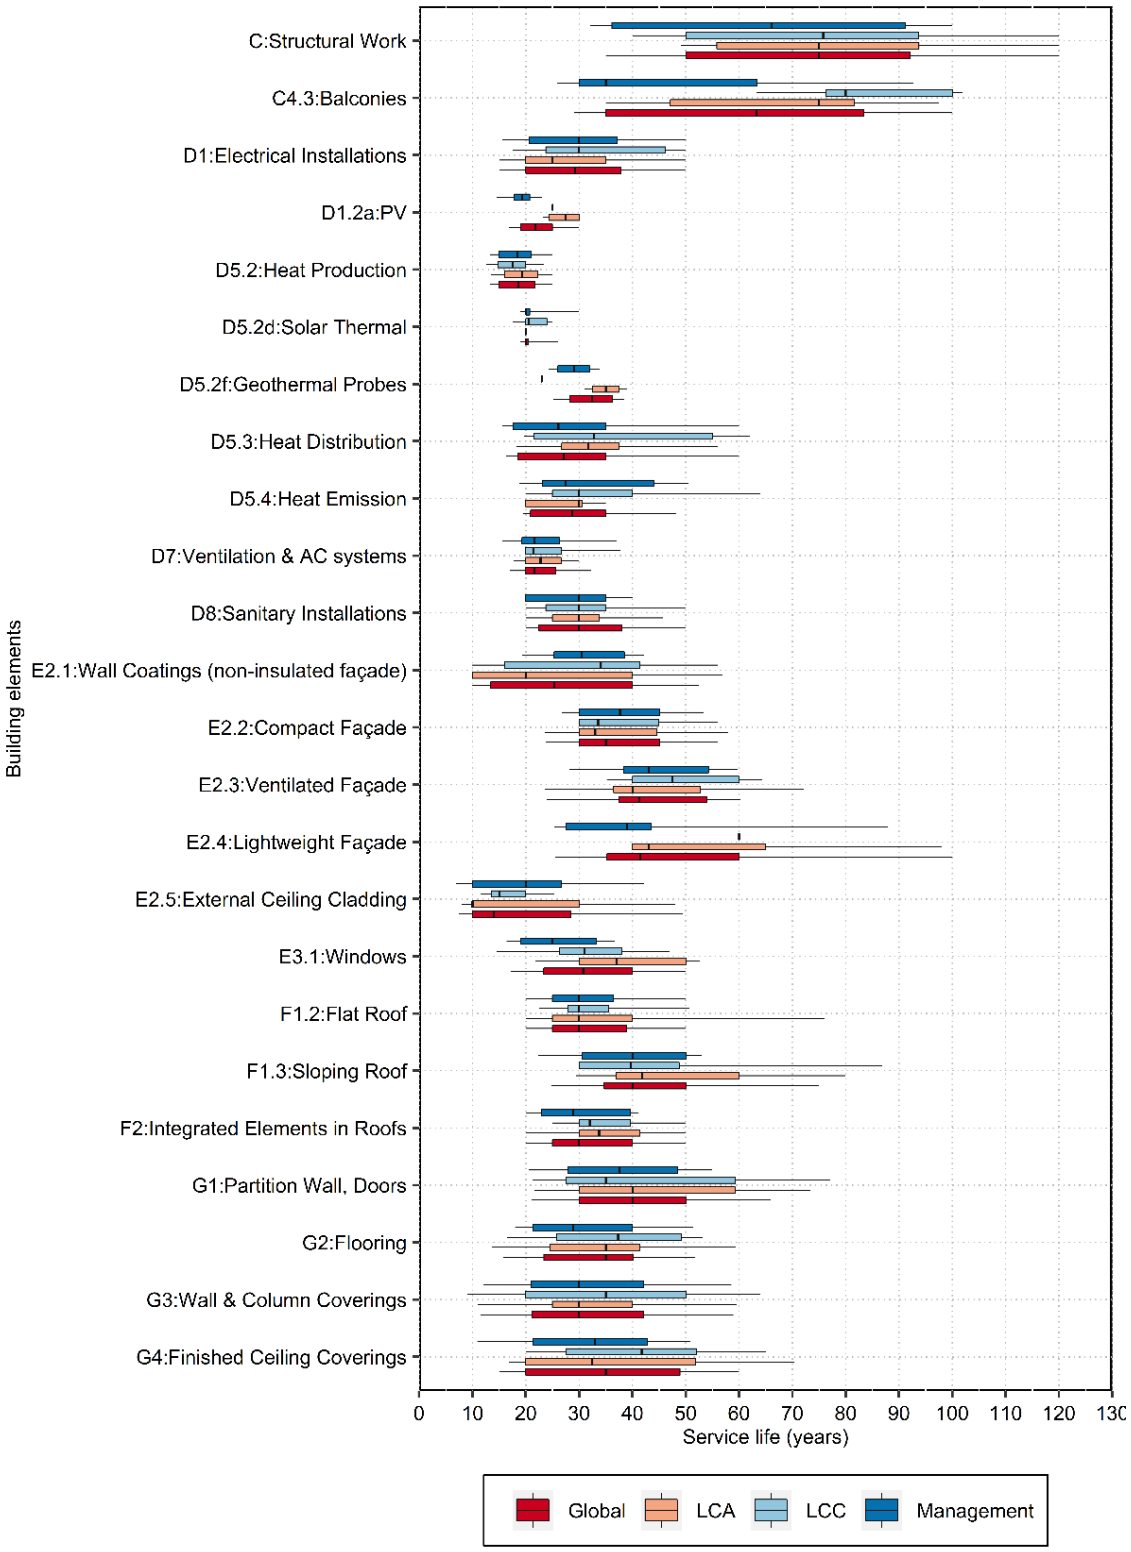

Figure 2. Boxplots for the 24 building elements, according to the SIA 2032 (see Figure 1) building LCA system boundaries.

4 Fitting to a Statistical Distribution

As stated in Dixit (2017), in order to deal with the variability of the service lives, statistical distributions can be determined, based on empirical service life data. Thus, using the DUREE database, such statistical distributions can be derived, with a systematic way for different building elements and levels of the database, *i.e.* service lives coming from the main groups or the sub-categories. Consequently, the service lives of the building elements can be taken into account, within a probabilistic framework, in further LCA and LCC calculations. In the literature, the lifetime data are often modelled using lognormal or Weibull distributions, (Aktas and Bilec, 2012; Kim and Yum, 2008). Input service life data constitute independent positive random quantities, for which the use of the lognormal process is well justified, (Voelkel, 2006), since according to the central limit theorem in the log domain, an infinite number of positive random values would approach the lognormal distribution (Limpert *et al.*, 2001). Thus, the latter can be used to model the service lives of building elements. In order to assess the goodness of fit of the lognormal distribution, two statistical methods were employed for the service lives of the building elements, using the statistical software R (R, 1997). First, the graphical method was computed, *i.e.* the Q-Q plots, which compares the theoretical and empirical distributions.

Figure 3 presents the empirical and theoretical density as well as the Q-Q plot of building element E.2 (Façade coatings above ground). The two graphs show that the two distributions are linearly related and that their points lie approximately on the line y=x. In addition, the p-value, according to the Anderson – Darling Test was calculated (R Documentation, 2002). The results confirmed the initial hypothesis of the lognormal distribution, (p-value > 0.05), (Goulouti *et al.*, 2019).

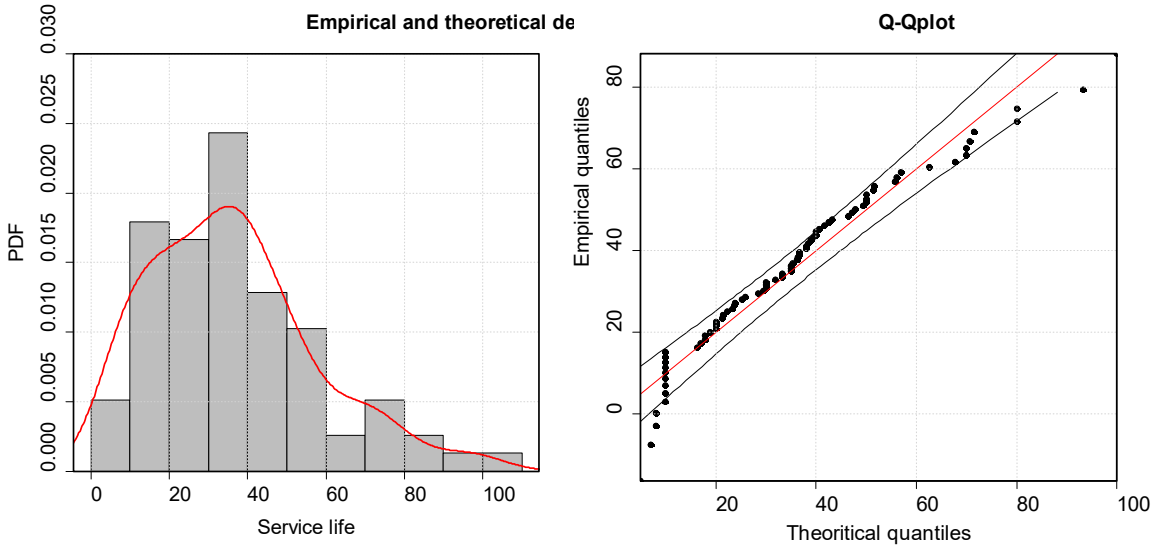

Figure 3. Example of goodness of fit (Q-Q plot) for the E.2 building element (Façade coating above ground).

5 Conclusions

This paper presents the development of a new database (DUREE database) for the service lives of building elements. International service life data were gathered and classified in three sub-samples, according to the scope of the sources application (LCA, LCC and Management sector). The main conclusions of the study are:

- The descriptive statistics show that there is a relative important variability and no general agreement, concerning the service lives of the building elements;
- There is no significant difference, among the three sub-samples, in terms of variability. As far as the median values are concerned, two of the three sub-samples present similar values, but they are not systematically the same. Thus, the total sample can be used in further LCA analysis;
- The structure of the database, *i.e.* main groups or sub-categories, offers the flexibility to the designer to attribute the service life data in different LODs, appropriate for BIM-based LCA analysis, *e.g.* screening LCA analysis (service lives from main groups), or more detailed LCA (service lives from sub-categories);
- The database offers the possibility to define statistical distributions, with a systematic way, for the service lives of the building elements. The goodness of fit for the different building elements confirmed the initial hypothesis of the lognormal distribution.

Abstract. *Chloride ingress in cracked concrete leads to rapid corrosion of embedded steel reinforcement and a decrease of the expected service life. Corrosion monitoring experiments showed that a 300 µm wide crack caused initiation of corrosion of a rebar (Ø 10 mm) with a concrete cover of 26 mm within three weeks of cyclic exposure to a 33 g/l NaCl solution. After a period of unstable corrosion activity during the first 20 weeks of exposure, corrosion propagated further at a relatively high rate (0.345 to 0.718 mm³/week). Application of a theoretical pitting model revealed that a reduction of about 50% of the rebar cross-section would occur after a period of 9 to 20 years of continuous cyclic exposure to chlorides. To avoid such rapid degradation, the use of self-healing concrete can be proposed. Introduction of macro-encapsulated polyurethane into the concrete matrix, will lead to the formation of a (partial) barrier against ingress of chlorides at the moment cracks appear. Corrosion monitoring experiments showed that the autonomous crack healing could not always prevent corrosion initiation, but caused an important reduction of the corrosion rate during the 44 weeks exposure period. The mean rate of volumetric loss of steel amounted to 0.042 mm³/week, about 15 times lower than for the untreated cracked samples. The rebars also showed no or very limited signs of corrosion after visual inspection. The simplified pitting model indicated that a 50% reduction in steel cross-section would take more than 5 times longer for samples with self-healing properties versus ordinary cracked samples.*

1 Introduction

1.1 General Introduction

Reinforced concrete is without doubt one of the most ingenious inventions in the construction industry. By combining concrete with steel, a composite material is created which has both a high compressive and tensile strength. Numerous structures, such as buildings, bridges, tunnels and roads have been made using reinforced concrete due to its high strength and high degree of freedom in shape and design. A huge amount of steel reinforced concrete structures were built by the mid-20th century. However, these structures are now over 50 years old and several have shown major deterioration. One very common problem in reinforced concrete structures is the appearance of cracks when the concrete element is subjected to tensile stresses. These cracks form preferential pathways for chlorides or carbon dioxide to penetrate the concrete and rapidly reach the steel reinforcement. This will increase the risk for initiation and possibly further propagation of steel reinforcement corrosion. Several studies have provided proof of a

shortening of the corrosion initiation period due to the presence of cracks and chlorides (Ahmadi *et al.*, 2015; Jaffer and Hansson, 2008; B. Otieno *et al.*, 2010; Sangoju *et al.*, 2011). In some cases corrosion onset is almost instantaneous after crack appearance (Schießl & Raupach, 1997). Moreover, once corrosion has initiated, there can be an acceleration of the corrosion rate in the propagation phase as the crack provides easier supply of chlorides, moisture and oxygen to the reinforcement (Ahmadi *et al.*, 2015; Li *et al.*, 2017; Otieno *et al.*, 2010; Schießl and Raupach, 1997). Mostly, an increase in the corrosion rate was found in short term tests (< two years) while less influence of cracks on the propagation rate was found in long-term studies (Käthler *et al.*, 2017).

Thus, cracks should be repaired as soon as possible to avoid major durability issues. However, cracks in certain structures can be invisible or inaccessible, impairing repair works. Moreover, repair works have a big economic impact due to the (in)direct costs involved. Therefore, the idea of providing the concrete with the ability of restoring cracks by itself without any human interference grew during the last few decades. One promising approach to create a so-called self-healing concrete consists of the embedment of encapsulated healing agents in the concrete matrix. Brittle macro-capsules are placed in regions subjected to high tensile stresses and where cracks would cross the steel reinforcement.

In this research, autonomous crack healing through the use of encapsulated healing agents was investigated for its efficiency to reduce the ingress of chlorides into the concrete matrix and to improve the corrosion resistance of reinforced concrete.

1.2 Steel Corrosion Monitoring

Chloride ions cause breakdown of the passive layer on the steel reinforcement when present at a certain threshold concentration. As the chloride ingress in concrete is not homogenous, this leads to a very localized corrosion. Chloride induced corrosion is actually a combination of a macro-cell corrosion process (leading to a current I_{macro}) between spatially separated anodic and cathodic areas on the steel and a micro-cell corrosion process between very small anodic and cathodic parts inside the corrosion pit (leading to a current I_{micro}). The macro-cell corrosion process will usually lead to much higher corrosion rates (Schießl and Raupach, 1997). According to Ohm's law, the current which is flowing between anodic and cathodic sites on the steel surface is directly proportional to the potential difference between those areas and inversely proportional to the resistances of the system. On this basis, the macro-cell corrosion process can be represented by an equivalent electric circuit.

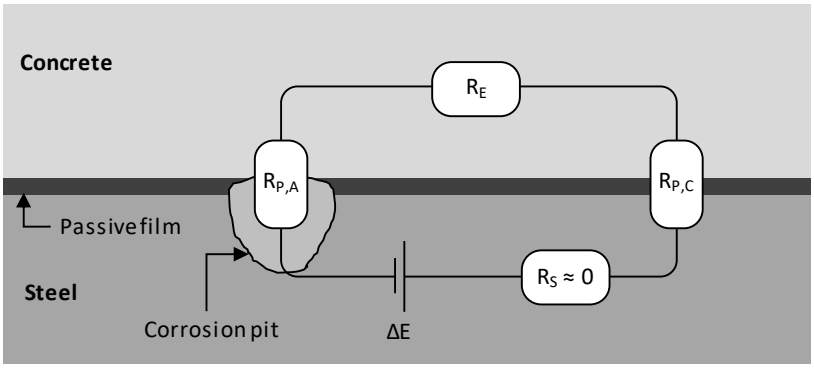

Figure 1. Equivalent circuit model for macro-cell corrosion, redrafted after Hiemer *et al.* (2015).

As can be seen from Figure 1, the equivalent circuit consists of four resistances: the resistance of the anodic partial reaction ($R_{P,A}$), the resistance of the cathodic partial reaction ($R_{P,C}$), the resistance of the concrete (R_E) and the resistance of the steel (R_S, which is assumed to be zero). The potential difference ΔE (driving potential) between the anode and the cathode can be seen as the driving force for the corrosion process. In order to estimate the rate of corrosion, the total corrosion current (I_{corr}) should be calculated, as in Equation (1).

$$I_{corr} = I_{macro} + I_{micro} = \frac{\Delta E}{R_{P,A} + R_{P,C} + R_E} + I_{micro} \quad (1)$$

2 Materials and Methods

2.1 Concrete Samples

A reference concrete as described in Van den Heede (2014) was used as a representative mixture for concrete in exposure class XS2, i.e. submerged reinforced concrete in contact with chlorides from seawater (Table 1). The mixture had a water-to-binder ratio of 0.41 and a fly ash-to-binder ratio of 15%, according to the k-value concept (NBN B15-001, 2004). The concrete had a slump class S4 and a compressive strength at 28 days of 65.2 ± 2.0 MPa.

Table 1. Mix proportions of the concrete mixture.

Sand 0/4 (kg/m³)	696
Aggregates 2/8 (kg/m³)	502
Aggregates 8/16 (kg/m³)	654
CEM I 52.5 N (kg/m³)	317.6
Fly Ash (kg/m³)	56
Water (kg/m³)	153
Superplasticizer (ml/kg binder)	3.0

Steel reinforced concrete prisms with dimensions of 120 mm x 120 mm x 500 mm were made for corrosion monitoring. The reinforcement scheme of the prisms (Figure 1), was based on Hiemer *et al.* (2015) and Keßler *et al.* (2017), and was adapted based on earlier experiments (Van Belleghem *et al.*, 2018). The steel reinforcement (BE500S) in the concrete prisms consisted of an anodic and a cathodic part which were electrically separated from each other. The anode was a central steel bar (∅ = 10 mm, L = 250 mm), partially coated with cement paste and epoxy resin to prevent crevice corrosion, with only the central 50 mm exposed. The cathode consisted of two electrically connected cages (each with four longitudinal rebars ∅ = 8 mm and five stirrups ∅ = 6 mm which were welded to each other). The anode/cathode ratio was kept small (1/58) to accurately measure the macro-cell corrosion process. Both parts were connected to the exterior by means of an insulated copper wire. In addition, two glass fiber reinforced polymer rebars (∅ = 6 mm) were placed in the compression zone. Four types of specimens were prepared (with 3 replicates): uncracked specimens (UNCR), cracked but not healed specimens (CR), and self-healing specimens containing two layers of 6 capsules filled with high (6700 mPas) or low (200 mPas) viscosity polyurethane (PU_HV_CAPS and PU_LV_CAPS). The samples contained an Ag/AgCl internal reference electrode, fixed to the coated part of the anodic rebar. After casting, the prisms were stored at 20°C and a relative humidity above 95%.

The prisms were demolded after 24 hours and stored at the same conditions until 28 days. Then, anode and cathode were connected to each other through the external copper wires.

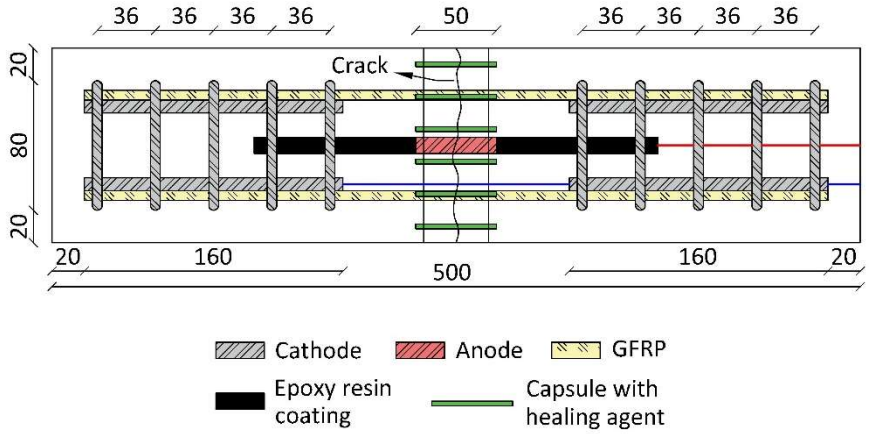

Figure 1. Reinforcement scheme and capsule positions in the concrete prisms (dimensions in mm) – top view, redrafted after Van Belleghem *et al.* (2018).

2.2 Crack Creation

At 28 days, a flexural crack with a target width of 300 µm was created in the concrete prisms by means of a three-point bending test. The concrete prisms contained a triangular notch with a height of 3.5 mm at mid-span to ensure that the cracks originated in the center of the prism and consequently crossed the anodic rebar (and the capsules). Cracks were kept open by means of a special frame (Figure 2). After crack creation, all samples were stored at 20 ± 2°C and a relative humidity of 60% for 48 hours to allow the polyurethane to cure inside the crack.

2.3 Exposure Regime

The prisms were placed with the crack facing upwards and the lateral surfaces were covered with aluminum butyl tape, extending beyond the upper surface of the samples, to create a basin with three compartments (Figure 2). The top (cracked) surface of the samples was exposed weekly to 1 d wetting and 6 d drying cycles for a total duration of 44 weeks. During the wet period, the central compartment was filled with a 33 g/l NaCl solution, while the outer compartments were filled with a 1.15 g/l $Ca(OH)_2$ solution.

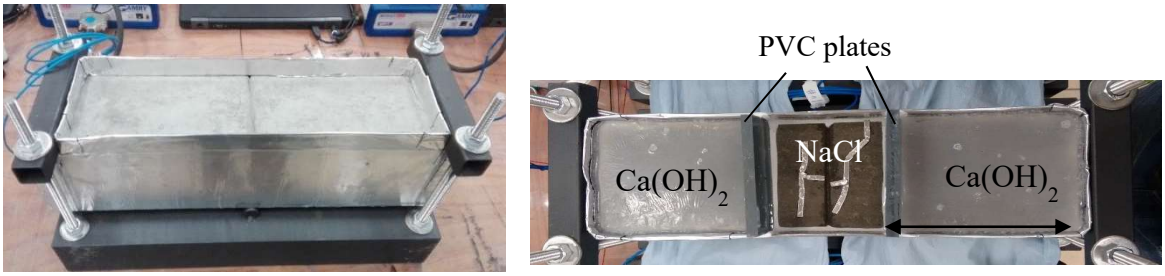

Figure 2. Concrete prism mounted in a three-point bending test frame (left); Basins on the surface (right).

2.4 Corrosion Measurements

The macro-cell corrosion current between anode and cathode (I_{macro}) was measured once every hour with a low resistance ammeter. Electrochemical measurements were performed at the end of the wet period with a potentiostat using the internal Ag/AgCl reference electrode (SAE). The corrosion potential (E_{corr}) was measured while anode and cathode were connected. Other parameters were measured as well (for results see Van Belleghem, 2018), such as open circuit potential (OCP) of anode and cathode, linear anodic and cathodic polarization resistance ($R_{P,A}$ and $R_{P,C}$), and concrete resistance (R_E). All electrochemical measurements were performed weekly during the first 12 weeks of the wet-dry cycles and thereafter every two to four weeks.

2.5 Chloride Profiling and Visual Evaluation

After the corrosion monitoring period, the chloride ingress was determined by means of chloride profile grinding (layers of 4 mm thickness) in an area of 10 mm x 30 mm around the crack next to the location of the anodic rebar. The total chloride content of each powder was determined by means of acid-soluble chloride extraction in a nitric acid solution followed by a potentiometric titration against silver nitrate. After determination of the chloride profiles, the anodic steel reinforcement bars were removed from the concrete prisms for visual inspection of the corrosion products. Next, all rebars were immersed in a chemical cleaner solution ($HCl:H_2O$ = 1:1 + 3 g/l urotropine) for 24 hours in order to remove all corrosion products and residual concrete. Afterwards, the steel rebars were visually inspected again to investigate the loss of steel due to chloride induced corrosion.

3 Results of Corrosion Experiments

3.1 Corrosion Monitoring

An overview of the measured electrochemical parameters during the 50 weeks monitoring period is given in Figure 3. The initial measurement in the uncracked state is shown as ‘week -1’, while ‘week 0’ represents the values after cracking but without exposure to a solution. From week 1 until week 44 the samples were exposed to the wet-dry cycles. The last measurement at week 50 was performed after a six week dry period.

The uncracked samples showed a non-active state of corrosion along the whole exposure period. No macro-cell corrosion current was detected and the corrosion potential was nearly constant at values of -70 to +80 mV_{SAE}. The cracked samples showed clear evidence of corrosion initiation within the first three weeks of exposure to 33 g/l NaCl solution: there is a steep rise in the macrocell corrosion current and a concurrent drop of the corrosion potential down to values between -200 and -400 mV_{SAE}. Every week a sharp increase of the macro-cell corrosion current can be seen for all the cracked samples, which corresponds to the start of each wet period. Apart from the occurrence of these peaks, the overall macro-cell corrosion current shows a decreasing trend during the first twenty weeks of exposure. It remains relatively constant in the period from 20 to 44 weeks in a range of 20 to 60 µA, which shows that the corrosion is propagating at a constant rate. The corrosion parameters measured at week 50, after a dry period of six weeks, indicate that the corrosion is propagating at a lower rate. This is logical as the continuous supply of chlorides and moisture act as catalysts for the anodic and cathodic corrosion reaction.

Generally, the corrosion behaviour of the self-healing samples with high viscosity PU (PU_HV_CAPS) was very similar to the corrosion behaviour of the cracked samples. However, the self-healing samples with low viscosity PU (PU_LV_CAPS) behaved more closely to the uncracked samples. The macro-cell corrosion current was negligible and the driving potential was comparable to the values found for the uncracked samples.

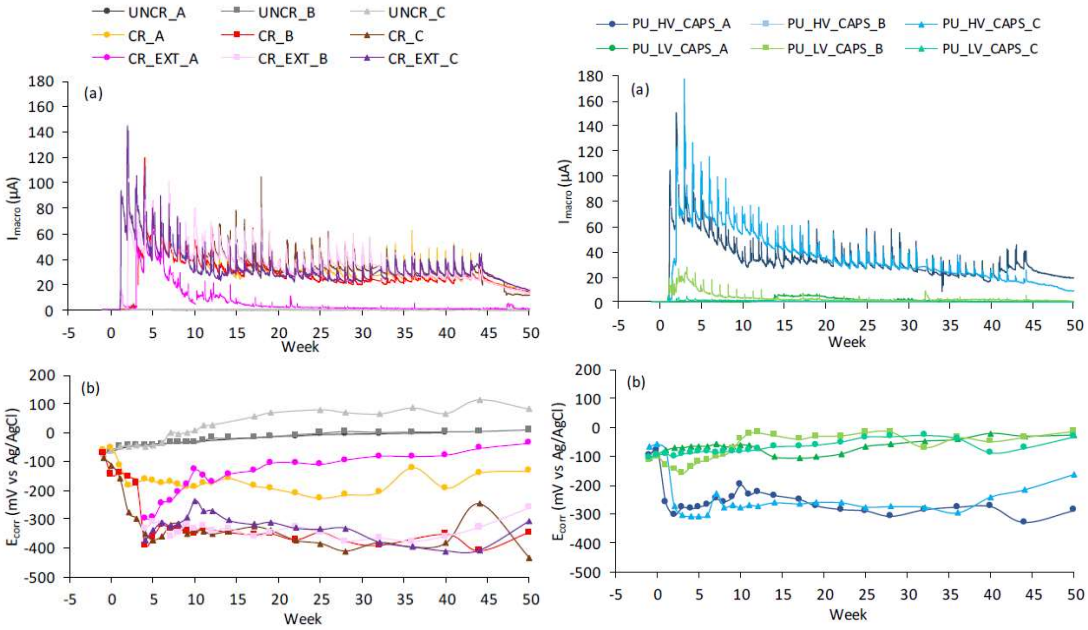

Figure 3. Macro-cell corrosion current and corrosion potential for uncracked (UNCR) and cracked (CR) samples (left) and for samples with high (HV) and low (LV) viscosity PU (right) (Van Belleghem, 2018).

3.2 Chloride Profiles and Visual Examination of the Rebars

The obtained chloride profiles are shown in Figure 4 together with the location of the rebar. For the uncracked samples the mean chloride concentration at the surface amounted to 3.43 ± 0.05 m%/binder and then dropped fast to nearly zero at a depth of 18 mm into the concrete matrix. The samples containing an untreated crack showed a very high chloride concentration close to the surface of the samples (up to 6 m%/binder). The chloride concentration drops steeply when going to the second layer (4-8 mm below the surface) and gradually decreases until a depth of 20-25 mm. At depths larger than 20 mm, the chloride concentration remained almost constant at about 1.3 to 1.5 m%/binder. Autonomous crack healing with low viscosity polyurethane (PU_LV_CAPS) led to a clear reduction of the chloride concentration compared to the cracked samples. At the level of the reinforcement the chloride concentration was about 0.26 m%/binder, which was three to seven times lower compared to the concentration found at the level of the reinforcement of the cracked samples.

Visual examination of the rebars from the uncracked samples showed no corrosion products and no visual damage to the rebars was observed after cleaning. For the cracked samples, clear formation of corrosion products on the central part of the anodic rebar was noticed. After cleaning, clear pitting corrosion was observed at the same location. The series PU_LV_CAPS showed negligible formation of corrosion products and no pitting corrosion.

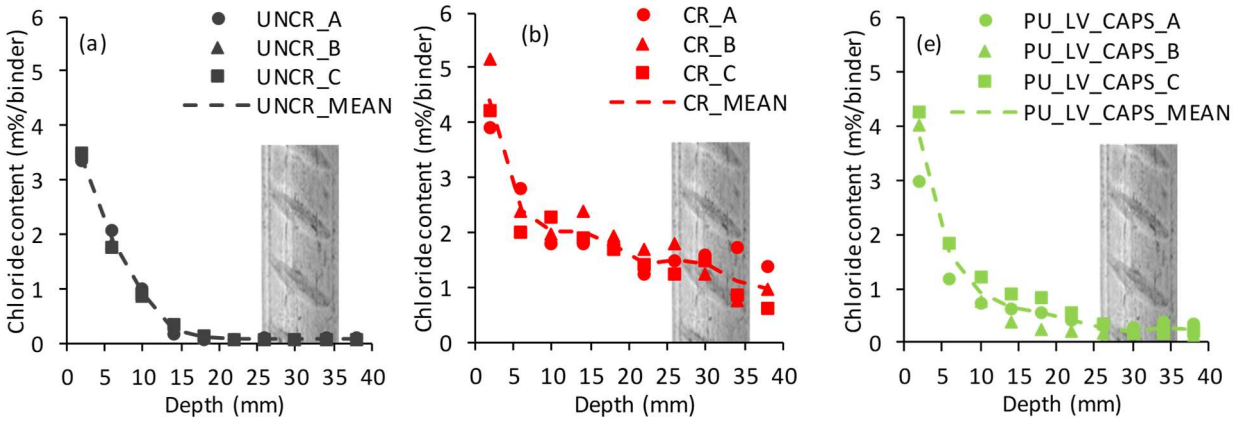

Figure 4. Chloride profiles of all sample series with indication of rebar location.

4 Prediction of Reduction of Steel Cross-Section

The mass loss of steel due to the macro-cell corrosion reaction can be determined theoretically from the measurement of the macro-cell corrosion current in time using Faraday's law according to Equation (2):

$$m = \frac{Q}{F} \cdot \frac{M}{z} \tag{2}$$

where m is the mass loss of iron (Fe) (g), Q is the total electric charge passed through the substance (C), F is the Faraday constant (= 96485 C/mol), M is the molar mass (here 55.845 g/mol) and z is the valency number (being 2 for oxidation of iron).

The total charge passed can be calculated by taking the integral of the measured current over time. The mass loss due to micro-cell corrosion is hereby not taken into account. The cracked samples showed a large mass loss ranging from 0.19 to 0.24 g at the end of the measurements. A further prediction can be made by calculating the volume loss in the initial 20 weeks of exposure (high and unstable corrosion current, leading to a volume loss of 6.36 to 15.45 mm³) and adding this to the volume loss in the secondary period, where a relatively stable macro-cell corrosion current develops (0.551 to 0.718 mm³/week). A similar calculation for the self-healing prisms with LV PU, resulted in an initial volume loss of 1.65 to 10.34 mm³ and a rate of volumetric loss of 0.042 mm³/week afterwards (14 times lower than what was found for the untreated cracked samples).

Application of a simplified pitting model proposed in Van Belleghem (2018) revealed that, for a steel bar with a diameter of 10 mm in cracked concrete, a reduction of about 50% of the cross-section would occur after a period of 9 to 20 years of continuous cyclic exposure to chlorides. However, for the self-healing concrete with LV PU, such a 50% reduction would take more than 100 years to occur.

5 Conclusions

- Cracks in concrete allow rapid penetration of chlorides and impair the durability of the structure. Within three weeks of cyclic exposure to a 33 g/l NaCl solution, the reinforcement in lab specimens with a 300 µm wide crack started to corrode. A volume loss of 6.36 to 15.45 mm³ was calculated for the initial 20 weeks of exposure, followed by a period of

relatively stable macro-cell corrosion current leading to a volume loss of 0.55 to 0.72 mm³/week. This means that 50% of the rebar cross-section (diameter 10 mm) would be lost after 9 to 20 years. Uncracked samples showed a non-active state of corrosion during the whole exposure period of 44 weeks.

- In the case of self-healing concrete with macro-encapsulated polyurethane, crack formation led to rupture of the capsules and release of healing agent in the crack. Low viscosity polyurethane induced a decrease of the corrosion rate in comparison to cracked and untreated samples. After an initial volume loss of 1.65-10.34 mm³, the mean steel loss rate amounted to 0.042 mm³/week only. At the end of the experiment the rebars showed no or very limited signs of corrosion. A 50% reduction in steel cross-section was estimated to take more than 100 years, using a simplified pitting model.

Abstract. *Decrease in performance of building facades, components, and materials before their service life is an unexpected situation. Therefore, detecting the probable causes of these anomalies plays a crucial role in maintenance planning. This study aims to determine the environmental deterioration factors which affect the performance of buildings, especially building façades, through two case buildings situated in the same university campus in Istanbul. The methodological framework of the study is based on visual observations and literature review. Through observations on a different period of time, anomalies have been detected and photographed. In the first case, it has been focused on metal claddings on building façade. In the second case, it has been focused on GFRC panels which have the majority of the North façade. Within the help of literature and observations, two cases have been compared to each other in terms of their deterioration factors and interpreted through graphs. In the first case, occurred deteriorations have been detected such as uniform dirt, corrosion, joint degradation, mechanical impacts, and delamination. in the second case, deteriorations have been observed such as biological staining, uniform dirt, moisture rising, and design failures.*

Keywords: *Environmental Deterioration Factors, Building Façade Failures, Metal Claddings, Glass Fibre Reinforced Concrete Façade.*

1 Introduction

Performance of a building deteriorates in time depending on environmental effects, usage, maintenance, detail design and type of materials which are used in building envelope. Therefore, defining the probable causes of deteriorations has high importance to propose appropriate solutions.

Environmental agents are divided into natural (wind, rain, freeze and throw, and solar radiation), and chemical and biological problems, issued by air pollution (Norvaišienė *et al*., 2003). The data reported in this paper investigates environmental agents which can affect performance of façade.

A research called "Climatic and Air Pollution Effects on Building Facades" has a deep literature review on degradation mechanisms that affect the durability of building materials (Norvaišienė *et al*., 2003). A study called "Evaluation of Damage of Building Facades in Brasilia" aims to evaluate age and climatic agents through quantitative research. Visual inspections and facade mapping were used as a method and some degradation agents such as grout and sealing failures and efflorescence are examined over the exposure to solar radiation

(Bauer *et al.,* 2014). By now, many kinds of research have been done on deterioration factors and durability of materials. Defining these factors/mechanisms correctly is essential in order to propose appropriate solutions in design, construction, and maintenance process.

2 Environmental Factors

Mechanisms are generally examined in three categories: physical, chemical, and biological (Dickinson *et al*., 1999). *Physical mechanisms* are related to the presence of water. Freezing and thawing processes with the temperature and moisture differences may cause stress and crack on the material (Norvaisiene *et al*., 2003). *Chemical mechanisms* involve some chemical compounds that can react with the building surface. Particulate matters in the air generally comprise dust, smoke and suspended particles. Dust particles being large and heavy, settle quickly and will not affect large areas. Smoke and suspended particles being smaller and lighter remain in the atmosphere for a longer time and affect larger areas (Chew *et al.,* 2003). Sulfur and nitrate have acidic concentrations, and they cause acid rain, which is a threat to human health and also building envelope (Norvaisiene *et al*., 2003). Besides, corrosion of materials can occur due to chemical interaction with the environment. If corrosion of materials does not prevent in time, it may cause even structural deteriorations.

In *biological mechanisms*, wind changing the direction of rain drops to façade and this is "one of the most important moisture sources" that effects durability of façade material. These destructive effects can be "frost damage, discoloring, biological and chemical degradations" and also structural cracking (Blocken *et al*., 2013). Also rain water is one of the reasons of stains on façade. It can wash the dirt through the façade and also is a major factor that causes biological grow on it. "Sunlight plays an important role in affecting the formation of stains on a facade. The intensity and duration of sunlight that a surface receives affect the limit of runoff flow, the type of biological stains and the pattern of staining" (Chew *et al*., 2003).

3 Case Studies

In this part, two case buildings where are located in Istanbul are selected in order to understand environmental deterioration factors. In this context, there is an approach from macro to micro scale, which begins with defining the surrounding of the buildings and continues with the building facade components.

3.1 Local Environment

Both of the case buildings are located in Maslak, where is one of the main business districts of İstanbul. The altitude is 120 meters, and distance from the sea is approximately 3 km. In the first case, the northern facade of the building is facing Buyukdere Street, which usually has heavy traffic flow. Also, there is viaduct which is passing near the case building and facing the northern facade of the first case building again. The other side of Buyukdere is a high-density urbanized area which has many commercial and residential complexes.

In the second case building, traffic direction is in North and East face. There is also a parking lot in the West side. The site plans of the case buildings are given in Figure 1:

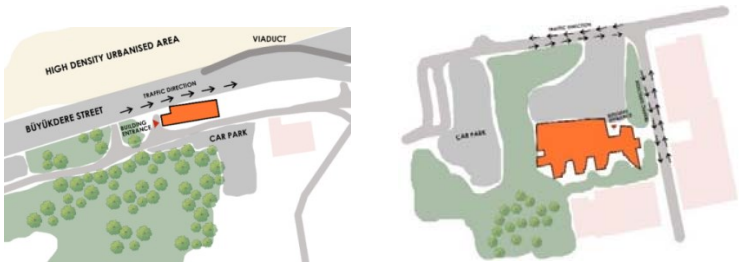

Figure 1. Site plans of the first and second case buildings.

3.2 Micro Environment

Istanbul where the case buildings are located has mild-humid climatic characteristics. According to the official statistics, the highest temperature is in July (41.5°C), and the lowest average temperature is in February (-16.1°C). The average number of rainy days is highest in January (17.3) and the lowest in July (4.3). Maximum daily precipitation is 128.9 mm (Turkish State Meteorological Service Official Web Sites, n.d.).

The dominant wind direction in the district is North – North East. Accordingly, it is assumed that the northern façade of the building is exposed to more wind and rain. Figure 2 shows the location of the case buildings in macro scale. Distance from the sea is approximately 3 km that can be an adequate distance to happen convection of salt.

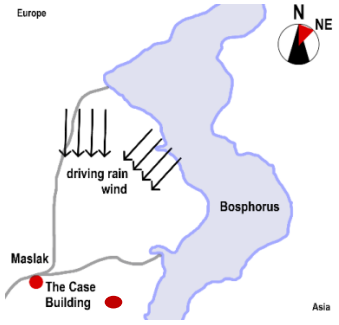

Figure 2. Location of the case buildings.

The recent measurements performed by Ministry of Environment and Urbanization show that PM10 and NO_2 values are comparatively increasing in the rush hours as a probable consequence of Buyukdere Street (SİM Project n.d.). Also, a report which has been prepared in 2018 by the Netherlands Enterprise Agency shows the existing situation within the context of air pollution in İstanbul. According to the European Directive, the number of permitted exceedances per year is 18. Figure 3 shows that NO_2 limit is exceeded more than 18 times in 6 stations in 2017 and Maslak district has the third highest exceedance level (Standards-Air Quality-Environment-European Commission, n.d.). As understood, the selected buildings are located in a highly urbanized area and air pollution in the district is quite a lot. Therefore, the selection of appropriate material for the building envelope is a critical issue.

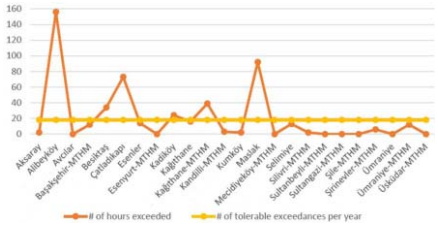

Figure 3. Frequency of hours the NO_2 limit was exceeded in 2017.

3.3 Facade Components

The first case building facade mainly has 4 mm thickness white colored *aluminum composite panel (1), siliconized glass system with an aluminum frame (2), structural steel columns (3), natural stone cladding (4),* silver-gray colored *aluminum mesh cladding (5) and white colored aluminum dynamic vertical and fixed horizontal shading elements (6)* (Figure 4).

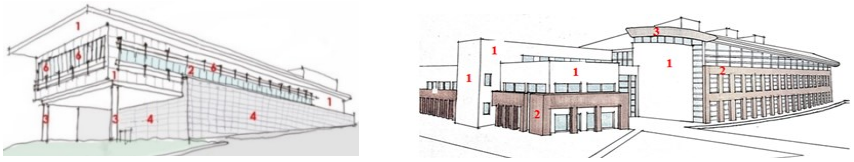

Figure 4. Façade components of the first and second case buildings.

Materials that have been used on façade for the second case building are (most to least); *glass fibre reinforced concrete (GFRC) (1), clinker based facade panels (2), aluminum (3).* It has been focused on metal claddings in the first case and GFRC panels in the second case since they have the most deterioration in comparison with other materials on the façade.

4 Preparation for Field Observation

The methodological framework of the study is based on visual observations and literature review. Firstly, façade deterioration factors have been defined in detail through literature. For the field observation, two datasheets have been prepared. The first datasheet contains the general information such as primary use of the building and construction process. The second one involves atmospheric exposures such as wind, rain, sun that affects the building façades, climate in the observation days and deterioration types. After collecting data, anomalies on building façade have been detected and shown in façade mapping (Figure 5).

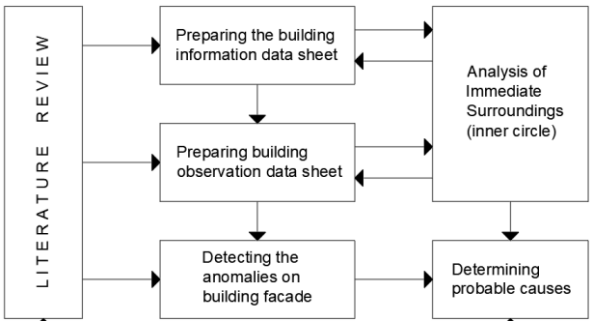

Figure 5. The methodology of the study.

5 Analysis and Discussions

For the first case building, four observations were made. The first one was made on 27th April 2015, in a cloudy day, 18°C at 09:30 am. The second one was on 25th September 2018, rainy day, 19°C. The third one was 9th October 2018, cloudy day, 16°C at 12:00 am and the fourth observation was on 4th December 2018, after rain, 10°C at 05:30 pm.

For the second case, the first observation was in 22th October 2018, 15:35 in partly cloudy weather. The second one was in 10th November 2018, 17:09 in a completely sunny weather. The last observation was made after two heavy rainy days in 19th November 2018, 14:22.

5.1 Case Study 1

According to the observations, anomalies detected on the selected building facades are examined. Deteriorations are classified into five categories. These are; uniform dirt (A), corrosion (B), joints degradation (C), mechanical impact (D), and delamination (E). The deteriorations which have been detected are shown in façade mapping (Figure 6).

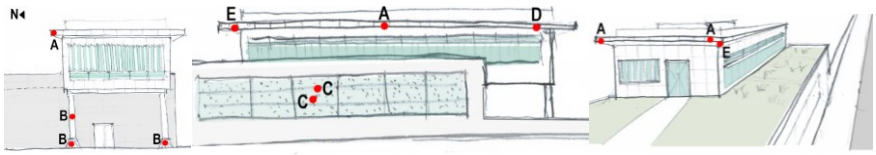

Figure 6. Deteriorations on the West, North, and East façade.

Uniform dirt has been mostly seen on the aluminum composite panels and shading elements (Figure 7). The most dirtiness has been concentrated on the overhangs that have 10-12 meter height from Buyukdere Street. Especially the North and East facade are the dirtiest facades of the building. The reason may be the viaduct which passes above the main road and brings all the pollution onto the façades within the help of dominant wind and driving rain.

Deterioration Type	**A**	**Date**	9.10.2018
		**Weather data**	Cloudy, 16°C
		Affected parts	Aluminum composite panel Overhangs and facades, shadings
		Affected facades	North, South, East, West
		Probable causes	Atmospheric pollution

Figure 7. Deterioration type A, 'uniform dirt'.

The observations which have been made in 25th September and 4th December 2018 show that two structural columns on the West façade of the building have been deteriorated by corrosion effect (Figure 8). The waterhole has been observed below the feet of the column after the rain. Accordingly, degradation on the feet is thought to be due to the wrong slope angle. Deterioration on the column head may be related with the storm water runoff.

Deterioration Type	B	Date	25.09.2018, 04.12.2018
		Weather data	Rainy, 19°C, after rain 10°C
		Affected parts	Structural steel column column head, body, and feet
		Affected facades	West
		Probable causes	Atmospheric pollution wrong slope (ground level) stormwater runoff

Figure 8. Deterioration type B, 'corrosion'.

According to the observation on 9th October 2018, joints degradations have been detected on the North façade, which has covered with aluminum mesh cladding (Figure 9). This deterioration may be the consequence of stiff breeze coming from the North and North-East direction. Also, wrong detail design may cause to happen in this situation.

Deterioration Type	C	Date	9.10.2018
		Weather data	Cloudy, 16°C
		Affected parts	Aluminum mesh cladding
		Affected facades	North
		Probable causes	Atmospheric effects (wind, rain) wrong detail design (WDD)

Figure 9. Deterioration type C, 'joints degradation'.

The observation on 9th October 2018 makes think about a mechanical impact on the North façade overhang, which is covered with aluminum composite panels (Figure 10).

Deterioration Type	D	Date	9.10.2018
		Weather data	Cloudy, 16°C
		Affected parts	Aluminum composite panels Overhang
		Affected facades	North
		Probable causes	

Figure 10. Deterioration type D, 'mechanical impact'.

According to the observation on 4th December 2018, delamination is seen on the North and East overhangs (Figure 11). Probable cause is thought to be the storm water runoff with the wind which is coming from the dominant direction. It may have penetrated from the joints and caused the delamination of layers on the composite panels.

Deterioration Type	E	Date	4.12.2018
		Weather data	After the rain, 10°C
		Affected parts	Aluminum composite panels Overhang
		Affected facades	North, East
		Probable causes	Stormwater runoff

Figure 11. Deterioration type E, 'delamination'

5.2 Case Study 2

According to the observations, anomalies detected on the selected building facades are examined. Deteriorations are classified into three categories. These are; biological staining (A), moisture rising (B), and joints degradation (C). The deteriorations which have been detected are shown in façade mapping (Figure 12).

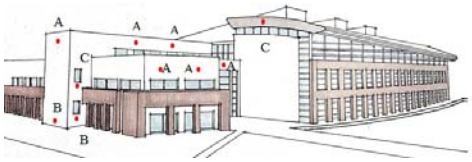

Figure 12. Façade mapping of the second case building.

According to observations, the building is exposures to the prevailing wind, which changes the direction of raindrops. As the most deteriorated part of the façade is the N/E (Figure 13), lack of sunlight slowdowns the procedure of drying after it had been wetted, and results as biological staining (due to algae, bacteria, and fungi).

Deterioration Type	**A**	**Date**	22.10.2018, 19.11.2018
		**Weather data**	Partly cloudy, Rainy
		Affected parts	GFRC panels
		Affected facades	North, East
		Probable causes	lack of sunlight after rains

Figure 13. Deterioration type A, 'biological staining'.

N/E façade is directly in contact with ground and grasses. Because of continues dampness, external wall of this part of façade is stained. As a result, mould growth appeared and there was discoloration to the wall (Figure 14).

Deterioration Type	B	**Date**	10.11.2018, 19.11.2018
		**Weather data**	Sunny, Rainy
		Affected parts	GFRC panels, Clinker panels
		Affected facades	North, East
		Probable causes	Continuous dampness, WDD

Figure 14. Deterioration type B, 'moisture rising'.

Panel joints and sealants on a façade provide for drainage of run-off on the facade. Joints affect runoff can locally rinse away deposited dirt stains at areas where a file of vertical joints is broken and where joints are slanted (Figure 15).

Deterioration Type	**C**	**Date**	10.11.2018, 19.11.2018
		**Weather data**	Sunny, Rainy
		Affected parts	GFRC panels, Aluminum
		Affected facades	North, East
		Probable causes	Atmospheric effects (wind, rain) wrong detail design

Figure 15. Deterioration type C, 'Joints degradation'.

7 Conclusion

In this study, field observation has been done for two case buildings, and probable causes on façade deteriorations have been examined with the help of literature.

The district of both cases has air pollution due to high urbanization and heavy traffic intensity. Especially in the first case, some deteriorations have been observed after only three years of usage on the North, East, and West façades which are close to the main road and the viaduct. According to the literature, aluminum composite panels should be cleaned at least once in a year. Besides, stormwater runoff should be controlled to prevent the corrosion of steel materials. To delay or prevent necessary significant renovations for the future, maintenance planning should be done and implemented periodically.

This paper helps to understand the expected behavior of GFRC panels and metal claddings for Istanbul province and similar climatic conditions. More data and laboratory analysis is required for this method to produce more reliable façade degradation mapping.

Abstract. *The service life of roofs depends not only on the quality of materials and components but also on several other factors such as workmanship, maintenance, design and substrate. The service life of materials is at production time estimated to a certain number of years. Later when some experience has been gained the service life can hopefully be better predicted. However, the predicted service life can always be questioned because no one knows how long the product or material will last. The durability of a two-layer roofing-felt membrane has been investigated through inspection of several 20 to 30 years old roofs that had aged naturally under in use conditions in a northern humid climate. In 50 % of the inspected roofs, samples were taken out for laboratory test. In this paper, the developed methodology to conduct a service life prediction of roofing membrane is presented. The paper includes a description of the on-site inspection; test conducted in the laboratory which was used as basis for predicting the service life of the two-layer roofing-felt membrane and how these information are extrapolated to a predicted service life. Further, it is discussed if the used methodology for prediction is generally applicable for other types of membranes.*

Keywords: *Natural Ageing, Prediction, Roofing Membrane, Building Survey.*

1 Introduction

The service life of a flat membrane roof is dependent of the material of the membrane but to a large extent also on the design of details and the workmanship. Among the factors affecting the service life are the slope, the number of details, the buildability (how easy it is to build the roof including underlay and details). However, it is a prerequisite that the membrane itself has a long service life and it is the scope of this paper to propose a way to assess the service life of the membrane material. The influence of design, workmanship and maintenance is also influencing the service life of the finished roof, however is less influencing the service life of the roofing-felt membrane as a material.

In Denmark, we use a lot of different materials for roof coverings. For flat roofs (little slope) the traditional material is (bitumen based) roofing felt, which still has the major part of this market. PVC, TPO and other plastic materials only have a small market share.

As well, the membrane materials as the underlays have undergone large changes during the years. The roofing felt was originally a cheap material with a short service life that depended on regular maintenance. Later materials with better composition and better reinforcement were developed but still the service life was very short compared to other roof coverings. One of the reasons for this was that roofs were made without slope. This meant that the membranes were exposed to water for long periods and, even worse, that they – due to the many freezing point

passages in Denmark – were exposed to forces from formation of ice. For some years, the service life for roofing felt in Denmark was only estimated to 12-15 years.

In the beginning of the 1970ies the codes were changed, so a slope of at least 1:40 were required in order to avoid standing water and problems due to ice. Since then, lots of development as regards substrates for roofing membranes and composition (including reinforcement) of roofing felt have taken place. The roofing felts used today are almost exclusively modified bitumen (SBS or APP modified) with reinforcement of polyester (sometimes supplemented with small amounts of glass fibre).

Service life of roofing materials has been a subject of many heated discussions and so far, it has in Denmark not been possible to agree on reference service lives for different roofing materials.

Some roofing materials like clay tiles and zinc have been used for a long time and their service life is relatively well known due to long times experience from practice. For membranes the composition of the materials is changing rapidly and long-term experience are consequently not available. Estimation of service life must therefore be based on other methods *e.g.* accelerated ageing or estimation of service life based on the condition of roofs in practice (which naturally means that the roofs should have a relatively long time of service under in use conditions). In the following, we set forth how estimation of reference service life for a roofing felt was performed in Denmark and give proposal to a methodology for assessing estimation of service life for roofing membranes.

2 Method

As mentioned above estimation of service life may be performed in different ways. In this small study, a combination of visual inspections and laboratory testing was used to estimate/predict the reference service life of a two-layer roofing-felt membrane.

The inspections were only related to the roofing felt itself (not to the welded joints, penetrations etc.). The roofs were located all over Denmark, and had an inclination between 1.4° and 45°. The roofing felt was laid out on an underlay of wooden boards or insulation materials. The 12 inspected roofs were chosen randomly amongst several other roofs constructed in the period 1990 to 1999, *i.e.* 20-30 years old roofing-felt membranes. Amongst the criteria for selecting, the roof was the geographical location, size and accessibility. One roof was new when the roofing felt was installed and 11 roofs were renovations. The inspected roofs had a total area of 26´639 m2. The age and history of the inspected roofs were known as they belonged to a database run by a guarantee body, and the inspected roofs were chosen from this database.

2.1 Inspections

Prior to the inspection, a systematic inspection scheme was developed to obtain a more consistent evaluation of the roofs. The evaluation of the different roof parameters, cf. Table 1, were ranked in four steps from a to d, which described the condition of the roof as

a) in good conditions,
b) with minor degradation,
c) with critical degradation,
d) in need of replacement.

The general information were determined before the inspection and validated on site; however, if a sample was not cut out it could difficult to determine the buildup of the roof and the membrane layers.

Table 1. Content of scheme used for visual inspection.

General information	Area, year of construction, type of membrane, layers, inclination, substrate, fixation
Relevant for evaluation	Overall condition, condition of slate granules, cracks in membrane, traffic areas, walkways, maintenance, biological growth, roof valley, residual service life
Other information	Quality of welded joints, depression or lump, number of details, cracks in coverings, roof light, damage at roof light, installations on roof and fastening, drainage

In connection with the inspection, samples measuring approximately 0.7 x 1.0 m were cut out of six roofs, cf. Figure 1, for later laboratory test, cf. Table 2. The sample was cut out between to welded joints thus; it was possible to repair the roof with a decent result.

a)  b) 
Figure 1. a) Test specimen cut out of roof with a wooden substrate and b) layers of welded roof membranes.

Table 2. The test methods used for testing of samples.

Test method	Title	Deviation
EN 13707:2013 + A2	Flexible sheets for waterproofing. Reinforced bitumen sheets for roof waterproofing. Definitions and characteristics	
FTIR-analysis	Determination of SBS content	None
EN 12311-1:1999	Flexible sheets for waterproofing - Part 1: Bitumen sheets for roof waterproofing - Determination of tensile properties	Only tested in the longitudinal direction
EN 1109:2013	Flexible sheets for waterproofing. Bitumen sheets for roof waterproofing. Determination of flexibility at low temperature	Tested on the entire system and in some cases on fewer specimens than prescribed due to lack of material
EN 12691:2006	Flexible sheets for waterproofing - Bitumen, plastic and rubber sheets for roof waterproofing - Determination of resistance to impact	Tested at -10°C on a substrate of mineral wool instead of testing at 23°C on a substrate of polystyrene or alu-board
EN 12730:2015	Flexible sheets for waterproofing. Bitumen, plastic and rubber sheets for roof waterproofing. Determination of resistance to static loading	None

2.1.1 Results of visual inspections

The results of the visual inspections are that the top membrane in all inspected roofs are assessed as being in good condition. Only minor changes compared to new membranes were visible. The protection in form of slate granules on the surface of the membrane was almost intact, and there were only minor signs of degradation even in valleys and depressions where water may gather occasionally (Figure 2a and 2b). There were in a few cases small cracks in the slate covering – known as “mud cracks” – but even here, there were no signs of degradation of the bitumen below (Figure 3a). In no cases, there were seen degradation to an extent where the reinforcement was visible. There were no signs of shrinkage of the membrane during the inspections, and there were no signs of moisture problems (neither were there reported leaks or moisture problems). On the north facing coverings biological growth was often seen (Figure 3b), which can be eliminated with a regular maintenance. Biological growth was often observed on roofs that were not maintained, however, this did not indicate any signs of degradation of the raw top-roof membrane.

a)

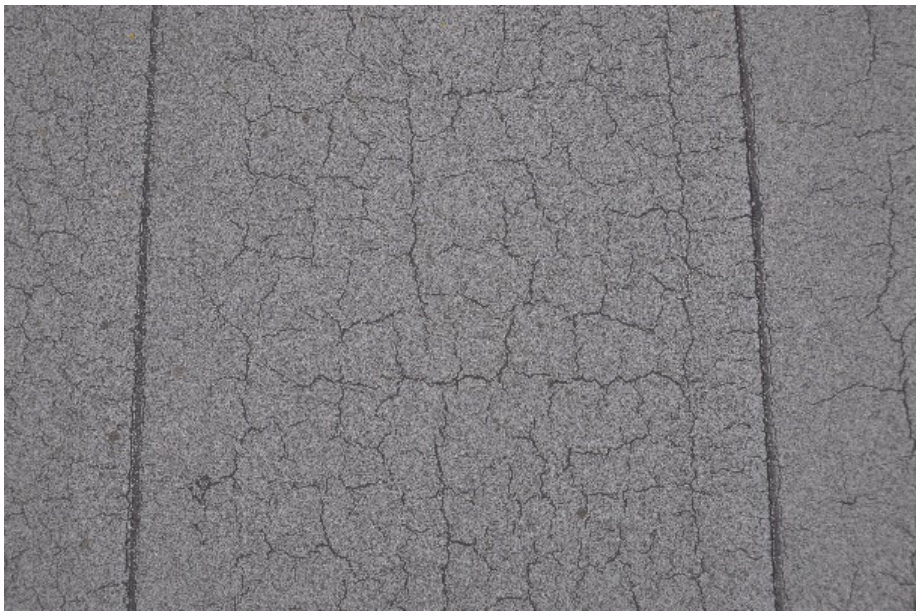
b)

Figure 2. Roof condition at different points. a) Condition of slate is generally good as shown, b) roof valley in equal conditions as other parts of roof membrane.

2.2 Laboratory Tests

In Denmark, we have no legal requirements to the properties of roofing materials apart from the requirement of watertightness. There are on the other hand a number of properties that are normally considered when discussing bituminous roofing membranes. These include:
tensile strength, elongation at break, flexibility under cold conditions and static and dynamic

a)



b)

Figure 3. Roof condition at different points. a) mud crack with fine amount of slate granules and b) biological growth was seen on north facing covering and surfaces, this limited biological growth is assessed not to influence the service life.

load. It seemed natural to base the study on the above mentioned properties. The testing was performed on smaller samples taken from larger samples of 0.7 x 1.0 m from the six roofs. The laboratory tests were conducted on the combined upper and lower roofing-felt membranes, because it was not possible to separate the two membranes. The results from the laboratory test were compared to a reference sample made from a virgin roofing felt (newly produced) as a combination with an upper and lower membrane welded together similar to the samples taken out from the inspected roofs.

The testing was performed at a laboratory that had all the necessary test facilities and was

approved by ETA Denmark. The test facilities was inspected and the testing was supervised by SBi (the Danish Building Research Institute /Aalborg University) and ETA Denmark A/S (that afterwards issued an ETA based on the results of the investigation).

2.2.1 Results of laboratory tests

Tensile strength is often required to be above 500 N/50 mm per sheet of bituminous roofing material and above 1000 N/50 mm for a finished solution with two layers of membrane. This requirement was fulfilled for all the tested specimens.

Elongation at break: The results achieved during testing was all above normal used requirements in many other European countries.

For *flexibility under cold conditions* results under -15 °C were achieved for membranes aged 20-30 years under in use conditions *i.e.* better than the requirements used for new membranes after accelerated heat ageing (often considered to be equivalent to 10 years of natural ageing).

Testing for *static and dynamic load* was passed by all samples with results similar to those for virgin materials.

The *SBS content* in the tested membranes lies in the same range as by production and within the deviations that may be expected by the test method.

In general, all samples that were tested performed very close to the reference samples of virgin welded material.

3 Service Life Prediction

There are no commonly accepted method to be used for prediction of service life based on tests. All predictions are consequently based on subjective judgements.

In this case the prediction of service life of the roofing membrane is based om visual inspections and tests in the laboratory. It is our opinion that both parts of the investigation are important and both should be taken into account when the service life shall be predicted. If one of the two parts gives unsatisfactory output, the service life can at best be assessed to a little longer than the actual service life of the inspected roofs. If both factors are on a good level, the service life can be assessed to be longer than the actual service life of the inspected membranes – the question is only how much longer. This depends on the actual results of both inspections and laboratory tests. Both tests should be weighted equally important and all the investigated parameters determined in the laboratory.

In this study inspections as well as laboratory tests showed very good results. Based on the results the reference service life was estimated to at least 50 years. This result is in accordance with earlier studies in Denmark performed by the Danish Roofing Advisory Board (Brandt and Bunch-Nielsen, 2008) and results from Finnish investigations (Kattoliitto, n.d.).

4 Discussion

The methodology for prediction the service life of 2-ply roofing felt was in this case chosen as explained in *3 Service life prediction* but other methodologies may be used if it appears more relevant. The laboratory test might have been complemented by other tests, cf. below, where it is explained why some test have not been part of this investigation.

Watertightness was not tested, as no leaks or moisture problems have been reported or noted

in the roofs. Further, no leaks were detected after the tests for static and dynamic load.

Strength of connections were not tested as it was impossible to separate the layers in the finished membrane (two layers welded together).

Dimensional stability was not tested as this is most important the first few years after installation (shrinkage is unwanted at installation). There were no signs of shrinkage by the inspections.

Peel and shear resistance is not relevant for 2-ply systems according to EN 13707 table A.1.

5 Conclusion

In this study we used a methodology based on a combination of visual inspections of "old" roofs in situ and test of material properties of samples taken from the inspected roofs. It is our opinion that this method is well suited for estimation of reference service life of roofing membranes. It should be noted that it is a prerequisite that the roofs to be inspected should be relatively "old" compared to the final estimated result of service life. It is also necessary to know the history of the roof membranes *i.e.* to avoid estimation of roof membranes that has been repaired or replaced roof, thus it interfere with the results. We believe that the used methodology may be used for other types of roofing membranes and maybe even more generally for estimation of service life for building materials.

When it comes to the service life of the finished roof it is necessary to take into account also the influence of design, workmanship and maintenance. In Denmark, we have for quite a long period used directions from the Danish Roofing Advisory Board as guidelines (also known as TOR and are published in Danish) for the design of bituminous membrane roofs. This has resulted in a significant decrease in the number of problems we had some 40 years ago *i.e.* good directions help to design properly and thereby reduce the number of failures.

In addition, the workmanship is important, and to ensure a good long lasting roof it is considered crucial that skilled persons are used for the job.

Abstract. *The service life of buildings and components is extremely difficult to model and predict, mainly due to the uncertainty and variability associated with the degradation phenomena. These uncertainties are usually related with the intrinsic randomness of natural phenomena, such as the environmental degradation agents. In order to deal with these uncertainties, in this study, a stochastic approach is used, to model the service life of timber claddings. For this purpose, a logistic regression analysis is used to evaluate the probability of timber claddings to reach the end of their service life over time. Moreover, the impact of the environmental exposure conditions (e.g. facades orientation, distance from the ocean, exposure to damp and exposure to wind/rain action), which influence the degradation and service life of timber claddings, is also evaluated. The proposed models are applied to 150 timber claddings, located in Valdivia (South Chile), which have been analysed during an extensive fieldwork survey. The results obtained in this study aid the definition of maintenance plans, in a technically informed manner, in order to promote the conservation of these claddings, which are an important symbol of the local identity of this region, depicting a complexity of cultural values, inherited by Spanish and German colonisations.*

Keywords: *Durability, Service Life Prediction, Timber Claddings, Chile.*

1 Introduction

A rational approach to the definition of maintenance policies and strategies requires an efficient evaluation of the service life of the building or element under analysis. External claddings are one of the most vulnerable elements of a construction, since are subjected to several degradation agents and mechanisms (Silva *et al.,* 2016). The façade is considered as a building component, acting as the first durability layer, contributing to the building's performance and aesthetic appearance, functioning as the interface of the exterior and the inner environment, thus also contributing to the users' internal comfort. The deterioration rate of timber façades depends on several variables, including location, solar orientation, architectonical details, exposure level, microclimate, and intrinsic properties of materials used in construction. The use of service life prediction methodologies allows a more rational management of the maintenance of buildings and its constructed components by supporting reduced life cycle costs of built assets. This study evaluates the probability distribution of the degradation condition of timber claddings, using the evaluation of the characteristics of 150 cladding systems inspected in Valdivia, Chile. For that purpose, a logistic regression analysis is used, which allows forecasting the probability of the timber claddings to reach the end of their service life over time and according to their environmental exposure conditions. This analysis is relevant in developing countries where there are few studies related to the service life prediction of building components (façades). The scarcity of funds to maintain and preserve the built park and infrastructures needs a more rational approach to decision-making regarding the inspection, maintenance and rehabilitation.

1.1 Degradation Phenomena of Timber Claddings

In 2011, Gaspar and de Brito (2011) proposed a numerical index (severity of degradation - S_w) to express the overall degradation condition of facades claddings. The severity of degradation (S_w) index is obtained by the ratio between the weighted degraded area and the total cladding area, assuming the highest possible level of degradation (equation 1). This methodology was originally developed for rendered facades, establishing a general framework model, and was adapted to new cladding materials, as natural stone claddings, ceramic cladding systems, painted surfaces (Silva *et al.,* 2016).

$$S_w = \frac{\sum(A_n \times k_n \times k_{a,n})}{A \times \sum k_{max.}} \quad (1)$$

Where S_w represents the severity of degradation of timber claddings, expressed as a percentage, k_n is the multiplying factor of anomaly "n", as a function of their degradation level, within the range K = {0, 1, 2, 3, 4}, $k_{a,n}$ is the weighting factor corresponding to the relative weight of the anomaly detected, A_n is the area of cladding affected by an anomaly "n", in m^2, A is the facade area, in m^2, and $\sum(k_{max.})$ is the sum of the weighting factors for the highest degradation level of each anomaly type in a cladding with an area equal to A. In Table 1, the different types of anomalies detected are classified according to five degradation levels, considering the extent of the cladding affected by them. The degradation levels proposed vary between level A (very good condition) - the most favourable condition, corresponding to claddings with no visible degradation - and level E (severe degradation) - the worst possible condition, corresponding to claddings with generalised degradation.

Table 1. Degradation levels adopted for timber claddings.

Degradation level	Anomalies group	Anomalies description	$k_{a,n}$	% Area of cladding affected
Level A (Very good) $S_w \leq 1\%$	-	No visible degradation	-	-
Level B (Good condition) $1\% < S_w \leq 10\%$	Aesthetic	AA1 Staining or color change (dirty surface)	0.3	≤ 15%
		AA2 Wearing or detachment of the finishing layer	0.7	≤ 10%
	Loss of integrity	AB1 Warping, swelling or other flatness deficiencies	0.5	≤ 10%
Level C (Slight degradation) $10\% < S_w \leq 20\%$	Aesthetic	AA1 Staining or color change (dirty surface)	0.3	> 15%
		AA2 Wearing or detachment of the finishing layer	0.7	> 10% to ≤ 50%
	Loss of integrity	AB1 Warping, swelling or other flatness deficiencies	0.5	> 10% to ≤ 50%
		AB2 Cracking of elements and/or joints (possibly from substrate cracking)	0.9	≤ 20%
		AB6 Moisture (Oxyde) / Biocostra	0.5	≤ 30%
		AB8 Delamination	1.0	≤ 10%
		AB9 Crumbling	1.2	≤ 10%
Level D (Moderate degradation) $20\% < S_w \leq 40\%$	Aesthetic	AA2 Wearing or detachment of the finishing layer	0.7	> 50%
	Loss of integrity	AB1 Warping, swelling or other flatness deficiencies	0.5	> 50%
		AB2 Cracking of elements and/or joints (possibly from substrate cracking)	0.9	> 20%
		AB3 Broken or splintered elements	1.0	≤ 20%
		AB4 Detachment of elements from substrate (lack of adherence)	1.2	≤ 10%
		AB6 Moisture (Oxyde) / Biocostra	0.5	> 30%
		AB5 Rot	1.2	≤ 10%
		AB7 Xylophage attack	1.0	≤ 10%
		AB8 Delamination	1.0	> 10% to ≤ 30%
		AB9 Crumbling	1.2	> 10% to ≤ 30%
Level E (Severe degradation) $S_w > 40\%$	Loss of integrity	AB3 Broken or splintered elements	1.0	> 20%
		AB4 Detachment of elements from substrate (lack of adherence)	1.2	> 10%
		AB5 Rot	1.2	> 10%
		AB7 Xylophage attack	1.0	> 10%
		AB8 Delamination	1.0	> 30%
		AB9 Crumbling	1.2	> 30%

2 Probabilistic Analysis of Timber Claddings Reaching the End of their Service Life Over Time

A logistic regression analysis is used to model the probability of timber claddings reaching the end of their service life over time and according to their environmental exposure conditions. Logistic regression is one of the most used statistical procedures, which allows describing the relationship between a categorical dependent variable and one or more explanatory variables, in terms of the probability of a given event. In this study, the dependent variable corresponds to the question "Has the timber cladding reached the end of its service life?", and this question presents two mutually exclusive classes: "yes" and "no". For the timber claddings under analysis, it is assumed that a cladding reaches the end of its service life, when presents a set of anomalies corresponding to a severity of degradation of 20%. Figure 1 shows an illustrative example of a timber cladding in the end of its service life. The limit to establish the end of service life is conventionally defined and is related to the Chilean context, and with the users' acceptance criteria. This theoretical limit can change according to the buildings' economic and social context or even funds available for maintenance actions. The sample analysed is composed by 150 timber claddings, located in Valdivia (South Chile), and only 8% of the claddings have reached the end of their service life. In the first analysis performed, only the age of the claddings is used as explanatory variable.

Figure 1. Case study that exemplifies the end of the service life of timber claddings.

The proposed model, described by Equation (2), allows evaluating the probability of a timber cladding reach the end of its service life according to its age. The goodness-of-fit of the proposed models to the dataset under analysis is evaluated through the Chi-square test (χ^2) and the Chi-square test of Hosmer-Lemeshow (χ_{HL}^2). These tests are easy to compute and are present in the statistical software used in this study; furthermore, as mentioned in Silva et al. (2016), these tests have been widely used mainly due to the nonexistence of better approaches. For the Chi-square test (χ^2) test, a *p*-value around 1 reveals a better fit to data than a model that only has the constant; on the other hand, a *p*-value around 1 for χ_{HL}^2 test, reveals that the age of the claddings or the other independent variables included in the model, are relevant for the end of service life of timber claddings. The model summary ($\chi^2(148) = 17.826$, $p = 1.00$) and the Hosmer and Lemeshow test ($\chi_{HL}^2(8) = 0.133$, $p = 1.00$) reveal an adequate adjustment of the model to the sample under analysis. The Wald test (χ_{Wald}^2 (1) = 12.163, with $p = 0.00$) shows that the age is statistically relevant to predict the probability of timber claddings reaching the end of their service life.

$$P(Y = "End\ of\ service\ life") = 1 - \frac{1}{1+e^{-18.200+0.539Age}} \quad (2)$$

Figure 2 shows the probabilistic distribution of timber claddings reaching the end of their service life over time. As expected, the probability of timber claddings reaching the end of their service life increases with the claddings' age. After 33.8 years, a timber cladding presents a probability higher than 50% of have reached the end of its service life, after 35.8 years, this probability is higher than 75% and after 37.9 years, it is higher than 90%.

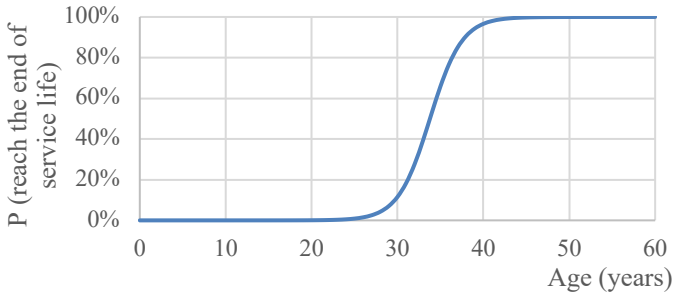

Figure 2. Distribution of probability of timber claddings reaching the end of their service life over time.

Table 2 shows the classification table of the proposed model, which allows evaluating the percentage of timber claddings correctly classified by the model, i.e. the classification table provides the accuracy of the model, evaluating the capability of the model discriminate the case studies that has reached the end of their service life from the case studies that has not reached this limit. The proposed model classifies correctly 97.3% of the timber claddings analysed, revealing that the model presents a good classification capability.

Table 2. Classification table of the proposed model.

Observed		*Predicted*		
		Has the timber cladding reached the end of its service life?		**Percentage correct**
		No	Yes	
Has the timber cladding reached the end of its service life?	No	136	2	98.6
	Yes	2	10	83.3
Overall percentage				97.3

3 Probabilistic Analysis of Timber Claddings Reaching the End of their Service Life according to the Environmental Exposure Conditions

Wood is frequently used as external cladding, mainly due to aesthetic, ecological or architectural reasons. Nevertheless, wood is extremely susceptible to various degradation agents and mechanisms (e.g. wetting, microorganisms, fungi or algae, xylophage agents), especially related with the environmental exposure conditions (Brischke *et al.,* 2017). In this sense, in this study, the influence of the environmental exposure conditions in the service life of timber claddings, located in Valdivia (Chile) is analysed. For this purpose, the influence of the exposure to damp, the façades orientation, the wind-rain action and the exposure to sea salts (distance from Pacific Ocean) is evaluated. In Figure 3, the probability of timber claddings reaching the end of their service life over time, according to their exposure to damp, is analysed. For the exposure to damp, two categories are considered (Silva *et al.,* 2016): i) high, for claddings located near to damp sources, in contact with the terrain, in areas with high relative humidity, and not protected by adjacent buildings; and ii) medium, for claddings that are not directly exposed to damp sources. Equation (3) allows estimating the probability of a timber cladding to reach the end of its service life over time and according to its exposure to damp, where the variable "Age" must be replaced by the age of the timber claddings and the variable "Damp" must be replaced by 1 if the timber cladding presents a high exposure to damp and by

0 if the cladding shows a medium exposure to damp. This model correctly classifies 97.3% of the timber claddings under analysis.

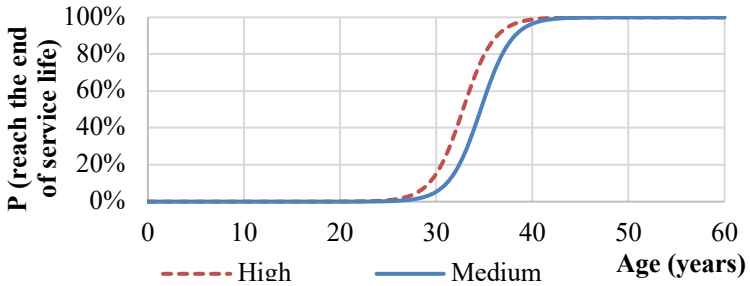

Figure 3. Distribution of the probability of timber claddings reaching the end of their service life over time, according to their exposure to damp.

$$P(Y = "End\ of\ service\ life") = 1 - \frac{1}{1+e^{-21.462+0.620Age+1.143Damp}} \quad (3)$$

Figure 4 shows the probability of timber claddings reaching the end of their service life over time, according to façades orientation. This probability can be estimated using Equation (4), where in the variable "façades orientation", the symbol of the category corresponding to the timber cladding analysed should be replaced by 1, and the remaining categories' symbols by 0. The logistic regression model obtained, adopting the variable age and façades orientation correctly classifies 98% of the sample analysed.

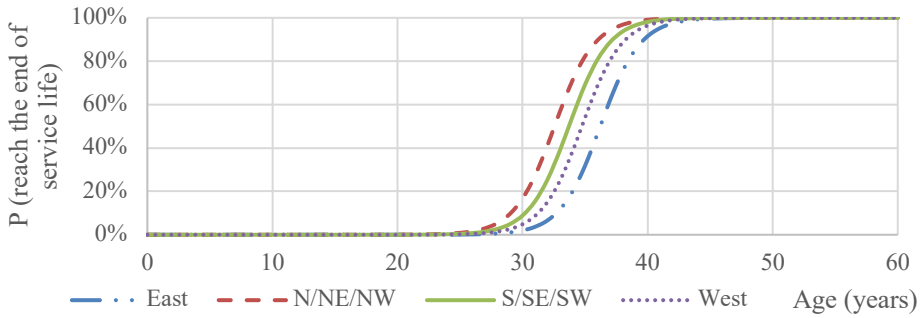

Figure 4. Distribution of the probability of timber claddings reaching the end of their service life over time, according to façades orientation.

$$P(Y = "End\ of\ service\ life") = 1 - \frac{1}{1+e^{-21.826+0.628Age-0.921E+1.375N/NE/NW+0.652S/SE/SW}} \quad (4)$$

Figure 5 presents the probability of timber claddings reaching the end of their service life over time, according to their exposure to wind-rain action. In this study, two categories are adopted to characterise the exposure conditions of timber claddings to the combined action of wind and rain: i) unfavourable, for claddings located in tall buildings, located in areas unsheltered by surrounding buildings or vegetation, thus exposed to prevailing winds; and ii) current, for claddings protected from the direct incidence of rain and prevailing winds. Equation (5) allows evaluating the probability of a timber cladding to reach the end of its service life according to its age and exposure to wind-rain action, where the variable "Wind" must be replaced by 1 if the timber cladding presents an unfavourable exposure to wind-rain action and by 0 if the cladding shows a current exposure. This model correctly classifies 97.3% of the timber claddings analysed.

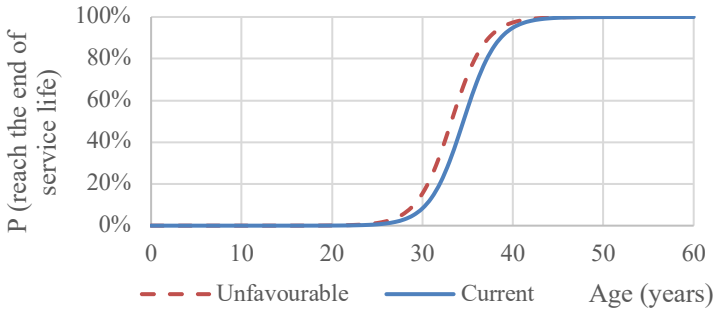

Figure 5. Distribution of the probability of timber claddings reaching the end of their service life over time, according to their exposure to wind-rain action.

$$P(Y = "End\ of\ service\ life") = 1 - \frac{1}{1+e^{-18.369+0.532Age+0.703Wind}} \quad \textbf{(5)}$$

In Figure 6, the probability of timber claddings reaching the end of their service life over time, according to their distance from the Pacific Ocean, is shown. In this analysis, two categories are considered: i) claddings located at more than 5km from the Pacific Ocean; and ii) claddings located at less than 5km from the Pacific Ocean. Equation (6) allows estimating this probability, where the variable "Ocean" must be replaced by 1 if the cladding is located at less than 5km from the Pacific Ocean and by 0 if the cladding is located at more than 5km. This model presents a classification capability of 97.3%.

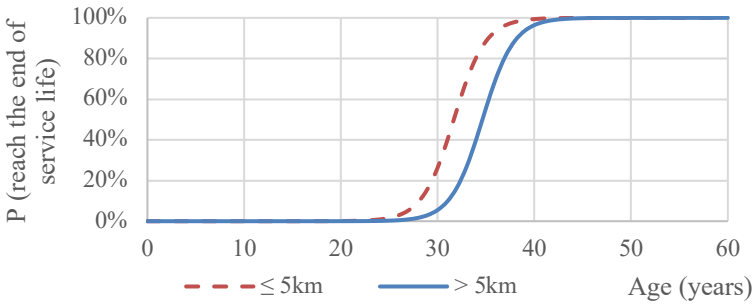

Figure 6. Distribution of the probability of timber claddings reaching the end of their service life over time, according to their distance from the Pacific Ocean.

4 Results and Discussion

Bio-materials, as timber, when applied in façade claddings, are exposed to several degradation agents, which generally are biotic agents (fungi, insects, moulds, algae) and abiotic agents (water, solar radiation, gradient of temperature, pollutants) (Sandak *et al.,* 2019). Other factors, such as the building orientation and its surrounding environment, presence of adjacent buildings, vegetation, and the proximity of water reservoirs (Silva *et al.,* 2016; Prieto and Silva, 2019), can also compromise the durability of timber claddings. Moreover, the degradation mechanisms usually occur simultaneously, affecting the degradation pattern over time and the extent damages among the different timber claddings analysed. Based on the sample analysed (150 timber claddings located in South Chile), and according to the stochastic models proposed, the following conclusions can be drawn (Table 3).

This analysis reveals that after 33.8 years, a timber cladding presents a probability higher than 50% of have reached the end of its service life and after 37.9 years, this probability is higher than 90%. These results are in accordance with the literature related with the durability of timber claddings, which suggests an estimated service life between 30 to 35 years for wood materials in outdoor exposure environments.

The weathering of timber claddings occurs mainly due to abiotic agents, which present a significant impact in the degradation process of timber claddings in South Chile due to their exposition to severe climatic conditions. In most cases, weathering leads to cracking, colour changes or alterations in the finishing layer (Sandak *et al.,* 2019).

A high exposure to damp contributes to the presence of fungi decay, insects, moulds and algae growth, among other biotic factors (Sandak *et al.,* 2019). Although the presence of mould does not affect the structural properties of wooden façades, it has a large effect on the aesthetical service life of the cladding. Mould leads to the claddings' discolouration, unpleasant odour, and health problems. This factor usually appears in environmental conditions like in Valdivia, where relative humidity (RH) is higher than 75% and the temperature ranges between 0 and 45 ºC. Algae, which promotes the colour change of timber claddings, normally occurs in contexts with RH > 95% and temperature fluctuations from 0ºC to 45ºC. Timber claddings with high exposure to damp reach the end of their service life sooner (with a probability of 95% of have reached the end of its service life after 37.5 years - Table 3), than claddings with a low exposure, which reach the end of their service life around two years later (39.4 years). In the sample analysed, timber claddings with high exposure to damp have a higher incidence of rot and xylophage attack.

Regarding the surfaces' orientation, claddings facing North are more exposed to UV radiation, suffering significant thermal gradients. On the other hand, timber claddings facing South, in Chile, are more exposed to the presence of damp. Claddings facing East and West are the most affected by wind-rain action in Valdivia. Table 3 shows that timber claddings facing North reach the end of their service life sooner (with a probability higher than 95% of reaching the end of their service life, after 37.2 years), followed by claddings facing South (38.4 years) and by the claddings facing the remaining orientations (West - 39.4 years; East - 40.9 years) (Table 3). The main anomalies detected in claddings facing North orientation were related with wearing or detachment of the finishing layer, broken or splintered elements and detachment of elements from substrate.

Table 3. Analysis of the probability of timber claddings reach the end of their service life, according to their environmental exposure conditions.

Environmental exposure conditions		Age where a timber cladding achieves a probability of 50% of have reached the end of its service life	Age where a timber cladding achieves a probability of 75% of have reached the end of its service life	Age where a timber cladding achieves a probability of 90% of have reached the end of its service life	Age where a timber cladding achieves a probability of 95% of have reached the end of its service life
Exposure to damp	High	32.8	34.6	36.4	37.5
	Medium	34.7	36.4	38.2	39.4
Facades orientation	N	32.6	34.3	36.1	37.2
	S	33.7	35.5	37.2	38.4
	W	34.4	36.5	38.3	39.4
	E	36.2	38.0	39.7	40.9
Exposure to wind and rain action	Unfavourable	33.2	35.3	37.4	38.8
	Current	34.5	36.6	38.7	40.1
Distance from the Pacific Ocean	< 5km	31.7	33.5	35.5	36.5
	> 5km	34.6	36.4	38.2	39.3

The level of exposure to the combined action of wind and rain is influenced by the façades orientation, as well as by the height of the building, the presence of adjacent buildings or even vegetation. In this study, façades with an unfavourable exposure to wind-rain action reach the end of the service life sooner (with a probability higher than 95% of reaching the end of their service life, after 38.8 years), when compared with façades with a current exposure (40.1 years).

In the sample analysed, timber claddings with a high exposure to wind and rain are more prone to present staining or colour change, cracking and presence of crumbling.

Finally, timber surfaces close to the Pacific Ocean (< 5 km) reached the end of their service life sooner (with a probability higher than 95% of reaching the end of their service life, after 36.5 years) than cases located at more than 5 km from the Ocean coastline (39.3 years) (Table 3). Timber claddings closer to the seashore show a higher incidence of anomalies such as cracking of elements and/or joints and wearing or detachment of the finishing layer.

5 Conclusions

In this study, a logistic regression analysis is used to evaluate the probability of timber claddings to reach the end of their service life over time and according to the claddings' environmental exposure conditions (*e.g.* facades orientation, distance from the ocean, exposure to damp and exposure to wind/rain action). According to the proposed model, the 150 timber claddings analysed present a probability higher than 50% of reaching the end of their service life after 34 years, which is in accordance with the literature and the empirical knowledge related with the degradation of these claddings. As expected, timber façades with unfavourable conditions (closer to the Pacific Ocean, facing North (N) and South (S) orientations and with high exposure to environmental agents, i.e. damp and wind-rain actions) are more prone to reach sooner the end of their service life. In the sample analysed, the most common anomalies detected were staining or colour change; wearing or detachment of the finishing layer; cracking of elements and/or joint; warping, swelling or other flatness deficiencies; and broken or splintered elements.

This model allows predicting the end of service life of timber claddings, i.e. the instant after which is necessary to intervene, in order to improve the claddings' condition, ensuring that the cladding is able to fulfil the users and owners' demands and expectations, in a probabilistic way. In this sense, the model allows knowing the risk associated with the service life values estimated by the model, and the risk of failure of the timber claddings over time and according to the environmental degradation agents that influence the degradation of the timber claddings under analysis. The results obtained can be useful for a further knowledge of the durability and service life of timber claddings and can be employed to aid the adoption of rational and adequate maintenance policies. In fact, the analysis of the timber claddings' degradation and service life in South Chile (Los Rios region), allows establishing new and adapted strategies and maintenance plans, to reduce the repair costs and to optimise the use of scarce resources, as well as promoting new approaches to maintain cultural identities of the southern regions of Chile, in which the wood is one of the main natural resources.

Abstract. *Inclined defects in pipelines can lead to failures in the form of mixed mode fracture. A review of the literature suggests that few studies have been carried out on reliability assessment of pipelines considering mixed mode fracture. This paper intends to present a reliability-based method for assessing fracture failures of pressurized pipes with inclined defects. Richard's criterion is employed in the development of the limit state function for reliability assessment. A Stochastic model of load effects is developed, and first passage method with a developed analytical solution is used to predict the pipe failures. A worked example is provided to illustrate the application of the proposed method. The method presented in this paper can help pipe engineers and asset managers to develop a reliability-based maintenance strategy for better management of pipelines.*

Keywords: *Pressurized Pipes, Inclined Crack, Mixed Mode Fracture, Time-Dependent Reliability, First Passage Probability.*

1 Introduction

Pipelines are widely used as one of the safest and most economical structures to transport gas or liquid (*e.g.*, water; natural gas) in industries (Keshtegar and Miri, 2014). However, most of them have been in service for a long time, and the exposure to the corrosive environment increases the likelihood of failures before the end of the intended design life (Carbal and Kimber, 1997). The consequences of pipeline failures can be economically, socially, and environmentally devastating (Mahmoodian and Li, 2017). Therefore, it is essential to fully understand the failure mechanisms of pipes and accurately predict its service life.

A literature review suggests that most of the previous researches on the pipe failure assessment mainly considered the loss of strength due to the reduction of wall thicknesses of pipes (*e.g.*, Ahammed and Melchers, 1997; Mahmoodian and Li, 2017; Liu *et al.*, 2019). Nevertheless, it has been found that pipe failures are more likely to be fracture type due to the stress concentration near the tips of crack-like defects (Li and Mahmoodian, 2013; Fu *et al.*, 2019). As the cracked structures often fail unexpectedly at the applied stress much below the material strength (Anderson, 2005), it is necessary to assess the integrity of pipeline based on fracture mechanics. Also, the defects on the pipe walls are often caused by corrosion, which can grow in any directions depending on the heterogeneity of surrounding soil properties (Wang *et al.*, 2018; Wang *et al.*, 2019). Moreover, the crack-like defects in pipes most likely grow in an inclined manner because of the complex stress state (Li *et al.*, 2016). As a result, in these pipes (*e.g.*, Figure 1), the failures can be induced by a mixed mode loading interaction. Some previous researches (*e.g.*, by Erdogan and Shih, 1968; Chang *et al.*, 2006) indicated that the single mode fracture failure criterion is seldom appropriate for assessing the integrity of structural components with inclined cracks. Thus, a method based on mixed mode fracture criteria is more appropriate to assess the fracture failures of pipes. To predict the pipe failures, time-dependent reliability methods have been successfully used since the parameters associated with pipe

failures are highly uncertain and changing with time (Fu *et al*., 2019). Although several researchers, *e.g*., Li and Mahmoodian (2013); Fu *et al*., (2019); Wang *et al*., (2019), have assessed the probability of pipe failures using time-dependent reliability methods for different defect types (*e.g*., sharp corrosion pit; elliptical corrosion pit), these works only focuses on Mode I (opening mode) fracture failure. The reliability assessment of pipelines with inclined defects considering mixed mode fracture, in comparison, is highly limited.

This paper presents a time-dependent reliability method for pressurized pipe based on first passage probability theory. The cast iron pipe with an external inclined crack-like defect is considered in this paper. A stochastic model of the stress intensity factor is developed by incorporating Richard's criterion into the limit state function. A case study is presented to illustrate the proposed method. The proposed method can be applied to the risk-based maintenance strategy for pipelines.

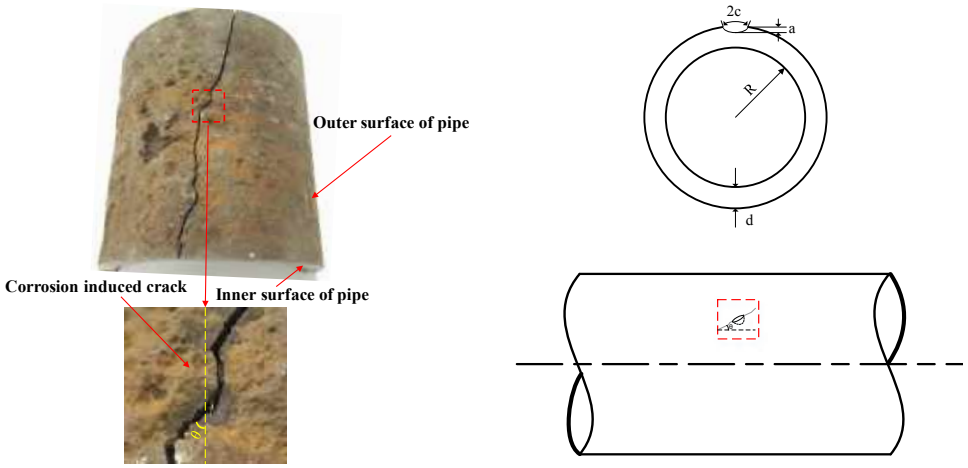

Figure 1. A pressurized pipe with inclined external surface defects.

2 Problem Formulation

To determine the probability of failure of a pipe, a failure criterion must be established. In the structural reliability theory, the criterion can be expressed in the form of a limit state function as follows (Melchers, 1999):

$$G(L,R,t) = L(t) - R(t) \tag{1}$$

where $L(t)$ is the load effect on the structures at time t; $R(t)$ is the acceptable limit (resistance) at time t. As both load effect ($L(t)$) and acceptable limit ($R(t)$) are time-dependent, all or some of the basic variables should be modelled as stochastic processes. For reliability problems involving the stochastic processes, the structural failure event is that the stochastic processes of the load action process $L(t)$ initially pass upwards an acceptable limit (threshold) $R(t)$ during the service life. With the assumption of Poisson processes, the probability of failure can be determined as follows (Melchers, 1999):

$$P_f(t) = 1 - [1 - P_f(0)]e^{-\int_0^t v\,dt} \tag{2}$$

where P indicates the probability of an event; $P_f(0)$ is the probability of failure at time $t = 0$ and v is the mean rate for the load action process $L(t)$ to cross upwards the threshold $R(t)$. The up-crossing rate v can be determined by the Rice formula (Rice, 1944)

$$v = v_R^+ = \int_{\dot{R}}^{\infty} (\dot{R} - \dot{L}) f_{L\dot{L}}(L, \dot{R})\, d\dot{L} \tag{3}$$

where v_R^+ is the up-crossing rate of the load action process $L(t)$ relative to the threshold $R(t)$; $\dot{R}$ is the slope of R with respect to time; $\dot{L}$ is the time derivative process of L; $f_{L\dot{L}}$ is the joint probability density function for L and $\dot{L}$. Li and Melchers (1993) derived an analytical solution to Equation (3) when $L(t)$ is a Gaussian process and the threshold R is deterministic. It is expressed as follows:

$$v_R^+ = \frac{\sigma_{\dot{L}|L}}{\sigma_L} \phi\left(\frac{R - \mu_L}{\sigma_L}\right) \left\{ \phi\left(\frac{\dot{R} - \mu_{\dot{L}|L}}{\sigma_{\dot{L}|L}}\right) - \frac{\dot{R} - \mu_{\dot{L}|L}}{\sigma_{\dot{L}|L}} \Phi\left(-\frac{\dot{R} - \mu_{\dot{L}|L}}{\sigma_{\dot{L}|L}}\right) \right\} \tag{4}$$

where μ and σ are the mean and standard deviation of random variables represented by subscripts L and $\dot{L}$; $'|'$ denotes the condition; ϕ and Φ indicate the standard normal density and distribution functions. For a given Gaussian stochastic process with mean function $\mu_L(t)$ and auto-covariance function $C_{LL}(t_i, t_j)$, all terms in Equation (4) can be determined as follows:

$$\mu_{\dot{L}|L} = E\left[\dot{L} \middle| L = R\right] = \mu_{\dot{L}} + \rho_L \frac{\sigma_{\dot{L}}}{\sigma_L} (R - \mu_L) \tag{5a}$$

$$\sigma_{\dot{L}|L} = [\sigma_{\dot{L}}^2 (1 - \rho_L^2)]^{1/2} \tag{5b}$$

where $\mu_{\dot{L}} = d\mu_L(t)/dt$; $\sigma_{\dot{L}} = \left[\partial^2 C_{LL}(t_i, t_j) / (\partial t_i \partial t_j)\big|_{i=j}\right]^{\frac{1}{2}}$; $\rho_L = C_{L\dot{L}}(t_i, t_j) / [C_{LL}(t_i, t_j) \cdot C_{\dot{L}\dot{L}}(t_i, t_j)]^{\frac{1}{2}}$; and $C_{L\dot{L}}(t_i, t_j) = \partial C_{LL}(t_i, t_j)/\partial t_j$.

For Equation (4) to be of practical use, the key is to establish an appropriate limit state function for the mix mode fracture failure of pipes. Richard (2001) developed a fracture criterion to simplify the prediction of crack growth under multiaxial loadings. According to Richard (2001), unstable crack growth in brittle materials would occur if the local loading condition along the crack front reaches a critical value, which described by the following expression (Richard, 2001):

$$K_v = \frac{K_I}{2} + \frac{1}{2}\sqrt{K_I^2 + 4(\alpha_1 K_{II})^2 + 4(\alpha_2 K_{III})^2} \geq K_{IC} \tag{6}$$

where K_v is an equivalent stress intensity factor; K_I, K_{II}, and K_{III} are the Mode I (opening mode), Mode II (in-plane shear mode), and Mode III (out-of-plane shear mode) stress intensity factors, respectively; K_{IC} is the Mode I fracture toughness which quantifies the material resistance to crack extension; $\alpha_1 = K_{Ic}/K_{IIc}$ and $\alpha_2 = K_{Ic}/K_{IIIc}$ with K_{IIc} as the fracture toughness for pure Mode II and K_{IIIc} as the fracture toughness for pure Mode III. With $\alpha_1 = 1.155$ and $\alpha_2 = 1.0$, Equation (6) was found having an excellent agreement with other criteria (*e.g.*, developed by Schöllmann *et al*., 2002) and the experimental data in brittle materials (Richard *et al*., 2014). Based on Richard's criterion, Equation (1) can be expressed as:

$$G(t) = \frac{K(t)_I}{2} + \frac{1}{2}\sqrt{K(t)_I^2 + 5.3361 K(t)_{II}{}^2 + 4 K_{III}{}^2} - K(t)_{IC} \tag{7}$$

The determination of stress intensity factors is presented in the next section.

3 Model of Load Effects

The stress intensity factor (K) represents the magnitude of the stress fields surrounding the tip of crack or crack-like defect. Its magnitude depends on the far-field stress level σ, the size of crack a, and the geometries of the bodies. For a pipe with an external inclined defect as shown in

Figure 1, the stress intensity factor K can be generalised as follows (Li *et al*., 2016):

$$\boldsymbol{K} = \frac{pR}{d}\sqrt{\pi\frac{a}{Q}}\boldsymbol{F}\left(\frac{a}{d},\frac{a}{c},\frac{d}{R},\xi,\theta\right) \tag{8}$$

where $\boldsymbol{K} = \{K_I, K_{II}, K_{III}\}^T$; p is the internal pressure; pR/d is the average hoop stress in pipes; ξ is used to define the position of an arbitrary point along the semi-elliptical crack; θ, c, d, and R are defined in Figure 1; Q is the shape function which can be expressed as follows (Shiratori and Miyoshi, 1986):

$$Q = 1 + 1.464\left(\frac{a}{c}\right)^{1.65}; \quad \frac{a}{c} \leq 1 \tag{9}$$

In Equation (8), $\boldsymbol{F}\left(\frac{a}{d},\frac{a}{c},\frac{d}{R},\xi,\theta\right) = \{F_I, F_{II}, F_{III}\}^T$, where F_I, F_{II}, and F_{III} are the influence coefficient functions for Mode I, II, and III, respectively. Li *et al*., (2016) have developed the influence coefficients of stress intensity factors for inclined cracks in pipes under internal pressure using three-dimensional finite element analysis. The approximations of the influence coefficients can be expressed as follows:

$$F_I = M_I N_I sin^2(h_I^{11} + h_I^{12}\theta) \tag{10a}$$

$$F_{II} = M_{II}[h^6(\xi) + h^7(\xi)^3]\, sin(h_{II}^8 + h_{II}^9\theta) \tag{10b}$$

$$F_{III} = M_{III} N_{III}\, sin(h_{III}^{11}\theta) \tag{10c}$$

where $M_i = h_i^1 + h_i^2\left(\frac{a}{d}\right) + h_i^3\left(\frac{a}{d}\right)^2 + h_i^4\left(\frac{a}{d}\right)^3 + h_i^5\left(\frac{a}{d}\right)^4$; $N_i = h_i^6 + h_i^7(\xi)^2 + h_i^8(\xi)^4 + h_i^9(\xi)^6 + h_i^{10}(\xi)^8$ with the coefficients, h_i^n $(n = 1 - 12)$ are given in Table 1.

The crack size a can be represented by the corrosion pit depth. A widely accepted model for corrosion pit depth is employed in this paper, which is expressed as follows (Kucera and Mattsson, 1987):

$$a(t) = kt^n \tag{11}$$

where k and n are empirical coefficients to be determined from field data.

Apart from the growth of corrosion pit, the operating internal pressure and pipe wall thickness also change with time. Therefore, it is justifiable to model the load effect $L(t)$ as a stochastic process. The randomness of the load effect can be taken into account by introducing a random variable, ξ_L. This variable is defined in such a way that its mean is unity, i.e., $E(\xi_L) = 1$, and its coefficient of variation, λ_L, is a constant (Mahmoodian and Li, 2017). The load effect can be expressed as follows:

$$L(t) = L_c(t) \cdot \xi_L \tag{12}$$

where $L_c(t)$ is treated as a pure time function determined by the load effect function. The mean and auto-covariance functions of $L(t)$ can be expressed as follows (Li and Melchers, 2005):

$$\mu_L(t) = E[L(t)] = L_c(t) \cdot E[\xi_L] = L_c(t) \tag{13}$$

$$C_{LL}(t_i, t_j) = \lambda_L^2 \rho_L L_c(t_i) L_c(t_j) \tag{14}$$

where ρ_L is the auto-correlation coefficient for $L(t)$ between two points in time t_i and t_j.

Table 1. Values of h in Equation (10) with $d/R = 0.1$ and $a/c = 0.4$ (Li *et al*., 2016).

Constant	i = I	i = II	i = III
h_i^1	0.957	-0.427	0.742
h_i^2	0.504	-0.123	0.076
h_i^3	0.256	0.114	-0.070
h_i^4	0.155	-0.019	0.073
h_i^5	0.088	-0.346	0.309
h_i^6	0.983	0.454	0.618
h_i^7	-0.059	0.186	-0.101
h_i^8	-0.044	3.142	-0.604
h_i^9	0.023	-2.001	1.279
h_i^{10}	-0.166		-1.016
h_i^{11}	1.589		1.997
h_i^{12}	0.994		

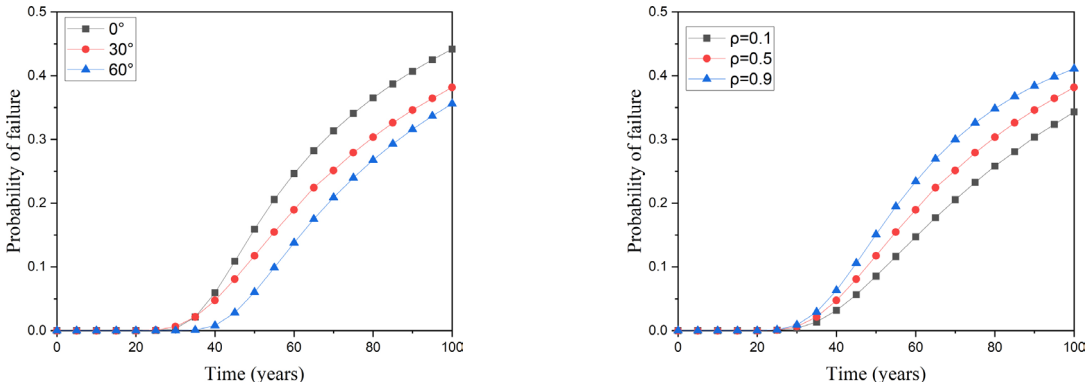
4 Worked Example

The proposed methodology is applied to a case study in which a cast iron pipe with inclined corrosion pits is considered. To calculate the stress intensity factors, the influence coefficient functions for Mode I, II, and III are determined by means of the constants in Table 1 and the assumption of aspect ratio $a/c = 0.4$. According to Li *et al*., (2016), for $a/c = 0.4$, the critical stress intensity factor occurs at the deepest points along the crack front. The crack front normalized coordinate ξ is assumed to be 0.1. The pipe characteristics and the geometric information of corrosion pit are summarised in Table 2.

Table 2. Values of variables for reliability analysis in the worked example.

Basic variables	Mean	C.O.V	Reference
k	2.540	0.197	Mahmoodian and Li (2016)
n	0.320	0.188	Mahmoodian and Li (2016)
R	127 mm	-	Li and Mahmoodian (2013)
d	16 mm	-	Li and Mahmoodian (2013)
P	0.45 MPa	0.27	Sadiq *et al*., (2004)
K_{Ic}	7.66 MPa/m$^{0.5}$	-	Marshall (2010)

The load effect is calculated by Equation (8), (9) and (10). The mean of function μ_L and standard deviation σ_L can be calculated as a function of time using Monte Carlo simulation together with the proposed model of pit depth. The up-crossing rate v_R^+ can be obtained from Equation (5) for a given auto-correlation coefficient, and the probability of failure can be calculated by Equation (2).



(a) (b)

Figure 2. Probability of pipe failure: (a) for different inclination angles with $\rho\rho = 0.5$; (b) for different auto-correlation coefficients with $\theta\theta = 30°$.

The calculation results of the probability of failure with different inclination angles and auto-correlation coefficients are shown in Figure 2. The probability of pipe failure increases with the exposure time due to the growth of pit depth. Also, it can be seen that the probability of failure decreases with the increase of the inclination angles since the equivalent stress intensity factor KK_{vv} in Equation (6) drops markedly with the increase of angles $\theta\theta$. Moreover, the auto-correlation coefficients affect the pipe fracture failure significantly since the fracture failure of pipes depends on many factors. These factors, such as pipe geometries, internal pressure, and corrosion pit depth, are interrelated at different time points in service life. As a result, the load effect is correlated in the time domain. The considerable difference in the probability of failure under different $\rho\rho$ justifies the necessity of using a time-dependent reliability method based on the concept of first passage probability theory.

5 Conclusion

In this study, the time-dependent failure probability of pipes with inclined crack-like defects was calculated, in which a mixed mode fracture criterion was used to establish the limit state function. First passage probability theory was employed to predict the pipe failures. A case study was provided to illustrate the proposed method. From the results of the case study, it has been found that the stress intensity factors increase rapidly with the increase of corrosion pits depth, and the probability of pipe failure increases for longer service time. Moreover, the probability of failure is highly sensitive to both the auto-correlation coefficients and inclination angles. The smaller the inclination angle is, the higher the probability of failure. As such, for engineering assessment of pipes with inclined defects, more attention should be paid to the defects with smaller inclination angles. The proposed method can be applied to the development of rehabilitation strategies for existing pipe networks.

Seismic Performance of the Reinforced Concrete Girders Obtained from an Existing Building Constructed in 1961

Hideo Araki

Faculty of Engineering, Hiroshima Institute of Technology, Asakita-ku Miyake 2-1-1, Japan,
h.araki.k4@it-hiroshima.ac.jp

Abstract. *This study examines, through experiments, two reinforced concrete girders obtained from a residential building constructed in 1961. The average concrete strength obtained from the material tests was approximately consistent with the specified strength. Honeycombs were observed in girders; hence, one of the girders was repaired using an epoxy resin injection to investigate the effect of retrofitting. The original and retrofitted girders were subjected to reverse loadings with displacement control and had a sectional area of 250 mm × 800 mm, according to the structural draft. Both girders were designed to exhibit a common shear span length of 1,200 mm to evaluate the validity of the current equations for shear capacity in seismic evaluation, as recommended in the criteria for seismic assessment in Japan. Using these equations, the ratio of the shear strength to flexural strength of the test girders was found to be 1.67. No significant difference was observed in the crack patterns of both girders. Their maximum strength reached the calculated flexural strengths; however, the shear cracks apparently progressed with the increase in drift angle. The hysteresis loops were slip-type because of the bond slippage of the main bars. The final failure mechanism was shear failure mode. The equation for flexural strength predicted the observed value of the original girder; the maximum strength of the retrofitted girder was approximately 1.1 times that of the original. Consequently, the epoxy resin injection recovered the seismic performance of the girders in this building.*

Keywords: *Reinforced Concrete Girder, Existing Building, Seismic Performance, Shear Capacity, Retrofitting.*

1 Introduction

The seismic performance of existing buildings in Japan is typically evaluated based on their structural drawings in accordance with the standards established in the Japanese Building Disaster Prevention Association's (JBDPA) 2001 guidelines. However, the actual components of the existing buildings frequently differ from their structural drawings; this complicates the accurate evaluation of their seismic performance. The equations recommended in the seismic evaluation were empirically derived using small scaled test specimens manufactured in the laboratory. In the field of building engineering, few experimental tests have been conducted on the actual reinforced concrete (RC) members of buildings constructed decades ago; however, full-scale loading tests were conducted on existing buildings by Osawa *et al*. (1968) and Matsushima (1970). Therefore, the research by Aoyama *et al*. (1983) and Araki *et al*. (2013, 2017) on the seismic performance of RC members obtained from old buildings is extremely valuable. In this study, the mechanical properties of concrete and the seismic performance of actual RC girders were investigated through experimental evaluations.

2 Existing Building

The building under investigation is a five-story RC building; it was constructed in 1961 and was used for residual purposes. Fig. 1(a) shows an image of the building. Its standard plan is star shaped, which was very popular in Japan between 1956 and 1964. The design of this building was based on the old structural code established by the Architectural Institute of Japan (AIJ) in 1958; the building's poor seismic performance could be attributed to a low amount of shear reinforcement. To estimate the mechanical properties of concrete, concrete cylinders were obtained from the first, the fourth, and the fifth stories by concrete core cutter when the building was demolished in 2017 as shown in Fig. 1(b). Additionally, two girders were obtained from the roof floor without any damage using a wire saw as shown in Fig.1(c).

3 Experimental Procedure

The material tests were performed using concrete cores and steel bars and seismic tests for the girders were performed to check the validity of the present equations used in the standard.

3.1 Materials

The mechanical properties of the concrete in existing RC buildings are directly related to the seismic performance of the structures and are important for seismic evaluations. Therefore, compressive and splitting tensile tests were performed. Table 1 summarizes the mechanical properties of concrete. The average concrete strengths of the roof floor were 19.2 N/mm^2. The concrete's strength in the building was distributed over a wide range from 14.3 N/mm^2 to 28.4N/mm^2. Although the average compressive strength exceeded the specified concrete strength, the COV of the compressive strength (0.263) exceeded the applicable upper limit of 0.25 for the seismic evaluation of existing buildings, as shown in a previous study by Sezen *et al*. (2011). The tensile splitting strengths were distributed over a range: from 1.13 N/mm^2 to 2.85 N/mm^2. The average yield strength of the main bars ϕ19 and the stirrups ϕ9 obtained by the tensile tests were 325 N/mm^2 and 292 N/mm^2, respectively.

(COV): Coefficient of variation

3.2 Test Girders

The sectional area of the girders in the structural drawing was 250 mm × 800 mm. The obtained girders were designed with shear span lengths of 1,200 mm, to investigate the validity of the shear capacity equation currently used for seismic evaluation. The original test girders were termed SG-1 and SG-2, respectively. The structural drawing indicated that the main and shear reinforcements were plain round bars (22 ϕ and 9 ϕ, respectively). Table 2 presents the details of the original test girders. Their flexural Q_{mu} and shear strengths Q_{su} were calculated using Eqs. (1) and (2), respectively, which are provided in the JDBPA standard (2001). The failure modes of the members are very important factors for the seismic performance of existing buildings; therefore, valuating the strength of the RC members is necessary.

$$M_u = 0.9at \cdot \sigma_y \cdot d$$
$$Q_{mu} = {}^{2M_u}\!/_{L} \tag{1}$$

where M_u is the yield flexural moment [N·mm], a_t is the area of main reinforcement in tension [mm^2], σ_y is the yield strength of main reinforcement [N/mm^2], d is the effective depth [mm], Q_{mu} is the strength at the flexural failure [N], and L is the length of shear span [mm].

$$Q_{su} = \left\{ \frac{0.053 p_t^{0.23} (18 + F_c)}{M/(Q \cdot d) + 0.12} + 0.85\sqrt{p_w \cdot \sigma_{wy}} + 0.1\sigma_0 \right\} b \cdot j \tag{2}$$

where Q_{su} is the strength at the shear failure [N], p_t is the tensile reinforcement ratio [%], F_c is the compressive strength of the concrete [N/mm^2], M/Qd is the shear span ratio, p_w is the shear reinforcement ratio, σ_{wy} is the yield strength of the stirrup [N/mm^2], and j is the distance between the resultant internal forces (7/8d) [mm]. Eq. (2) denotes the minimum shear strength as empirically proposed by Arakawa (1960), which is most commonly used in Japan. M/Qd = 1 was assumed in the equation following the RC standard when M/Qd was less than 1. The yield strength of reinforcements (SR24) was assumed to be 294 N/mm^2. This strength is recommended in the standard (JDBPA, 2001), because tensile tests for the reinforcing bars were not required in the seismic evaluation. The estimated concrete strength of 16.7 N/mm^2 was obtained by subtracting half the standard deviation of the concrete strength from the average value in accordance with the standard (JDBPA, 2001). Using Eqs. (1) and (2), the ratio of Q_{su} 314 kN to Q_{mu} 186 kN of the original test girder was 1.66. RC stubs were manufactured at both ends of each girder to enable fixing to the testing machine. Steel plates (t = 10) mm were welded at both ends of the main reinforcements for anchorage before casting concrete for the stubs. Shear connectors of 24-D16 were installed to the girder sides with epoxy mortar to ensure that the original girder was connected to the stub concrete. Fig. 2 presents the details of the test girder.

Table 2. Details of the test girders.

Test Girder	Concrete (N/mm^2)	Section [mm]	Shear span [mm]	Main bar [SR24]	Stirrup [SR24]
SG-1	16.67	250 × 800	1200	2-19ϕ	2-9ϕ@250
SG-2				Pg = 0.61%	Pw = 0.20%

Specified concrete strength in the structural draft Fc: 17.6 [N/mm^2] (180kg/cm^2)

3.3 Loading and Measurement of Girders

The test setup was designed to subject the test girders to shear – force reversals. The top stub was fixed to an L-shaped steel beam, while the bottom stub was fixed to the reaction floor with high-tension bolts. Shear force was applied using a horizontal jack under displacement control. One cycle was attempted per peak displacement level with drift angle R = 1/800, 1/400, 1/200, 1/133, 1/100 rad for both the girders. A pantograph system was used to ensure that the top and bottom stubs remained parallel during the reverse loadings. Fig. 3 shows the test setup. The shear displacement between the top and bottom stubs was measured using a linear viable differential transducer (LVDT). To measure the local displacements of the test girders, 17 LVDTs were mounted on one side of the test girder. Finally, the lateral load was measured using a load cell.

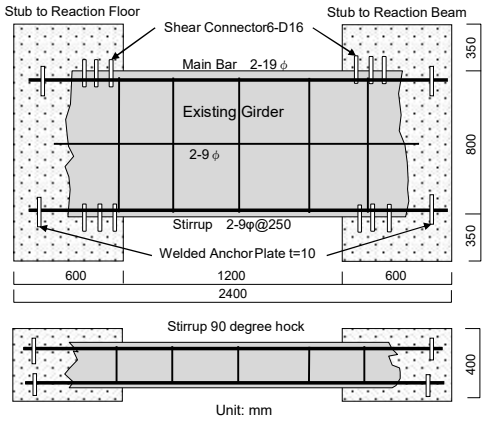

Figure 2. Dtails of the test girder.

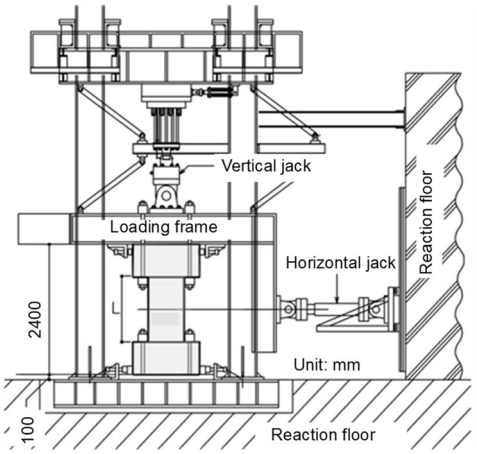

Figure 3. Test setup.

3.4 Retrofitting

Epoxy resin was injected into one of the original girders before loading to investigate the retrofitting effect. The injected epoxy resin filled the vacant space in the concrete and bonded the concrete and the reinforcing bars together. The epoxy resin injection alone may improve the seismic performance of moderately damaged buildings, although epoxy resin injection is usually associated with wrapping steel plates or CFRP sheets. In contrast to the conventional

(a) (b) (c)

Figure 4. Retrofitting process of test girder SG-2: (a) perforation; (b) sealing and attachments for capsules; (c) epoxy resin injection with capsules.

method in which epoxy resin injected at the concrete surface of the members, epoxy resin was injected with spring capsules at the position of the reinforcing bar or at the distance of 50 mm from the concrete's surface. The epoxy resin was also injected at the location of deficiencies as honeycombs. Fig. 4 presents the retrofitting process. The total amounts of epoxy resin injected into the original test girder SG-2 was 5.73 kg.

4 Experimental Results

4.1 Crack Patterns

The figures below show the location the slabs on the right side of the girders. Slight flexural cracks developed in the ends of both girders during the positive loading of the first cycle at drift angle R = 1/800 rad. The shear cracks started to occur around the small openings; then, the shear cracks appeared throughout the entire girders under increasing controlled displacement until drift angle R = 1/50 rad. The specific width of the shear cracks increased, whereas the flexural cracks did not progress. Shear cracks of 45 degrees were observed at both ends of the test girder SG-1, and diagonal shear cracks were observed in the retrofitted test girder SG-2. The final collapse mechanisms were the shear failure type. Fig. 5 (a) and (b) illustrate the crack patterns of the test girders at the final stage at drift angle R = 1/30 rad.

(a) SG-1 (b) SG-2

Figure 5. Crack patterns at final stages.

4.2 Shear Force and Drift Angle Response

Fig. 6 depicts the relationships of the shear force Q with drift angle R in both the test girders. The calculated flexural and shear strengths of the original girders were 186 kN and 314 kN, based on the standard. The stiffness degradations for both the test girders were observed at the first loading cycle. In both girders, the peaks of the shear forces were measured at drift angle R = 1/200 rad. The maximum shear forces exceeded the calculated flexural strength and did not reach the calculated shear strength. Although the shear cracks progressed, the apparent strength degradations were not observed. Therefore, the main bars were estimated to be yielding. In contract, the hysteresis loops were of a slip - type from the initial stage. The bond slippage of the main bars from the concrete may have occurred because the reinforcement was a plain round bar, and the concrete strength was low. No significant degradation of the shear force Q was observed until drift angle R = 1/50 rad. The maximum strength of the retrofitted girder (297

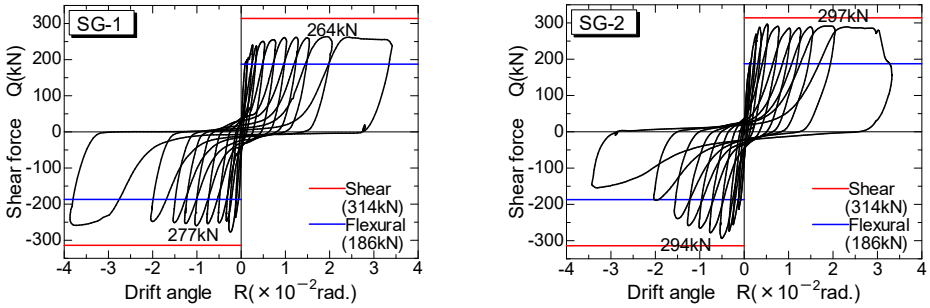

Figure 6. Shear force and drift angle response.

kN) slightly increased in comparison with those of the original test girder (277 kN). Those values were much greater than the flexural strength calculated with Eq. (1) using the recommended material strength based on the standard (JBDPA, 2001).

5 Discussions

5.1 Strength

5.1.1 Shear cracks strength

Investigating the shear crack strength is important for guaranteeing serviceability under a long-term load. The following two equations for the shear crack strength are commonly used in Japan. Eq. (5) is theoretically derived from the principal stress theory, and Arakawa (1960) empirically derived Eq. (6) from the broad experimental data on RC members. The tensile stress σ_T was recommended by Collins *et al*. (1991).

$$V_c = \sigma_T \frac{b \cdot D}{\kappa} = 0.33\sqrt{\sigma_B}\frac{b \cdot D}{\kappa} \tag{5}$$

$$Q_{sc} = \left\{ \frac{0.085 k_c \left(50 + \sigma_B\right)}{M/\left(Q \cdot d\right) + 1.7} \right\} b \cdot j \tag{6}$$

where σ_T is the tensile stress [N/mm^2], κ (= 1.5) is the shape factor of the section in Eq. (5), and k_c (= 0.72) is the scale factor in Eq. (6). For the concrete strength σ_B of the test girders, an average concrete strength of 19.2 N/mm^2 was used. The comparisons of the observed and calculated strengths of the shear cracks are shown in the first half of Table 3. The shear crack strength as calculated by Eq. (5) was underestimated, while that calculated by Eq. (6) was overestimated.

5.1.2 Maximum strength

The validity of the present equation for the shear strength was compared with that of the observed maximum strength. The flexural strength was calculated using Eq. (1). The yield strength of the reinforcement in the equation was obtained through tensile tests. The test pieces for the tensile test were taken out from the test girders after loading. Bar arrangements in the girders were inspected by removing the concrete cover after the loadings. The stirrups (9ϕ)

$$Q_{su} = \left\{ \frac{0.068 p_t^{0.23} (18 + F_c)}{M/(Q \cdot d) + 0.12} + 0.85\sqrt{p_w \cdot \sigma_{wy}} \right\} b \cdot j \tag{7}$$

were arranged with a 300 mm - 600 mm space, unlike the structural draft, and a 600 mm space was used in the calculation. The empirical equation for the shear strength was used in this study. Eq. (7) expresses the mean values of the test results taken from previous studies on RC members. This equation was also proposed by Arakawa (1960) and was used for the direct comparison of the observed maximum strength in shear failure. The observed and calculated values for maximum strength are summarized later in Table 3. The predicted maximum strengths, as calculated by Eq. (1), were consistent with the observed values of the original girders. The maximum strengths of the girders were 277 kN and 297 kN, respectively. Those maximum values were 7% and 15% greater than the flexural strengths calculated by Eq. (1). However, the researchers noted that the crack patterns of both girders through the loadings were mainly shear failure modes.

5.2 Effect of Retrofitting

The maximum strength of the retrofitted girder was 1.07 times that of the original girder, although the girders before repair contained some honeycombs. Researchers estimated that the epoxy resin injected into the honeycombs or around the main bars protected the progress of the flexural failure or the bond slippage. Fig.7 shows the comparisons between the observed envelope curves of the shear force responses and the shear strength calculated by Eqs. (1) and (7).

Table 3. Lists of strength.

Test Girder	Cracking strength [kN]			Maximum strength [kN]		
	Obs.	Eq.(5) V_c	Eq.(6) Q_{sc}	Obs.	Eq.(7) Q_{su}	Eq.(1) Q_{mu}
SG-1	198	193 (1.03)	257 (0.77)	277	360 (0.77)	259 (1.07)
SG-2	209	193 (1.08)	257 (0.81)	297	360 (0.83)	259 (1.15)

* ( ): Observed/Calculated

6 Conclusions

The following conclusions are drawn from the results of the experimental investigation on actual RC girders obtained from an existing building constructed in 1961:

- Material tests revealed that eight concrete cylinders obtained from each floor of the building exhibited average compressive strengths of 19.2 N/mm^2 and an average tensile splitting strength of 1.72 N/mm^2.
- The failure modes of the girders could be appropriately predicted through the method recommended in the standard. However, the phase of the bond slippage was observed in the hysteresis loops because of the plain round bars.
- The predicted flexural strengths were consistent with the observed maximum values.
- Epoxy resin injection improved the seismic performance of the RC girders.
- The researchers noted that the crack patterns of both the girders through the loadings were mainly shear failure modes.

Further experimental investigation with actual RC members from the building is required to evaluate the validity of the current equations and the quantitative effect of epoxy resin.
