In previous research studies, the *Design for Maintainability (DfM)* guidelines (Chew *et al.* 2019) and checklist (Conejos, *et al.* 2019) for vertical greenery systems has been established. In this study, the checklist is further developed into a graded scoring system which will assess

the vertical greenery systems' total performance according to the five green maintainability factors. The DfM scoresheet for high rise vertical greenery systems, highlights fourteen (14) design criteria with corresponding DfM good practice measures/guidelines and corresponding percentage scores with a total score of 100% when summed up (Table 2). The design criteria are grouped under the five green maintainability factors with corresponding percentages that totaled to 100% such as (1) maximizing performance – 21.47%; (2) minimizing cost – 17.45%; (3) minimizing risk – 30.81%; (4) minimizing negative environmental impact – 13.85%; and (5) minimizing consumption of matter and energy – 16.42%. Each design criterion is equally distributed according to the scoring percentage of each green maintainability factor. Based on the practitioner and expert survey results, the most critical green maintainability factor to be considered is minimizing risk which pertains to safety measures including fire safety and quality workmanship.

The importance of considering the green maintainability of a building throughout its life cycle will improve the sustainability and performance of high-rise vertical greenery systems in the tropics. The proposed checklist may aid in addressing the maximum performance and efficient maintainability of VGS applications on facades while minimizing cost, risks, negative environmental impacts and consumption of matter/energy.

6 Conclusions

This research has shown that considering maintainability right at the design inception is of great importance. Designing vertical greenery systems that are highly performing and easy to maintain guarantees long term sustainability. This paper highlights the evidence based defects and issues of vertical greenery systems under tropical conditions and through ascertaining best and good practices has introduced a set of Design for Maintainability (DfM) guidelines translated into a weighted scoresheet for assessment. The development of the Design for Maintainability (DfM) scoresheet for VGS is a valuable method in assessing the sustainability and maintainability potential of high-rise vertical greenery systems. The best practices and evidence based defects derived from these case studies and stakeholder insights will be useful in improving the decision making process for designers when it comes to the choice and design of VGS, as well as the expansion of the vertical greenery defects library. Lastly, one of the most important goals of VGS implementation is to promote a biophilic environment within high density areas as well as support climate change adaptation through the greening of the built environment.

Name of Building and Location:			
Building Profile:			
Instructions: Please refer to the following Guide Statements when assessing the Vertical Greenery Systems applied to high rise building. The scoring system is categorized ac corresponding total percentage at the leftmost column as reference. The Ranking result will be: Level 1 – 0% to 40% indicates low maintainability potential; Level 2 – 41% t – 61 to 100% indicates high maintainability potential.			
Design Categories		**Design Criteria**	**Good Practice Measures (incl. standards/guidelines/expert sourc**
Maximising performance	Climatic conditions	Availability of natural elements	Consider the proper orientation of the VGS, as well as the areas with strong winds due to location of the buildin altitudes. Provide sufficient soil depth for the roots to grow more freely (i.e. planter box size of 500w x 600d wi
			Consider alternative approaches such as hydroponics, light soil in skyrise greenery, as well as artificial lighting on VGS.
	Design considerations	Green wall systems	Consider VGS height, system capacity, lifespan and its replaceability.
		Plant suitability and sustainability	Specify the right plant species (e.g. native plants which are adapted to the local climate; plant appropriately for areas, etc.), as well as ensure that it considers the maintenance frequencies and cost issues.
			Avoid selecting plant species with excessive shedding of leaves and do not use some plant species (e.g. species require regular monitoring for signs of mosquito breeding.
			Recommend more than one species to ensure even coverage a and ensure the correct plant spacing for the desir
		Coordination among professions	Ensure that all involved stakeholders; design and construction professionals involved in the project are properly in from the design, construction, operations and maintenance aspects/process.
	Structural stability and material durability	Structural stability	Structural integrity of the green wall system should be certified by a professional structural engineer. Design th climber plants for high-rise VGS, as it can grow from ground level to the 10th storey.
		Material durability	Specify the use of quality materials (i.e. durable and stain-resistant materials) and ensure that the material selec cost issues.
Minimising cost	Maintenance considerations	Life cycle cost	LCC considerations include capital cost, ownership cost, operating cost and disposal cost.
		Maintenance Access	Provide easy and safe maintenance access (i.e. access via the front of green wall and access system considerati access provided) to all facade areas at every level. Each maintenance walkway level should have direct access worker movement during normal operations and emergencies. All designated access/inspection points shou maintenance access such as footpath leading to the tap. The greenery cascading down should not be encroachi water features. No unmaintained vegetation over private spaces.
			Provide permanent rear access and workspace (e.g. walkways and platforms) alongside the elevated greenery su parts of the green wall. The rear access must be designed with edge protection to prevent worker falling out d should have a minimum 600mm internal clearance width. Access should be designed via passive means as muc BMUs and other equipment required to facilitate accessibility but also to reduce instances of inconvenience to b
			For green wall no more than 2m in height, allow maintenance access from the front via suitable elevated wo scaffold, etc.), pole pruner and/or a combination of these equipment. For green wall more than 2m in height, p loading capacity in-front to allow safe and effective deployment of suitable elevated work platform and equipm landing with adequate load bearing capacity for safe deployment of elevated work platform such as MEWPs (mo wall more than 4m in height, the foreground when turfed/vegetated, should be designed, dimensioned and in provide adequate load bearing capacity for safe and effective deployment of MEWPs. Structural elements sho inspection.
		Frequency of Inspection and Maintenance	Put in place a regular maintenance schedule conducted by qualified workers to look out for potential risks, haza of supporting structures to ensure that structural integrity is maintained. Perform visual inspection for structural for plants' health status (i.e. pruning and ensure proper soil and irrigation, prevent unlikely planter bursting/ Install pre-planted panels safely and ensure quality workmanship. Provide a growing medium that is dense to nutrient needs. Follow and maintain a three-month pre-planting period for plant replacement so that plants will
	Drainage system	Drainage system management (e.g. gradient and water ponding)	Conform to BS 4428:1989 for proper drainage layout and system of landscape areas and ensure that planters sl towards the drain. Specify drains adjacent to planters at the base of the VGS. Drain gradient should be in the ra Consider using drainage trays at the base of the installation and provide metal drain covers. The width: depth ra

			facilitate ease of access. Provide anchor points or ladders to facilitate safety and access to drains and supporting maintenance.
			Drainage systems require regular maintenance and fixtures should be checked visually on a regular basis and th Test to ensure that during and after installation, the drainage systems effectively convey water to the storm wate systems, especially modular systems, for water ponding due to clogged drainage holes which allow mosquito br
Minimising risk	Installation and maintenance methods	Safety measures (incl. fire safety and quality of workmanship)	Safety and maintenance concerns must be thought of and addressed early during the design stage. Adhere to th the safe design, construction and maintenance of scaffolding, working platforms and gondolas (BS 6150:2006+ quality control during the installation of green wall components, installation of fixtures and fittings and vege performed by registered and specially trained workers to ensure quality workmanship. Ensure quality control du fixtures and fittings.
			Adequate site supervision should be performed to make sure that workers understand and comply with the esta work methods, including the proper usage of all personal protective equipment provided to avoid fall from heig SS CP 14:1996 and ensure the proper supervision of workers at heights. Implement a comprehensive safety plan fall prevention systems and personal fall arrest, and a permit-to-work system. Ensure that maintenance perso systems (BS EN 363:2008). Conform to ASME A120.1-2014 for the safe use of permanently installed building
			Considerations for fire-rated VGS materials to be specified as per SCDF requirements. Specify fire-rated VGS sufficient buffer between VGS and facade openings (e.g. balconies, windows) to prevent fire encroachment into biomass which contributes to fire risk. Ensure that chances of biomass contributing to fire risk should be reduce
Minimising negative environmental impact	Biological growth and animal management control	Algae and mould prevention	Choose plants that do not trap water and harbour pests and disease pathogens. During and after installation, pre algae) as much as possible. When necessary and not on regular basis, treat such growth with anti-algae/anti-fun growths with a stiff brush.
			Planters or modules should be designed to be sufficiently deep to contain the spread of roots. Roots should b encroaching onto building's facade walls. Keep the plants away from the building's walls by having a gap in be inspections to ensure that root growth are controlled to avoid penetration on walls. Waterproofing system at lan and made to be root resistant and/or alongside a suitable root barrier. Ensure good housekeeping practices waterproofing membrane.
		Pest and bird nesting control	Inspect systems, especially modular systems, for water ponding due to clogged drainage holes which allow mos contractors should include looking out for mosquito breeding sites (e.g. instances of water ponding) near VGS. pathogens should not be introduced into any new or existing planting areas, as eradication of pests and patho plants that do not trap water and harbour pests and disease pathogens. Inspect plants periodically for pest infesta and fungicides to prevent them from contaminating run-offs and eventually the groundwater. Fertilizers and inse & Veterinary Authority of Singapore.
			Conduct periodic inspections to ensure that branches have not thickened to avoid bird nesting. Conduct annual bird interaction with VGS for plant survival.
Minimising consumption of matter and energy	Water and irrigation and electrical and lighting systems	Water and energy efficiency	Specify a drip-based irrigation system complete with built-in rainwater harvesting and recycled water to min automatic-irrigation system with rain sensor. Recommend the use of an adjustable automated irrigation system of water. Energy efficiency considerations should include material selection, testing, fixing/ mounting/ installat

Abstract. *Timber has been widely adopted as a global structural material. However, timber sometimes deteriorates due to various factors such as termite infestation, which may reduce its strength and durability. It is difficult to ascertain the degree of deterioration of timbers by visual inspection because deterioration by termites causes severe damage to the inner parts of the timber. Therefore, the damage is often discovered after the deterioration progresses. The restoration and refurbishment method currently implemented is removing the degraded parts and partially replacing them with new healthy wood. Although it is as desirable to reinforce the original part as it is to restore its strength, especially for historical timber structures, this approach has not yet been put into practical use. This study investigates the possibility of restoring timber deteriorated by termites with little changes in its appearance by using resin filling. Deterioration by termites occurs at the base of the timber. Therefore, the specimen is assumed to be the joint of a foundation and column. First, the deteriorated specimen was filled with epoxy resin, and then, the effectiveness of the filling was confirmed by a nondestructive test method using ultrasonic pulse velocity. Finally, shear strength test was performed for the joint. As a result, ultrasonic velocity significantly increased because of the resin filling. The strength of the specimen filled with epoxy resin was restored and was close to the strength of a healthy one. It was confirmed that this strengthening method with resin filling was useful for improving the structural performance of timber deteriorated by termites with little change in appearance.*

Keywords: *Strength, Termite Damage, Nondestructive Test, Epoxy Resin, Ultrasonic Pulse Velocity.*

1 Introduction

The damage caused by termites is one of the main degrading factors of timber structures. Termites are active in wet conditions; hence, they can cause damage to the base of timber that is close to the ground. In addition, in timber buildings, joint strength is very important. It is clear that the deformation and strength capacity of the joint strongly affects the deformation and structural capacity of the building. Therefore, in this study, the authors focus on the reinforcement of the base joint.

The authors examine the reinforcing method of injecting synthetic resin into the deteriorated parts of the timber. The reinforcing method is characterized by a little change in appearance, as shown in Figure 2.

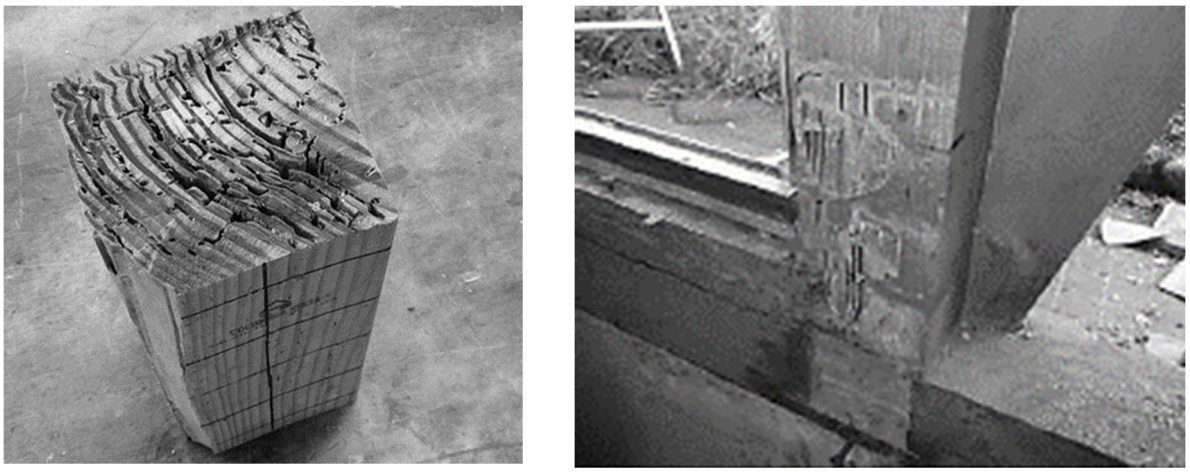

Figure 1. Timber damaged by termites. (Source: KAWATA Tasturo, 2017)

Figure 2. Timber filled with resin.

2 Shear Test of Pillar-Base Joints

2.1 Objective

The objective of this experiment was to examine the reinforcing effect of filling the synthetic resin on the restoration of timbers deteriorated by termites. The reinforcing method is as follows. First, the entire surface of the specimen is covered with tape. Next, the side of the specimen is drilled in a staggered manner at 100-mm intervals (Figure3). Finally, using a static mixer, the synthetic resin is injected through the hole into the specimen (Figure4).

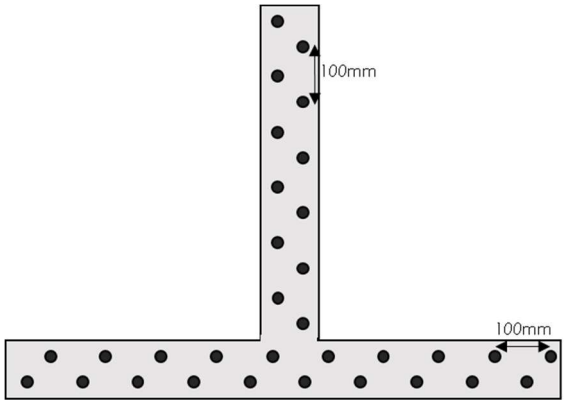

Figure 3. Image of filling hole.

Figure 4. Resin filling work.

2.2 Summary of Specimens

The specimen was prepared using Douglas fir. The dimensions of the column were 105 mm x 105 mm x 600 mm, and those of the base were 105 mm x 105 mm x 1000 mm. The joint was a stub tenon. The dimensions of the tenon were 30 mm x 75 mm x 50 mm, and those of the mortise were 30 mm x 75 mm x 80 mm. Ten sets of column and base specimens were prepared, and two of them were used as control. The deterioration was carried out for four months at a test site where termites live (Figure5). The degree of damage was evaluated by the mass reduction rate before and after the damage treatment. The specimens are listed in Table 1.

Regarding the resin filling, two types of synthetic resin, epoxy resin and polyamine resin, were used to examine the change in strength depending on the type of synthetic resin. In Table 1, “Resin A” is hard type, and “Resin B” is elastic type. Three specimens were prepared and filled with resin A, and two were filled with resin B. In this test, five restored specimens were used.

Figure 5. Soil exposure due to feeding damage caused by termites.

Table 1. Name of specimens and test parameters.

Name	Feeding damage rate[%]	Resin					
		Name	Materials	Fit ratio	Method	Tool	Feature
0-N①	0	None	-				
0-N②							
10-N	10						
15-N	15						
20-N	20

15-A	15						
20-A	20						
10-B	10	B	epoxy resin +polyamine resin	3:2	filling	static mixer	elasticity
15-B							

2.3 Loading Method and Loading Protocol

The experimental setup of a joint member with a column and base is shown in Figure 6. The base was fixed to the foundation steel member by passing bolts through the steel plate on the left and right sides and tightening each bolt with a strength of 20 N. In addition, by assuming the actual building weight, an axial load of 10 kN was applied to the column through a drop jig. Then, a positive and negative cyclic load testing was applied 500 mm height from the upper surface of the base portion. The applied rotation angle (θ) was 1/450, 1/300, 1/200, 1/150, 1/100, 1/75, and 1/50 [rad] in each three cycles, and then 1/30, 1/15, and 1/10 [rad].

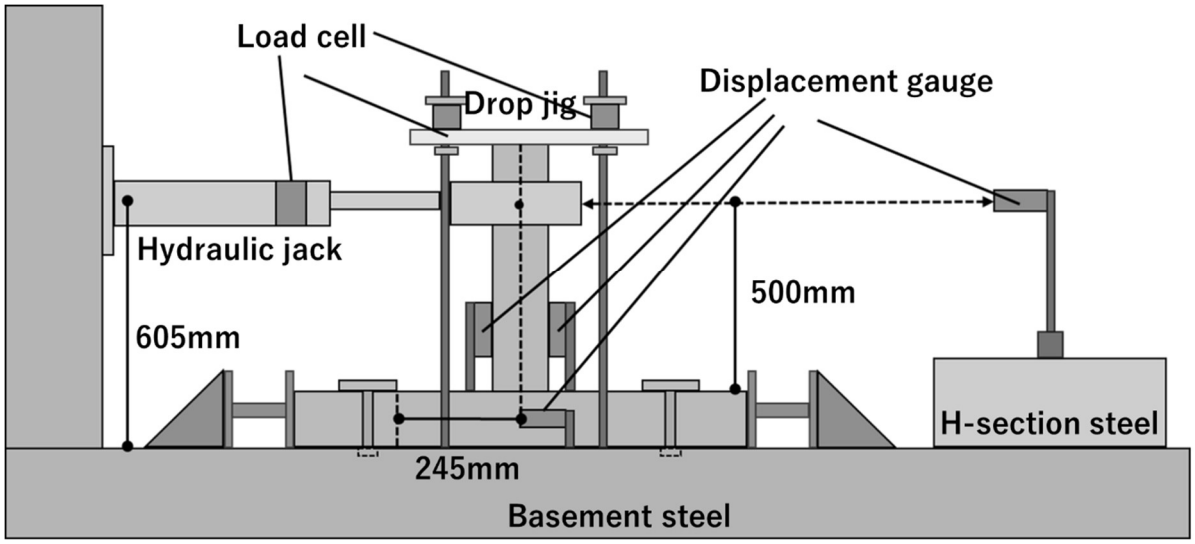

Figure 6. Experimental setup of flexural shear test.

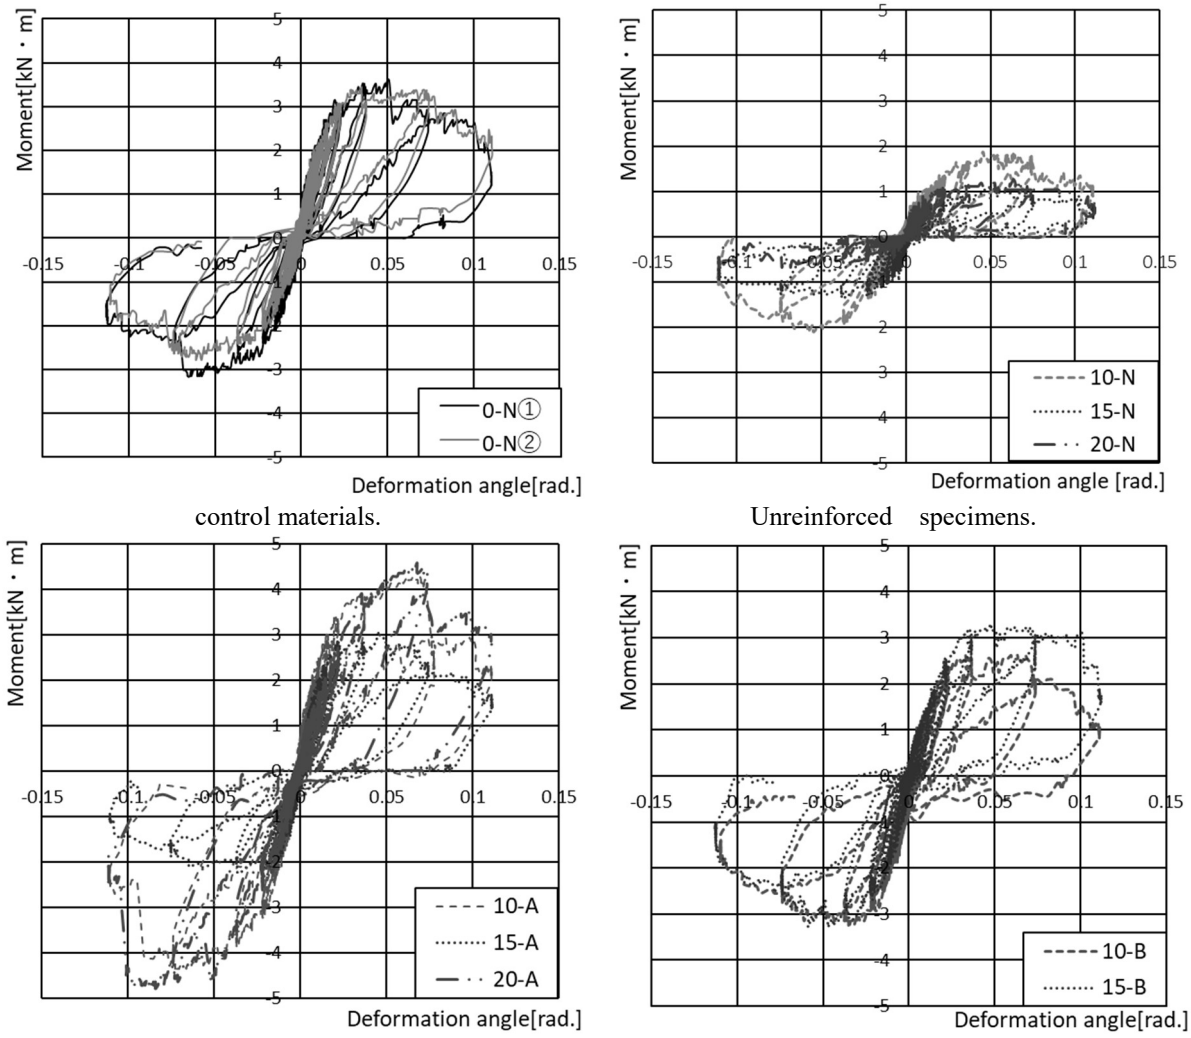
2.4 Result of Experiment

Figure 7 shows the relationship between the moment and deformation angles of joint specimens. “0” means without termite damage. “10”, “15,” and “20” represent 10%, 15%, and 20% weight losses due to termite damage, respectively. For 0-N, 10-N, and 20-A, the bending moment was increased up to 1/30 rad (0.03 rad), and for the others, it was increased up to 1/50 rad (0.02 rad). It can be observed that the strength significantly decreased with an increase in damage rate. Furthermore, the decreased strength was significantly restored by resin reinforcement.



control materials. Unreinforced specimens.

Specimens filled with resin A. Specimens filled with resin B.

Figure 7. Relationship between the moment and deformation angle.

The volume ratio of the resin to be filled into the specimen was calculated by using its density information and the mass reduction rate of the deteriorated specimens, as shown in Figure 8. All specimens were filled with resin as described above, and a significant difference in the filling rate for each specimen was confirmed.

Figure 2 shows the skeletal curve between the moment and the deformation angle. Regarding the specimens without filling, the values of both rigidity and strength were lower than that of 0-N as a reference specimen. Regarding the specimens filled with resin A, a significant recovery in both rigidity and strength was observed. The rigidity and strength of 10-A and 20-A were higher than those of 0-N. The filling ratio of 15-A was about 10%. Therefore, it was observed that there would not be a considerable recovery of rigidity and strength because of insufficient filling. Overall, when the deteriorated timbers were filled with resin A, they exhibited a possibility of recovery in rigidity and strength. In contrast, the strength and rigidity of the specimens filled with resin B did not match that of 0-N. They exhibited higher strength and

rigidity than those without filling for the same feeding rate.

It was observed that the strength and rigidity of 10-B did not recover because of insufficient filling. In the case of 15-B, which had the highest filling rate, a complete recovery was not confirmed. This result might indicate that the low elasticity of resin was not effective for reinforcement. Despite the filling rate of approximately 40%, 10-A exhibited similar rigidity and strength to 0-N. If the filling level increased beyond a certain value, it might be unnecessary to fill the specimen completely. The variation in the filling rate was caused by bubbles generated due to the heat reaction of resin during curing. It will be necessary to evaluate the effect of the filling rate, filling position, and curing temperature of the resin on the mechanical properties of deteriorated timber members in the near future.

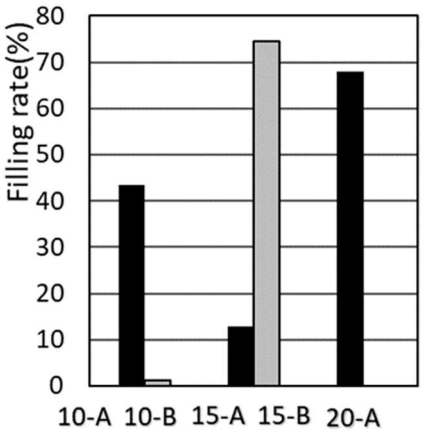


Figure 8. Filling rate.

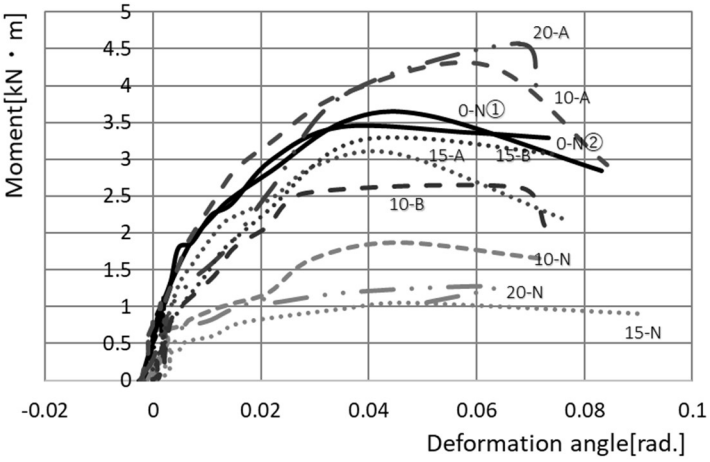

Figure 9. Relationship between moment and deformation angle

3 Ultrasonic Pulse Velocity Test

3.1 Aim

The damage caused by termites is significantly hidden inside the timber and often invisible. The ultrasonic testing machine (pundit) shown in Figure10, would be an effective method for detecting internal defects in timber. Ultrasonic pulse velocity can be measured by sandwiching both sides of the specimen. Filling conditions and restoration might be confirmed by evaluating the rate of change in ultrasonic velocity before and after resin filling.

3.2 Deterioration Detection

Figure11 shows the relationship between the mass reduction rate and the reduction in ultrasonic velocity before and after damage treatment. The reduction rate of ultrasonic pulse velocity is defined as the rate of the velocity to the velocity of the sound timber. A high correlation was observed between the mass loss rate and the reduction rate of ultrasonic velocity, as shown in Figure11. Hence, the mass loss rate can be identified by measuring the ultrasonic pulse velocity. As a result, it was suggested that the ultrasonic pulse velocity test might be effective in evaluating the deterioration by termites.

3.3 Check of Filling

The relationship between the filling rate and the increased rate of ultrasonic velocity is shown in Figure12, a high correlation was observed between them. Hence, the effectiveness of resin filling was confirmed by an increase in the ultrasonic pulse velocity

Figure 10. Ultrasonic testing machine. (pundit)

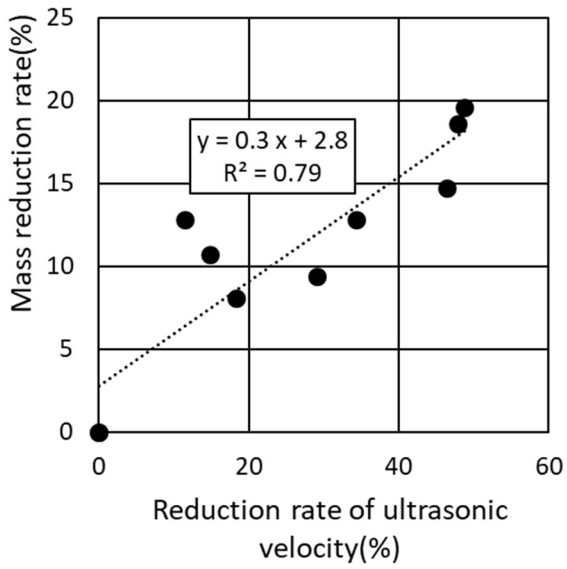

Figure 11. Relationship between mass reduction rate and reduction of ultrasonic velocity before and after feeding damage.

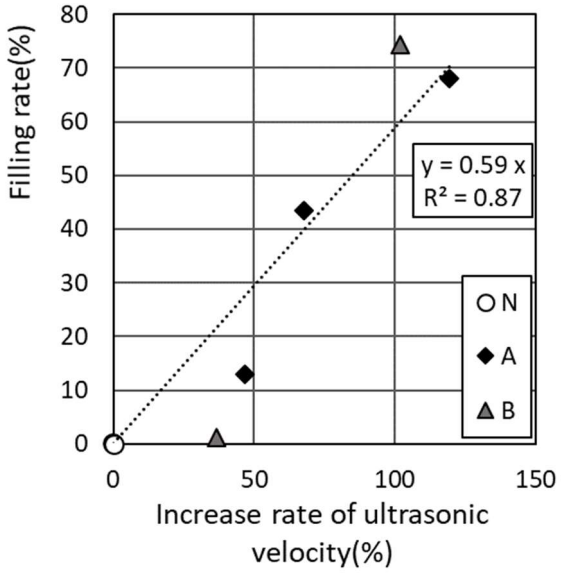

Figure 12. Relationship between filling rate and increase rate of ultrasonic velocity.

4 Conclusion

The following conclusion were obtained in this study:

- Throughout the shear test of pillar-base joints, filling the deteriorated timbers with the hard type resin led to the recovery of rigidity and strength. Hence, the effectiveness of resin filling as a reinforcement method was demonstrated.

- All test bodies were filled with resin in a staggered manner, and a significant variation in the filling rate for each specimen was confirmed. Even though the filling rate was approximately 40%, there was a specimen that showed rigidity and strength close to 0-N. If the filling level increases beyond a certain value, it might be unnecessary to completely fill the specimen. It will be necessary to examine the effect of the filling rate, filling position, and curing temperature of the resin on the mechanical properties of deteriorated timber members.
- A high correlation was confirmed between the mass loss rate and the reduction rate of ultrasonic velocity. Thus, it was suggested that the ultrasonic pulse velocity test might be effective in evaluating the deterioration by termites.
- A high correlation was observed between the filling rate and the increased rate of ultrasonic velocity. Therefore, the filling rate can be confirmed by an ultrasonic pulse velocity test in a non-destructive manner.

Use of Steel Fiber Reinforced Concrete for the Protection of Buildings Against High Dynamic Actions

Vahan Zohrabyan, Thomas Braml, Tobias Zircher and Manfred Keuser

University of German Armed Forces, Chair for Concrete Construction,
Werner-Heisenberg-Weg 39, 85577 Neubiberg, Germany, vahan.zohrabyan@unibw.de

Abstract. *Nowadays ensuring the safety of people and the protection of infrastructure is a socially relevant topic, which requires a thorough investigation.*
The Institute of concrete construction at the University of the German Armed Forces in Munich is investigating the possibilities of using steel fiber concrete for the protection of military facilities and state-owned special buildings in Germany. In this research project steel fiber reinforced concrete is investigated under high dynamic loads specifically under contact detonation loading. Plates with varying reinforcement systems, different thicknesses, different fiber geometries, fiber contents and fiber types were produced.The following concrete compressive strengths C20/25, C40/50, C80/95 were used in this research project.The plates were loaded with 500 g, 750 g, 1000 g, 1500 g and 2000 g PETN explosive at the test facility of the German Armed Forces Technical centre for Protective and Special Technologies. An important property of construction material during ballistic threats and contact detonation is the concrete tensile strength. Through the addition of fibers, the post cracking behavior and the ductility of concrete components can be improved. All fiber-reinforced specimens showed less damage than the non-fiber reinforced elements. The aim of the study is to optimize the concrete mixture for the fiber concrete protection components considering the following factors: concrete quality, fiber content, fiber geometry, as well as aggregate size of the concrete. Another aim is to record and evaluate the damage parameters of the steel fiber reinforced concrete slabs after the highly dynamic load, and to investigate to offer suggestion for retrofitting. In this article, the test results of different steel framed concretes under highly dynamic conditions are presented.

Keywords: *High Dynamic Load, Protective Components, Contact Detonation, Steel Fiber Reinforced Concrete, Damage Crater.*

1 Introduction

As the number of people increases, the demand for both residential and public and state-owned buildings and infrastructures is increasing.

Taking into account the fact that mass influx of people to major cities is taking place lately, the demand for these buildings is increasing, resulting in higher prices for their construction, rent and service.

As the problem grows more serious and attracts a lot of construction space, it should be resolved as soon as possible by offering clear solutions. A solution to the problem for example can be the use of construction materials, structures and construction technologies that will make the structure more robust and durable (suitable for long-term use).

The resistance, security and durability of buildings for state and military facilities are set in completely different criteria such as embassies, military bases, nuclear power plants, chemical factories, government buildings, and so on.

doi:10.23967/dbmc.2020.145

Reconstruction or retrofitting work in these structures is always associated with high costs and high risks e.g.:

- the control should be increased during the construction works
- depending on the technological process, the production lines are partially or completely shifted which are associated with additional costs and effort
- auxiliary things, ammunition and workers should also be resettled

as a result, these buildings become more vulnerable and their normal operation is disrupted (one should not forget the fact that these facilities are the target of recent terrorist attacks).

In general, the protection of state-owned special buildings from possible terrorist attacks can be done in the following ways:

1. **newly constructed buildings:** depending on the significance of the building and the risks of the attack, the material must be defined and selected so that during the possible attack it ensures the safety of the objects and people (excluding of injuries and hazards in the shelter).
2. **already constructed buildings:** Depending on the significance of the building, the risks involved in the attack and the design, the protection can be implemented in the following ways:
   a) by reinforcing work
   b) by using an additional facade protection panel

2 Material and Constructions

The Institute of Concrete Construction at the Bundeswehr University Munich is investigating the possibilities of using steel fibre reinforced concrete for the protection of military facilities and state-owned federal buildings in Germany.

In this research project, reinforced concrete plates as well as steel fiber reinforced concrete plates made of different geometries and steel fiber content are produced and tested under different high dynamic loads (Zohrabyan *et al.*, 2019).

The impact on the components can consist of impact stress as well as contact detonation, near or far, from e.g. suicide bombers, vehicles loaded with explosives, etc.

For the construction of sensitive German Armed Forces infrastructure buildings and for buildings in out-of-area-operations, it is therefore necessary to consider these scenarios in design and service and to show to which extent the use of fiber reinforced concrete can lead to an improvement of the protective effect.

Within the framework of this research project, the protective wall and facing structures made of steel fiber reinforced concrete are investigated. Numerous experimental investigations are carried out.

The aim of the study is to make the panels as thin and light as possible in order to allow them to be attached to existing facades as a protective element. (Zircher *et al*., 2019)

Since in many buildings the panels cannot be fixed to the front of the building depending on the architectural solution, the protective wall would be used as a second alternative. The crash barrier panels should also be as light and thin as possible and must withstand both shock waves and impact loads. Here it is important that the panels can be produced in an economically favourable way and installed easily.

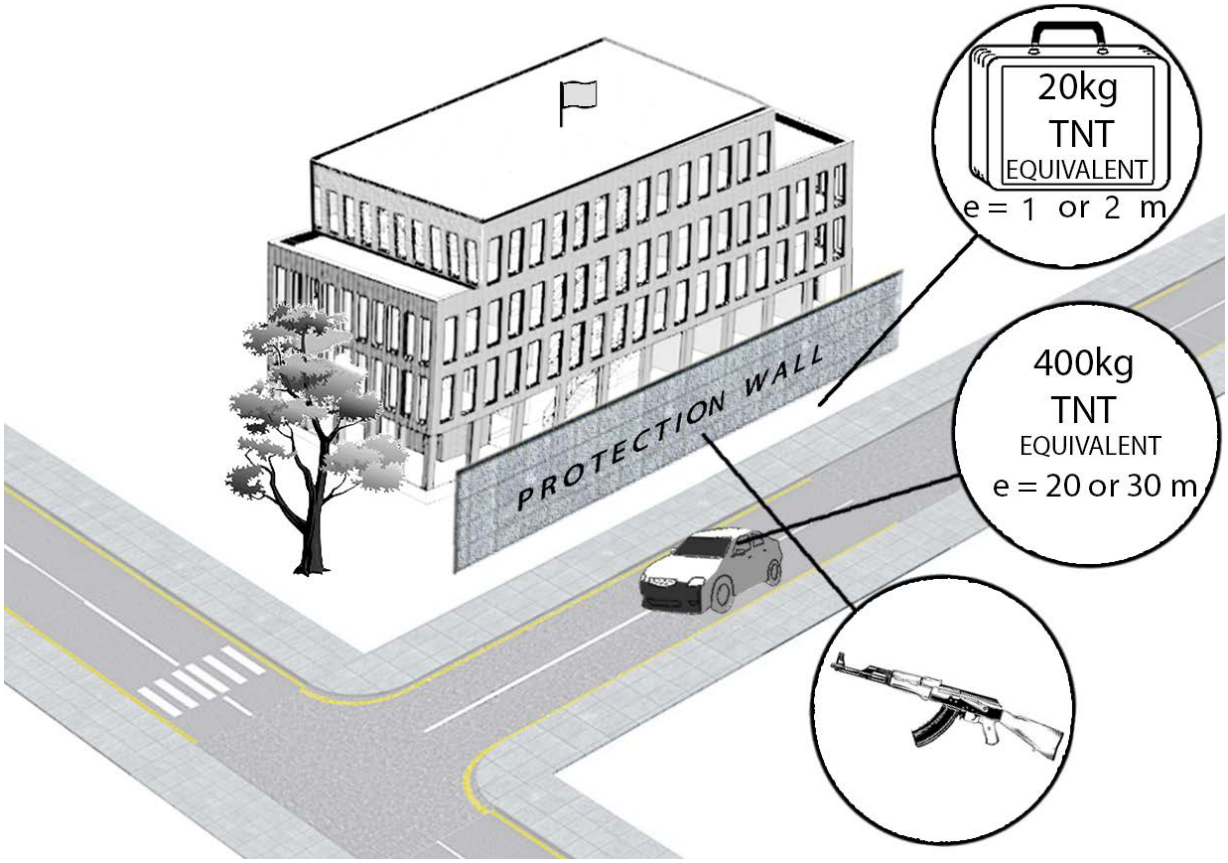

Figure 1. Scenarios of terroristic attacks on a building (Picture: V. Zohrabyan).

The hand gunshots represent a high risk for soldiers in action. If it were possible to eliminate this danger by using a protection system made of fiber concrete components with exclusion of secondary debris, part of the task would be solved. In order to slow down or completely intercept the secondary debris that flakes off as a result of the bombardment, the fiber reinforced concrete slabs will in future be equipped with a kind of steel grid curtain. In the following, the first test results of the fiber reinforced concrete slabs with high compressive strength concrete C80/95 under hand gunshot are presented.

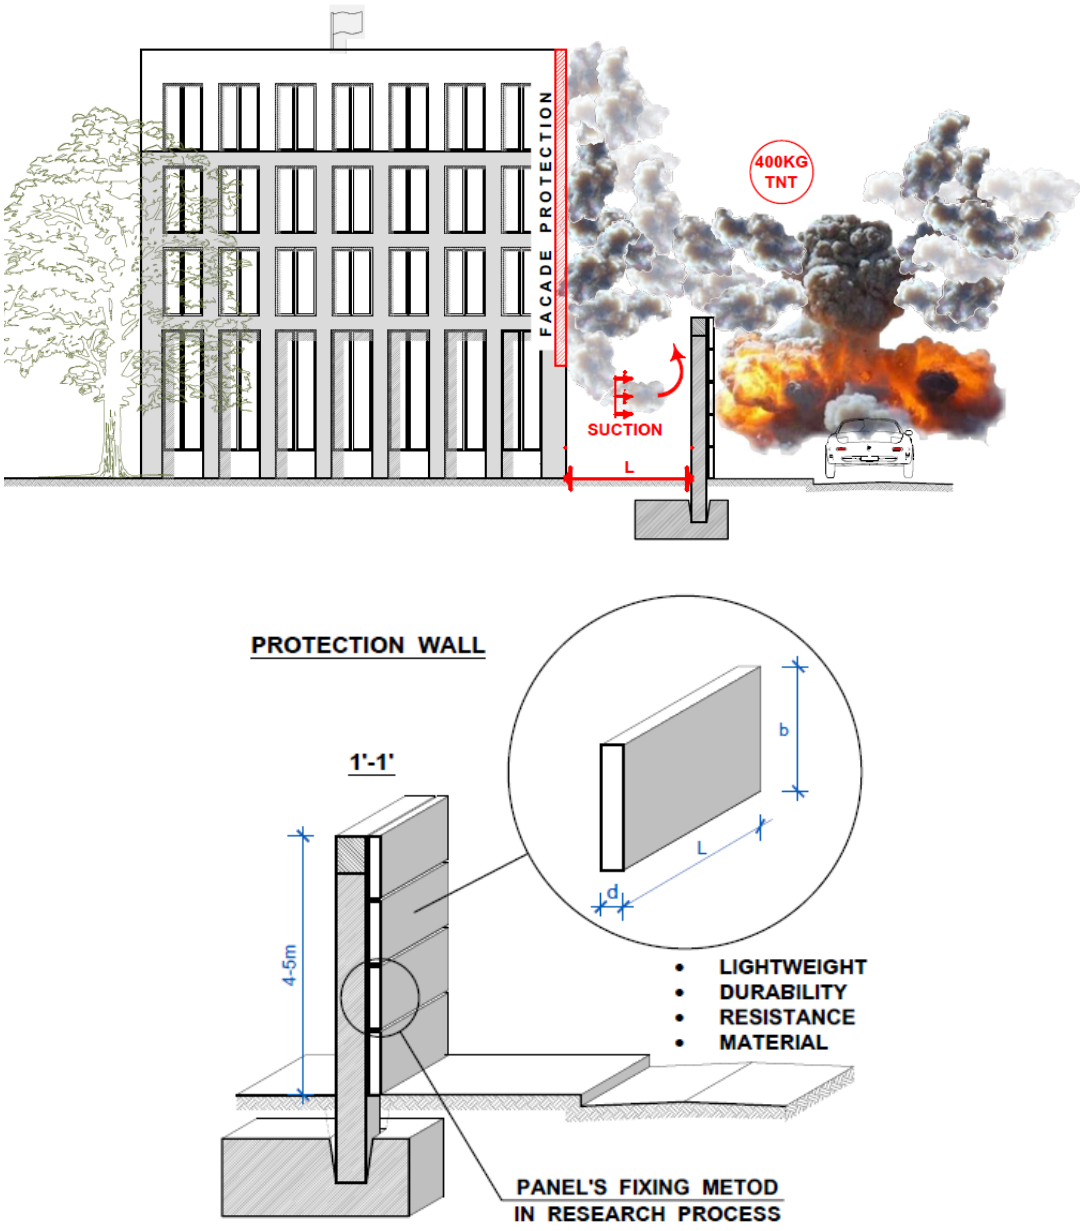

Figure 2. Attack with a car bomb with 400 kg TNT equivalent according to STANAG 2280 (Picture: V. Zohrabyan).

3 Concrete Mixtures and Plate Production for Hand Gunshot Tests

In this project there were produced four concrete mixtures, each consisting of 3 test specimens with different fiber types (polypropylene fibers and steel fibers). As steel fiber types, here it is used: Krampeharex KH DE35/0,55 N (length: 35 mm, diameter: 0,55 mm, tensile strength: 1350 N/mm²), (KRAMPEHAREX GmbH and Co. KG, 2017) BASFMF 254 (length: 54 mm, diameter: 0,81 mm, tensile strength: 552 N/mm²), BASFMF 249 (length: 48 mm, diameter:

0,85 mm, tensile strength: 400 N/mm²) and BASF MF 244 (length: 40 mm, diameter: 0,81 mm, tensile strength: 552 N/mm²) (BASF, 2017). The composition of the fiber concrete C80/95 is shown in Table 1.

Table 1.Concrete Composition Mix 1-4. (Kustermann *et al*., 2005) (Günter and Vollenschaar, 2011) (Richter, 2002) (Thienel and Kustermann, 2017)

Ingredients concrete mixture	**Mix 1-4**
Cement II/BM(S-D)52,5N	459 kg/m³
Stoneash	---
Aggregate 0/4 NfGK	784,9 kg/m³
Aggregate 4/8 NgGK	419,8 kg/m³
Aggregate 8/16 NgGK	620,6 kg/m³
Water	145 kg/m³
(W/C-ratio)	0,316
Superplasticizer	2,55 %
Fiber content	1 Vol % for Mix 1 to 4
Steel fiber KH DE35/0,55 N	78,5 kg/m³ (Mix 1)
Polypropylene fiber MF 244	9,1 kg/m³ (Mix 2)
Polypropylene fiber MF 249	9,1 kg/m³ (Mix 3)
Polypropylene fiber MF 254	9,1 kg/m³ (Mix 4)
Plate thickness	6 cm
Consistency	F4

The dimensions of the fiber reinforced plates are 300 x 300 x 60 mm.

Figure 3. Production of test specimens.

4 Hand Gunshot Test

The hand gunshot tests were carried out in the laboratory of the Institute of Ballistics Weapons and Munition at the Bundeswehr University Munich.

4.1 Test Setup and Execution

The 300 x 300 x 60 mm thick fiber concrete plates were shot with both soft- and hard-core shot caliber 7.62 mm x 51 308 Winchester. The projectiles have a weight of 9.5 g for soft core and 9.8 g for hard core. These were fired by the ammunition tester series 1055, which can be seen in the foreground in Figure 4.

The velocities of the projectiles were determined by measurement of two light barriers LS 23 F3/K2. These measure the speed with an accuracy of ± 0,1 %. An average bullet speed velocity is 842.75 m/s and an average projectile energy computed 3373.03 Joule. The camera was used in the bullet trap (Figure 4) which was triggered as soon as the projectile hit the plate.

Figure 4. Setup and execution of hand gunshot test.

4.2 Results

In order to measure the damage caused by the projectile, the 6 cm thick plates fired on were analyzed with regard to the crater volume (Figure 5).

The crater volume on the firing frontside and the opposite side as well as their mean values are given in Table 2 and compared Figure 6.

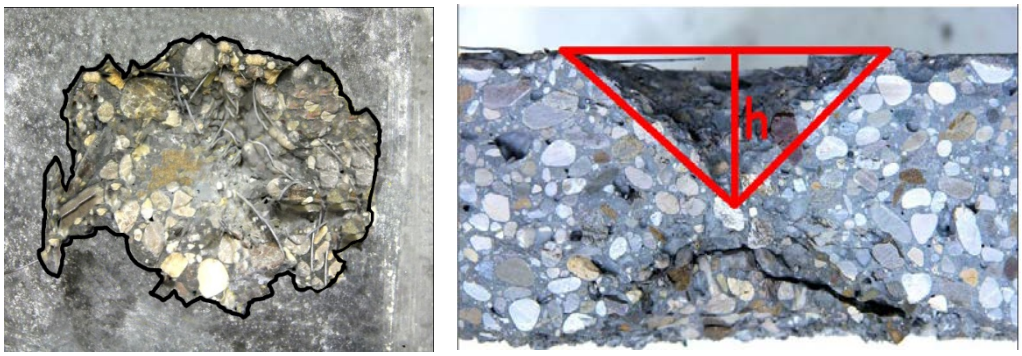

Figure 5. Crater volumes.

Table 2. Mean crater volume front and backside.

Steel Fiber Type	Munition	Crater vol. in front [cm ^{3}]	Crater vol. in backside [cm ^{3}]
MF 254	SC	59,93	148,58
MF 244	HC	65,71	68,33
MF 249	SC	130,74	239,66
KH DE35/0,55 N	SC	117,95	252,43

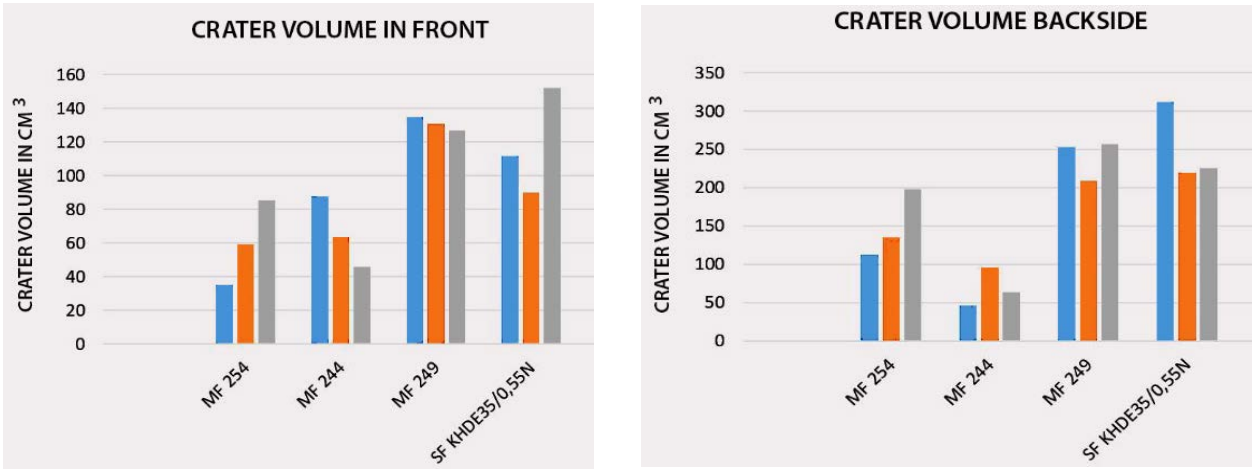

Figure 6. Evaluation of crater volumes.

5 Conclusions

The aim of the presented study was to develop a high-performance concrete mix of high – strength fiber concrete for the production of protective components, which was achieved.

- During the processing of the high-strength standard and fiber concrete, it turned out that a very high use of personnel compaction energy is required to ensure target-

oriented processing.

- The steel fibers KH DE35/0.55 N have the best effect in concrete in terms of increasing compressive strength and improving energy absorption when shot at with soft-core ammunition. The plates of this mixture showed a good protective capacity and withstood the shots well. (Michal *et al.*, 2014)
- It can be said that the specimens produced with fiber Masterfiber 249 also showed good results. It has to be said, however, that the fiber MF 249 only slowed down the projectile and did not stop it.

In conclusion, it can be said that it is possible to manufacture protective components from fiber reinforced, high-strength concrete.

Depending on the dimension and depth of damage after dynamic loading, the created cracks and voids in concrete components can be repaired and strengthened by impregnation and injection. The following variants are possible:

1) Closing the damage area: The aim is corrosion protection. It prevents the chloride entering the component.
2) Sealing the damaged area: The aim is to eliminate water-bearing cracks.
3) Frictional connection: The aim is to create a frictional connection between the two sides of the crack.

Abstract. *Discoloration of building facades due to airborne algae is observed in our surroundings. The growth conditions of these algae are not fully clear yet, and efficient preventive measures have not yet been determined. This study was aimed at investigating the influence of ambient environment and building structure on algal growth. A residential building in the cold region of Japan was surveyed. The roof was a multilayered structure consisting of a semi-transparent film, an air layer, an outside insulation layer, and was supported by rafters. The soiled state was visually observed and recorded through pictures, and seemed to be particularly increased in autumn. Several black stripes appeared on the northeast (NE) roof four months after its cleaning. The soiling first appeared on the film backed by the rafter, and then extended to the film backed by the air layer. It rarely appeared on the southeast roof. The roof-surface temperature was measured and a stripe-shaped distribution was observed. The temperature of the film with rafter was higher and lesser than that of the film with the air layer during the night and in the early morning, respectively. Although condensation occurred nightly, its frequency showed no orientational difference. Algae can die when exposed to a temperature higher than 40 °C. The southwest roof had the longest period of a surface temperature over 40 °C, while the northwest (NW) roof had the shortest period of this surface temperature. These measurements corresponded well to the survey results according to which soiling mainly occurred on the NE and NW sides of roofs. The time for algal growth was estimated assuming that algae can grow at surface temperatures between 0 and 40 °C.*

Keywords: *Roof Soiling, Airborne Algae, Surface Temperature, Condensation, Membrane Structure.*

1 Introduction

An observation of the exterior walls of building walls shows many black or/and green soiling. Some studies showed that this is caused by the adhesion and growth of airborne algae. Currently, the main countermeasures against the algal soling are cleaning and repainting of such walls; however, efficient preventive measures have not been developed yet.

Sharma et al. showed that airborne algae reported to date are species of 103 classes of the three divisions. Tsujimoto et al. investigated the algal soiling in Japan and showed that algal soiling could occur in all Japanese climatic zones. Häubner et al. showed that *Stichococcus* sp. and *Chlorella luteoviridis* could grow at 1–35 °C, and their growth rate increases with increasing temperature and reaches the maximum at 10–25 °C and is nonexistent at 30–35 °C. Agrawal et al. showed that the survival rate of algae is greatly reduced when algae are exposed to high temperatures over 40 °C for several tens of minutes. Nakajima et al. surveyed the soiling conditions of a building with respect to the surrounding environment and showed that algae could grow even on walls rarely exposed to rainwater when the humidity is high and if

temperatures remained below 40 °C. They thus proposed a predictive model of the algal growth and death on exterior walls as a function of the solar radiation, temperature, and humidity.

Although several studies have shown the qualitative relationship between airborne algal growth and the environment, their quantitative relationship has not been fully evaluated yet. This study was aimed at determining this relationship by focusing on a residential building with membrane-structured roofs in a cold region of Japan.

2 Method of Survey and Measurements

2.1 Overview of Measured Building and Climatic Conditions

The one-story residential building that was considered for this study is located in Taiki town, Hokkaido, Japan, and is surrounded by open grassland. It has a hipped roof structure, with rafters arranged at intervals of 40 cm and insulations packed between them (Figures 1a and 1b). The part with a thermal insulation layer has a cross section with a six-layer structure comprising an exterior film, an outside air layer, the thermal insulation, a vapor-barrier, an inside air layer, and the glass cloth, from the outside (Figure 1c). All the materials are semi-transparent. The exterior film is made of a vinyl chloride film and a polyester base fabric and coated by fluororesin.

Taiki town is located close to the sea and has subarctic climate. Figure 2 provides a graphical representation of the outdoor temperature, relative humidity, and precipitation. The daily average temperature falls below freezing point in winter but rises to approximately 20 °C in summer. The relative humidity is over 80% in summer.

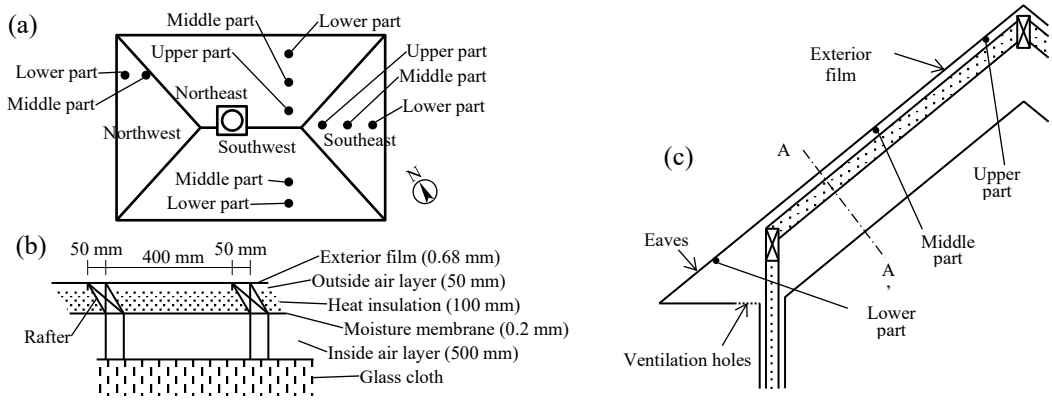

Figure 1. Overview of the measured house: (a) roof plan, (b) A–A' section of roof in (c), and (c) vertical section of the roof.

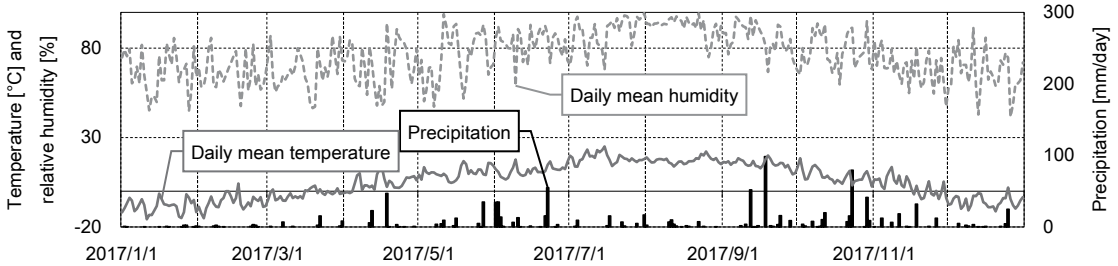

Figure 2. Outdoor temperature, relative humidity, and precipitation in Taiki Town, Hokkaido, Japan.

2.2 Measurement of Roof Surface Temperatures and Climatic Conditions

The surface temperatures of the roofs were measured through thermocouples and hygrothermal sensors. The thermocouples were fixed to the indoor side of the exterior film by tape, and the measured values were regarded as the surface temperatures because the film thickness was very thin at 0.68 mm. The surface temperature was measured at the upper, middle, and lower parts on the NE and southeast (SE) roofs, and at the middle and lower parts on the NW and southwest (SW) roofs, as shown in Figure 1a.

The outdoor temperature and humidity were measured by a thermometer and hygrometer (U23-002, Onset Computer Corporation), respectively, about 5-m NW to the building, where the vertical and horizontal global solar radiations were measured through pyrheliometers (ML-01, EKO Instruments).

2.3 Survey on Roof Soiling

The soiling of roofs was recorded through photographs captured by fixed-point cameras set around the building on September 2017; the NE, NW, and SE roofs were photographed every 4 h.

3 Surveyed and Measured Results

3.1 Soiling of Roof Surface

3.1.1 Soiling difference depending on roof orientation

The photos of each roof are shown in Figure 3. The stripe-shaped soiling extends vertically from the top to the bottom in the center of the NE roof. In the same manner, the stripe-shaped soiling is also generated in the center of the NW roof. The soiling cannot be seen on the SE and SW roofs.

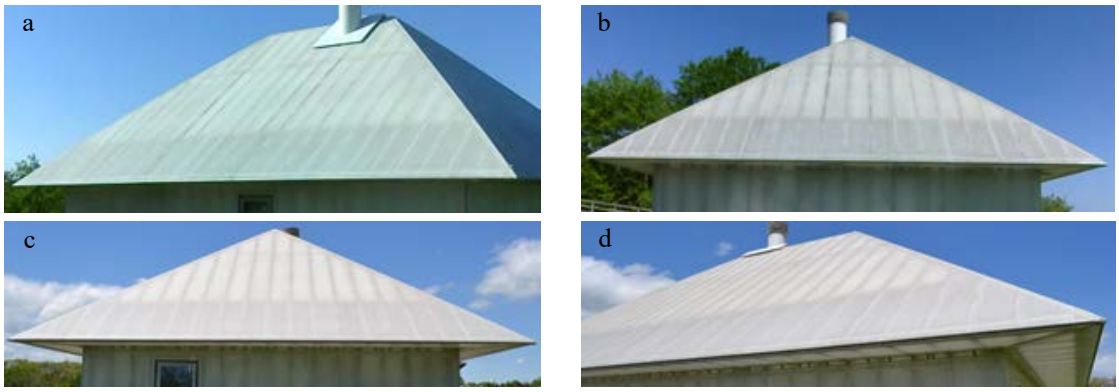

Figure 3. Photographs of (a) NE roof, (b) NW roof, (c) SE roof, and (d) SW roof on May 2018.

3.1.2 Time profiles of soiling on NE and NW roofs

The photos of the NE and NW roofs from September 19, 2017 to March 19, 2019 are shown in Figures 4 and 5, respectively. The roofs were cleaned by brushing and high-pressure washing

on April 4, 2017, after which soiling was not observed on July 5, 2017. The soiling occurred again at the mid-left part of the NE roof on September 19, 2017, and was observed on the roof part downward from the chimney on October 20, 2017. On November 18, 2017, the soiling darkened but did not show further change until December 15, 2017. The soiling on the eaves faded on May 27, 2018, then became darker between June 21 and July 26, 2018. On August 26, 2018, the soiled area increased, the color darkened more than that on July 26, and gradually darkened further from September 22 to October 15, 2018. The roofs were cleaned again on October 22, 2018, after which soiling occurred at the left part of the roof downward from the chimney on November 19, 2018; this remained unchanged from December 23, 2018 to January 23, 2019. The stripe-shaped soiling increased in the area downward from the chimney and darkened on March 19, 2019.

In summary, the soiling hardly increased in the summer (July and August) and winter (December, January, and February) but increased from March to June and from September to November. The NW and NE roofs showed the same soiling tendencies.

Figure 4. Photographs of NE roof from September 2017 to March 2019.

Figure 5. Photographs of NW roof from September 2017 to February 2019.

3.1 Surface Temperature of Roofs

3.2.1 Difference in film temperature between parts backed by rafter and air layer

The surface temperature of the NE roof in summer and winter is shown in Figure 6. In summer, the temperature of the film backed by the rafter (hereafter referred to as rafter part) was almost the same as that of the film backed by the air layer (air layer part) (Figure 6a). The temperature of the rafter part was approximately 1 °C higher than that of the air layer part during the daytime, and the temperatures of both were almost the same at night. In winter, the temperature of the air layer part was 3–5 °C higher than that of the rafter part in the daytime and 1–2 °C higher at night (Figure 7a).

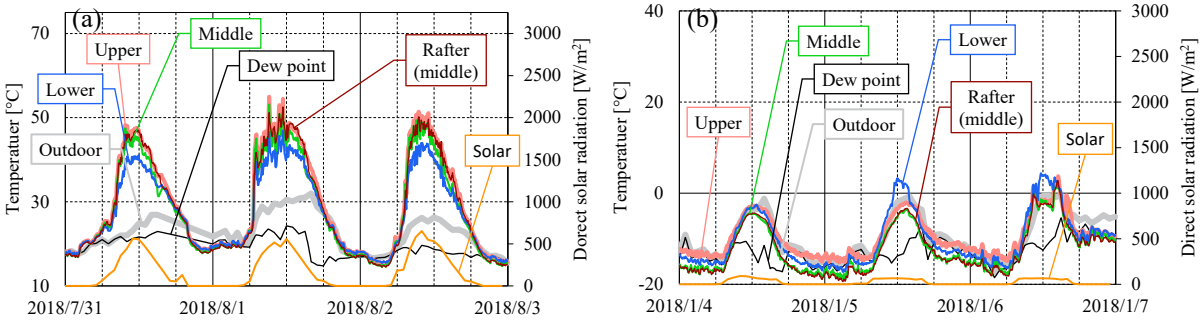

Figure 6. Direct solar radiation and surface temperatures of NE roof in (a) summer and (b) winter.

3.2.2 Annual change in surface temperature on each roof

The annual surface temperature on the NE and SW roofs is shown in Figure 7, where high temperatures of over 45 °C can be observed from June to August on the NE roof, and from February to December on the southwest roof. On the NE roof, where the incident direct solar radiation was the least, the frequency of temperature higher than 45 °C was least (Figure 7a). The daily fluctuation of the surface temperature was large on the SW roofs (Figure 7b).

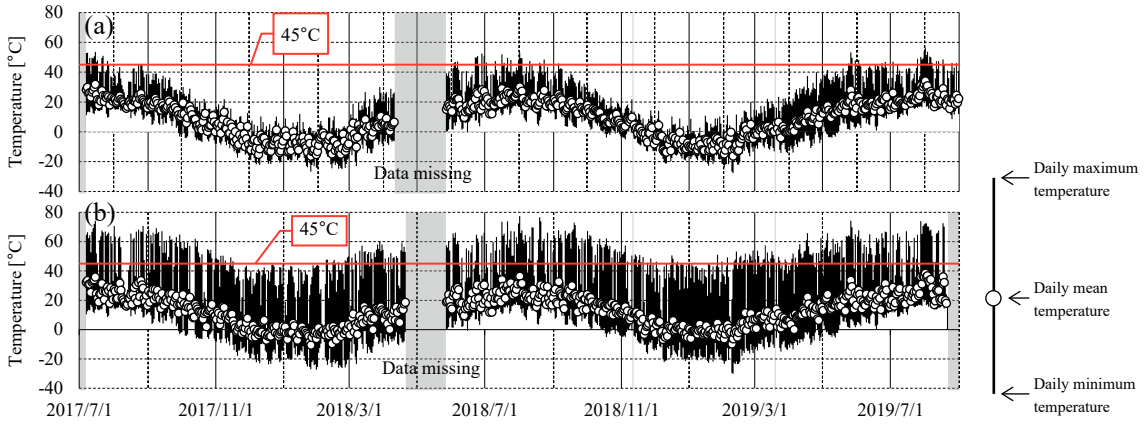

Figure 7. Annual surface-temperature change on (a) the NE and (b) SW roofs. The bar length and circles represent the daily-temperature difference and daily mean temperature, respectively.

3 Discussion

3.1 Relationship between Roof Surface Temperature and Roof Structure

In general, the roof surface temperature is higher at the upper part than at the lower parts (Figures 6). This is probably because the outside air layer was warmed by solar radiation, leading to thermal stratification. This stratification is likely to be accelerated by the nonuniform structure of the roof. The upper and middle parts comprise the air layer of 50-mm thickness and a 100-mm-thick insulating material, while the lower part does not have thermal insulation. Therefore, the air volume at the upper and middle parts was smaller than that at the lower part and their heat capacities were smaller.

4.2 Surface Condensation on Roof

Figure 8 shows the time when the surface temperature was below the dew-point temperature of the outdoor air. Frost was assumed to occur when the surface temperature was below 0 °C. As shown in Figures 6, the surface temperatures on all roofs decreased below the dew-point temperature of the outdoor air because of the nocturnal radiation, and they dropped below 0 °C at night from November to April. Condensation occurred from May to October, and condensation per day was long especially from September to October. This period of condensation differs depending on the roof orientation; however, the frequency of occurrence shows only a very small dependence on the orientation.

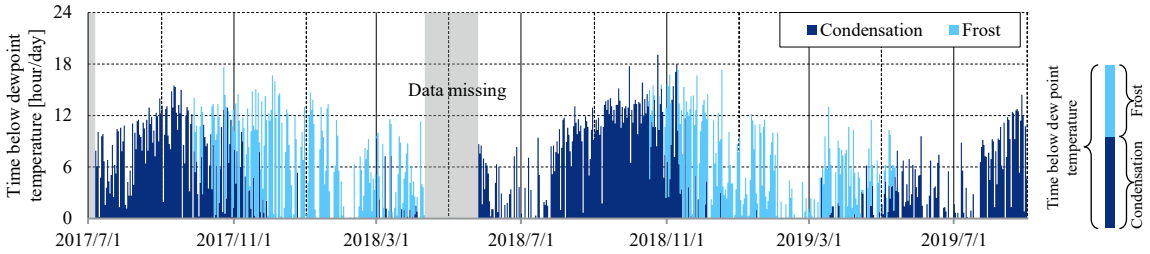

Figure 8. Time per day that the surface temperature was below the dew-point temperature of the outdoor air. Air-layer part at middle part of NE roof.

4.3 Dependence of Soiling on Roof Orientation

The soiling situation at the surveyed building was evaluated by focusing on the surface temperature and available water (condensation). Algae can grow in the temperature range of 1–30 °C, and they die when exposed to the high temperatures. Thus, we focused on the occurrence frequency of high temperatures of over 45°C.

On all the roofs, the surface condensation occurred (the source of water supply to the algae) at night from May to November. Therefore, the algae can grow from May to November.

The measured roof temperatures showed that the SW, SE, NW, and NE roofs, in this order, show high temperature frequency of over 45 °C. From May to November, the surface condensation on the SE and SW roofs occurred during the night but was over 45 °C almost every day. Therefore, the algae are considered to die because of high temperatures during daytime, and soiling did not occur despite sufficient water supply. Compared to all roofs, the frequency of the high temperature of over 45 °C was least on the NE roof when surface condensation occurred, and thus the algae grew most actively on this roof. These results correspond well to the surveyed results where soiling was observed to occur on the NE and NW roofs but not on the SE and SW roofs (Figure 3).

4.4 Difference between Soiling on Rafter and Air-Layer Parts

For the rafter and air-layer parts of the NE roof, the frequency of high temperatures of over 45 °C was almost same. However, the surface condensation on the rafter part occurred more frequently than on the air-layer part, and the condensation period per day was longer on the rafter part from March to November. Therefore, the algae are considered to grow more likely at the rafter part than at the air part (Figure 3).

4.5 Occurrence of Soiling Based on Time of Year

Considering the water supply and temperature suitable for algal growth, the estimated time of the year when the algae can survive is shown in Figure 9. For example, on the NE roof, the surface temperatures were from 0 to 45 °C and condensation occurred from August to September 2017, the middle of July 2018, and from September to October 2018. Thus, the algae are predicted to grow during these periods. This prediction corresponds well to the result that the soiling was observed from July to November 2017 and from June to November 2018, as shown in Figure 4.

On the SW roof, the high temperatures of over 45 °C occurred all year round. Therefore, it is predicted that the algae could grow only in a limited time in February 2017, from the end of November to the beginning of December 2017, and a part of January 2018. These predictions well correspond to the observed result that soiling did not occur on the SW roofs.

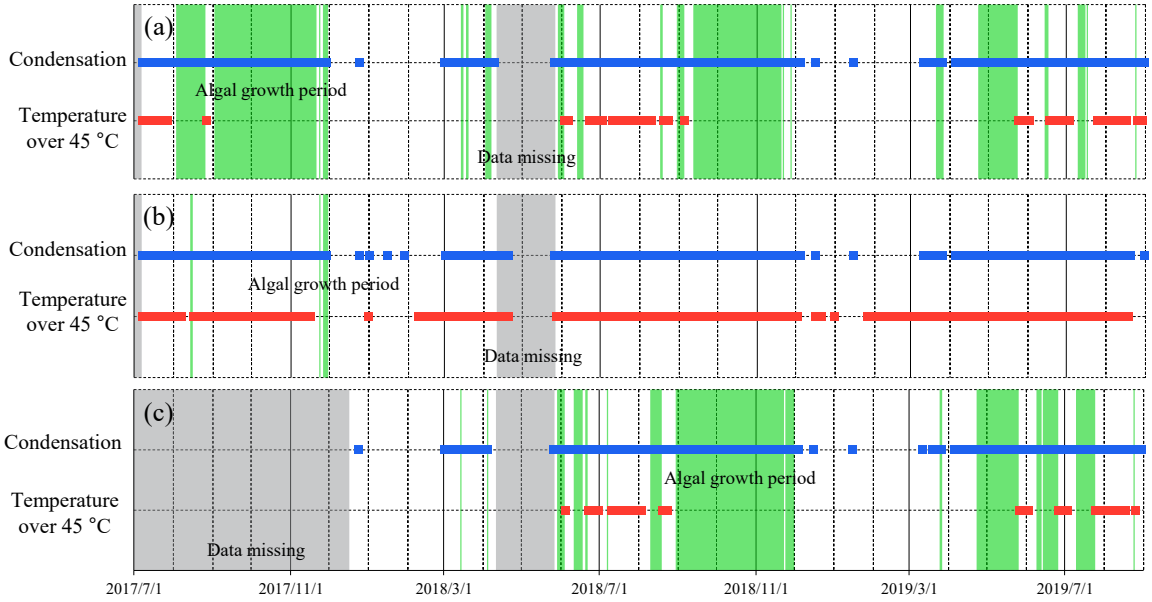

Figure 91. Estimated period for algal growth because of the occurrence of the condensation and high temperature. Air-layer part of middle part of the (a) NE and (b) SW roofs. (c) Rafter part of the middle part of the NE roof. Condensation: the day when the condensation occurred. Temperature over 45 °C: the day when the daily maximum temperature reached over 45 °C.

5 Conclusion

This study was aimed at clarifying the quantitative relationship between airborne algal growth and the surrounding environment. The following conclusions can be drawn.

- The stripe-shaped soiling extended vertically from top to bottom on the NE and NW roofs. In contrast, soiling did not occur on the SE and SW roofs. On the NE and NW roofs, the soiling hardly increased in the summer and winter but increased from March to June and from September to November.
- The SW, SE, NW, and NE roofs, in this order, showed the highest frequency of surface

temperatures of over 45 °C because of solar radiation.

- The surface condensation occurred on all roofs from May to October, and the daily condensation time was long, especially from September to October. The frequency and period of the condensation were almost the same for all roofs (orientation).
- The surface temperature of the SE and SW roofs was higher than 45 °C during the daytime from May to November. Therefore, despite the occurrence of the condensation, the algae died owing to the high temperature, and thus soiling did not occur.
- The comparison of the rafter and air-layer parts of the NE roof showed an almost same frequency of high temperatures of over 45 °C. However, the condensation time per day at the rafter part was longer than that at the air-layer part. Therefore, the algae could grow more on the rafter part, where the soiling was first observed to occur.

Analysis of the Degradation Condition of Elementary Schools

Sónia Raposo

Buildings Department, Laboratório Nacional de Engenharia Civil, Av. do Brasil 101, 1700-066 Lisboa, Portugal, sraposo@lnec.pt

Abstract. *Currently, there is still no information regarding the performance of public buildings after their construction and the relationship with the needs for carrying out maintenance activities. This paper presents some of the main anomalies detected in six schools, built between 1997 and 2003 in Lisbon. The analysis of the degradation condition of these schools was based on data obtained through detailed visual inspections, carried out in three distinct periods of their operation phase, 2007, 2013 and 2018. The highest level of severity mainly concerns defects on buildings structure and buildings envelope and results from bad decisions made during design and/or construction. Therefore, there are serious problems related to the premature deterioration of these educational buildings, requiring expensive, complex and unplanned major repairs to achieve their specified design service life. This work highlights the need for greater involvement of school building management entities, in the early stages of the building process, including design, tendering, construction and handover.*

Keywords: *Elementary School, Building Condition, Anomalies, Durability.*

1 Introduction

The building condition assessment (BCA) is a systematic inspection, review, and report on the state of a building's structure, construction elements and systems. The BCA provides an identification of elements anomalies and the expected costs to remedy those deficiencies. This is an important step for the management of buildings maintenance and should be applied to the existing elementary public school portfolio of Lisbon. This network of schools includes more than 100 buildings with construction ages ranging from the nineteenth century to the beginning of this century (Raposo, 2011). Despite the existence of schools operating in very old buildings, are the most recent schools, built after 1980, that present major problems of conservation and maintenance (Raposo *et al.*, 2008).

In the present paper, the results obtained through visual inspection of six school establishments, built between 1997 and 2003, are presented. Inspections were carried out in 2007, 2013 and 2018 and it was possible to identify some recurring anomalies and causes for the accelerated and premature degradation that occurs in these buildings.

2 Research Methodology

In 2007 Raposo, Fonseca and Brito (2008) carried out a preliminary research on six elementary school of recent construction in Lisbon. The work was developed in two phases: (i) collection and treatment of information from the design phase and from the use and operation phase, (ii) fieldwork with detailed visual inspection of the buildings. In 2013 an inspection and BCA was performed of the building's structural and envelope components and playgrounds and outdoor spaces (Luís, 2013), and of the building's interior elements, including finishes, walls, ceilings, doors and plumbing (Nogueira, 2013). In 2018, the National Laboratory for Civil Engineering

carry out an assessment of the maintenance condition of 55 kindergarten (k) and elementary schools (EB1), for the Municipality of Lisbon (Vilhena *et al.* 2019). Extensive and detailed photographic and written records were made about anomalies detected allowing its comparison over time.

Table 1 shows the building characteristics of Prista Monteiro School (PM), Vale de Alcântara School (VA), Alto da Faia School (AF), Padre Rocha e Melo School (PRM), Alta de Lisboa School (AL) and Vasco da Gama School (VG) integrating the kindergarten and three levels of basic education.

Table 1. School Buildings Characteristics.

Schools	Year	Pupils	Level	GA (m2)	Floors	Year of Inspection
PM	1997	110	EB1	2200	2	2007-2018
VG	1999	600	k+EB1/2/3	8800	3	2007-2018
VA	2001	130	k+EB1	1700	2	2007-2018
AF	2001	340	k+EB1	4000	3	2007-2013-2018
PRM	2002	330	k+EB1	3000	2	2007-2018
AL	2003	330	k+EB1	3300	2	2007-2013-2018

3 Results

3.1 Foundation and Structure

The structure of VA School building is a system of slabs, columns and beams in reinforced concrete. The inspection carried out at this school in 2018, revealed the existence of serious anomalies in the structure namely, the existence of extensive structural deformations and the existence of wide opening cracks in multiple walls and ceilings on the two floors of the building.

Figure 1 shows the result obtained through inspections carried out in 2007 and 2018, where it is possible to observe the degradation mechanism of the building's structure and interior and exterior partition walls. They were identified foundations settlement problems and water infiltration through the roof in several classrooms (Vilhena *et al.*, 2019). Following this inspection, the school was closed for further rehabilitation intervention.

Figure 1. VA School: deterioration process of the exterior partition wall in 2007 (a) and 2018 (b). Cracks in walls in 2007 (c) and 2018 (b).

The 2018 survey, carried out in AF school, revealed the existence of anomalies in the outdoor constructive elements. The most frequent anomalies in these elements are oriented cracking,

severe fracture, differential settlements and deteriorated expansion joints without sealant. Some of these defects were detected since 2007, when only six years had passed on handover of the building. Figure 2 shows the result obtained through inspections carried out in 2007, 2013 and 2018, on the supporting wall located in AF school's outdoor spaces. It is possible to observe the existence of settlements and structural movements that remain unsolved.

Figure 2. AF School-outdoor spaces: deformation and settlement of the supporting wall and the recurring appearance of cracks. Anomaly evolution in 2007 (a), 2013 (b) and 2018 (c).

AL School was implanted on a landfill site, which is very steep along the longitudinal and transversal development of the building. The building structure is in reinforced concrete and is made of two blocks connected by an access ramp and stairs. In 2007, the existence of several anomalies resulting from the differential settlement of the two blocks was already visible (cracking in walls and broken elements). Although several repairs have been carried out in the building, 2013 and 2018 surveys revealed that the settlement movement remains active and the cracks in the walls and floors continue to appear (Fig. 3a). In AL, AF and PRM Schools, deteriorated expansion joints without filling material and sealant was observed (Fig. 3b,c,d,e). Lack of repair of the joints exposes the building elements to water infiltration and mechanical actions.

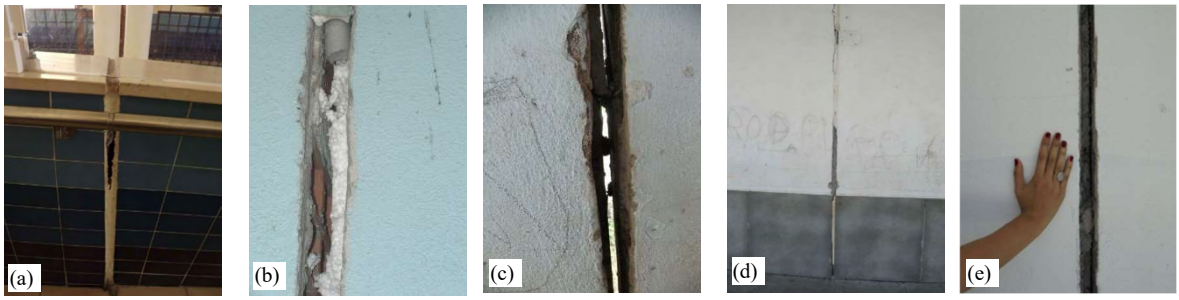

Figure 3. AL School: foundation settlement movement: broken stone and construction joint opening in 2013 (a). Expansion joints without sealant: AF School in 2007 (b) and 2018 (c); PRM School in 2007 (d) and 2018 (e).

3.2 Building Envelope

3.2.1 Roofs

Three of the six buildings have flat roofs (PRM, AL and VA schools), AF school presents a mixture of flat and sloping roofs in metal sheet, PM school present a sloping roof covered with

ceramic tiles, and VG School presents a non-traditional roof covering made of ceramic pellets. In PM School, infiltrations water problems continue to be observed since 2007 survey, in the area of the gymnasium affecting both the ceiling and the floor. The AF School continues to present problems between the several flat and sloped roofs boundary buildings (Fig. 4a). Skylights are the element that most frequently presents anomalies caused by water infiltration. It was possible to observe the degradation mechanism in ceilings, walls and floor coatings, caused by water infiltration through skylights in PMR School (Fig. 4b,c).

Figure 4. AF School: mixture of flat and sloping roofs in metal sheet (a). Water infiltration problems betewen the building´s roofs. PMR School skylights problems in 2018 (b), (c).

3.2.2 Exterior walls, windows and doors

Part of the exterior walls of AF School is made up of *Corten* steel panels and it was found that over the years, colour changed from orange-brown to dark brown as expected (the rust layer transforms into a patina layer) (Fig. 5a, 5b). However, aesthetically the overall wall covering did not result because there are panels with different colors, which may have been the result of localized repair work or replacement of some panels over the years. The wall facade presented serious problems of corrosion and lack of fixation, with risk for building users (Fig. 5c). In PRM School, the cladding of ventilated facades in wooden panels presented several anomalies related to acts of vandalism (scratches and graffiti), stains and non-uniforme darkening of the surface and unequal joint opening (with large local openings) without any filling (Fig. 5d,e) exposing the building elements to water infiltration.

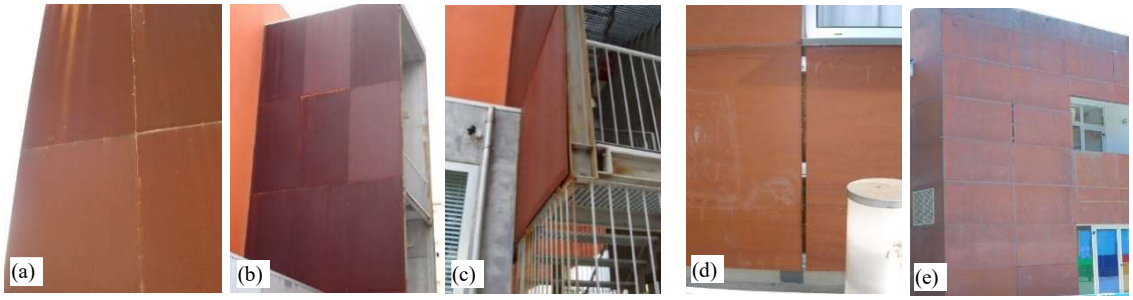

Figure 5. AF School – exterior walls in *Corten* steel panels: colour change from 2007 (a) to 2018 (b). Corrosion and fixation problems in panels in 2018 (c). PRM School wooden panels degradation in 2007 (d) and in 2018 (e) with 16 years of service life.

In PRM School, damaged or missing door locks and handles were observed in the surveys. These failures severely reduces the adequate serviceability of the exterior doors (Fig. 6a,b).

These anomalies were detected in 2007 in doors with 5 years of service life. In general, some problems with rain penetration were observed in windows and non-operational interior polystyrene blinds is a very frequent anomaly. In AF School the outdoors shading were broken and deformed caused by its proximity to the playing field (Fig. 6c,d).

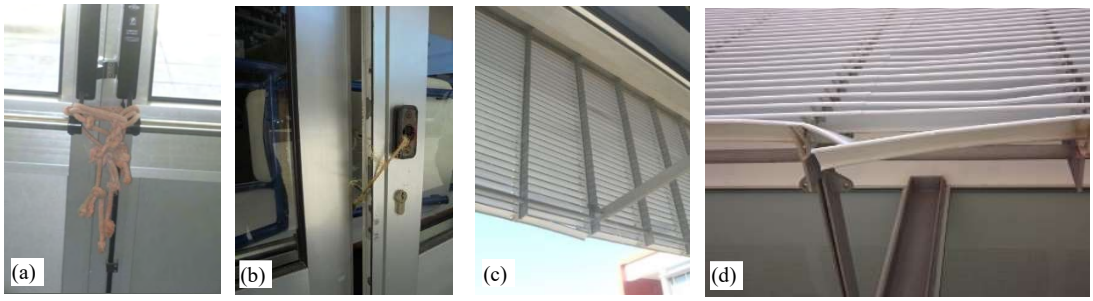

Figure 6. PRM School: missing door locks and handles 2007 (a) and 2018 (b). AF School: outdoors shading broken and deformed in 2007 (c) and 2018 (d).

3.3 Building Interior

3.3.1 Floors, walls, ceilings and doors

At PRM School, the degradation mechanism of the floor finishes, in the arts and crafts areas, next to the classrooms, caused by frequent water leakages from the washbasin siphons, has been observed since the 2007 inspection. In 2018, the placement of floor covering patches in this area was observed. Figure 7 (a,b,c) shows three stages of the vinyl floor covering degradation process caused by wet-dry cycles exposure conditions.

Figure 7. PRM School: vinyl floor degradation process caused by wet-dry cycles exposure conditions. Area in good condition and severely damaged area in 2007 (a,b); floor repaired in 2018 (c).

In the VA, AL, VG and PM Schools, cracks in interior to exterior walls and partitions walls were observed in 2018. In VA School, the severity and extent of the affected areas, indicates that the emergence of cracks is related to structural problems and differential settlements. In general, the most frequent anomalies in walls are related with deficient protection of corners and lack of adoption of wainscot/paneling elements in corridors and areas of intensive use.

Degradation in wall painting due to the use of adhesive tape for the exhibition of students' work was observed in the inspection carried out in 2007. In 2018 survey this anomaly was observed more frequently and over a larger area of walls (Fig. 8a).

In ceilings, moisture and water ingress are the most frequent anomalies. Figure 8 (b,c) shows the increased severity of this phenomenon in VA School, that may have resulted initially from lack or loss of waterproofing capacity of the building envelope (in 2007) and later resulted from the combination of several causes including building structural and foundations settlement problems (in 2018).

Figure 8. AF School: degradation in wall painting due to the use of adhesive tape for the exhibition of students' work in 2018 (a). VA School: water infiltrations in the ceilings in 2007 (b) and in 2018 (c).

The model of the sliding doors used to separate the classrooms from the arts and crafts areas and in bathrooms (PRM, PM and AF Schools) presented several functional problems related to unsuitable serviceability, vertical misalignment and deficient fixation tracks causing localized wear on the floors finishes (Fig. 9a). The use of large bellows doors to separate the gym from school cafeteria is a widely used solution in these recent buildings schools. This solution aims to open the spaces with an area for students to perform shows/theaters an area for the audience. Due to their characteristics, theses doors are large (length and height) and are heavy, which makes manual maneuvering difficult. These doors are now permanently closed and are not used because they require maintenance and repair actions without which their safe use is not guaranteed (Fig. 9b). At PRM School, door closer need to be repaired in interior fire doors. In 2007, these elements were damaged (Fig. 9c), while in the 2018 survey it was found that the element was not placed where it was supposed to be (Fig. 9d).

Figure 9. AF School: sliding door anomaly (a) non-operational bellows doors (b). PRM School: door closer anomaly in fire doors in 2007 (c) and 2018 (d).

3.3.2 Sanitary services

In 2018 survey, it was found that all schools continue to have recurrent problems and anomalies in the sanitary equipment and in the water supply and wastewater drainage networks. These installations are used intensively and not always in the most appropriate way. The most frequent

anomalies in these systems continue to be (i) the breakdown of the toilet flushes, (ii) fixing problems of water faucets and (iii) problems with the drainage capacity of the wastewater network. The lack of proper maintenance and misuse, results in nonfunctional equipment and sometimes in floods. Figure 10 (a) shows the poor fixing of the water tap and deficient drainage of the wastewater, (b) failure in the flushing system causing waste of water and (c) anomaly in the floor box of the wastewater network.

Figure 10. PRM School: anomalies on water tap and in the water flow, 2007 (a) failure in the flushing system, 2018 (b) and anomaly in the floor box covering finish of the wastewater network, 2018 (c).

4 Conclusions

This article presents the results of three inspections carried out in 2007, 2013 and 2018, on six school buildings built after 1997. The study revealed the existence of severe and unexpected degradation in these buildings. Anomalies related to the settlement of foundations and movements in the structure, are probable causes for the problems in other construction elements (cracking in interior and exterior walls and water infiltration). Observations made over the years showed that many of the structural problems are not stabilized what may have been caused by execution and/or design errors. It was found that one of the schools, with 19 years of service life, had to close, due to the existence of structural failures that endangered the health and safety of building users. Structural problems must be solved before carrying out many of the minor repairs, but they are complex, expensive, and so postponed.

Building schools should be designed to have a long service life, up from 50 years, so premature degradation of buildings is a problem with negative environmental, social and economic impacts. This work highlights the need for greater involvement of school building management entities, in the early stages of the building process, including design, tendering, construction and handover, to ensure that buildings and building elements fulfil their function for their specified design service lives.

Abstract. *For rehabilitation of existing concrete structures, strength and durability related properties of the reinforced element are of high importance. Assessment of these properties of existing structures can be performed by (i) destructive testing of drilled cores and testing the extracted samples in lab environment and (ii) indirect methods by using non- or semi-destructive techniques on site. The use of core-drilling is a time-consuming and labour-intensive method that weakens the existing concrete structure, leaving a lasting impression on it. As an alternative, many different non and semi-destructive techniques are available for the in-situ determination of compressive strength and durability related properties. An experimental program is conducted on concrete slabs of different strength classes intended for various exposure classes (according to EN206), based on a limestone aggregate matrix, which is typically used for Belgian applications. The plates have an age of approximately 5 years, which were also characterized at younger stage (in 2014). Besides destructive core drilling and testing (compressive strength tests, chloride migration testing, and determination of carbonation rate), several non-destructive techniques were selected for this study: the rebound hammer, the ultrasonic pulse velocity tester, the Wenner probe for concrete resistivity and the air permeability tester. Best fit correlations between the output of these different techniques were established. The effect of age (e.g. carbonation) on the established predictive models is being evaluated.*

Keywords: *DT vs. NDT, Strength, Durability, Transport Properties, Age Effect.*

1 Introduction

For characterization of existing concrete structures, insight in the strength and durability related properties are necessary in order to come to an adequate rehabilitation or repair strategy (Hobbs *et al.* (2007)). Assessment of these properties can be performed by (i) time-consuming and labour-intensive destructive testing of drilled cores and testing the extracted samples in lab environment and/or (ii) indirect methods by using non- or semi-destructive techniques on site, as an alternative. In this study, an experimental program was conducted on concrete slabs with an approximate age of 5.5 years, intended for various exposure classes (variation in W/C-ratio, cement type and cement content), based on a limestone inert matrix, and frequently used for Belgian applications. These slabs were intensively investigated, both in 2014 and 2019, by means of destructive testing (compressive strength tests, chloride migration testing, and determination of carbonation rate), and non-destructive techniques: the rebound hammer, the ultrasonic pulse velocity tester, the Wenner probe for concrete resistivity and the air permeability tester. Best fit correlations between the output of these different techniques were

established. The effect of age (*e.g.* carbonation) on the established predictive models is being evaluated.

By measuring the propagation speed of ultrasound waves through the material, the concrete quality is investigated. A high pulse velocity will result in a good quality concrete and, therefore, a higher compressive strength and more durable material can be expected. In this study, only ultrasonic techniques were used to determine to ultrasonic pulse velocity (direct transmission), according to EN 12054-4. The main influencing parameters on the output of the UPV are the type, content and hardness of the aggregates, the presence of cracks/voids in the structure and the moisture content of the concrete (Breysse (2012)). The W/C-ratio also affects the readings in pulse velocity. Furthermore, relative humidity also influences the output. The pulse velocity might increase up to 5% between dry and saturated test specimens, according to Solís-Carcaño *et al.* (2008).

The rebound hammer measures the rebound of a spring-loaded mass impacting on the surface of a concrete sample or structure, generating the rebound number, according to EN 12504-2. The higher this number, the harder the surface, indicating a high concrete compressive strength. A correlation exists between the compressive strength of standard cubes and the rebound number obtained by the hammer. However, this correlation is not universal and has to be modified for different devices, different concrete mixes or different conditions of testing. The condition of the surface has a high influence on the readings. Furthermore the type and the hardness of the aggregate and the carbonation degree, as it increases the surface hardness of the concrete, will have a big influence on the rebound number (Kim *et al.* (2009)).

Measuring concrete resistivity on site can be performed in various ways. It is often measured with a Wenner probe consisting of four equally spaced point electrodes that are pressed onto the concrete surface. Results show that there is no appropriate relationship between surface resistivity and strength, generally due to different mechanisms support compressive strength and electrical resistivity. Consequently, it is not recommended to use surface resistivity as an indicator for evaluation of compressive strength (Ramezanianpour *et al.* (2011)). Nevertheless, the electrical resistivity of concrete is an important parameter, e.g. used to describe the corrosion rate of reinforced concrete elements for durability assessment. This parameter is related to the water content, the cement type, the W/C-ratio of concrete and the hydration degree. Environmental conditions such as relative humidity and temperature also affect the resistivity of the concrete matrix.

Several researches have shown that the coefficient of air permeability k_T correlates quite well with other standardized durability related tests (Jacobs *et al.*, 2009). For instance, carbonation depth of concretes after 500 days of natural exposure correlates well with their k_T values measured at 28 days: higher air permeability leads to higher carbonation rate. These concretes have W/C-ratios in the range 0.26-0.75 and are made with CEM I (except few mixes to which 5-8% silica fume was added). Torrent *et al.* (2012) also found a rather good correlation between k_T and results of the rapid chloride permeability test (ASTM C1202), with data originating from mixes with Portland cement, slags, fly-ashes and micro silica, and varying W/C-ratios (0.4-0.9).

2 Materials and Methods

2.1 Concrete Composition

The study was initiated in 2013, with the casting of 14 non-reinforced slabs using 7 concrete mixtures with strength classes varying from C12/15 up to C50/60. For each mix two slabs (600 x 100 x 100 mm³) were cast and tested (destructive compressive strength and various non- or semi-destructive techniques, as mentioned in (Craeye *et al.*, 2017)). The properties of these mixtures are given in Table 1. These concrete mixtures are frequently applied in Belgium for different exposure classes. Limestone aggregates are used (max. grain size 22 mm), except for mixture C25/30 (which used porphyry 8 mm). Blends of three different cement types are selected: Portland CEM I 52.5R and blast furnace slag CEM III/A 42.5N – CEM III/B 42.5N.

Once this research project was finished, the slabs were stored in an unconditioned but sheltered outside environment. For this research study, the slabs are tested with an approximate age of 5.5 years.

Table 1. Concrete composition in different strength classes.

Strength class	**Exposure Class**	**Slump W/C**	**Aggregates** Max. grain size	**Cement** Min. content
C12/15	X0	S4 1.00	Limestone 22 mm	CEM III/B 42.5N LH SR LA 260 kg/m³
C20/25	XC2	S3 0.60	Limestone 22 mm	CEM III/B 42.5N LH LA 280 kg/m³
C25/30	XC3-XF1	S3 0.55	Porphyry 8 mm	CEM III/B 42.5N LH LA 280 kg/m³
C30/37	XC4-XF1	S3 0.50	Limestone 22 mm	CEM I 52.5R + CEM III/B 42.5N LH LA 300 kg/m³
C35/45	XC4-XD3-XF4	S3 0.45	Limestone 22 mm	CEM III/A 42.5N LA 320 kg/m³
C40/50	XC4-XD3-XF4	S3 0.40	Limestone 22 mm	CEM I 52.5R + CEM III/A 42.5N LA 320 kg/m³
C50/60	XC4-XD3-XF4	S4 0.40	Limestone 22 mm	CEM I 52.5R + CEM III/A 42.5N LA 340 kg/³

2.2 Selection of (Non-)Destructive Methods

Out of each slab 7 cores (diameter 100 mm, height 100 mm) are drilled to perform compressive strength, chloride migration and carbonation tests. To determine the actual compressive strengths of the concrete slabs, 3 cores are tested per slab, according to EN 12504-1. The core strength is converted into the equivalent cube compressive strength ($f^*_{ccub150}$) by means of a shape factor (averaged value of 1.05, NBN B15-001).

Prior to the drilling the slabs are examined in a non-destructive way: ultrasonic pulse velocity (direct transmission), air-permeability, surface resistivity, and rebound hammer tests are executed, according to EN 12504-2, SIA 262/1, AASHTOT277 and 12504-4 respectively. The location of the tested area on the slab are identical for each test.

Chloride migration is determined in a non-stationary way, according to the NTBuild 492 regulations on 3 cores per slab. The depth of carbonation (or the carbonation coefficient) is determined on 1 core per slab, according to EN 14630, using 1% phenolphthalein solution.

3 Results and Discussion

3.1 Strength Assessment

In Figure 1a) the results of the individual tests on both slabs per strength class are given and compared to the results obtained in 2014. There is a time difference of 5.5 years in between the 2014 and 2019 results. In general, there is a slight decrease in strength, except for C20/25. Lower strength loss was observed for the lower strength classes: 1.3% and 4.9% for C12/15 and C20/25, while for C30/37-C35/45-C40/50-C50/60 the decrease is 20.9%-9.0%-4.4%-8.4% respectively.

The output of the equivalent cube compressive strength results is linked to the test results of the ultrasonic pulse velocity (direct transmission), the rebound hammer measurements and the air permeability measurements, as shown in Figure 1b), Figure 1c) and Figure 1d).

Linear regression analysis is performed the obtain the best fitting curve between destructive and non-destructive test, and the reliability of the correlation of one method specifically, is quantified by means of the coefficient of determination (R^2-value) and the standard deviation (shown in the graphs). A linear correlation exists between cube compressive strength and the ultrasonic pulse velocity and compressive strength and the rebound number, with comparable correlation R^2 of 0.701 and 0.726 respectively. Compared to the 2014 study, there is a noticeable drop in R^2 (0.957 for the rebound number, 0.886 for the ultrasonic pulse velocity): measurements on concrete surfaces that were subjected to environmental effects, have a significant lower linear coherence compared to tests performed on young concrete. It is known that carbonation has an effect on strength-hardness correlation (Kim *et al.*, 2009) which is also identified in this study. There is a noticeable shift in the correlation in between the 2014 and 2019 correlation curve (Figure 1a)). Furthermore, the difference in between the correlation provided by the provider of the supplier and the one obtained in this research is worth mentioning. For a given strength, the rebound number increases due to carbonation, and this effect is more prominent for higher strength classes. Comparable conclusions can be drawn regarding the correlation in between strength and ultrasonic pulse velocity. However, the effect of carbonation is less clear. Furthermore, the compressive strength is inversely proportional

with the air permeability (Figure 1c)): increasing the permeability of matrix leads to a decrease in strength. A good correlation is found in this project, R^2 equals 0.83.

As the resistivity meter is not designed for strength estimation, the measurements cannot be related to each other. In comparison with the 2014 study, it appears that the surface resistivity of the concrete slabs increased over a period of 5.5 years.

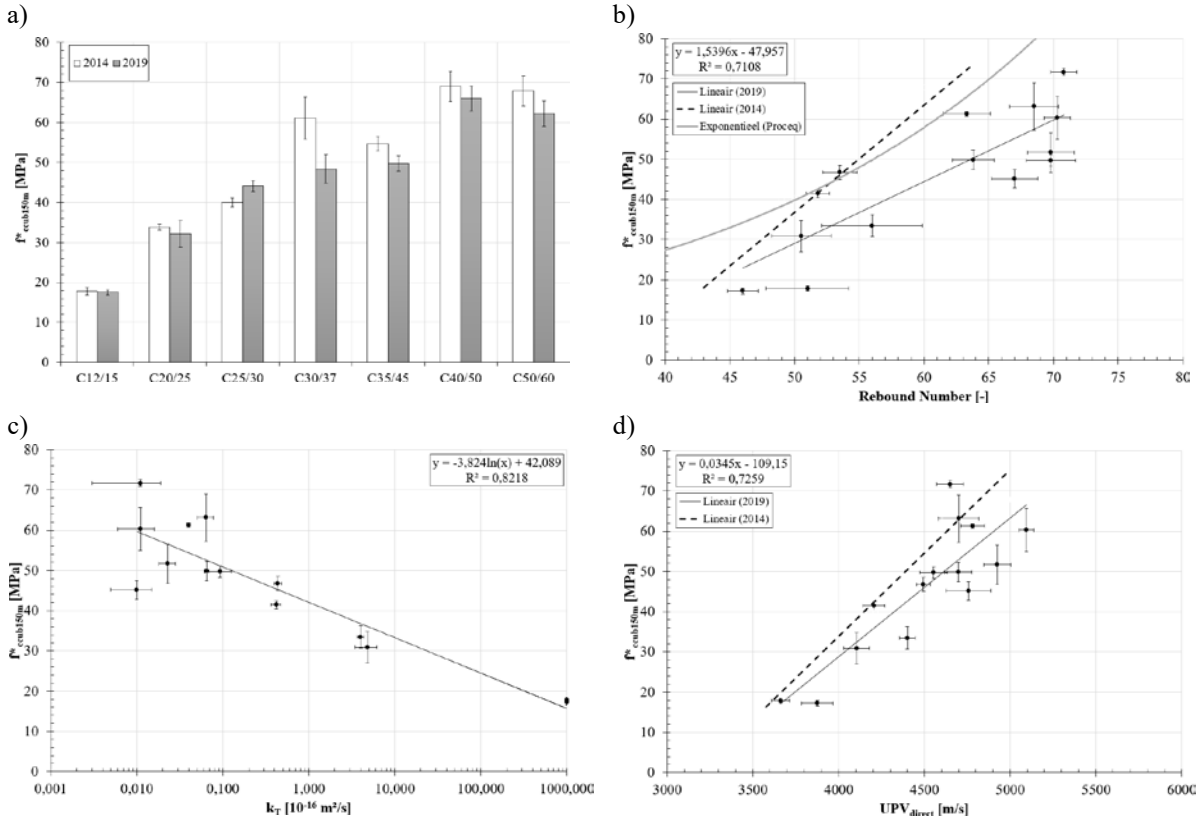

Figure 1. a) Equivalent cube compressive strength 2014-2019, b) correlation $f^*_{ccub150m}$-rebound number, c) correlation $f^*_{ccub150m}$-air permeability, d) correlation $f^*_{ccub150m}$-ultrasonic pulse velocity.

3.2 Durability Assessment

The depth of the carbonation and the chloride migration coefficient is determined destructively on the cores drilled out of the slabs. The results are presented in Figure 3a). The effect of the strength class is clearly noticeable. However, as the cement type has a decisive effect on durability and corrosion related properties such as carbonation and chloride migration (Hiemer *et al.* (2018)) a subdivision of the results is needed. The carbonation coefficient decreases with increased strength class for the slabs with a lower strength class concrete (C12/16 to C25/30) with blast furnace slag cement (CEM III/B) (Figure 3a)). For the higher concrete strength classes, using blends of Portland CEM I 52.5 and blast furnace slag CEM III, no effect of strength class on carbonation is found. The higher carbonation coefficient is noticed for the

slabs with strength class C35/45. This is due to the single use of blast furnace slag CEM III/A, which is more susceptive to carbonation. It is known that carbonation leads to precipitation of $CaCO_3$ which leads to an increase in hardness of the concrete surface and densification of the matrix, however without increasing the strength of the material. As carbonation of the concrete cover increases, the permeability of the matrix increases (Figure 3c)) and a decrease in pulse velocity can be identified (Figure 3b)). The permeability of concrete has an effect on the speed of propagation of the ultrasonic pulse, which is shown in Figure 3d). Elements with high permeability have a lower pulse velocity, mainly due to the scattering of the pulse through air present in the pores. It is important to note that the use of the air permeability meter can be a good alternative for the ultrasonic pulse velocity tester.

No trend is noticeable regarding effect of strength class on chloride migration (Figure 3a). The cement type has a decisive effect on transport of chlorides through concrete: using blast furnace slags has a more positive effect on chloride migration compared to the strength class. Finally, a higher chloride migration is found in case of higher air permeability or surface resistivity (Figure 3e), Figure 3f)), however the scatter on the results is quite high, and therefore a clear correlation cannot be established.

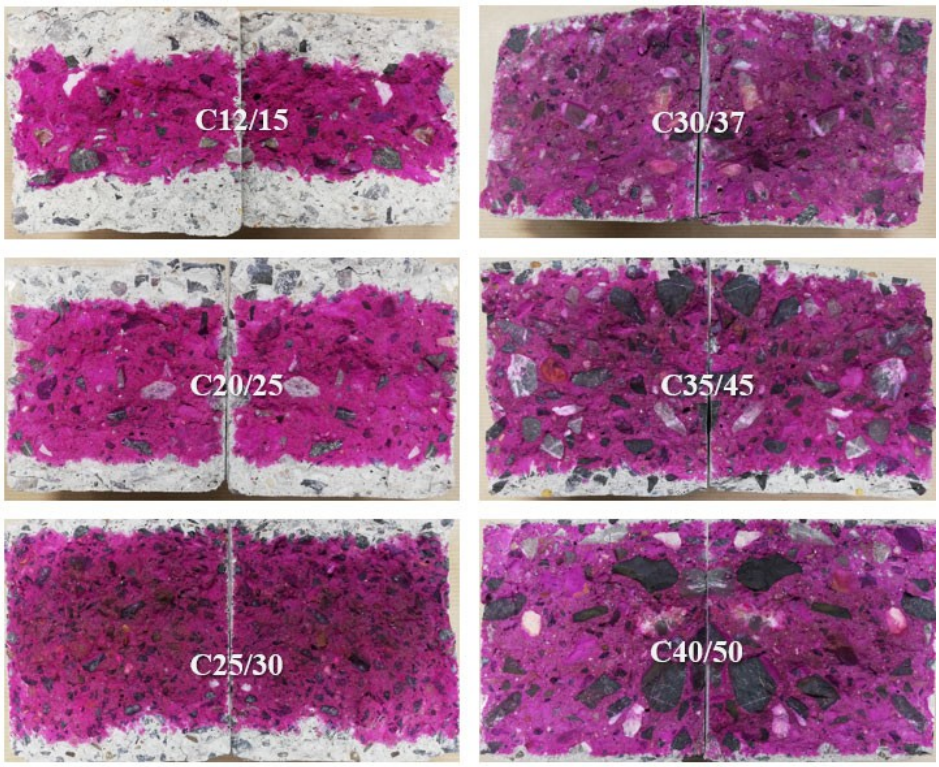

Figure 2. Carbonation depth of concrete with different strength classes.

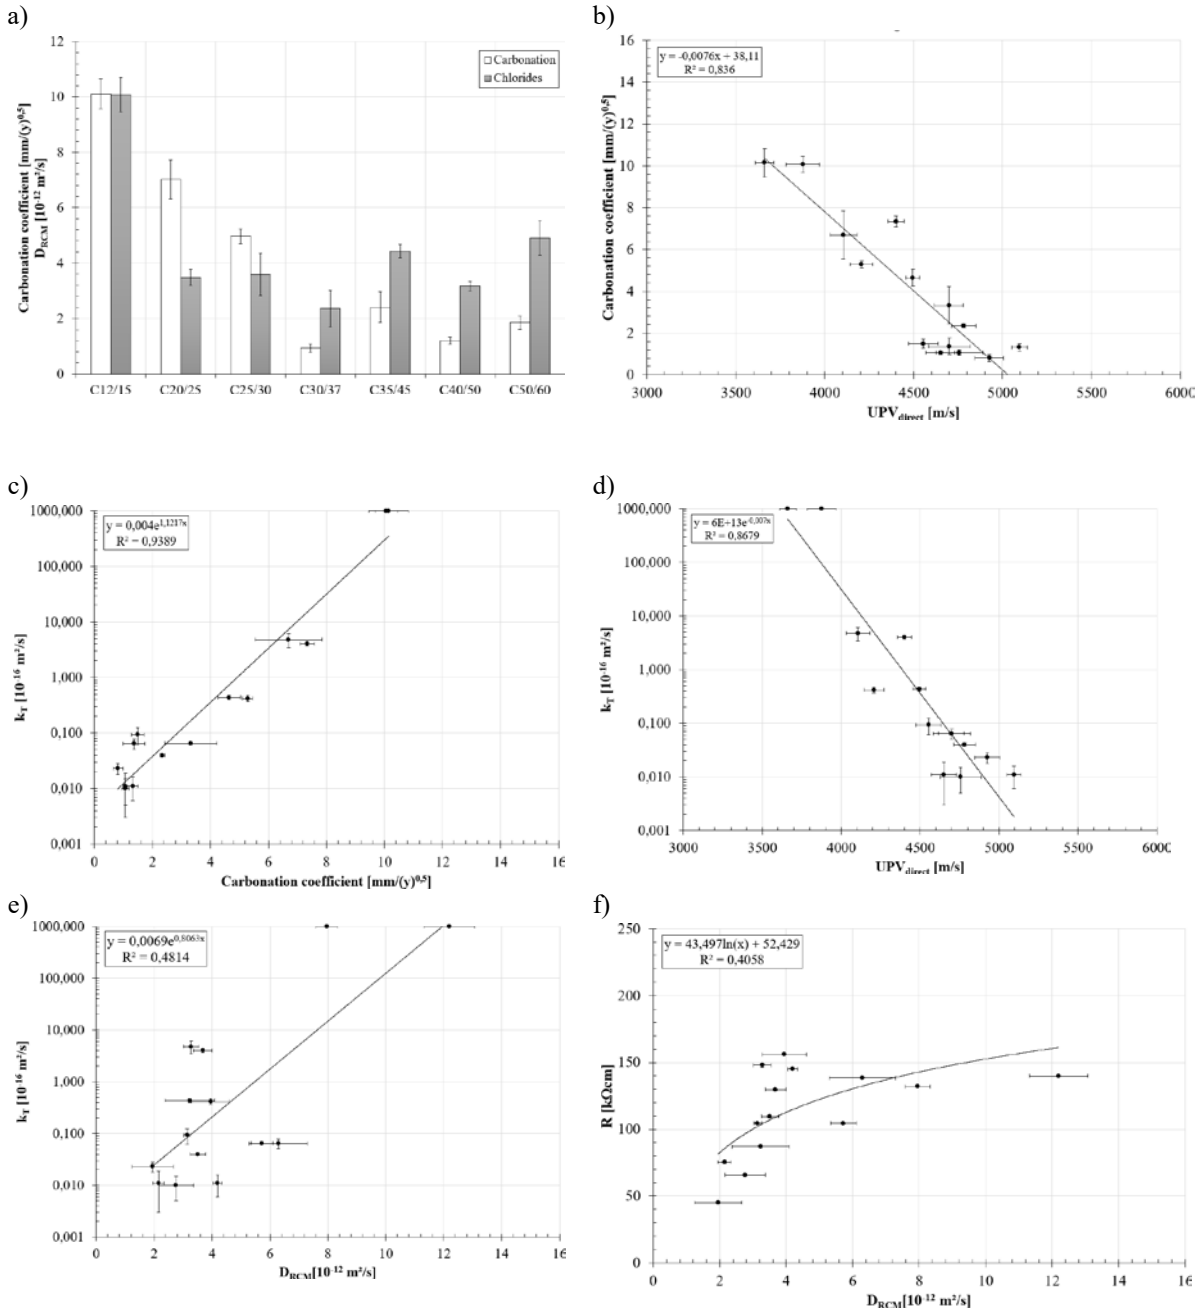

Figure 3. a) Results of carbonation coefficient and chloride migration D_{RCM}, b) correlation carbonation coefficient-ultrasonic pulse velocity, c) correlation air permeability-carbonation coefficient, d) correlation air permeability-ultrasonic pulse velocity, e) correlation air permeability-D_{RCM}, f) correlation surface resistivity-D_{RCM}.

4 Conclusions

In this study an experimental program is conducted on concrete slabs of different strength classes intended for various exposure classes, based on a limestone aggregate matrix. The plates have an age of 5.5 years, and are also characterized at younger stage (in 2014). Destructive core drilling and testing and several non-destructive techniques are used to assess strength and durability related properties of the slabs.

A slight strength decrease is found after 5.5 years with higher strength loss is for higher strength classes. Furthermore, the strength is linear proportional with surface hardness and ultrasonic pulse velocity and inversely proportional with air permeability. Compared to the results of 2014 (i) higher coefficient of determination on the obtained correlation curves is found and (ii) a shift on the correlation curves is noticeable, linked to the aging effect due to carbonation. This aging effect is more pronounced for the rebound hammer results. The effect of strength class on carbonation rate is clearly noticeable for slabs of lower strength classes (up to C25/30). For higher strength classes the effect of cement type is more pronounced.

A linear correlation with high coefficient of determination is found between carbonation coefficient, air permeability (directly proportional) and ultrasonic pulse velocity (inversely proportional). Note that the air permeability test is a good non-destructive alternative for the ultrasonic pulse velocity test: elements with high permeability have a lower pulse velocity, mainly due to the scattering of the pulse through air present in the pores.

Finally, no trend is noticeable regarding effect of strength class on chloride migration and a higher chloride migration is found in case of higher air permeability or surface resistivity, however a clear correlation cannot be established.

Abstract. *The purpose of this study is to improve the recruitment of flat oyster larvae, an endangered species, by means of a specific marine infrastructure made of concrete. This work aims to develop and optimize concrete formulations by varying the type of cement and introducing shellfish by-products into their composition and determine which concrete formulation is the most sustainable to marine organism colonization. Indeed, it is essential to obtain a sustainable concrete submitted to aggressive marine environment (chloride ions diffusion and bio-colonisation). Four concrete formulations were tested with two types of cements (CEMII and CEMV) and with or without the incorporation of shell aggregates. The durability of these materials was tested after 3 months of immersion in the Rance of Dinard (France). It appears from this study that the CEMII concrete exhibits a good mechanical resistance independently of the presence of shell, after immersion in situ. This concrete also shows better resistance to chloride ions diffusion than CEMV. However, CEMV possess larger compressive strengths than CEMII, and mollusc shells incorporation does not decrease this strength as much as for CEMII. Shell incorporation in the concretes has an effect on strength, chloride penetration and porosity which depend on the used cement and seawater.*

Keywords: *Flat Oyster Larvae, Marine Infrastructure, Concrete, Bio-Colonisation, Durability.*

1 Introduction

Coastal areas play a crucial role in the economic, social and political development of most countries. As a result, the maritime coasts are increasingly urbanized. Indeed, human activities (ports, tourism, fishing ...) require maritime structures and infrastructures which are often made of concrete. These coastal developments are responsible for the loss of many marine species habitats (Firth *et al*., 2013, 2014).It is therefore important to offset the residual impacts by generating an equivalent gain in biodiversity.

This study is carried out within the framework of the European Marineff project, which is part of this context. One of this study‘s objectives is the design of maritime infrastructures for flat oysters (*Ostrea edulis* Linnaeus, 1758) restoration in the Channel. Indeed, the flat oyster is an endangered species.

Over the years, a new approach has emerged, in the aim of enhancing marine infrastructure (surface condition, structure and composition) to promote ecological succession (Firth *et al*.,

2014; Perkol-Finkel and Sella, 2014; Sella and Perkol-Finkel, 2015). Thus, the term "ecological engineering" emerged (Bergen *et al*., 2001; Dennis *et al*., 2018; Firth *et al*., 2014, 2016; Pioch *et al*., 2018; Strain *et al*., 2018). The effectiveness of eco-engineering interventions varies according to habitats and marine biological communities. Indeed, each marine organism has a different response depending on the infrastructure (Coombes *et al*., 2015; Hanlon *et al*., 2018; Jones *et al*., 1994).
One of the solutions could therefore be the design of bio-receptive and sustainable concrete for the implementation of these infrastructures. Concrete immersed in the marine environment will undergo chemical, physical and biological attacks that can lead to its deterioration (Bastidas-Arteaga *et al*., 2008; Sanchez-Silva and Rosowsky, 2008). It is therefore important to design concrete that is as durable as possible in order to ensure its sustainability in its immersion environment.

Using a combination of laboratory and field experiments, we aimed to: (1) develop and optimize concrete formulations by varying the type of cement and introducing shellfish by-products into their composition (2) determine which concrete formulation is the most sustainable following the colonization of marine organism.

2 Material and Methods

2.1 Concrete's Formulations

For this study, 4 concrete formulations were designed with 2 types of cement, Portland cement (Calcia), CEM II/A-LL 42.5 R CE PM-CP2 NF and CEM V/A (S-V) 32.5 N-LH CE PM-ES-CP1 NF. These two types of cement are suitable for use in sea waters. Siliceous alluvial sand was used in granular class 0/2. Alluvial aggregates were also used and are composed of two sizes, 4/10 and 10/20 (Figure 1). A substitution of 20% of the aggregates (D4/10) by oyster shell aggregates was made to study the effect of this biomineral by-product on the recruitment of oyster larvae. Indeed, the incorporation of mollusc shell aggregates can increase the bio-receptivity of concrete because they provide an ideal substrate for the settlement of marine organisms (Graham *et al*., 2017; Hanlon *et al*., 2018).

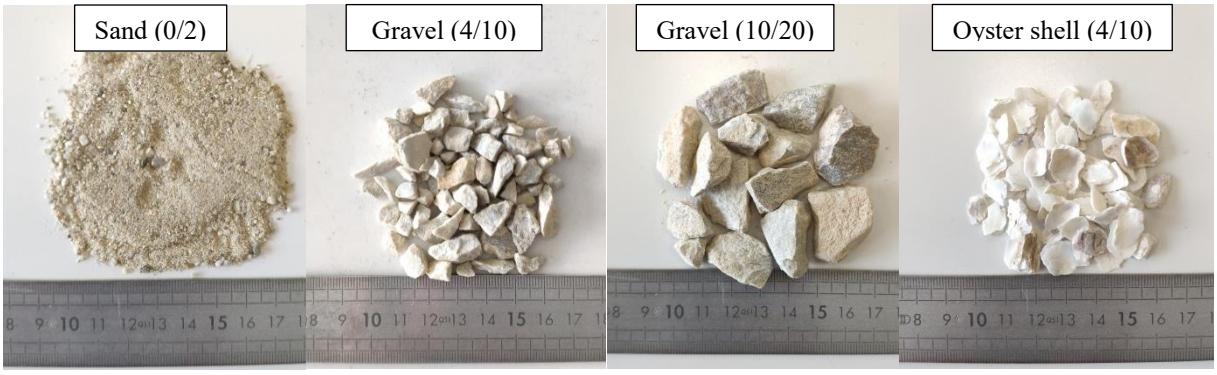

Figure 1. The various types of aggregates used to elaborate the concretes of this study.

After the characterization of the raw materials, concrete mix designs formulation was carried out in accordance with EN 206-1. The four studied concrete formulations are given in Table 1.

Table 1. Concrete's formulations (Proportions given in kg/m^3 of concrete).

Formulations / Components	F1 : CEM II without shell	F2 : CEM II with 20 % shell	F3 : CEM V without shell	F4 : CEM V with 20 % shell
Cement	350	350	350	350
Sand	800	800	800	800
Gravel 4/10	600	479	600	479
Gravel 10/20	500	500	500	500
Shell	-	121	-	121
Water	175	175	175	169
Superplastifiant	1.28 %	2%	1.28 %	2%

2.2 Concrete Durability Against Marine Environment

To study the sustainability of the concretes in marine environment, 11-cm diameter cylindrical samples with heights of either 22 cm or 5 cm were elaborated. Before their immersion in the Rance river of Dinard (France), the samples were placed in cages (iron grids). The immersion was carried out during 3 months to study marine organisms colonisation on the samples. After this period, mechanical and durability tests were carried out.

2.2.1 Compression test

The compression tests were carried out on the 11 cm × 22 cm cylindrical samples using a 3R press (4000 kN) after 90 days of curing (reference concrete) and after 90 days immersed in natural seawater. The test was operated in accordance within the NF EN 12390-3 standard.

2.2.2 Chloride ion diffusion tests

Ion chromatography was used to measure chloride ions concentrations for a total depth of 1 cm into the samples (using a 2 mm step). The powder produced by drilling was collected, filtered and diluted to 1/25th before being analyzed by a 883 Basic IC Ion Chromatograph using standard preparation procedures. The obtained leachate is also used to measure the pH of the material. This test was carried out on the samples immersed natural seawater and in artificial seawater.

2.2.3 Porosity accessible to water

Porosity is an important factor that influences the material's durability. This test was carried out on the immersed samples (natural seawater*)* and after 90 days of curing (reference concrete), according to the NF P18-459 standard.

The value of the porosity (p) is obtained by the equation (1):

$$p = \frac{M_{sds} - M_d}{M_{sds} - M_w} \times 100 \quad (1)$$

Where M_{sds} is the saturated dry surfaces sample mass, M_d the dry sample mass and M_w the mass in water.

3 Results and Discussion

In order to choose the best concrete formulation, several mechanical strength and durability tests were carried out. The 11x22 samples were colonised by sessile fauna and some macro-algae after 3 months of immersion in natural seawater. We could count some bryozoans, sponges, serpulid and spiral tubes of Spirorbs (Figure 2).

Figure 2. Concrete samples (11x22) after immersion for 3 months in natural seawater.

3.1 Compression Test

Mechanical strength results (Figure 3) show that, without shell incorporation, the compressive strength obtained after 90 days of curing is significantly higher for the CEMV type concrete (70.53 MPa) compared to CEMII (46.3 MPa) (Figure 3, A). A decrease in compressive strengths is noticed when adding shell aggregates, with values decreasing to 49 MPa and 32 MPa respectively. The compressive strength increases for all concretes except for CEMV without shells after 3 months of immersion in natural seawater compared to the reference concrete. This increase is larger for concretes containing shell aggregates, with approximately 35% larger strengths for CEMII with shells and 24% without (Figure 3, B). Interestingly, in CEMV concretes this latter tendancy is even increased, immersion in seawater inducing a decrease of compressive strength after 3 months without shell incorporations, while addition of shells increases the compressive response inside seawater. CEMV even exhibits the same compressive strength after 3 months of immersion with or without shells.

Rica *et al*., 2016 also studied the effect of colonisation on the mechanical strengths of several cementitious materials with and without shells at different timescales *in situ*. It was found that self-placing concrete with 40% of shells showed an increase in resistance (+8%) after an immersion of 22 weeks in seawater compared to 28 days of curing in the laboratory.

Shells are natural biominerals that do not modify intrinsically after immersion in seawater, even for long times after death. Consequently, if shell-cement interfaces are enough bounding them together, the resulting mechanical strength variations of the concrete over time are assumed to depend more on the cement behaviour. In our experiments bonding properties are not probed, but even after 90 days of curing, the cementing part of the concretes are not fully

matured and are potentially subjected to suffer some alteration in the aggressive seawater medium. This is at least the case for CEMV which exhibits a clear decrease in compressive strength after 3 months of immersion, and contraily to CEMII. But in shell-containing concretes compressive strength increase is observed for the two types of concretes. The effect of shell incorporation cannot be a simple steric effect with less deterioration thanks to shell additions, since this would only reduce the compressive strength decrease of CEMV comparing with and without shell.

We are then concluding that another effect occurs, beneficial to and not only buffering strength decrease. The mechanism for such an effect is not monitored by our experiments, and further investigations are needed to explain our results. A modification of the concrete microstructure due to calcium carbonates and organic species contained in the shells could be at the origin of the observed behaviour.

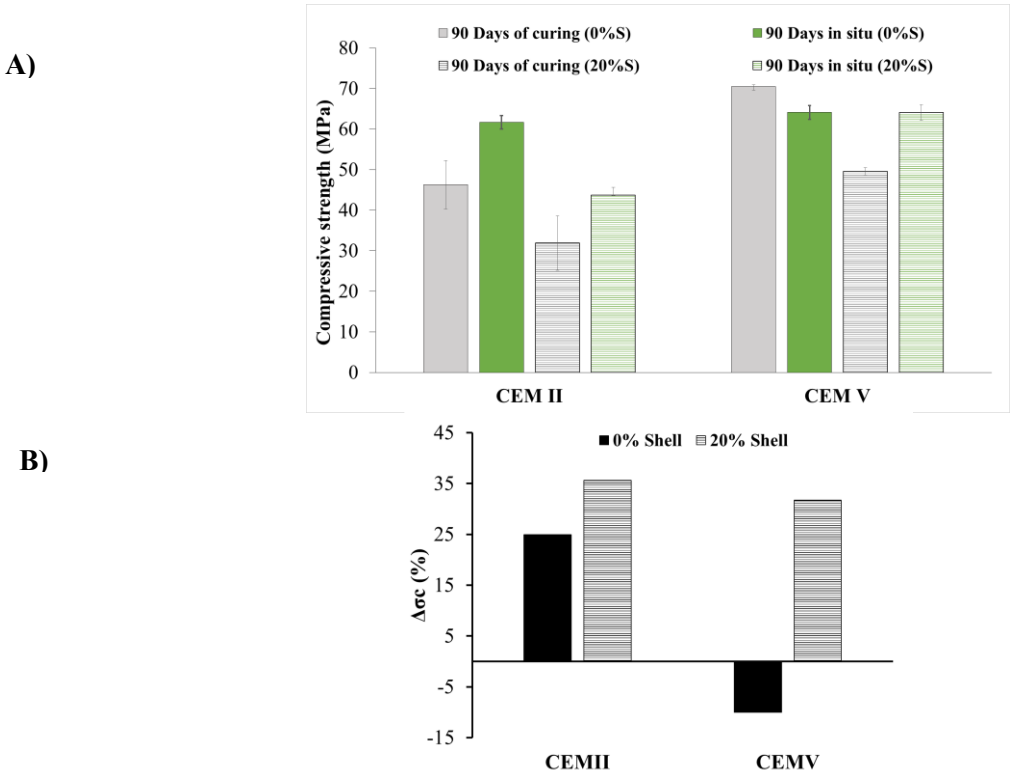

Figure 3. (A): Compressive strength of the different concrete formulations after 90 days of curing and after 90 days in natural seawater; (B) : Difference between the resistance of concretes immersed in seawater for 90 days vs. cured at 100% RH (90 days).

3.2 Chloride Ion Diffusion Tests

The durability of concrete mix designs against chloride ions diffusion were then studied after immersion in two different environments: artificial and natural seawaters. The evolution of the chloride ions content (as a function of depth and environment) is represented in Figure 4. We can also notice that after 3 months of immersion in natural seawater, we obtain higher chloride ions content between 0 and 6 mm for the concrete mix designs manufactured without shells

compared to those immersed in artificial seawater (Figure 4 A and C). This result can be explained by the fact that the bio-colonisation of samples facilitates the penetration of Cl^- ions.

In artificial seawater (ASW, Figure 4, solid lines), the presence of shells in the concrete (Figure 4B and D) tends to enhance chloride content by a factor of nearly 2 in the first millimeters compared to concretes without shells (Figure 4A and C). This tendancy is not observed for immersions in natural seawaters (NSW, dotted lines). The reason for such a behaviour could be seen in partial dissolution of shell pieces, which is more pronounced in artificial seawaters. Part of the molecules and macromolecules contained in shells are Water Soluble (WSM), and present in NSW but not in ASW. Consequently, immersing shells in ASW gives rise to larger chemical potentials than in NSW, tending to operate more dissolution and element infiltrations, the process being or not mediated by chloride ions.

The total chloride content in our concretes varies according to the cement type. In the first six millimetres, whatever the used conditions (with and without shells, seawater) the concretes made with CEMII are more sustainable from the point of view of chlorine penetration than those elaborated with CEMV. For CEMII, chloride content does not exceed 1500 ppm in the first millimetres (Figures 4A and B), while in CEMV (Figure 4C and D) this concentration is at least twice this amount (up to 3700 ppm).

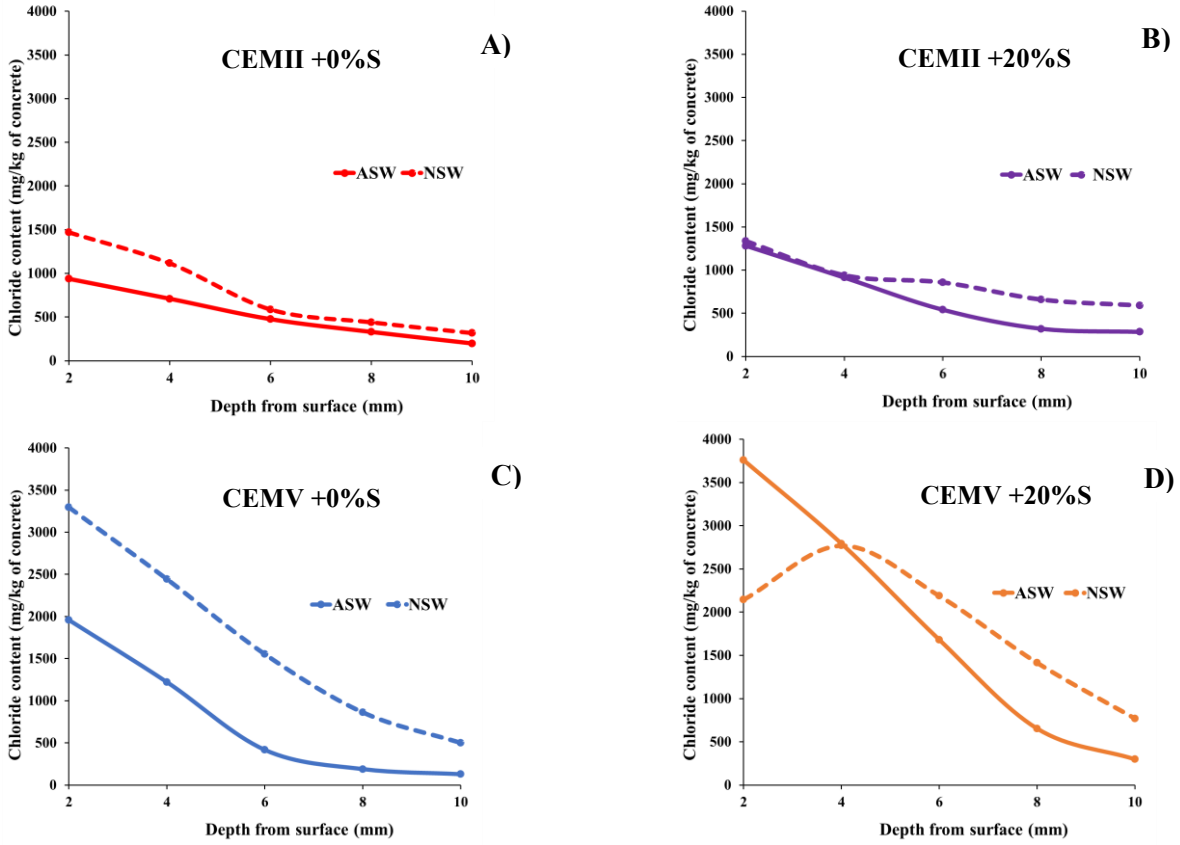

Figure 4. Chloride ions content after an immersion of 1 month in Artificial SeaWater (ASW) (solid line) and after 3 months in Natural SeaWater (NSW) (dotted line) for two different concrete composition CEMII and CEMV without Shells (S) (Respectively A et C) and CEMII and CEMV with Shells (Respectively B et D).

3.3 Porosity Accessible to Water

Measurements of porosity accessible to water (Figure 5) indicate that, except for a slight increase in porosity of around 0.1-0.2%, the two concrete formulations made with CEMII remain stable after immersion for 3 months in natural seawater. This is not the case for CEMV concretes for which we observe a decrease of porosity up to 4% after 3 months. The shell-containing CEMV concrete however exhibit less porosity decrease compared to such a concrete without shells. Such porosity decrease contributes undoubtfully to the compressive strength increase of the CEMV sample with shells.

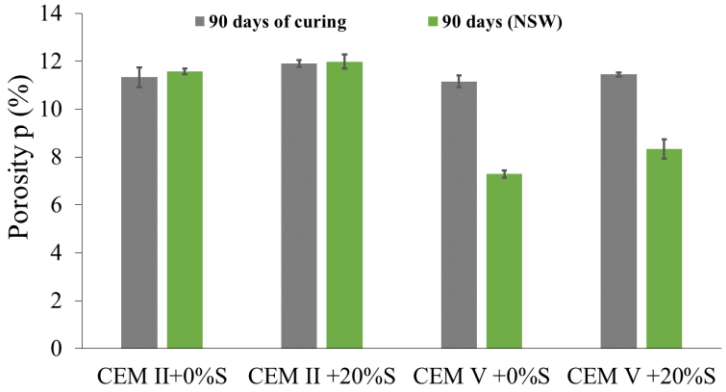

Figure 5. Porosity accessible to water after 90 days of curing and immersed after 90 days in NSW.

4 Conclusion

Our results indicate that the CEMII concrete formulations are the more resilient to chloride penetration in artificial and natural seawaters than CEMV concretes. The incorporation of shell aggregates does not significantly modify chloride penetration in natural seawater but increases it in artificial seawater. Porosities significantly decrease in CEMV concretes after 3 months of immersion, which partly explains the compressive strength increase of this material, while only slight porosity variations are observed in CEMII with aging in seawater. Calcium carbonates partial dissolution is more pronounced in artificial sea water, and combined with an increased chloride ion penetration inside the first millimeters of the materials. Longer term tests of durability are on-going (6 and 12 months), together with monitoring of colonisation by studying photosynthetic parameters.

Acknowledgements

We would like to thank the MNHN (Natural History National Museum) of Dinard for allowing us to immerse the concrete samples and have recover them after 3 months of immersion in the Rance of Dinard. Thanks to the Luc-sur-Mer Marine Station (Université de Caen Normandie) for allowing us to immerse our concrete samples for the long term tests.

Development of a Damage Detecting Method for RC Slabs by Means of Machine Learning

Yutaka Tanaka and Takahiro Nishida

Port and Airport Research Institute, 3-1-1, Nagase, Yokosuka, 239-0826, JAPAN,
tanaka-yu@p.mpat.go.jp, nishida-ta@p.mpat.go.jp

Abstract. *It is beneficial to understand damage conditions of RC structural members by non-destructive methods. In this study, K-means clustering method was applied to the AE wave data in order to develop a damage detection method. From the result of this study, the damaged area had the relatively large number of AE hits and AE energy. In addition, from the result of the K-means clustering of the power spectral density of AE waves, the data could be separated into the obviously damaged area and other areas.*

Keywords: *AE, Non-Destructive Method, Machine Learning, Damage Detection, RC Slab.*

1 Introduction

It is beneficial to understand damage conditions of RC structural members by non-destructive methods for long term use of RC structures. Capturing AE signals is one of the effective methods to detect the damaged position and area in the structural member.

In the previous research, Nishida *et al*. (2019) developed an aggregation detector. The detector is equipped AE sensors to capture AE waves generated by the internal damage of the RC bridge deck. Nishida et al. focused on the AE energy in order to detect the damaged area and they proposed the method to decide the threshold value of AE energy to judge the damaged area.

In this study, authors applied a clustering method to the AE wave data that was obtained in previous research. The aim of this study is to develop a damage detecting method for RC slabs with machine learning.

2 Analysis of AE Waves

2.1 The Outline of Analysis of AE Waves

In this study, the AE wave data obtained in the previous research (Nishida *et al*., 2019) was analyzed. In the previous research, Nishida et al. focused on the total AE energy and did not focus on the number of AE hits. In general, the number of AE hits in damaged area is larger than that in sound area because the damaged area has a lot of AE source. Therefore, authors focused on not only the AE energy but also the number of AE hits. The AE wave data was separated into a group by 1.0 m for each measurement line, and then, the number of AE hits was counted in each group, and the average of AE energies was calculated in each group.

Authors also focused on the frequency domain of AE waves. The power spectral density (PSD) of each AE wave was calculated and averaged in each group. In this study, the averaged

doi:10.23967/dbmc.2020.034

PSDs were regarded as the representative values of each group and selected as the input data for the clustering method.

The K-means clustering method (MacQueen, 1967; Arthur and Vassilvitskii, 2007) was applied in this study. This method is a non-hierarchical clustering method and an unsupervised machine learning method. This method is used to divide automatically a data into k groups. The objective function of the K-means clustering that should be minimized is;

$$\mathrm{J} = \sum_{i=1}^{N} \sum_{k=1}^{K} w_{ik} \|x_i - c_k\|_2 \tag{1}$$

where N is the number of a data set, K is the number of the cluster, x_i is the i-th data in a data set, c_k is the centroid of the k-th cluster, $w_{ik} = 1$ if the data x_i belongs to cluster k, otherwise $w_{ik} = 0$ and $\|v\|_2$ is the Euclidean norm of a vector v.

The algorithm of the K-means is shown as follows.

1. Choose k initial centroids $\boldsymbol{C} = \{c_1, ..., c_k\}$.
2. For each $i \in \{1, ..., k\}$, set the cluster C_i to be the set of points in X that are closer to c_i than they are to c_j for all $i \neq j$.
3. For each $i \in \{1, ..., k\}$, set c_i to be the center of mass of all points in C_i.
4. Repeat Steps 2 and 3 until $\boldsymbol{C}$ no longer changes.

In this study, the number of the cluster k was changed to be from 2 to 5 due to find the optimal k for the clustering of the data.

The calculation of the K-means clustering and the power spectral density was conducted with Python, and the Scikit-learn (Pedregosa *et al*., 2011) was used for the K-means clustering and the SciPy (Virtanen *et al*., 2019) was used to calculate the power spectral density of the AE wave data.

3 Results and Discussions

Figure 1 shows the damaged area that was the result of the visual and the hammering inspection in the previous research. The red colored area is the damaged area where the crack or the delamination were observed.

3.1 The Number of AE Hits and the Average of AE Energies

Figure 2 and Figure 3 show contour maps of the number of AE hits and the average of AE energies in each group respectively. In Figure 2, the number of AE hits may have a close relation with the damaged area as shown in Figure 1, and the average of AE energies also have a relation with the damaged area.

In general, the defect such as the crack and the delamination become the source of AE signal. Therefore, the area where the number of AE hits is larger than the other areas has potential to be the damaged area.

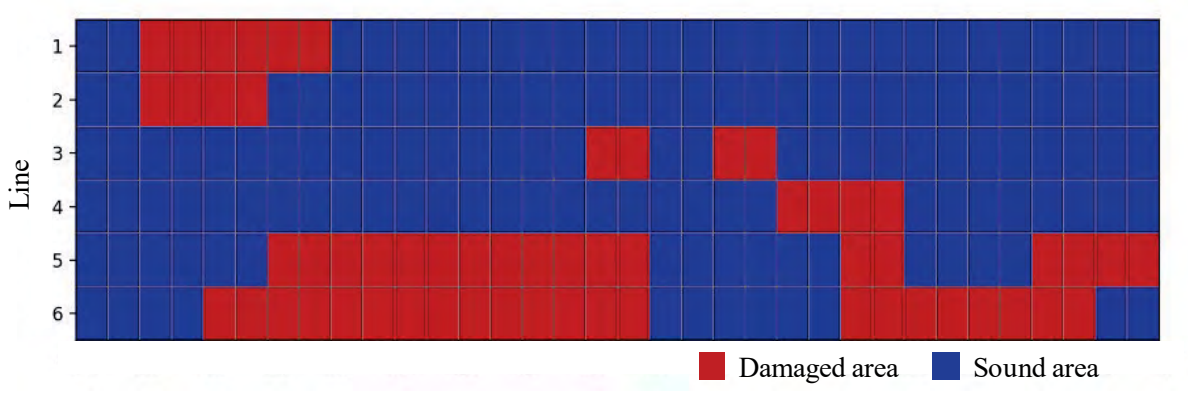

Figure 1. The result of the visual and the hammering inspection.

Figure 2. The number of AE hits in whole groups.

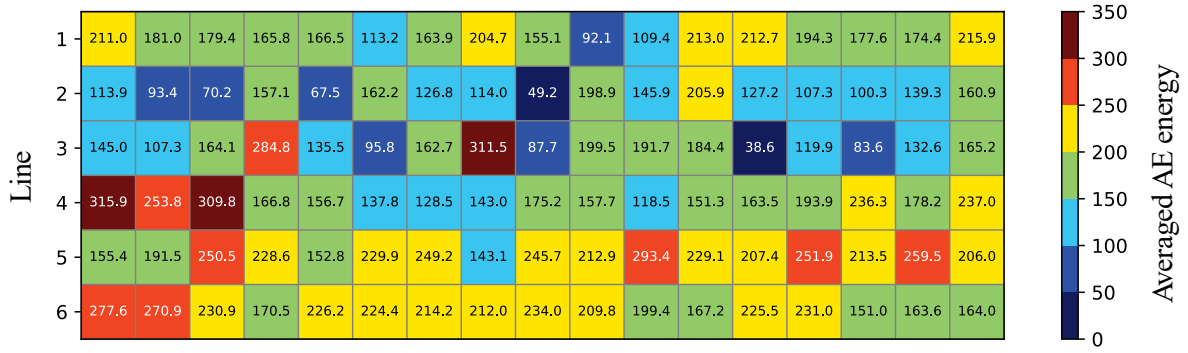

Figure 3. The average of AE energies in whole groups.

3.2 Clustering the PSD Data

Figure 4 (a) shows the PSD of the centroid of each cluster when the number of clusters was 2. The peak frequency and value of each PSD were different. Figure 4 (b) shows the scatter plot of each group. The number located beside each plot is the line number. In this figure, the all data belong to the cluster 2 was in the line 6 where a lot of defects were observed. From this result, the data was separated into the obviously damaged group and the other group, and the peak frequency of the PSD in the damaged area became lower than that in the other area.

Figure 5 (a) shows the PSD of the centroid of each cluster when the number of clusters was 3, and Figure 5 (b) shows the scatter plot of each group. From these figures, the cluster 1 in Figure 4 (b) was divided into two groups based on the average AE energy. In Figure 5 (a), the peaks of frequency and the forms of the PSD was also almost the same, but the peak values of the PSD were different in clusters 1 and 3.

Figure 6 (a) shows the PSD of the centroid of each cluster when the number of clusters was 4, and Figure 6 (b) shows the scatter plot of each group. From these figures, the cluster 1 in Figure 4 (b) was divided into three groups based on the average AE energy. In Figure 6 (a), the peaks of frequency and the forms of the PSD was also almost the same, but the peak values of the PSD were different in clusters 1, 3 and 4.

Figure 7 (a) shows the PSD of the centroid of each cluster when the number of clusters was 5, and Figure 7 (b) shows the scatter plot of each group. From these figures, the cluster 1 in Figure 4 (b) was divided into three groups and the cluster 2 in Figure 4 (b) divided into two groups based on the average AE energy. In Figure 7 (a), clusters 2, 3 and 4 were the same as clusters 2, 4, and 3 in Figure 6 (a) respectively. In addition, the peaks of frequency and the forms of the PSD was also almost the same, but the peak values of the PSD were different in clusters 1 and 5.

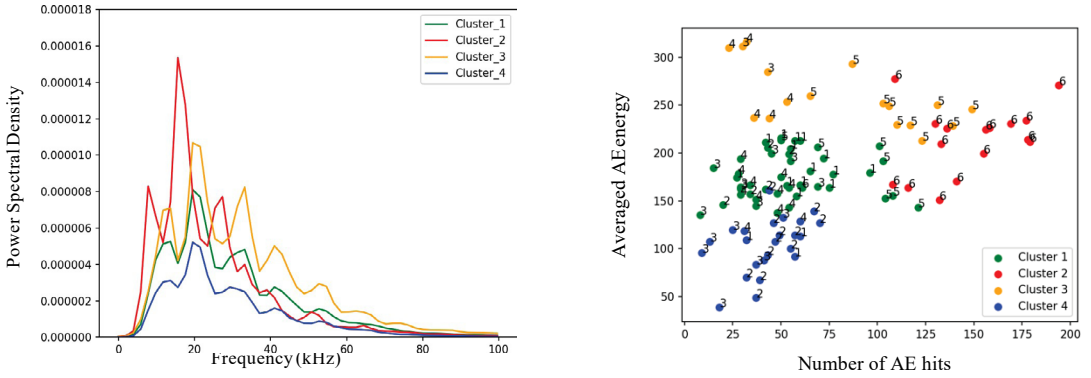
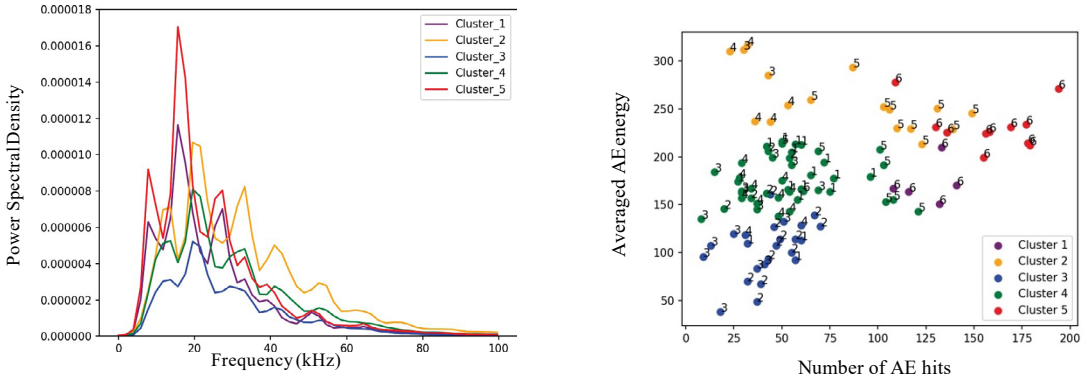
Figure 5. Clustering result of the data (k = 3).



(a) PSD of each cluster centroid (b) Scatter plot of each group

Figure 6. Clustering result of the data (k = 4).



(a) PSD of each cluster centroid (b) Scatter plot of each group

Figure 7. Clustering result of the data (k = 5).

To evaluate the optimal k for the clustering, silhouette analysis (Rousseeuw, 1987) was conducted. The silhouette score of the data point i is:

$$s(i) = \frac{b(i) - a(i)}{max\{a(i), b(i)\}} \tag{2}$$

$$a(i) = \frac{1}{N_i - 1} \sum_{j \in C_i, i \neq j} d(i,j) \tag{3}$$

$$b(i) = \min_{k \neq i} \frac{1}{N_k} \sum_{j \in C_k} d(i,j) \tag{4}$$

where N_i is the number of data points in the cluster C_i, C_i is the cluster to whom the data point i belongs and $d(i, j)$ is the distance between data points i and j.
The range of the silhouette score is from -1 to +1, and a high value means that the data point is well matched to its cluster. From the plotting of the silhouette scores, the optimal number of the clusters can be determined graphically.

Figure 8 show the plotting of the silhouette score of each data. The black dotted line means the average of the whole silhouette score, and the thickness of the silhouette score of each cluster means the number of the data. In Figure 8 (a), the number of the data that belong to cluster 1 was larger than that to cluster 2, therefore, $k = 2$ may not be the optimal value for the clustering of the data. In Figures 8 (b) and 8 (d), some silhouette score was negative, therefore, $k = 3$ and 5 may not be also the optimal value for the clustering of the data. In Figure 8 (c), the thickness of the silhouette score of the cluster 1 was slightly thicker than those of other clusters, however, there was no negative silhouette score and many of silhouette scores exceeded the average silhouette score. Thus, $k = 4$ may be the optimal value for the clustering of the data.

The optimal k might be determined by the silhouette score, however, it is necessary to evaluate the accuracy of the clustered groups with the actual damage condition of the target structure. This is the future work for our study.

4 Conclusions

Following conclusions were derived from this study.

- The area where the number of AE hits and the average of AE energies were relatively lager than other areas might be the damaged area.
- From the result of the K-means clustering, the data was separated into the obviously damaged area and other areas. In addition, the characteristic of the power spectral density of the centroid of the damaged cluster was different from those of other clusters.
- As the increase of the number of centroids k, the data was separated into some groups based on the average of the AE energies.

Dynamic Observability Method for Durability Assessment Considering Measurement Noise

Tian Peng, Juan R. Casas and Jose Turmo

Department of Civil and Environmental Engineering，Universitat Politècnica de Catalunya-BarcelonaTECH, Campus Nord UPC, 08034-Barcelona, Spain, {tian.peng, joan.ramon.casas, jose.turmo} @upc.edu

Abstract. *Due to the inevitable degradation of material properties in structures in daily use, such as stiffness degradation due to cracking in concrete elements, their durability will definitely be influenced, and their serviceability and safety could be in danger. Thus, understanding and identifying the change in the structural parameters provides new approaches to evaluate their durability. Structural system identification by dynamic observability method, which is using subsets of masses, natural frequencies and modal shapes, is a powerful tool to detect the change of structural parameters. Taking into account the presence of noise in the measurement data in real world structures, this method establishes the relative dynamic equation with the error separation items. The equation is solved by error minimization of an objective function combining the measured frequencies and mode shapes through the parameter MAC (Modal Assurance Criterion). Additionally, the algorithms and the steps are introduced based on the dynamic eigenvalue equation, which can fully demonstrate the performance of observability techniques. The present paper provides an example on how to successfully identify structural parameters. Its suitability for practical applications is demonstrated in a large frame structure. The result is a much more accurate identification of the parameters involved in the durability of the structure even in the case of noise-corrupted measurement signals*

Keywords: *Durability, Structural System Identification, Dynamic Observability Method, Frequencies，Mode Shapes.*

1 Introduction

Existing structures are inevitably exposed to the natural environment (wind, earthquake, temperature difference, or even some extreme climate) and human operationt (traffic, impact, daily degradation by use). Thus, the material properties are degraded such as the bending stiffness, axial stiffness, and mass. In this case, the durability of the structures may be influenced, leading them structures into a dangerous condition instead of the originally safe state.

Regarding the durability of structures, understanding and identifying the change in the structural parameters is a great way to estimate the structure condition and safety. Structural system identification (SSI) has become a powerful tool to help engineer decision making during the life cycle of civil and infrastructures systems. SSI can be classified as the static and dynamic analysis, as well as deterministic and probabilistic methods. The former research classification depends on the type of excitation and the latter is related to the uncertainty of the parameters involved.

It is worth mentioning that the development of Observability method (OM) makes relevant contributions to deal with the remaining problem of SSI, and has been used in several engineering fields, such as hydraulics, electrical and power networks, or transportation. The

SSI by OM under static conditions was proposed to identify 2-D beam element models in its plane, dealing with the partial observability problem and achieving an accurate assessment. While it is much easier to dynamically excite a large structure than statically, especially in large scale structures, the dynamic data are more difficult to deal with than the static one. As a result, the standard observability method used with dynamic data has shown deficient in identifying degradation processes endangering durability.

Thus, this paper proposes a new constrained dynamic observability SSI methodology, which allows the identification of a subset of characteristics of a structure, related to its durability parameters such as stiffness and mass. Subsets of natural frequencies and modal shapes are used. Firstly, the description of dynamic constrained OM method is demonstrated step by step. Secondly, the verification of this method is revealed by one example considering the measurement noise. Lastly, the potential of dynamic constrained OM when applied to large structures is shown.

2 Methodology

The dynamic equation of motion of a system with no damping and no external applied forces is shown in equation (1), expressing what is the eigenvalue or characteristic value problem.

The equation can be expressed for a two-dimensional structure with $\mathrm{N_N}$ nodes, $\mathrm{N_B}$ boundary conditions and R vibration modes as:

$$[K]^{[(3N_N-N_B)\times(3N_N-N_B)]}\{\emptyset_i\}^{[(3N_N-N_B)\times 1]} = \lambda_i\{M\}^{[(3N_N-N_B)\times(3N_N-N_B)]}\{\emptyset_i\}^{[(3N_N-N_B)\times 1]]} \quad (i = 1,2,3\ldots,R) \tag{1}$$

Where λ_i and $\emptyset_i$ are the eigenvalues and mode shapes of ith mode, and the $[K]$ and $[M]$ represent the stiffness matrix and mass matrix. $\emptyset_i$ includes the displacement in the x-direction (u_{ik}), y-direction (v_{ik}) and rotation (w_{ik}) at each node k for each vibration mode i.

The arrangement of equation (1) is done in a similar way to the static observability method, all the unknowns of the system are set up to one column vector and the known variables are joined into a vector $\{D\}$. In this way, the previous equation might be written as:

$$[B_i]\{z_i\} = \begin{bmatrix} K_{i,0}^{*(3N_N-N_B)\times rx} & -M_{i,0}^{*(3N_N-N_B)\times mx} \end{bmatrix} \begin{Bmatrix} \emptyset_{Ki,0}^{*rx\times 1} \\ \emptyset_{Mi,0}^{*mx\times 1} \end{Bmatrix} = \left\{ M_{i,1}^{*(3N_N-N_B)\times nx}\emptyset_{Mi,1}^{*nx\times 1} - K_{i,1}^{*(3N_N-N_B)\times sx}\emptyset_{Ki,1}^{*sx\times 1} \right\} = \{D_i\} \quad (i = 1,2,3\ldots,R) \tag{2}$$

Where z_i represents all the unknowns, B_i and D_i are the corresponding coefficient matrix and augmented matrix of ith mode.

Equation (2) is the description in ith mode. When multiple modes are considered together, the equation will be built by combining information of several modes. For example, the first R modal information is given by $[B]\{z\} = \{D\}$ shown as follows:

$$[B]\{z\} = \begin{bmatrix} B_1 & 0 & 0 & 0 \\ 0 & B_2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & B_R \end{bmatrix} \begin{Bmatrix} z_1 \\ z_2 \\ \vdots \\ z_R \end{Bmatrix} = \begin{bmatrix} D_1 & 0 & 0 & 0 \\ 0 & D_2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & D_R \end{bmatrix} = \{D\} \tag{3}$$

Expression in which $[B]$ is a matrix of constant coefficients, $\{D\}$ is a fully known vector and $\{z_i\}$ contains the full set of unknown variables. This system contains coupled and single variables. Thus, the identified coupled variables (*e.g.*, $EI_j w_{ik}$ that exist in Eq.(2)) are referred as observed variables. In other to uncouple the observed variables, e.g., $EI_j w_{ik} = EI_j * w_{ik}$, the dynamic COM (constrained observability method) is here proposed based on a similar procedure as in the static case. However, in this case, the objective function is defined as:

$$E = \sum_{i=1}^{R} (\Delta f_i)^2 + \sum_{i=1}^{R} \left(1 - \frac{\left[\emptyset_{mi}^T \overline{\emptyset_{mj}} \right]^2}{(\emptyset_{mi}^T \emptyset_{mi})(\overline{\emptyset_{mj}}^T \overline{\emptyset_{mj}})} \right) \tag{4}$$

The modal assurance criterion (MAC) is used in Eq. (4), which consists of computing the so-called MAC values as a measure for the correspondence between the calculated mode shape $\emptyset_{mi}$, obtained from the inverse analysis using the estimated stiffnesses and areas, and the measured shape $\overline{\emptyset_{mj}}$ as shown in Equation (5). Besides, Δf_i are the differences between the measured and estimated frequencies.

$$\text{MAC}\,(\emptyset_{mi}, \overline{\emptyset_{mj}}) = \frac{\left[\emptyset_{mi}^T \overline{\emptyset_{mj}} \right]^2}{(\emptyset_{mi}^T \emptyset_{mi})(\overline{\emptyset_{mj}}^T \overline{\emptyset_{mj}})} \tag{5}$$

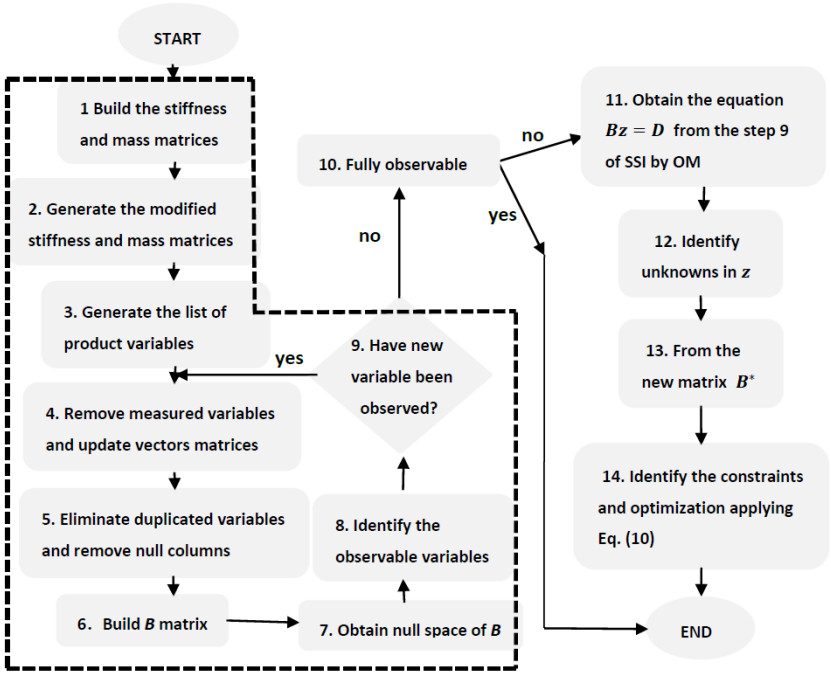

Figure 1. Flow-chart of algorithm of dynamic observability method.

The solution is obtained by minimizing equation (4) with the imposed constraints of the form: $EA_j u_{ik} = EA_j * u_{ik}$, $EI_j v_{ik} = EI_j * v_{ik}$, $EI_j w_{ik} = EI_j * w_{ik}$ present in equation (3), which is the so-called Constrained Observability Method .

The specific steps about the method are shown in Figure.1, which is developed on the base of the static COM method.

3 Example Analysis

3.1 Reinforced Concrete Beam

The dynamic constrained observability method is verified in a reinforced concrete beam. This beam is shown in Figure 2, with a length of 6m and equally divided into 30 elements, 10 parts, whose divisions can be seen minutely in Figure 2. The free vibration test of the beam was conducted by Ellen Simon, with the aim of obtaining its dynamic information, frequencies and mode shapes. The structure stiffnesses are estimated in the following way: $EI_i = x_i EI_{int}, i = 1{\sim}10, EI_{int} = 7.23 \times 10^6 \frac{N}{m^2}$, $x_i = [1.15, 1.04, 0.86, 0.90, 0.80, 0.54, 0.51, 0.57, 0.72, 0.86]$ by using the experimental data after some controlled damage was produced in the beam.

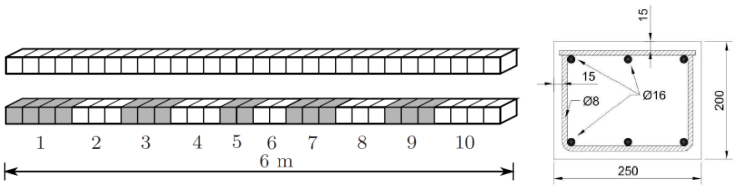

Figure 2. Set-up of static loading.

There is one way in using the estimated stiffnesses of EI_i as the input to do the direct analysis of the first four frequencies and mode shapes since the real experimental data is difficult to get from paper. Therefore, 100 samples of frequencies are generated for this set with an error of 2% while 100 samples of mode-shapes are obtained with an error of 10%, because frequency accuracy obtained from dynamic tests is normally higher than for mode. One sample for a given measurement set is the collection of the associated measurements generated by Eq. (6).

$$\tilde{\delta} = \delta(1 + E_{level} \cdot \S) \quad (\tilde{f} \text{ yielded in the same way}) \tag{6}$$

Here, the measurements $\tilde{\delta}$ are simulated by adding proportional errors to the theoretical values, δ are obtained by direct analysis. E_{level} is the error level in the measurement and § is a random number following a normal distribution with mean zero and standard deviation 0.51 to guarantee the 95% confidence interval. The samples of $\tilde{f}$ are yielded in the same way.

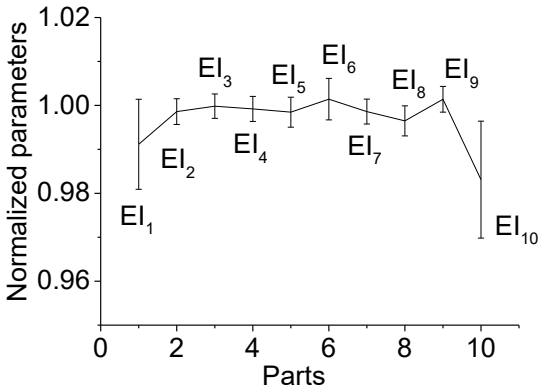

Figure 3. Mean and standard deviation of stiffness.

Figure 3 shows the estimated mean values of the 100 samples and their standard deviation for the estimated stiffness along the beam. It is shown how the errors in the mean values are less than 2% and the biggest standard deviations less than 1.5%, which is a reasonable range for parameter evaluation. However, it can be obviously observed that the standard deviations of EI_1 and EI_{10} are higher than other parameters, which may be due to the error accumulation from middle to the ends of the beam in the computational solution. Also the area of EI_1 and EI_{10} provides little information to the solution algorithm because of their free ends. This case can effectively explain the operability of the dynamic observability method to obtain the actual condition of the structure or its elements in relation to their durability.

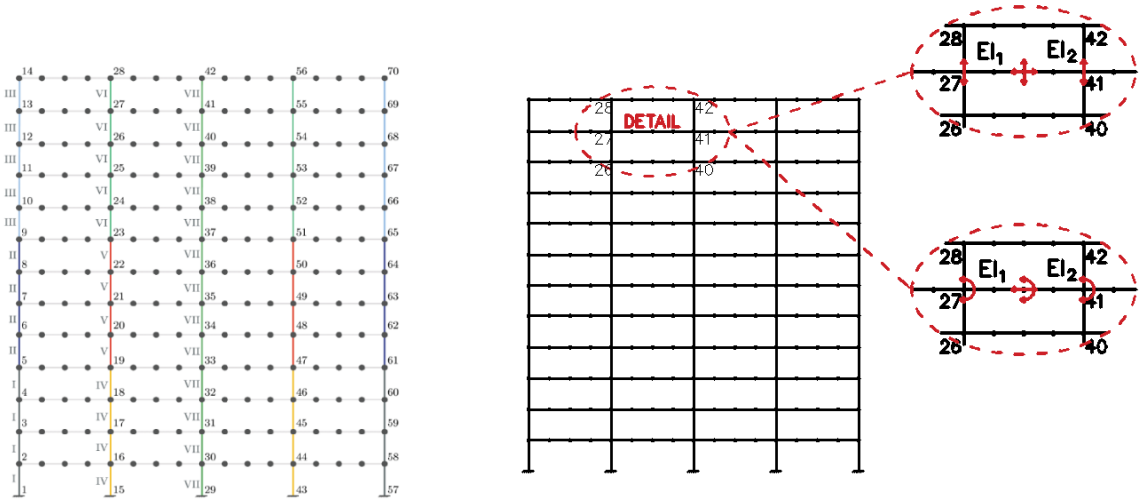
3.2 Example of 13-Story Building

In order to show the possible applications and potential of the proposed methodology, a more complex example is presented in this section. The 13-story building shown in Figure 4 is taken under study. This structure was considered in Reference [16].

This frame is modeled using a total of 226 nodes and 273 elements and it is composed of a set of 8 different sections described in Figure 4, and the parameters are the same as in [16]. Therefore, the size of the system of equations is 678×678. The study will be performed for the first two vibration modes, which can provide relevant modal information. This structure is analyzed from a local perspective, using the constrained dynamic observability technique to only a part of the unknowns as shown in figure 4.

In fact, there are occasions in which there is interest of obtaining only the properties of one or a few members of the structure to check, for example, if it is locally damaged. This leads to a more economically efficient application of the technique. The normal procedure is to measure some of the displacements around this element or elements in order to activate its matrix components.

For this example, an assumption is made that the bending stiffnesses EI_1 and EI_2 of the structure are unknown and that the mechanical properties of the floor slab of the 12th floor are different from the theoretical one, because this part of the structure is damaged. Its modal frequency (only the first frequency is required) and mass are assumed to be known. Therefore, the properties to be observed are the bending stiffnesses of the elements between nodes 27 and 41.



a) b)

Figure 4. a) Members with different characteristics are represented with different colors.
b) Sets of measurements used in the local analysis.

Two sets of measurements are proposed. The first one includes the vertical displacements in three nodes and the horizontal displacement in one node，which can be seen in the A detail in Figure 4(b) (4 measurements+ 1 frequency). The second one includes rotations in three nodes and horizontal displacements in one node, as shown in the B detail in Figure 4(b) (4 measurements+ 1 frequency).

After performing the analysis, the stiffnesses EI_1 and EI_2 can be identified by Constrained Observability assuming 2% and 5% errors in the frequencies and mode shapes respectively. The 100 samples are gained by Eq. (6). The estimated mean values and standard deviations of the 100 samples under the two measurement sets are illustrated in figure 5.

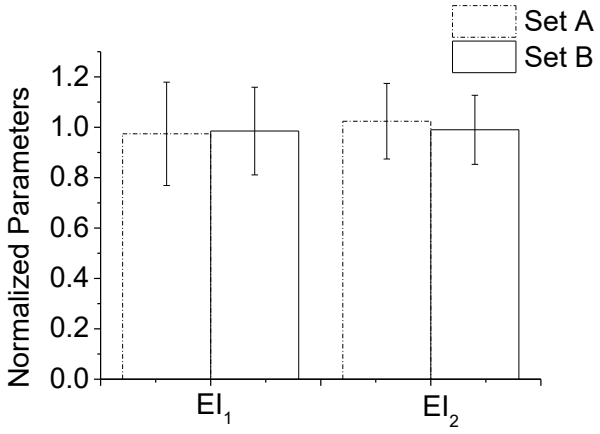


Figure 5. Mean and standard deviation of stiffness EI_1 and EI_2.

From figure 5, the maximum standard deviations are 2.0% and 1.7% for set A and set B

respectively, and the mean of EI_1 and EI_2 under both sets are very close to the true value, with a 2.3% error. No matter the set of A or B, the estimated value of EI_2 is a bit better than for EI_1 because of the slightly smaller standard deviations, which may be due to the stronger boundary conditions of node 41 than node 27. It has to be emphasized that these bending stiffnesses can be observed without knowing the surrounding ones, which shows the potential of the method when applied to large structures where only a small number of measurements can be obtained. The potential application of constrained dynamic observability method to large scale structures is then fully illustrated.

4 Conclusions

The main objective of this paper is the application of constrained observability techniques for parametric estimation of structures using dynamic information such as frequencies and mode-shapes. The final objective is to show the applicability of the method in efficiently identify the possible damages existing in the structure that may affect its durability (mainly cracking affecting the bending stiffness). A new algorithm is introduced based on the dynamic eigenvalue equation. The merit of the dynamic constrained observability analysis is demonstrated in the analysis of a RC beam and a large frame structure.

Abstract. *Rainwater and moisture control are key factors for maintaining the durability of wooden houses. Wall assemblies with sidings are installed on vented cavities to build durable wooden houses. Moisture condensation does not occur generally behind a vapor retarder in walls assembled with a vented cavity; however, it is reported that the condensation mechanism which occurs in the wall assembly due to the high humidity of the vented cavity by rain penetration in Japan, there are only a few studies that investigate hygrothermal behaviour considering effects such as rain penetration in the exterior system. To unravel the mechanism of internal condensation derived from rain penetration, lab-experiments and field measurements were conducted. In the lab experiments, rain penetration from siding joints were quantitated using a water spray test. In the field measurements, for the exterior finishes of the experimental house, the sidings were installed on three types of vented cavities. To verify hygrothermal behavior within the wall assembly, intermittent long-term rain penetration into the vented cavity was reproduced for the experimental house. The measurements confirmed that internal condensation occurs with low ventilation performance, when moisture retained in the vented cavity is released into the wall assembly. This phenomenon is caused when the surface temperature on the sidings is increased because of solar radiation after rain. In conclusion, rain penetration through exterior finishes has a significant effect on the moisture behavior of wall assemblies. The obtained results verify that moisture condensation at the vapor retarder was caused by several factors including rain penetration, insufficient ventilation, and solar radiation. To maintain durability, it is important to ensure a ventilation performance and not retain moisture.*

1 Introduction

Rainwater and moisture control are key factors for maintaining the durability of wooden houses. Wall assemblies with claddings are installed on vented cavities to build durable wooden houses (Figure. 1). In Japan, a fiber reinforced cement siding (hereinafter, called siding) is provided as an exterior system for outer walls in several houses. In this system, a vented cavity is provided between the siding of the primary waterproof layer and a water resistive barrier sheet of the secondary waterproof layer; the rainwater from the siding joints and the moisture from inside the house are discharged quickly (Figure. 2).

Recent years have seen an increase in houses designed with low eaves that experience rain penetration through the sidings under heavy rain; thus, the risk of rain penetration is increasing. It is difficult to completely prevent rain penetration into a vented cavity (Sahal, Lacasse and

Kimura). Technical note of National Institute for Land and Infrastructure Management of Japan has reported moisture condensation and structural decay of the wall assembly caused by rain penetration and insufficient ventilation. It is suggested that the condensation mechanism which occurs in the wall assembly due to the high humidity of the vented cavity by rain penetration (Umeno, 2011). Rain penetration have been considered evaluation methods such as ASHRAE Standard 160 in North America. However, there are only a few studies that investigate hygrothermal behavior considering effects such as rain penetration in the exterior system in Japan.

To maintain durability of wooden houses with the exterior system, this study confirmed the quantity of rain penetration from the siding joints using a water spray test, measured the temperature, humidity, and moisture content within the wall assembly during intermittent rain penetration into the vented cavity in the field survey. These results were used to clarify the mechanism of moisture accumulation in the wall assembly. Furthermore, the vented cavities of different cases were compared, the verification data on the ventilation performance of each case were verified. The impact of rain penetration on the exterior system of the hygrothermal behavior within wall assemblies was discussed.

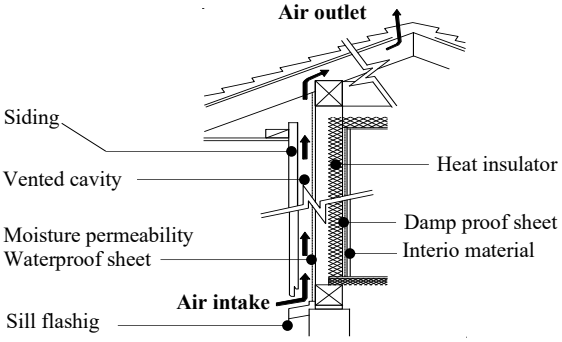

Figure 2. Siding standard installation method.

2 Quantification of Rain Penetration from the Siding Joints Using a Water Spray Test

To measure the quantity of rain penetration from the siding joints of an exterior system, the water spray test (JIS A 1517: Water tightness test under dynamic pressure) was performed.

As for the water penetration through the siding joint under strong wind, it is generally assumed that the rainwater flows over the shiplap joint and penetrates the vented cavity (Fig. 3(1)). When the wind is weak, the rainwater flows across the surface of the shiplap and penetrates into the vented cavity through the sealing area between the horizontal joints of sidings (Fig. 3(2)). The horizontal joint of the siding was placed at the center of the test specimen, and the quantity of rain penetration was measured with a plastic container. Figure 4 shows an outline of the experimental apparatus.

2.1 Experimental Conditions

General water spray tests are conducted under the conditions of high pressure difference (150–

350 Pa) and high water volume (4 l/min・m^2). However, frequency of these conditons are rare in real crimate data. To understand the quantity of rain penetration under the condition that may frequency occur in rainy day, this test was conducted at low pressure (0–250 Pa) and low water volume (0.2–0.8 l/min・m^2). The duration of the water spray test was 11 min; the pressure condition was not a pulsating pressure but a constant pressure.

To confirm the difference caused by the siding application method, test specimens were assembled using two application methods for a typical shiplap joint. Case A has a two-way shiplap with the top and the bottom; the left and right sides are joint using a sealant. Case B has a four-way shiplap with the top, bottom, left, and right. Figures 5 and 6 show the outline of specimen. In addition, the quantity of penetrated water and the water penetration rate in the water spray test were obtained from the following equation:

$$J_p = \frac{m_w}{t} \tag{1}$$

$$f = \frac{J_p}{R_w} \times 100 \tag{2}$$

where J_p is the quantity of penetration water (g/s), m_w is the measured total quantity of penetration water (g), t is the duration of the water spray test (s), f is the water penetration rate (%), and R_w is the quantity of water spray (g/s).

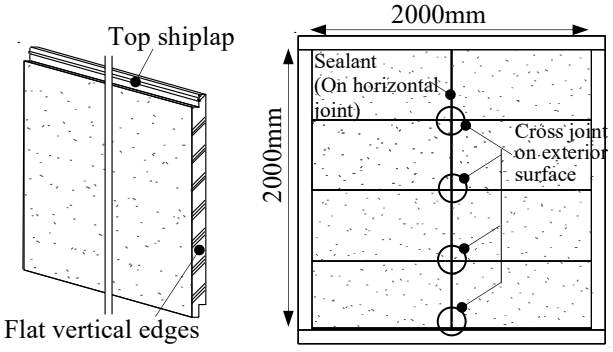

Figure 5. Siding shape of Two-way shiplap and Test specimen of Case A.

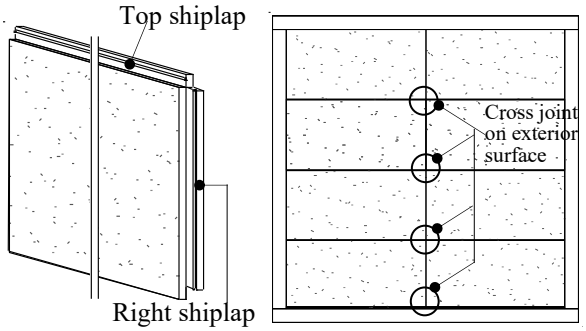

Figure 6. Siding shape of Four-way shiplap and Test specimen of Case B.

2.2 Relation Between Water Penetration Rate and Pressure Difference

Table 1 and Figure 7 show the experimental results. There are differences in the water penetration rate with the siding application.

For case A, under the conditions that rain penetration water was observed with a pressure difference of less than 150 Pa, the water that ran across the surface of the shiplap—the path shown in Fig. 3(2)—was transmitted to the sealant part of the horizontal joint, and it flowed down to the vented cavity. This water was accumulated in the plastic container at the bottom. When the pressure difference was 250 Pa, the water flowed over the sealant gasket of the shiplap joint shown in Fig. 3(1) and then flowed down the back of the siding. As a result, the water penetration rate increased significantly. For Case B, continuous flow occurred even in a pressure-equalized condition because there were pinholes at the cross joint on the exterior surface (Fig. 8). Thus, considerable penetration water that the water penetration rate was 5–11% was measured when the pressure difference was 0 Pa.

Owing to the difference in the siding application method, it is conceivable that there is no waterproofing performance criterion for driving rain. Furthermore, there is a possibility that the quantity of penetration water may increase because of the deterioration of sealants and the opening of the siding joint, which was caused by hardening shrinkage.

In consideration the above results, it is necessary for maintaining durability to consider the assumption that rainwater enters the vented cavity.

Table 1. Quantity of penetration water and water penetration rate.

Quantity of water spray (L/min・m²)	Pressure difference (Pa)	Case A			Case B		
		m_w (g)	Jp (g/s)	f (%)	m_w (g)	Jp (g/s)	f (%)
0.2	0	0	0.00	0.00	788	1.19	11.31

3 Field Survey of Hygrothermal Behavior within Wall Assembly Derived from Rain Penetration

From the results in the previous section, it was suggested that wall assembly with a vented cavity using the siding has a risk of rain penetration from the shiplap joint. In this section, to unravel the mechanism behind internal condensation caused by moisture from the rainwater, an experimental house that reproduces intermittent long-term rain penetration into the vented cavity was constructed, and the hygrothermal behavior within the wall assembly was measured.

3.1 Outline of the Experimental House

The experimental house with a wood panel construction was constructed on the grounds of Ashikaga University in Tochigi (about 80km north of Tokyo). Three types of cavity configurations were installed in experimental house to compare the ventilation performance, Figure 10 shows the configuration of cavity. Case (1) is a horizontal furring strip (cavity depth: 12 mm), case (2) is a panel clip (cavity depth: 6 mm), and case (3) is a panel clip (cavity depth: 15 mm), horizontal furring strips is insufficient ventilation, while panel clips secure a ventilation path. The cavities are at 910 mm intervals.

The bottom of the vented cavity is open with a sill flashing. The upper end of the vented cavity is open to the outside by ridge ventilation through the attic space (Fig. 2).

For the quantity of rain penetration into the vented cavity, the rainwater collected with a pouring funnel attached to the eaves was injected directly into the vented cavity from the center of the wall surface using a tube. The diameters of the funnel were selected to reproduce the intermittent long-term rain penetration in proportion to the precipitation. For Case (1), 80mm funnel size was installed in three places, and water injection was divided into three parts: upper, middle, and lower areas of the horizontal furring strips. For Case (2) and (3), three times size of the funnel was installed respectively.

3.2 Measurement Item

Figures 9 and 10 show the measurement items and measurement positions in the wall. The temperature, humidity, and moisture content were set near the center height of the first floor (FL + 1300 mm). The temperature and humidity were measured outside the insulation and

inside the insulation; the moisture content was measured for the outer plywood facing the vented cavity. The measurement interval was 60 min, and the measurement period started from September 2018. Air conditioning in the room was not used.

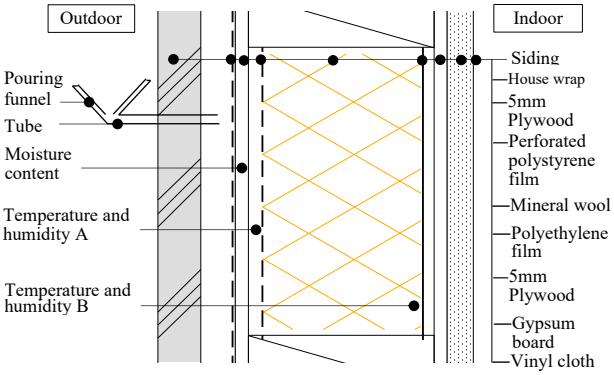

Figure 9. Wall configuration and sensor location.

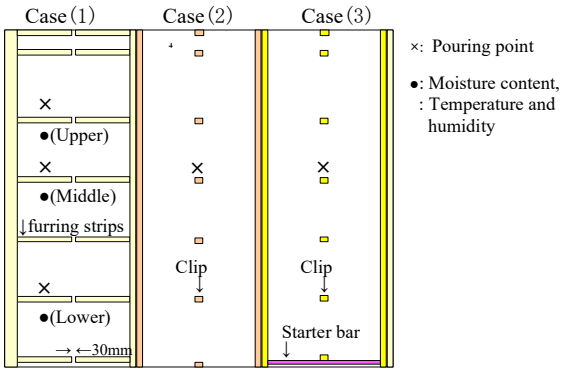

Figure 10. Configuration of cavity.

3.3 Results and Discussion

3.3.1 Increase in humidity and plywood moisture content due to rainfall in autumn

As an example of the measurement results in autumn, Fig. 11 shows the relative humidity between the insulation and vapor barrier. The outdoor temperature and precipitation are based on the weather data of the neighboring City. The relative humidity in the wall assembly increased after the rainy day, and moisture derived from rain penetration gradually accumulated in the wall due to repeating rainy and sunny days. Intermittent moisture condensation observed in some cases in early October.

The moisture in the wall assembly gradually decreased with reducing the quantity of precipitation since October 8. From this result, it can be indicated that rain penetration has a considerable impact on moisture accumulation in the wall assembly.

3.3.2 Process of hygrothermal behavior within wall assembly and the impact of ventilation performance.

Figures 12 and 13 show daily variations of relative humidity on the east side of wall on October 7, at location A (between outside plywood and perforated polystyrene film) and location B (between insulation and vapor barrier) were shown in Figure 9. Moisture condensation continues more than 9 hours at the location B with case (1) and (2), while it occurs less than 1 hour at the location A. In addition, relative humidity at location B increases with rising outdoor temperature.

From this result, it can be confirmed that moisture from rain penetration is accumulated on the indoor side. This phenomenon is thought to be the result that moisture retained in the sidings and the vented cavity was released by solar radiation; moisture that could not be discharged from the vented cavity moved to the wall assembly of the indoor side at a low temperature. Thus, temperature fluctuations due to solar radiation have a significant effect on hygrothermal behavior within a wall assembly. Temperature fluctuations release moisture retained in the

building materials, which forms water vapor and move through wall assembly and materials. Consequently, the moisture condenses on the indoor side of the low-temperature part.

Compare the ventilation performance with different cavity configurations. The rain penetration water in case (1) with 12 mm of the cavity depth tends to accumulate within the wall assembly, because it generally remains at the horizontal furring strips. Furthermore, insufficient ventilation performance extended duration of moisture condensation to more than 12 hours at the location B. Although the remained water in the vented cavity of case (2) is less than case (1), duration of moisture condensation reached 9 hours because of less ventilation performance due to thin cavity depth. As for case (3) with the panel clip and 15 mm of cavity depth, the moisture condensation did not occur because adequate ventilation and drainage performance was secured.

From the above results, the impact of ventilation performance on hygrothermal behavior within the wall assembly was confirmed. As in case (3), adequate ventilation performance tends to reduce moisture accumulation in the wall assembly. To maintain durability, it is important to ensure a ventilation performance and not retain moisture within the vented cavity.

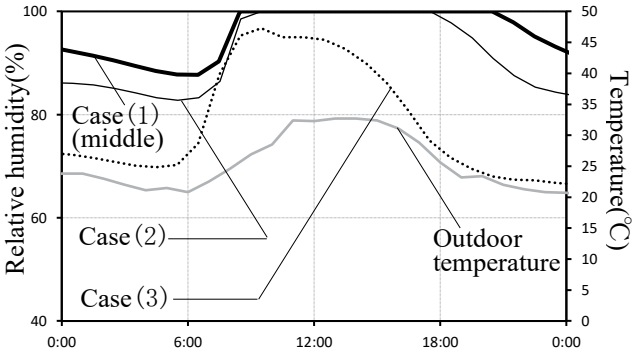

Figure 13. Relative humidity variation on east wall ocation B（10/7）.

4 Conclusion

This study was demonstrated the moisture accumulation in the wall assembly caused by rain penetration from the siding joints. In addition, the authors obtained an outline of the hygrothermal behavior within the wall assembly based on ventilation performance in the experimental house. The findings of the study are as follows:

- According to the quantity of rain penetration into the siding joints performing the water spray test, it was confirmed that there were significant differences in the water penetration rate between the application methods. For case B, continuous flow occurred even in a pressure-equalized condition because there were pinholes at the cross joint on the exterior surface. The rain penetration rate is 5–11% at low pressure difference (0–15 Pa) where the frequency is high. Thus, it is necessary for maintaining durability to consider the assumption that rainwater enters the vented cavity.
- According to the field survey of the experimental house, the relative humidity in the wall assembly increased after the rainy day, and moisture derived from rain penetration gradually accumulated in the wall. Intermittent moisture condensation observed in some cases. From this result, it can be indicated that rain penetration has a considerable impact on the moisture accumulation in the wall assembly.
- For the cases of low ventilation performance, the moisture condensation in the wall assembly observed more than for 9 hours in daytime. The case of high ventilation performance did not occur the moisture condensation. To maintain durability, it is important to ensure a good ventilation performance and not retain moisture.

Further studies are needed to develop a design method that can maintain the durability of wooden houses using the exterior system; in a future study, the authors expect to indicate the behavior of rain penetration water in the vented cavities and the ventilation characteristics.

Abstract. *Building inspection systems are a useful tool for surveyors, standardising the collection of information. This research is framed within the development of a global inspection system based on twelve expert inspection systems for twelve types of building elements used in the envelope of current buildings. Homogenised classification lists replace the use of several records and unify designations used in fieldwork. A homogenised global classification list of repair techniques comprises, in a single component, all the techniques used to repair defects and eliminate their causes for different types of building elements. It includes curative and preventive repairs, as well as planned maintenance works. Well-defined criteria guided the harmonisation process of a large set of repair techniques in a user-friendly list. For instance, the association of different operations in a single repair technique took into account: similarities between procedures, applicability to one type of building element, solving identical defects and the use of similar repair materials. Considering data from the validation samples of the expert inspection systems, it is observed that techniques "R-A1 Cleaning" in painted façades and "R-A12 Application of a new (adequate) cladding/finishing coat over the existent/replacement" in wall renders are the most commonly prescribed. The provision of a homogenised classification list of repair techniques is expected to improve the quality of information collected on-site and give a comprehensive view of the most relevant repair techniques used in the envelope of current buildings.*

Keywords: *Building Pathology, Degradation, Inspection Systems, Maintenance, Repair Techniques.*

1 Introduction

Building inspection systems are useful for surveyors as they (i) help implementing uniform methodologies, (ii) guide the procedures through all the stages, and (iii) use standard designations. In this way, the collection of data on-site and inspection reports become methodic, hence standardising building inspections. This paper addresses the development of a global inspection system for the building envelope by a research team at Instituto Superior Técnico (IST), Universidade de Lisboa (UL), based on individual expert inspection systems (Pereira *et al.*, 2018).

The global inspection system under development at IST-UL is directed at current buildings. It is a broad tool including classification lists, correlation matrices, detailed information on degradation parameters, and an inspection form. It is based on existing expert inspection systems for individual building elements, which implies homogenising the system's components.

The homogenisation of classification lists simplifies the inspection process, replacing several lists with harmonised lists, more manageable to use. In this way, the identification of pathological phenomena in a painted façade or flat roof requires only one list of defects, for instance.

Additionally, standard designations may improve communication.

In this paper, the methodology of development of the harmonised list of repair techniques in the global inspection system is described, and the proposed classification list is presented. Then, using relative frequency results, the most common repair techniques are analysed. The paper ends summarising the research in concluding remarks.

2 Classification List of Repair Techniques

Following the structure of individual inspection systems, the global building inspection system includes a list of repair techniques. It contains techniques used to repair defects and eliminate their causes in the group of building elements taken into account in the inspection system. The particulars of each procedure are described in detail in files of repair techniques, out of the scope of this paper.

2.1 The Context of Developing a Global Inspection System

The development of the global building inspection system considered a well-defined range of building elements, corresponding to twelve expert inspection systems previously devised by researchers at IST-UL (Table 1). Those expert inspection systems have an identical structure and were all validated through the inspection of significant samples of building elements, hence providing a solid base for a new global system (Ferraz *et al.*, 2016).

All the selected individual expert inspection systems provide a classification list of repair techniques that may be recommended by surveyors following the detection and diagnosis of defects in visual and detailed building inspections. Those lists were based on the literature and experience, including curative and preventive techniques and planned maintenance works (Silvestre and de Brito, 2010). Curative repair techniques are those used to repair a defect directly, removing it. Preventive repair techniques refer to interventions on building elements that are not directly associated with a specific defect but, instead, act to eliminate the causes of potential issues. Curative and preventive repair techniques may include partial or complete replacement and changes in the characteristics of the building element (*e.g.* materials and geometry). Planned maintenance works are not intended to correct the behaviour of building elements, but to delay the natural ageing process and the resulting loss of performance and decrease of the service life.

2.2 Harmonisation Criteria

To achieve the goal of having a single list of repair techniques applying to different building elements within the global inspection system, all the expert classification lists had to be collected. Then, going through each list consecutively, the repair techniques referring to the same type of work were merged. For instance, ten out of twelve expert classification lists included cleaning works. Therefore, the global classification list comprises cleaning as one of the repair techniques. After that step, the list of repair techniques was still too long. So, similar techniques were grouped in a single repair technique considering equivalent scopes of intervention, identical procedures, and the resolution of the same kind of phenomena. For instance, different intervention techniques acting on the layers of cladding systems of flat roofs were gathered in a single and broader repair technique referring to the application, repair or replacement of the waterproofing system or separation layer in flat roofs (Conceição *et al.*, 2017). Despite the attempt of decreasing the extent of the global classification list of repair techniques, some specific techniques relating to only a type of building element were kept separately in the list, as no basis for merging applied.

Table 1. Expert inspection systems developed at IST-UL that were the basis of the global inspection system.

While merging and grouping repair techniques to obtain a more concise global list, balancing a simultaneously elaborate and succinct list is paramount for its broadness and user-friendliness. For instance, in the expert inspection system of wall renders (Sá *et al.*, 2014), five separate repair techniques were considered to express the idea of applying a new render with higher performance, namely: application of a reinforced rendering; execution of an external thermal insulation composite system (ETICS); execution of a reinforced render coating independent from the bearing wall; application of a render with higher thermal performance; and application of a drainage or corrective rendering. These five types of repair work refer to slightly different operations, but they are all based on the same concept: the existing render is not enough to prevent the occurrence of further defects and should be replaced or overlaid with a new one. Although separately considering each of these techniques may be reasonable in an inspection system only for wall renders, in a global building inspection system, it would hinder the ease of use of the classification list. For this reason, a single repair technique for the application of a higher performance render was proposed.

Still, other repair techniques could not be linked with any others, as they were too specific. For instance, executing a roof slab in pitched roofs is not comparable with other repairs. So, in the global classification list, it was considered separately, although not decreasing the list's complexity.

To guide the harmonisation of the global classification list of repair techniques, taking expert classification lists into account, a set of criteria was determined:

1. Building a **brief and concise** list of repair techniques without repetitions;

2. To decrease the extent of the list, coupling techniques in one repair technique considering:
    a. The **procedure** of the repair technique;
    b. The applicability of similar repair techniques to a **single type of building element**;
    c. Correcting **similar defects**;
    d. Using **repair materials** with **similar** properties;
3. Including all relevant repair techniques in the list, even though some may apply only to a single type of building element, so that the global classification list is **comprehensive**;
4. Grouping repair techniques into **categories** according to the intervention area within the cladding systems, namely: surface of the cladding, cladding system, change in the bearing structure/substrate and singularities.

2.3 Proposed Classification List of Repair Techniques

Table 2 presents the proposed classification list of repair techniques within a global inspection system. It is organised in four categories, according to the harmonisation criteria. Each technique is identified as constituting a curative (cr) or a preventive repair (pr) or planned maintenance work (pmw). Each category is linked to a code composed of letter R (for repair), a hyphen and a sequential capital letter (from A to D). Each repair technique also corresponds to a code, following that of its category, by adding a sequential number (*e.g.* R-A1, R-B2, R-C5 and R-D11).

Technique "R-D6 Application/repair/replacement/cleaning of drainage systems/plumbing" results from grouping similar repair techniques. R-D6 is a curative and preventive repair technique used in the drainage and plumbing equipment to eliminate or avoid clogging, accumulation of rainwater and leakages. In the expert system of flat roofs, the application, repair and replacement of the drainage system are mentioned (Conceição *et al.*, 2017), while the adhesive ceramic tiling expert system refers to the repair of defects in plumbing, separating embedded and exposed plumbing (Silvestre and de Brito, 2010). In turn, the classification list for natural stone claddings mentions the repair of defects in existing elements inside/outside the wall (Neto and de Brito, 2011). Plumbing is also mentioned for wood floorings (Delgado *et al.*, 2013), while, in door and window frames, the repair or execution of drains in the frames is pointed as a repair technique (Santos *et al.*, 2017b). In this context, technique R-D6 is an example of how conciseness influenced the development of the global classification list of repair techniques, as very similar techniques were harmonised in a single and broader repair technique.

Other techniques result from a direct transfer from the expert to the global classification lists. It is the case of "R-D9 Protecting or smoothing of protruding corners or edges", applying to adhesive ceramic tiling, natural stone claddings, wall renders, ETICS and architectural concrete surfaces.

3 Discussion

An analysis of the most frequently prescribed repair techniques may be performed using the data from the validation samples of the expert inspection systems (Table 1). To build Figure 1, the absolute frequency of recommendation of each repair technique was considered (Amaro *et al.*, 2014; Carvalho *et al.*, 2019; Conceição *et al.*, 2019; Delgado *et al.*, 2018; Garcez *et al.*, 2012a; Garcia and de Brito, 2008; Neto and de Brito, 2012; Pires *et al.*, 2015b; Sá *et al.*, 2015; Santos *et al.*, 2017a; Silva *et al.*, 2017b; Silvestre and de Brito, 2010), adapting the original repair techniques to the proposed global classification list. Then, those absolute frequencies were divided by the number of detected defects in each validation sample.

Table 2. Proposed classification list of repair techniques within a global inspection system.

Code	Category	Code	Repair technique
R-A	Surface of the cladding	R-A1	Cleaning (cr, pr, pmw)
		R-A2	Application of a protective coat (paint, varnish, water-repellent, antifungal, biocide) (cr, pr, pmw)
		R-A3	Corrosion removal and re-establishment of the anti-corrosion protection in metallic elements (cr)
		R-A4	Surface rehabilitation of the plastic external claddings of pitched roofs (cr)
		R-A5	Repair/execution of supplementary watertightness measures in pitched roofs (cr, pr)
		R-A6	Creation of pathways (pr)
		R-A7	Application of ventilation systems/accessories (cr, pr)
		R-A8	Encapsulation of asbestos-cement external claddings of pitched roofs (pr)
		R-A9	Application of spray polyurethane foam (SPF) on the external surface of pitched roofs (cr, pr)
		R-A10	Glazing repair in door and window frames (cr)
		R-A11	Replacement or reapplication of the cladding/glazing (partially or completely) (cr, pr)
		R-A12	Application of a new (adequate) cladding/finishing coat over the existent/replacement (cr, pr, pmw)
		R-A13	Application of another type of cladding (not epoxy) (cr)
		R-A14	Treatment of cracks or other holes in the cladding (cr)
		R-A15	Treatment of biodegradation in wood floorings (cr)
		R-A16	Complete/partial removal of the existing coat in painted façades (cr)
		R-A17	Correction of surface irregularities or evening an architectural concrete surface with mortar (cr)
R-B	Cladding system	R-B1	Application of underlayment in pitched roofs (pr)
		R-B2	*Flocage* in metallic claddings of pitched roofs (pr)
		R-B3	Application of spray polyurethane foam (SPF) on the interior surface of pitched roofs (cr, pr)
		R-B4	Application/repair/replacement of the vapour barrier (cr, pr, pmw)
		R-B5	Application/repair/replacement of the thermal insulation (cr, pr)
		R-B6	Application/repair/replacement of the waterproofing system or separation layer in flat roofs (cr, pr)
		R-B7	Injection of filling resins (bedding material) (cr)
		R-B8	Reinforcement of the bedding layer in localised areas (cr, pr)
		R-B9	Reinforcement with metallic elements or composite materials in wood floorings (cr)
		R-B10	Consolidation with concrete in wood floorings (cr)
		R-B11	Execution of prostheses or application of reinforcement profiles in door and window frames (cr, pr)
		R-B12	Deformation repair (distortion/shrinkage/warpage/expansion) in door and window frames (cr)
		R-B13	Change/replacement/repair of the fastening system or correction of holes in plates or substrate (cr, pr)
		R-B14	Application of a higher performance render (cr, pr)
		R-B15	Perforation/gap filling in ETICS (cr)
		R-B16	Repair of corroded reinforcement/concrete cover spalling in architectural concrete surfaces (cr)
		R-B17	Application of an additional concrete layer in architectural concrete surfaces (cr, pr)
R-C	Change in the bearing structure/substrate	R-C1	Execution of a roof slab in pitched roofs (cr)
		R-C2	Repair/reinforcement/replacement of the bearing structure in pitched roofs (cr, pr)
		R-C3	Application/replacement of the shaping or levelling layer (cr)
		R-C4	Repair of dead cracks in the substrate and reapplication of the cladding (cr, pr)
		R-C5	Pavement levelling in epoxy resin floor coatings (cr, pr)
R-D	Singularities	R-D1	Application/repair/replacement of expansion joints (cr, pr, pmw)
		R-D2	Replacement/repair of current joints' filling material and/or joints cleaning (cr, pr, pmw)
		R-D3	Application of fungicide, biocide or herbicide in joints (cr, pr)
		R-D4	Joint thickness increase or joint insertion (cr, pr)
		R-D5	Repair/application of tail-ends and associated protection elements (cr, pr, pmw)
		R-D6	Application/repair/replacement/cleaning of drainage systems/plumbing (cr, pr)
		R-D7	Removal of corroded or damaged metallic elements, with hole and notch filling (if applicable) (cr, pr, pmw)
		R-D8	Repair of water penetration spots (cr, pr)
		R-D9	Protecting or smoothing of protruding corners or edges (cr, pr)
		R-D10	Cleaning of façade's horizontal areas in adhesive ceramic tiling (pr, pmw)
		R-D11	Repair, insertion or replacement of sealants or insulation mastics in door and window frames (cr, pr)
		R-D12	Replacement of degraded, or missing, elements in door and window frames (cr, pr)
		R-D13	Adjustment, replacement or additional installation of hardware (hinges/locks/span-frame connections) in door and window frames (cr, pr)
		R-D14	Lowering of the tail-end area in epoxy resin floor coatings (cr, pr, pmw)
		R-D15	Execution of coves in epoxy resin floor coatings (cr, pr, pmw)
		R-D16	Correction of geometrical construction details (pr)

cr - curative repair; pr - preventive repair; pmw - planned maintenance works

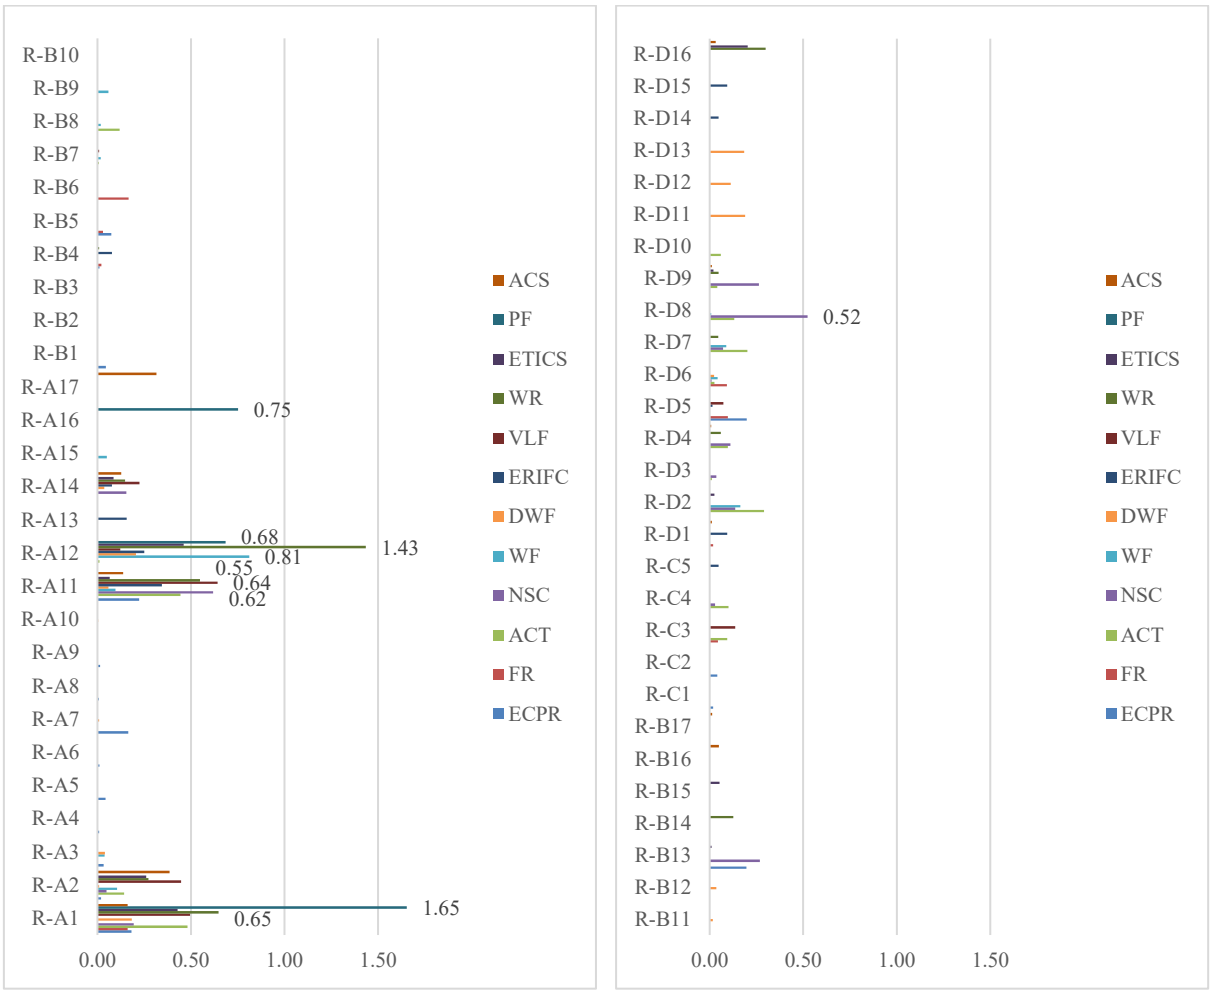

Figure 1. Relative frequency of prescribed repair techniques for detected defects in each expert inspection system.

Due to the adaptation to the global classification list, Figure 1 values may result from the sum of absolute frequencies, referring to the union of repair techniques from each expert classification list.

The highest relative frequency in Figure 1 refers to the prescription of "R-A1 Cleaning" in painted façades. R-A1 corresponds to four specific techniques in the expert inspection system of painted façades, which divide the act of cleaning in different operations, namely (Pires *et al.*, 2015a): scrubbing/dusting, manual washing with water and a sponge, washing with a low-pressure water jet, and chemical cleaning. As the result in Figure 1 (1.65) comes from the sum of four absolute frequencies, it exceeds the number of detected defects. It may be interpreted that, in many occurrences, more than one type of cleaning operation was prescribed considering (i) the combination of different activities for better results, or (ii) the prescription of different types of cleaning operations allowing the selection of the best method by decision-makers taking the available equipment and staff into account. Additionally, in the sample of Pires *et al.* (2015b), the category of anomalies referring to stains represents about 46% of all detected defects, partially explaining the recommendation of a high number of cleaning operations. Finally, cleaning a painted surface may frequently be considered as preliminary work to prepare the surface for further repairs.

"R-A12 Application of a new (adequate) cladding/finishing coat over the existent/replacement" is highly recommended in wall renders. Again, the value in Figure 1 (1.43) results from the sum of the absolute frequency of three repair techniques from the wall renders' expert classification list: full/partial replacement of the finishing coat, application of a new finish coat over the existing render, and application of cladding over the existing render (Sá *et al.*, 2014). Considering that inspected renders were protected with a paint coating, and the average age of the sample of buildings is 27 years (Sá *et al.*, 2015), many likely lacked maintenance or repainting according to the standard service life of paint coatings in façades—an average of 8.5 years, according to Chai *et al.* (2015). Additionally, in the sample of Sá *et al.* (2015), the cause referring to an irregular repainting periodicity was the most often identified among the group of wear and maintenance faults.

In general, observing Figure 1, it may be concluded that repair techniques in category "R-A Surface of the cladding" are the most commonly prescribed. The outer layer of a building element is the most exposed to aggressive agents. Furthermore, its integrity is of high importance to protect the conditions of the building element and the whole building.

4 Conclusions

The use of a single list of repair techniques in the context of building inspections is user-friendly for surveyors and contributes to the standardisation of inspection procedures and the improvement of communication between players in the construction sector. Such a single list of repair techniques may also be useful as it determines the general scope of repair techniques that should be expected within a maintenance plan, namely for this selection of twelve materials used in the building envelope. Additionally, analysing frequency data on the prescription of repair techniques allows building owners and maintenance managers to prepare the staff for the execution of the most common procedures, training workers and acquiring adequate equipment while balancing costs and benefits.

Higher Incidence Pathologies in Installations of Solar Energy, Gas, Cooling, Heating and Ventilation

Manuel J. Carretero-Ayuso

Musaat Foundation and University of Extremadura, Spain; *carreteroayuso@yahoo.es*

Abstract. *This paper focuses on the study and quantifications of pathologies in solar energy, gas, cooling, heating and ventilation installations, based on complaints filed in the courts by the owners of a large number of houses in which errors appeared in those installations. The relevant complaints filed across all of Spain were studied, in what is an important contribution to forensic engineering, given that access to the outcome of civil court cases is seldom obtained. The representativeness of the data is not partial but total, since the entirety of cases existing in the period under study was part of the sample, enabling us to consider this to be a general exposition on the epidemiology of construction pathologies in installations in houses in Spain. It should be noted that the Spanish construction sector is one of the most problematic ones, due to the dissatisfaction generated in homeowners, and as it is one of the ones leading to the highest number of complaints filed with consumer protection bureaus and in the courts. In the investigation, results have been obtained for each of the installations (183 cases in total), according to the type of anomaly (the most important are dysfunctions, leaks and humidity), the pathological origin (poorly arranged encounters, omissions of elements, among others) and the type of construction where it is produced (especially in block dwellings).*

Keywords: *Installations, Complaints, Construction Pathologies.*

1 Introduction

The purpose of an HVAC installation is to provide correct heating, ventilation and cooling, reliably maintaining comfortable values of humidity, temperature, and air quality, despite changes that might occur externally (Cohen *et al*. 2017). Accordingly, these installations (heating, ventilation and cooling) are key in air treatment, dehumidification, etc. Solar energy and gas supply installations further meet these needs, providing greater comfort. Indeed, in some context the set of these five types of installations are referred to as comfortability installations.

Recently, Yang *et al*. (2018) planned a fault detection mechanism for these installations, developing a method based of prognoses using synthetic data of temporal series through simulations in computer programmes. A year earlier, Turner *et al*. (2017) published a procedure for fault detection in buildings with some of these installations.

The scientific literature especially covers heating, ventilation, and cooling installations, from different perspectives. In 2018, a study was published identifying various factors affecting risk to cost and time in construction (Mosaad *et al*. 2018). In another perspective, Ruano *et al*. (2018) showed that half the energy consumption in residential and non-residential buildings was basically used by heating and cooling. It is for this reason that other authors (Wu and Sun 2011) consider it useful to develop methods of verification of certain parameters, through the use of energy flow models; including the study of air flow and the cooling/heating load (Cetin and Kallus 2016).

doi:10.23967/dbmc.2020.073

For Behfar *et al*. (2017), the detection and diagnosis of faults in buildings' installation systems (especially when those faults convert into pathology problems) is of interest given that they allow the reduction of consumptions and operating costs, thus being a useful work tool for all technicians (engineers as well as architects).

One of the main limitations for the ample and in-depth knowledge of problems in installations is that a part of the reviewed literature has relied on observation processes or on surveys more or less focused on buildings of a specific developer or builder. Moreover, the lower number of problems existing therein in relation to other units more prone to pathologies (such as roofs, facades and structures) lead to them being less known.

The purpose of this research is to identify the most important types of anomalies in these types of installations, as well as their recurrence, based on judicial complaints made across all of Spain by building owners. The knowledge of these anomalies will be useful to designers, construction managers, and maintenance supervisors.

2 Methodology

This research analysed the data corresponding to the policies dated 2014-2016 of the civil responsibility insurance of Spanish technical architects and building engineers (Musaat 2014 2016) that saw complaints by owners related to construction problems (Serjuteca 2014-2016). This data was sourced from the Musaat Foundation's study "National statistical analysis on construction anomalies" (Carretero-Ayuso and Moreno-Cansado 2016), that aimed to identify the most frequent anomalies in the Spanish construction sector.

When a building user experiences problems in the construction, and the developer and builder do not solve them, users often resort to the judicial route. At this point, they also file complaints against the technicians that participated in the construction process: the designer and construction managers. This is done mainly because these technicians should be covered by civil responsibility insurance, which, in turn, is not required in Spain for developer and builder companies.

Once the judicial process is initiated, expert reports are produced indicating the types of anomalies and in which construction elements or installations the problems occur. It is from this database, owned by the insurer of the technical architects and building engineers in question, that this study obtains all its resources and values. In this regard, it should be mentioned that, as a requirement to include the data in this research, it was determined that data points would only be considered when the respective court sentence was final and unappealable in any higher courts, often years after the complaint was first filed.

All the complaints filed in the country were analysed and protocolised, with 183 cases being found (number of times an anomaly was counted) related to the installations being study: 'Solar Energy' (I1), 'Gas' (I2), 'Cooling' (I3), 'Heating' (I4) and 'Ventilation' (I5).

The classes were classified into 4 groups, each representing a different type of anomaly that was the object of a complaint by owners, according to the conclusions of the relevant technical reports. The types of anomalies are: 'Fissures in the cladding' (A1), 'Deficient ventilation (A2), 'Leaks or humidities' (A3) and 'Dysfunctions' (A4).

The pathological origins leading to these anomalies were identified and catalogued into 4 types: 'Inadequate tail-ends' (OP1), 'Omission of elements' (OP2), 'Irregularities and deficiencies' (OP3), and 'Various' (OP4).

The types of construction studied were: 'Detached houses' (V1), 'Attached houses' (V2) and 'Block dwellings' (V3).

3 Results

3.1 General Values by Installation

The values obtained in the five installations were very different from one another. As shown in Figure 1, ventilation (I5=42%) accounts for the greatest percentage, followed by heating (I4=32%). In last place are solar energy installations (I1=2%).

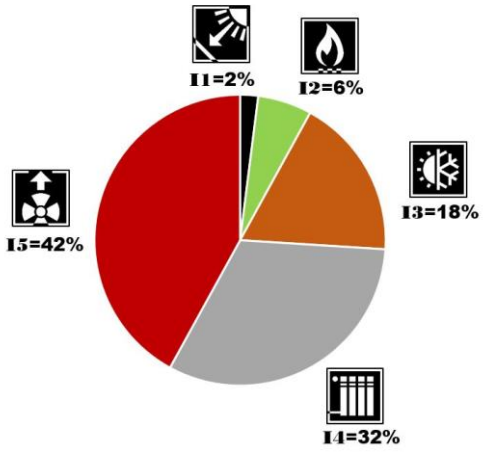

Figure 1. Percentages of cases existing in each installation.

3.2 Values by Type of Anomaly

As indicated above, each of the 4 types of anomalies that were the object of complaints were analysed. The one with the greatest prevalence was 'Dysfunctions' (A4=64%), a term that has grouped within it a series of anomalous and poorly functioning processes. As shown in Figure 2, 'Leaks or humidities' (A3=19%) are placed second.

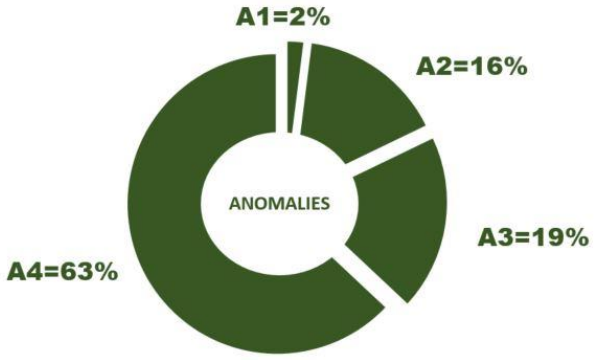

Figure 2. General percentages of the types of anomalies found in the research.

In order to further deepen and break down the information on the prevalence of the anomalies for each installation, Figure 3 was produced, showing the weight of each of them. It can be seen that heating and cooling have three types of anomalies each, while ventilation and gas installations have two types. Finally, we can observe that thermal solar energy installations concentrate all their anomalies in a single type ('dysfunctions').

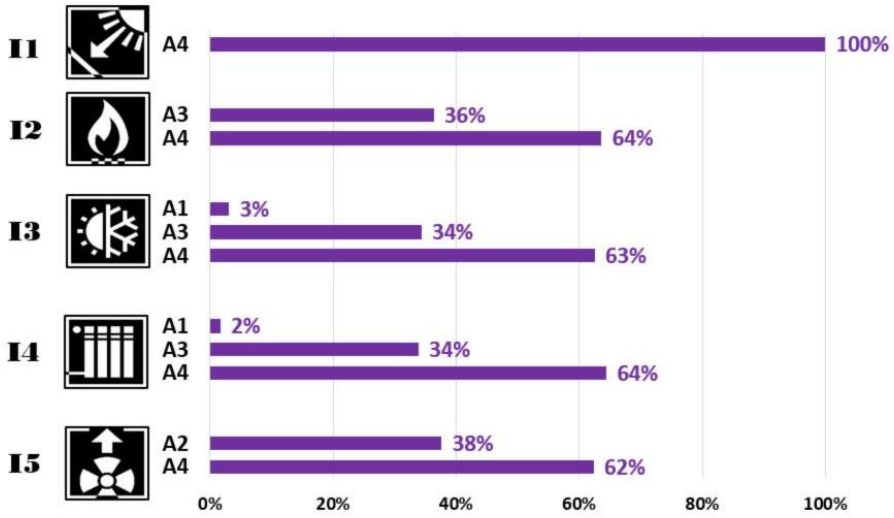

Figure 3. Distribution of the anomalies present in each of the installations.

It should be noted that in each of the installations there is clearly a dominant anomaly, aggregating approximately 2/3 of all cases (between 62% and 64%, except for I1, in which case it is 100%, as it is the sole anomaly). On the other hand, in those installations with three types of anomalies (I3 and I4), the anomaly with the lowest percentage always has a residual value (only 2% or 3% of the cases).

3.3 Values According to the Pathological Origin

The pathological origin (cause) with the greatest prevalence is OP4, with 35%, followed by OP3 with 34% (see Figure 4).

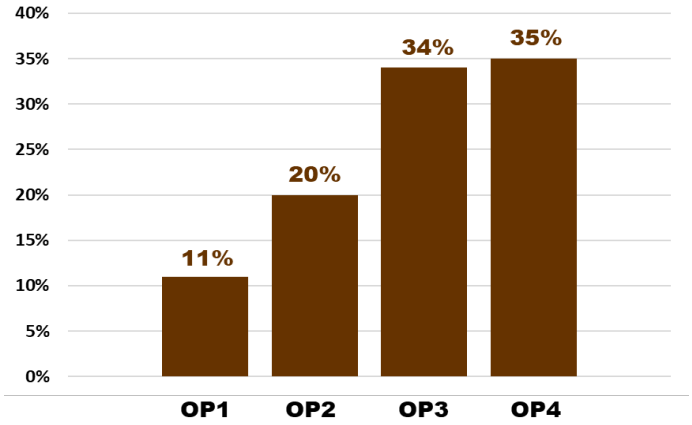

Figure 4. Values from smallest to largest of the different pathological origins found.

If the origins are broken down for each of the five installations, the following results are obtained:

-Solar energy (I1) = OP3(100%)
-Gas (I2) = OP1(45%) + OP3(36%) + OP4(18%)
-Cooling (I3) = OP1(16%) + OP2(13%) + OP3(31%) + OP4(41%)
-Heating (I4) = OP1(8%) + OP2(24%) + OP3(39%) + OP4(29%)
-Ventilation (I5) = OP1(8%) + OP2(25%) + OP3(27%) + OP4(40%)

It can be seen that the installations I3, I4, and I5 have 4 pathological origins each. In turn, I2 has 3 types of origins, and I1 has only 1 type.

3.4 Values According to Type of Construction and Type of Anomaly

One parameter that was also characterised by each of the anomalies was the type of construction in which they occurred. Based on Figure 5, they are most concentrated in 'block dwellings' (V3=60%), followed by 'attached houses' (V2= 26%). In all cases, the most frequent anomaly were 'dysfunctions' (A4 between 8% and 39%), with 'leaks or humidities' (A3 between 3% and 9%) in second place. Lastly, anomaly A1 is not present in the type of construction V2.

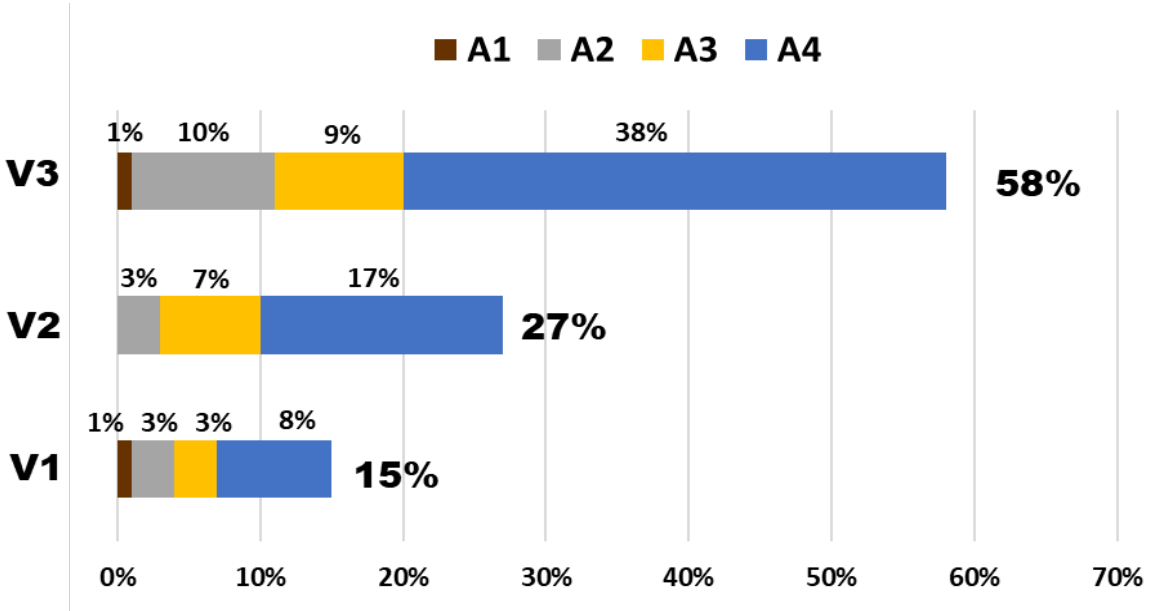

Figure 5. Relation between the type of anomaly and the type of construction.

3.5 Processes of Functional Deterioration

A 'process of functional deterioration' (p.f.d.) is the simultaneous and joint interrelation between each installation, its anomalies, and pathological origins; in this regard, each of the cases were studied and their anomalies were counted, differentiating them according to pathological origin.

A total of 30 different p.f.d. were detected in this study (see Table 1), demonstrating the variability of the situations that can take place. The ones with the most cases were I5-OP3-A4

and I5-OP4-A4 (18 cases each). They are followed by I4-OP2-A4 (14 cases).

With regard to installations, the one with the greatest percentage was I2, with two combinations: I2-OP1-A3 and I2-OP3-A4. Each represented 27% of anomalies found in gas installations. Solar energy (I1) has only one p.f.d., while cooling (I3) has the greatest variability: 9 p.f.d.

Table 1. Percentages of recurrence of each process of functional deterioration.

Installation		Pathological origin	Type of anomaly	% of the installations	% of the total
Icon	**Code**				
	I1	OP3	A4	100%	2%
	I2	OP1	A3	27%	2%
			A4	18%	1%
		OP3	A3	10%	1%
			A4	27%	2%
		OP4	A4	18%	1%
	I3	OP1	A3	13%	2%
			A4	3%	1%
		OP2	A3	3%	1%
			A4	9%	2%
		OP3	A3	6%	1%
			A4	25%	4%
		OP4	A1	3%	1%
			A3	13%	2%
			A4	25%	4%
	I4	OP1	A3	8%	3%
		OP2	A4	24%	8%
		OP3	A1	2%	1%
			A3	19%	5%
			A4	19%	5%
		OP4	A3	6%	2%
			A4	22%	7%
	I5	OP1	A2	1%	1%
			A4	6%	3%
		OP2	A2	16%	6%
			A4	10%	4%
		OP3	A2	4%	2%
			A4	23%	9%
		OP4	A2	17%	7%
			A4	23%	10%

The anomaly A4 (‘dysfunctions’) is present in all installations, being associated to three types of pathological origin: ‘inadequate tail-ends’ (OP1), ‘irregularities and deficiencies’ (OP3), and ‘various’ (OP4). The combinations occurring lest frequently (1 case) are: I2-OP3-A3, I3-OP1-A4, I3-OP2-A3, I3-OP4-A1, I4-OP3-A1 and I5-OP1-A4.

The determination and knowledge of each process of functional deterioration have not been identified nor calculated by any of the bibliographic references reviewed for this research. As such, this inclusion is considered to be a novel and important contribution to the technical-scientific knowledge on this type of installations, in addition to assisting technicians in focusing their attention on those combinations that are most problematic. In this manner, it will be possible to reduce anomalies in both the design and construction phases, as well as minimise non-quality costs.

4 Conclusions

- It was shown that the installations with the most cases are ‘Ventilation’ (I5=42%) and ‘Heating’ (I4=32%), representing practically 3/4 of the total. As such, efforts to reduce anomalies should be focused in these installations.
- The most frequent pathological origins were ‘Diverse’ (OP4=35%) and ‘Irregularities and deficiencies’ (OP3=34%), and most cases were concentrated in ‘block dwellings’ (V3=58%).
- Lastly, it was shown that the expert technical reports used as a basis for owners to be able to file their complaints were a very helpful procedure to determine the installations in which anomalies occur the most.

Abstract. *The monitoring of reinforced concrete structures allows us to detect the presence of aggressive agents into of the concrete matrix, on site and in a real time. These aggressive agents can produce the unexpected failure of the structures, thus discovering their presence is a fundamental aspect in the preservation of people safety and the durability of the structure. On the other hand, helps to reduce the cost of maintenance and repair operations, due to allow us to identify the problems faster, minimizing the intervention to be done. The present research paper was focused in the hydronium detection; the reduction of this species generates hydrogen, the hydrogen produces the embrittlement and cracking of the steel, which seriously compromises the right behaviour of the structure. The problem of hydrogen appears in industries such as ammonia processing or petrochemistry industries and nuclear power plants. All of them are industries in which a failure seriously compromises the welfare of people and the environment. Therefore, the detection of hydrogen penetration in reinforcement concrete structures in these cases are very interesting. In this study, with the purpose to detect the hydronium or hydrogen in the hardened concrete matrices is proposed the use of voltammetric sensor, which is part of a multisensory system called Electronic-Tongue. This is a preliminary study. The objective of these initial steps was to evaluate the detection capability of the sensor. Currently, have been designing a sequential test in order to evaluate the sensor in different partial hydrogen pressures with the purpose to develop mathematical models to the hydronium or hydrogen detection and quantification in hardened concrete matrix.*

Keywords: *Durability, Monitoring, Sensors, Hydrogen Embrittlement.*

1 Introduction

The detection of hydronium and hydrogen availability variations in the reinforcement concrete structures is interesting due to the presence of H^+/H_2 are involve in reactions that produce the durability loss of the structures.

The reaction and molecular recombination of the hydrogen with metals have a greatly impact on their mechanical properties (C A Zapfpe, Member, Sims, and Aime, 1941; Mansilla, Brandaleze, and Ines, 2018; Schroeder and Müller, 2003). In the case of the steels we can classify the damage produced by the hydrogen in:

- High-temperature Hydrogen Attack (Decarburization), in this process the high-temperature (<200˚C) reaction of absorbed hydrogen with carbides in the steel results in the decarburization forming methane which can not spread due to the size of its molecules producing intergranular fissuring (Ovejero,2009).

doi:10.23967/dbmc.2020.151

- Hydrogen-Induced Cracking (HIC), results from the penetration and molecular recombination of atomic hydrogen produced in the steel surface because of a corrosion process. This reaction generates high pressures which produce cracks or blisters in the steel (Ovejero,2009).
- Hydrogen Embrittlement (HE), produce the decrease of the metal ductility and load bering capability due to the absorption of hydrogen as atomic or molecular form by the metal. The hydrogen difuses to the metal grain boundaries producing pressure on the metal grains, this pressures can reach values that reduce the ductility and strength of the steel (Schroeder and Müller, 2003; Industrial Metallurgists, LLC).

In the case of reinforcement concrete structures these problems can produce the brittle failure of the structure (Ramón Zamora, 2018) which seriously threatens the people safety, also the failure generates high economical costs.

These phenomena affect in structures particularly in those industries that work with environments or substances that contain hydrogen. For instance: nuclear reactors, chemical industry, etc. Also, the hydrogen can be generated in structures where is used without any control of the potential the cathodic protection (impressed current) (Byrne, Norton, and Holmes, 2016; Enos, Williams, Clemeña, and Scully, 1998; Ishii, Seki, Fukute, and Ikawa, 1998).

There are other reactions where H_2/H^+ compromise the reinforcement durability such as the carbonation of the concrete and chlorides attack.

In the carbonation of the concrete the CO_2 penetrates reacting with the hydroxide ions and increasing (H_3O^+) activity. The pH drop of the concrete pore dissolution will produce the rebars passive layer destruction (Lee, Lee, Min, Lim, and Singh, 2018).

On the other hand, when the chlorides arrive to the rebar surface the following reaction take place (Neville, Wharf, Street, and The, 1995):

$$Fe^{2+} + 2Cl^- \rightarrow FeCl_2 \quad (1)$$

$$FeCl_2 + 2H_2O \rightarrow Fe(OH)_2 + 2HCl \quad (2)$$

This reaction produces a significant decrease of pH in the local solution inside the pits, so in this area the presence of H_2/H^+ increase (Andrade, Garcés, and Martínez, 2008).

As is widely known, concrete carbonation and chlorides attack produce the passive layer destruction and the active corrosion of reinforcements starts if thermodynamic conditions are favourable.

Therefore, the increase detection of the H_2/H^+ can help us to avoid the problems related to the absorption of the hydrogen or hydronium in the steel and also to prevent the corrosion of the rebars when the carbonation of the concrete or the chlorides attack is produced.

With the purpose of preventing or controlling these phenomena will be effective use monitoring systems to control the conditions of the rebars embedded in the concrete and also identify the presence of aggressive substance into of the concrete such as H_2/H^+.

In this study is proposed the use of a novelty and promising monitoring system formed by cross-sensitivity voltammetric sensor and named Electronic Tongue (e-Tongue). These systems are widely used in the food industry being very effective (Bataller, 2001; Ramón Zamora, 2018).

In this monitoring system, a potential signal vary over time is applied on the sensors, producing the reduction or oxidation over the sensors surfaces of different electroactive species presents in the electrolyte, being recorded an electrical current response from each sensor. The

reactions that produce these responses depend on the quantity of the electroactive species and the experimental conditions, such as the sensor material and the potential sweeping range. Therefore, depending on the agents of interest (oxygen, water, chlorides, H^+/H_2, etc.) the experimental conditions will be defined. Then, by means of multivariate analysis of the sensors response, can be developed forecasting and quantification mathematical models to modelling the presence of the interest substance in the hardened concrete matrix.

In this study was performed an initial evaluation of the Rh voltammetric sensors capability in order to detect variations in the couple hydronium/hydrogen inside of the hardened concrete.

These sensors form part of the novel multisensory system e-Tongue, which are currently under development. In a previous work was verified the capability of INOX voltammetric sensors to detect oxygen availability variations inside of the hardened concrete matrix (Martínez-Ibernón et al., 2020) which is going to form part of the e-Tongue.

2 Materials and Methods

Concrete sample (10 cm x10 cm x10 cm) of water/cement ratio 0.4 was made, the composition of the concrete is specified in Table 1.

Table 1. Composition of the concrete.

Materials	kg/m^3
Cement I 42.5 R-SR5	490
Water	196
Superplasticizer	3.4
Siliceous sand	1115
Aggregate	601

In the concrete sample was embedded one e-Tongue which is under development (Figure 1). This Electronic Tongue are made by a stainless-steel hollow cylinder filling with epoxi resin where are embedded the voltammetric sensors of the e-Tongue.

The purpose of this study is analysed the response of one of the sensors that forms the e-Tongue, this is the Rh voltammetric sensor, this are made with thread of this metal (1mm of diameter and 2mm of length).

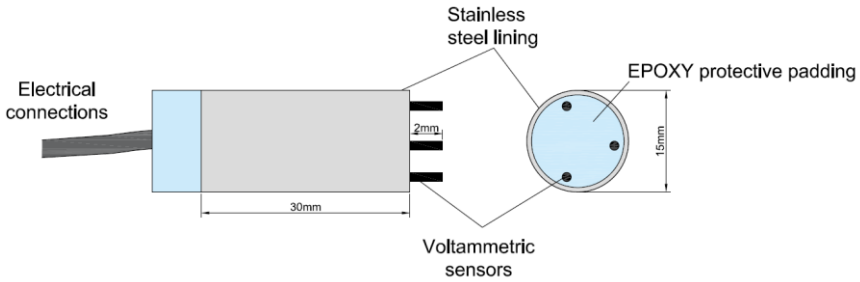

Figure 1. Electronic Tongue.

The samples were studied in two different conditions:

- State 1: Concrete in atmospheric conditions (dry conditions).

- State 2: Concrete saturated with water. In order to ensuring the higher quantity penetration of water inside of the concrete matrix, the samples were inserted in a deposit with an airtight lid. In this deposit was reached the vacuum conditions by means of a pump, these conditions were kept during three hours. Then was let the entrance of water until the samples were totally submerged. After two hours the vacuum was broken and the specimens were kept submerged in water as show the Figure 2.

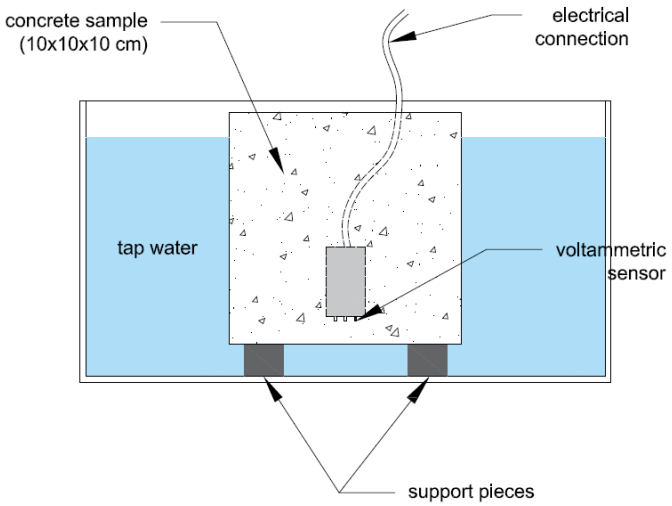

Figure 2. Test set-up, for submerged conditions (state 2).

Two different testing experiences were defined:

- Experience 1: First, the cyclic voltammetry (CV) technique was applied in the Rh sensor with the sample in state 1 (atmosphere conditions), then, the sample was saturated with water (state 2) and the voltammetry test was repeated in this condition. In the cyclic voltammetry test were applied three potential sweep signals with different potential ranges.
- Experience 2: In this experience, was used a high amplitude cathodic potential pulse (-1.6V amplitude signal), during 3 min, to ensure the generation of atomic and molecular hydrogen. The samples in this experience were in water saturated conditions (state 2). The test sequence was: Previously to apply the potential pulse was tested the sample with a CV, in order to define a baseline of the system conditions, then, the hydrogen generation pulse was applied, finally a cyclic voltammetry was applied. The experience was repeated for two different potential sweeps.

The electrochemical techniques were applied with three electrodes and Autolab PGSTAT10 equipment was used. Specifically, these three electrodes were:

- Reference electrode: a saturated calomel electrode (SCE).
- Counter electrode: Stainless steel lining (Figure 1).
- Working electrode: Rh voltammetric sensor.

The experiences defined allowed us to check the presence of peaks related to reactions associated with the hydronium and the hydrogen. It was possible through the comparation of

the results with the voltagrams for alkaline systems showed in the paper Jaksic, Johansen, and Tunold, (1994).

3 Results and Discussion

The Rh voltammetric sensors used in the Electronic Tongue are capable to detect the presence of hydronium and hydrogen in the concrete matrix. As we can see in the Figure 3, the morphology of the electric current density curve, obtained with the embedded sensor in the conditions of the state 2, is similar to the curve obtained in an alkaline system in dissolution (Jaksic, Johansen, and Tunold, 1994), we can identify the same peaks associated with reactions that involve H^+/H_2.

However, when the samples are in non-saturated conditions (state 1), meaning the water availability inside of the hardened concrete is very low, the peaks related to the hydronium and hydrogen do not appear (Figure 4).

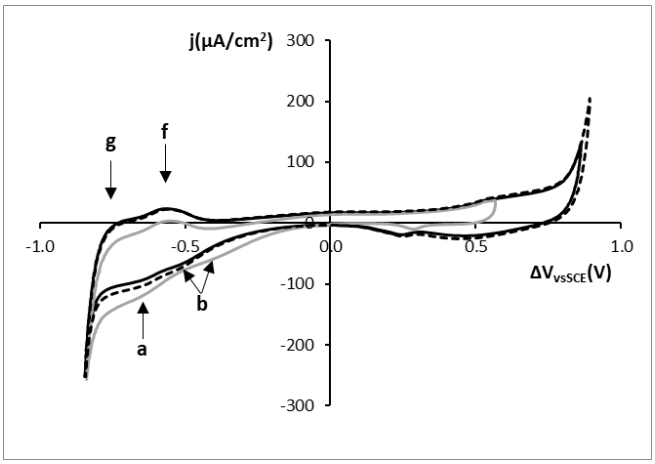

Figure 3. Results Experience 1: Successive cyclic voltagrams on the Rh electrode embedded in sample of w/c=0.4 concrete in saturated state (state 2). The points g, f, a and b are the peaks associated to the proton reactions as defined by Jaksic, Johansen, and Tunold, (1994).

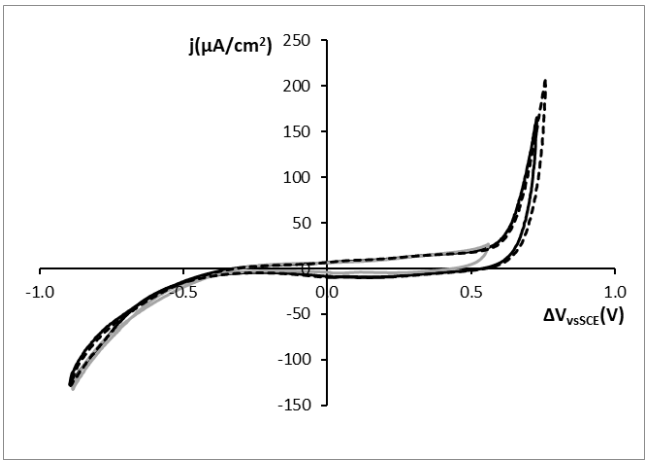

Figure 4. Results of Experience 1: Successive cyclic voltammograms on the Rh electrode embedded in sample of w/c=0.4 concrete in atmospheric state (state 1).

On the other hand, after to apply a high amplitude potential pulse with negative value, the generation of hydrogen was assured. The amplitude of the pulse was -1.6 V, at this potential and for pH similar to the concrete (pH≈12.5), water reduction is already taking place, in this reaction H_2 is generated.

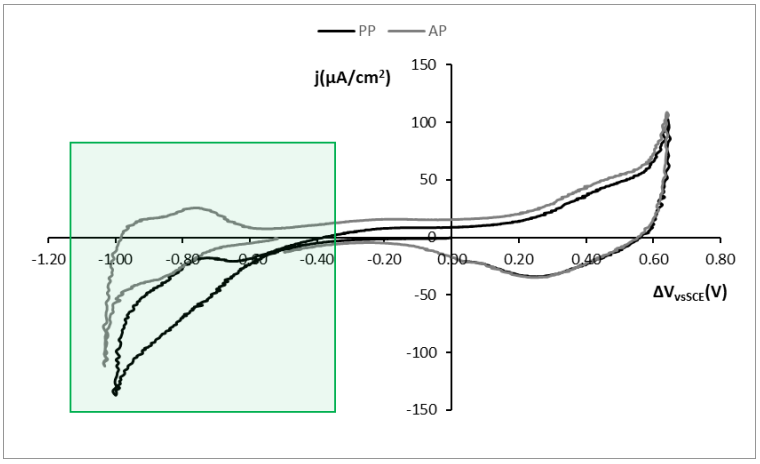

Figure 5. Results of Experience 2: Line black: Voltagram of the system previously cathodic pulse (PP). Line grey: Voltagram of the system after cathodic pulse (AP). Green square: Indicates the zone where the response is associated to reactions where are involved H+/H2.

The Figure 5 shows how after to apply the cathodic pulse (AP), the peaks associated with the desorption and adsorption of the H^+/H_2 risen. The increasement of the desorption peaks causes the upward movement of the curve, due to in this potential range the mainly reaction is with H^+/H_2, whereas previously to the potential pulse application the mainly reaction was the water reduction.

If the test is repeated doing several sweep cycles in each situation (AP and PP), we can see how in the PP situation (previously to the cathodic pulse application) (Figure 6 a) there are a negligible change from initial sweep. However the results obtained when the cathodic potential

pulse is applied (-1.6V) shows the increasement of the total electric density current as cycles are done (Figure 6 b).

This demonstrates that the Rh electrode has a region of potential sensitive to the generation and adsorption/desorption processes of H^+ / H_2. Therefore, this sensor could be used in hardened concrete matrix to detect the species involved in the redox couple.

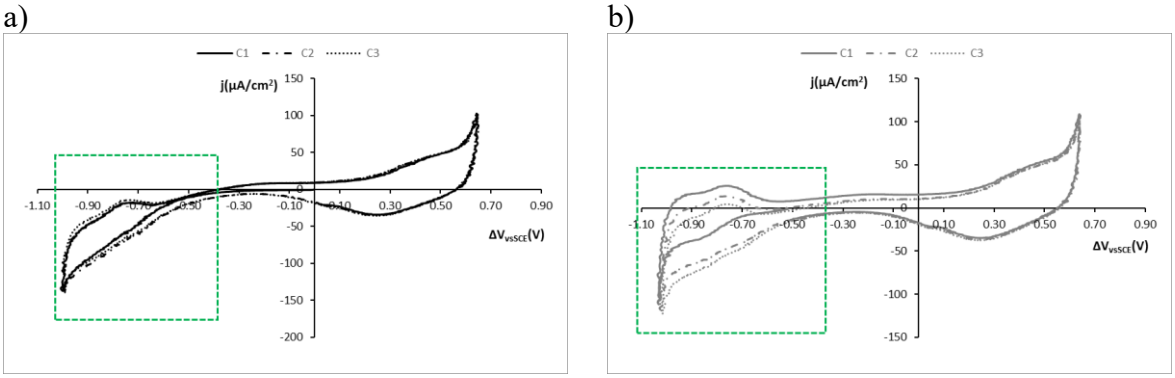

Figure 6. Results of Experience 2: a) Voltagram of the system previously cathodic pulse (PP). b) Voltagram of the system after cathodic pulse (AP). C1, C2 and C3 are successive cycles. The zone under examination are pointed with the green rectangle.

3 Conclusions

According to the results, the developing voltammetric sensors are capable to detect variations in the presence of the system hydronium/hydrogen inside of the hardened concrete matrix, and thus the Rh electrode could be useful to determine the pH or the hydrogen activity inside of the materials.

Abstract. *Electrical resistivity is a parameter sensitive to several properties of concrete, including water content, which is one of the key parameters governing concrete long-term durability. In this paper, the monitoring of the concrete water content profile throughout its entire thickness is discussed using an electrical approach as a measurement method. This is very relevant to applications requiring a centimeter resolution over a large thickness. The aim of this paper is to implement a multi-electrode embedded sensor in a concrete slab to determine the resistivity profile over concrete depth in order to monitor its drying. The sensor, designed as a printed circuit board (PCB), is integrated in two 30 cm thick concrete slabs. Different measurement configurations are presented. Following qualification in laboratory and controlled conditions, the study focuses on characterizing the sensor's response during the drying of the slabs. The results demonstrate the capability of the sensor to monitor concrete drying by measuring the resistivity profiles with a spatial centimetric resolution.*

Keywords: *Electrical Resistivity, Embedded Sensor, Monitoring, Thick Concrete Structures, Drying Process.*

1 Introduction

The durability of a concrete structure is characterized by its ability to keep the use functions for which it was designed. The main degradations of reinforced concrete structures are due to reinforcement corrosion, for which the parameter responsible for its development is the concrete water content.

The determination of the concrete water content using non-destructive testing (NDT) methods has been the subject of many studies (*e.g.* Balayssac and Garnier, 2017; Kaplanvural *et al*., 2018). Among these NDT methods, DC-electrical methods, which provide access to the electrical resistivity of the material, are particularly sensitive to the concrete water content (Millard, 1991; Andrade *et al*., 2007; Du Plooy *et al*., 2013; Fares *et al*., 2015). However, the electrical methods that are implemented on the surface have reduced resolutions with respect to the thickness of the concrete structures and the investigated depth does not generally exceed a few centimeters in the concrete cover. In addition, it is necessary to wet the surfaces of the electrodes to avoid high resistance contact. Hence, Badr *et al*. (2019) developed an embedded sensor based on a printed circuit board (PCB), which presents various advantages such as:

measuring profiles with a centimeter resolution through the whole thickness of a reinforced concrete structure, ensuring good and lasting electrical contact between the concrete and the electrodes, reducing invasiveness, allowing a high geometric accuracy together with a low fabrication cost and mitigating wiring problems. This new resistivity embedded sensor and the measurement chain were validated in various solutions and in small concrete specimens (Ø11x22 cm) but not in full scale concrete structures (Badr *et al*., 2019).

The main aim of this study is thus to characterize the PCB sensor in more realistic operational conditions, namely two 30 cm thick reinforced concrete slabs, one reinforced with carbon steel bars (HA), and the other one with fiberglass rebars (an electrically insulating material) (FV). The variability of the measurements and the impact of the reinforcements are evaluated in order to test the sensitivity of the sensors by determining the electrical resistivity profiles as a function of the depth. The evaluation of the water content profile requires a material-dependent calibration procedure which is not presented in this article.

The paper starts with a description of the experimental program carried out on the slabs HA and FV each instrumented with two embedded PCB sensors. Then the characterization of the embedded sensors is presented regarding the repeatability, reproducibility and influence of the reinforcement. Finally, we discuss the monitoring of the resistivity profiles during 372 days of drying at 45 °C and we conclude.

2 Experimental Program

The PCB sensors are embedded in the slabs HA and FV. The descriptions of the experimental program regarding the geometry and measurement configurations of the PCB sensors as well as the instrumentation of the slabs, are detailed in the following section.

2.1 Geometry of the PCB Embedded Sensor and Measurement Configurations

The PCB sensor has a ladder shape in order to improve the anchoring of the electrodes in the concrete. The number of electrodes in the PCB sensor used in this study was increased from 19 (Badr *et al*., 2019) to 28 electrodes, each having dimensions of 5x1.5 mm^2 staggered on either side of the circuit, to investigate the entire 30 cm thickness (Figure 1). The spacing between the electrodes is 2 cm on each side, hence 1 cm taking into account both sides.

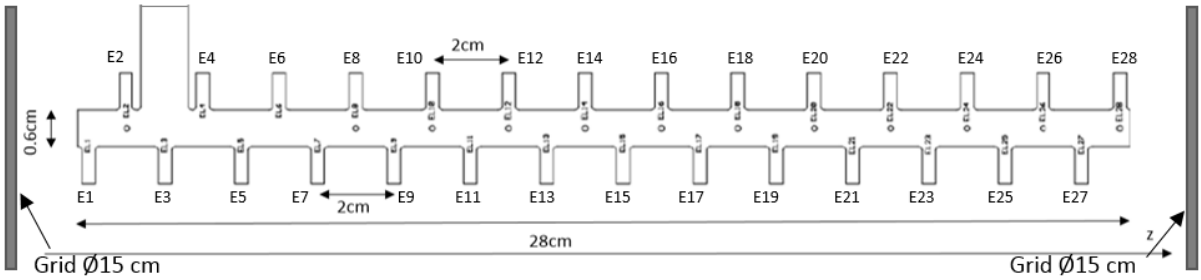

Figure 1. Schematic diagram of the PCB sensor with 28 electrodes.

The PCB sensor presents two measurement configuration modes: the Transmission configuration and the Wenner configuration. In the Transmission configuration mode, an electrical current of intensity *I* is transmitted through the two stainless steel grids (Ø = 15 cm)

placed on both sides of the PCB sensor and a potential drop (ΔV) is measured between all pairs of consecutive electrodes located on the same side of the PCB sensor (E1E3, E2E4, E3E5, …, E26E28) (Figure 1). In Wenner configuration mode, the quadrupole measurements C1C2P1P2 (where electrodes C1 and C2 are used for current injection and electrodes P1 and P2 are used for potential drop measurements) are successively E1E7E3E5, E2E8E4E6, E3E9E5E7, ..., E22E28E24E26 (Figure 1).

The apparent resistivity ρ_a is obtained for each configuration, using equation (1):

$$\rho_a = G\frac{\Delta V}{I} \tag{1}$$

where G (in meters) is a geometric factor which depends on the geometry of the structure and on the shape and positions of the electrodes. G is numerically determined in a homogeneous medium by a finite element calculation using COMSOL Multiphysics®.

2.2 Slabs Instrumentation

The concrete used in this study was based on cement type 1 (CEM I) with a water-cement ratio of 0.59 and a porosity of 15.0% ± 0.9%. Two concrete slabs measuring 75x75x30 cm^3, equipped with 12 mm diameter reinforcement, spaced 20 cm apart, were cast. The cover concrete thickness is equal to about 5 cm so the distance between the two rebar beds is about 20 cm. In one of the slabs the reinforcements are made of fiberglass (FV), and in the other the reinforcements are made of high-adhesion steel (HA), in order to check the possible influence of the reinforcement on the measurements with the embedded sensors.

Two PCB sensors of 28 electrodes are embedded in each slab, between two stainless steel grids of diameter 15 cm, and spaced by 29 cm. They are placed on the right (Ed) and on the left (Eg) hand side relative to the surface of the slab exposed to drying (Figure 2).

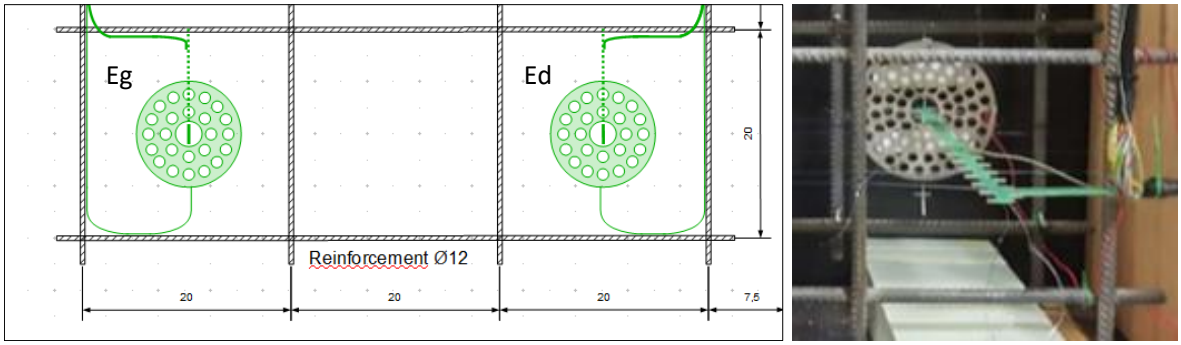

Figure 2. Instrumentation of the HA slab: (a) schematic diagram of the lower part of the slab where the PCB sensors Ed and Eg are placed (dimensions in cm), (b) close-up photo on the PCB sensor Ed in the mesh reinforcement (with only one of the grids).

The slabs were conditioned during 41 days in wet cure in a room at a temperature T = 20 ± 2 °C, and at a relative humidity HR = 95 ± 5%. The method of generating the water content profile consists in inducing a unidirectional drying by exposing a single face to drying and waterproofing the other five faces by coating them with aluminum foil. The FV slab was exposed to 5 months of drying at 20 °C and 1 year of drying at 45 °C in order to accelerate the

establishment of the resistivity profile. The HA slab was exposed to 13 months of drying at 20 °C and 3 months of drying at 45 °C.

3 Characterization of the PCB Sensors

This part of our work examines the characterization of the PCB sensors embedded in the two reinforced concrete slabs HA and FV. First, we check the repeatability and reproducibility of the measurements made with each sensor, then we show the influence of reinforcement (HA and FV) by comparing the response of the sensors in the two slabs.

3.1 Repeatability

The evaluation of the repeatability of the apparent resistivity measurement is obtained by performing three measurements, repeated with few minutes interval. These measurements are acquired, under both saturated conditions (Table 1) and unsaturated conditions (Table 2), for a chosen electrode configuration, in the middle of the slab ($z = 15 \pm 0.5$ cm), depending on the orientation of the sensor and the position associated with each configuration.

Table 1. Coefficient of variation (CV) of apparent resistivity measurements at the initial saturated state t0 with the PCB sensors in the slabs HA and FV for both Transmission and Wenner configurations.

ρ_a [Ω.m]	FV_Ed	FV_Eg	HA_Ed	HA_Eg
Transmission CV %	15.5 ± 1.5 9.6 %	9.5 ± 0.9 9.4 %	9.1 ± 0.3 3.3 %	17.7 ± 0.9 5.1 %
Wenner CV %	13.5 ± 0.1 0.7 %	13.8 ± 0.1 0.7 %	16.3 ± 0.1 0.6 %	16.1 ± 0.2 1.2 %

Table 2. Coefficient of variation (CV) of apparent resistivity measurements at an unsaturated state with the PCB sensors in the slabs HA and FV for both Transmission and Wenner configurations, where t'0 marks the beginning of concrete drying at 45 °C.

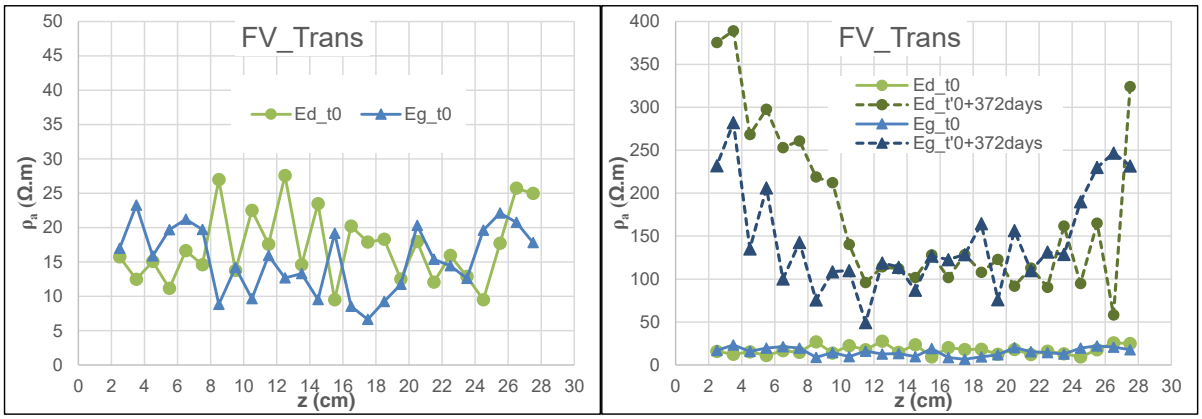
	t'0+268 days		t'0+62 days	
ρ_a [Ω.m]	FV_Ed	FV_Eg	HA_Ed	HA_Eg
Transmission CV %	71.9 ± 3.2 4.5 %	69.9 ± 4.1 5.9 %	24.1 ± 1.1 4.6 %	8.7 ± 0.8 9.2 %
Wenner CV. %	103.5 ± 0.6 0.6 %	82.7 ± 0.8 1.0 %	12.6 ± 0.2 1.6 %	19.9 ± 0.2 1.0 %

At the saturated state, the coefficient of variation CV for the repeatability ranged between 3.3% and 9.6% for the Transmission configuration and between 0.3% and 2.1% for the other configurations. At the unsaturated state, the CV varies between 4.5% and 9.2% for the Transmission configuration and between 0.5% and 2.1% for the other configurations. We note that the CV for the repeatability is consistently larger in the Transmission configuration. We recall that with this configuration, the current is injected through the metallic grids and the potential drop is measured between two consecutive electrodes of the PCB sensor. Therefore, a difference exists between the injection electrodes and the potential measurement electrodes concerning their size and the nature of the material that constitutes them. This may explain poorer repeatability compared to other configurations for which injection and potential

measurement electrodes are identical. We have also verified that these CVs do not increase with the drying of the concrete which is promising for our application.

3.2 Reproducibility Between PCB Sensors in the Right and Left Sides of Each Slab

In this section, our goal is to evaluate the difference in response between the PCB sensors located on the right and left side of each slab (respectively denoted Ed and Eg). The reproducibility between the sensors is associated here with both the sensor change and the variability of the concrete material. We present the results obtained in the FV slab where the drying is more advanced to show the extreme states (saturated and unsaturated), knowing that similar behaviors are observed in the HA slab. Figure 3 shows the apparent resistivity profiles measured with both PCB sensors, Ed and Eg, using the Transmission configuration.



(a) (b)

Figure 3. Comparison of the apparent resistivity profiles measured with the PCB sensors on the right and left sides of the FV slab using the Transmission configuration: (a) at the saturated state, (b) at the saturated and unsaturated states (where t'0 marks the beginning of concrete drying at 45 °C).

The differences observed in Figure 3 can be related to the variability of the concrete. Indeed, a measurement is essentially sensitive to a restricted volume of material between (and around) the two electrodes where the potential is measured (Badr *et al*., 2019). This volume is less than the representative elementary volume (REV) of an electrical measurement in concrete, the dimensions of the REV having to be at least three times the maximum size of aggregates (Du Plooy *et al*., 2013), in this case 3Dmax = 36 mm. At the scale of these very local measurements, the material cannot be considered homogeneous. Measurements are therefore expected to be sensitive to the natural variability of the material, and, in particular, to the distribution of aggregates in the immediate vicinity of the electrodes.

On the other hand, from the point of view of the global trends, the measurements exhibit the same evolution of the concrete water content between t0 and t'0 + 372 days (Figure 3 (b)) on the left and right sides of the slab, which is also promising for our application. The reproducibility between both PCB sensors is therefore verified.

In the following, we only detail the results of the Ed sensors to simplify the presentation and interpretation. The measurements obtained from the Eg sensors are similar.

3.3 Influence of the Reinforcement

The presence of steel reinforcement can disturb the electrical resistivity measurements, due to the fact that steel is a much better electrical conductor than the liquid phase in concrete. Various authors have cited the importance of steel's influence on the electrical resistivity measurement in a reinforced concrete structure (Millard, 1991; Polder *et al*., 2000; Bungey *et al*. 2006, Reichling *et al*., 2015; Alhajj *et al.,* 2019; Villain *et al.,* 2020).

In this section, we compare the response of the PCB sensors between the HA and FV slabs to evaluate the influence of the reinforcement. At the saturated state, the slabs HA and FV are similar in all aspects except that of the reinforcement nature, it is therefore relevant to make this comparison at this state. Figure 4 shows a comparison of the measurements obtained with the PCB sensors in the slabs HA and FV using the Transmission configuration.

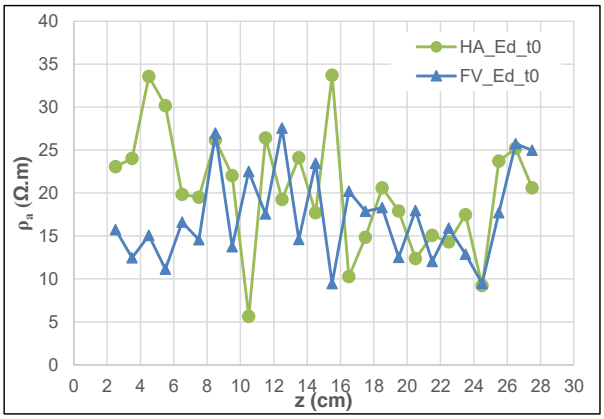


Figure 4. Comparison of apparent resistivity profiles measured with the PCB sensors in the saturated slabs HA and FV using the Transmission configuration.

Differences between the sensors' responses in the two slabs are observed in Figure 4. At the saturated state, a normalized mean root squared error (NRMSE) of 9.1% is obtained in Transmission configuration between HA and FV, comparable to 8.4% obtained, for the same configuration, between the PCB sensors on the right and on the left sides of the FV slab (section 3.2). Therefore, the difference in nature of the reinforcements (HA steel or FV fiberglass) has a small influence on the apparent resistivity measurements obtained by the PCB sensor placed in the center of the reinforcement mesh. Differences between the sensors' responses can be attributed to variations between the investigated materials in the two slabs.

Thus, in this study, the presence of steel reinforcements does not significantly affect the response of the PCB sensors.

4 Monitoring of the Resistivity Profiles

The purpose of this section is to study the apparent resistivity profiles of the PCB sensors during the drying of FV slab.

Due to the low resistivity gradient observed under drying at 20 °C, and in order to test the sensitivity of the sensors to a higher gradient with depth, we accelerated the drying of the slabs by exposing them to an increased temperature of 45 °C. The variation of the apparent resistivity profile with time for the FV slab, using Transmission and Wenner configurations, is illustrated

in Figure 5.

The monitoring carried out during the drying of the FV slab at 45 °C indicates a resistivity gradient between the surface exposed to drying (z = 0 cm) and the protected surface (z = 30 cm) revealing a lower saturation level at the surface, as we can observe in Figure 5. Near surface resistivity values (z = 3 ± 1 cm) increase gradually during the 372 days of drying.

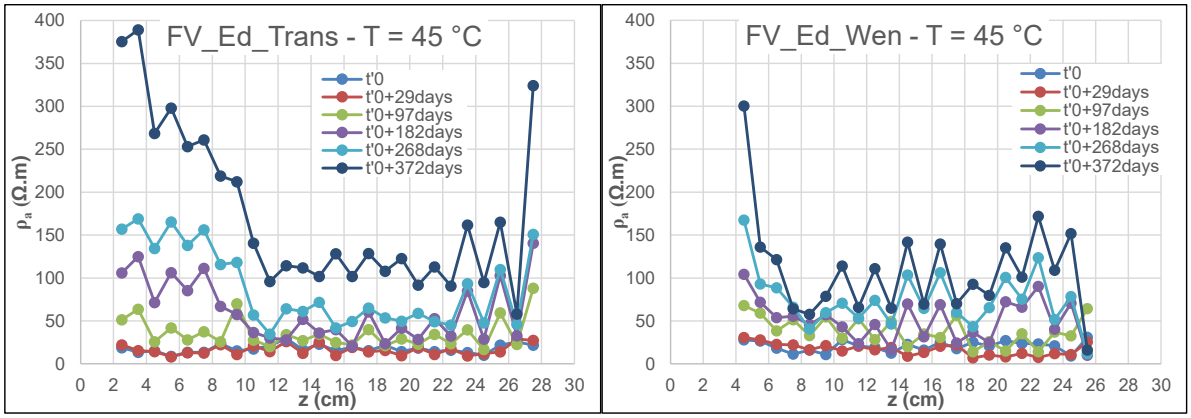

Figure 5. Monitoring of the apparent resistivity profiles measured with the PCB sensors during drying of the FV slab: (a) using the Transmission configuration, (b) using the Wenner configuration.

5 Conclusion

In this paper, a PCB sensor based on an electrical resistivity technique is used to evaluate the resistivity profile of two 30 cm thick reinforced concrete slabs, one reinforced with carbon steel bars (HA) and the other with fiberglass bars (FV). The repeatability and reproducibility of the measurements are checked in saturated and unsaturated conditions, confirming that the results measured with the PCB sensors are within an acceptable range of variability. A monitoring of the electrical resistivity profiles as a function of depth is carried out on the slabs at different times of drying. Resistivity measurements increase over time, showing the sensitivity of the sensors to the evolution of concrete during drying. Thus, this new embedded sensor is validated in a real size reinforced concrete structure and we showed that it reaches its monitoring requirement with a centimetric resolution. In perspective, it is expected that the developed PCB sensor will be used in concrete structures to monitor water content profiles by means of a specific calibration.

Macrocell Processes in Reinforced Concrete Structures

Josep R. Lliso-Ferrando, José E. Ramón Zamora, Román Bataller and Juan Soto

Instituto Interuniversitario de Investigación de Reconocimiento Molecular y Desarrollo Tecnológico (IDM), Universitat Politècnica de València, Camino de Vera, s/n 46022 Valencia, Spain. E-mail: jollife2@arq.upv.es

Abstract. *Corrosion of steel embedded in reinforced concrete is the phenomena that most affects the durability of this type of structures. The control and analysis of the rebars can help detect this problem beforehand, contributing to prevent costly repairs made when the damage is quite advanced. Currently, there are several techniques for measuring the corrosion rate of steel, but they have the disadvantage of being slow or requiring specialized tools. In addition, these techniques need direct connection to the rebars, so removing the concrete cover layer is necessary. This destructive technique is sometimes impossible to do because there are analysis zones which are inaccessible due to they are buried or submerged. Recently, using sensors embedded previously casting and external electrical connections let analyse the corrosion without using invasive techniques. This study presents the complementary technique of analysing macrocell currents in order to know the origin and direction of current in reinforcements. This technique requires less time and non-advanced material, only an ammeter and electrical connection to the rebars, executed before casting. In addition, this parameter provides information about the real corrosion of the different parts of the structure. In this study it is performed the laboratory analysis of this technique by the use of specimens containing one anode and one cathode inside them creating a macrocell. The influence of different environments on macrocell current intensities shall be studied and compared with other studied parameters as corrosion density.*

Keywords: *Macrocell Currents, Reinforced Concrete Durability, Corrosion Potential, Corrosion Density, Concrete Resistivity.*

1 Introduction

Reinforced concrete is the most used construction material worldwide due to its characteristics, mechanical properties, low-cost and durability. The durability concept is defined as the ability to withstand the mechanical actions, environmental conditions, chemical attack or any other kind of damage that affects the initial state and reduces the lifespan. Durability parameter became a key aspect during design process since nineties. (Tang *et al.,* 2015; Garcés *et al.,* 2008).

One of the most frequent problems that affects the durability of reinforced concrete structures is the corrosion of the rebars. High alkalinity generated by cement matrix (pH usually higher than 12.5) generates a passive layer on the reinforcements, which is transparent, continuous, compact and protects the rebars. In addition, the cement matrix entails a dense barrier between the rebars and the atmosphere where pieces are located. Nevertheless, the cover layer is porous and presents a certain permeability to gas and water, becoming an access path for aggressive agents. The aggressive agents, as chlorides or CO_2 are able to destroy the passive layer and trigger active corrosion, which is the main cause of reinforced concrete structures failure (Bertolini *et al.*, 2013; Garcés *et al*.,2008).

One of the greatest problems of steel corrosion in reinforced concrete is its difficult

detection. Corrosion phenomena develops itself internally and it is visible externally once the damage is quite advanced, through rust stains or cover layer cracks. As a result, corrosion generates expensive repairs due to the belated detection and the necessity of periodic reviews because it is not possible to eradicate the problem completely. Last reports and statistics show the great amount governments invest for repair of reinforced concrete structure (François *et al.*, 2018).

During the last twenty years, a lot of corrosion measurement techniques have emerged in order to help detecting corrosion beforehand. The main disadvantage of these techniques is the rebar connection necessity, so removing the concrete cover layer is required. Sometimes, this fact is impossible when the structural elements are submerged or buried. (Andrade *et al.,* 2001; Bertolini *et al*., 2013; Ramon Zamora, 2018; Ramón Zamora *et al*. 2016).

Using sensors embedded before casting has become an alternative during last years. Electrical connections executed previously casting let analyse the local corrosion without using invasive techniques. However, most of data collection require a lot of time or specific tools, which are really expensive (Ramón Zamora *et al*., 2016; Ramon Zamora, 2018).

The main inconvenient of using isolated sensors for corrosion monitoring is that it can be only measured the local corrosion. However, in structures, real corrosion is completely different to the local corrosion due to macrocell currents. Different parts of the reinforcements are electrically connected and macrocell currents generate currents becoming areas in anodes and cathodes.

This study shows the effectiveness of using macrocell current analysis as an important complementary measurement to the corrosion analysis. Macrocell analysis allows to observe the currents direction and to detect the zones shedding electrons (anodes) and demanding them (cathodes). In addition, using macrocell analysis, it is possible to know the general behaviour of the reinforcements and not just the local corrosion parameters.

2 Macrocell Currents Analysis

Galvanic macrocell is the most important electronic transference process in corrosion (Andrade *et al*., 1992). The macrocell is generated by the presence of great passive areas connected electrically to active areas, where corrosion phenomenon occurs. In this situation, active zones are the anodes (electrons source), while the rest of the passive rebars are the cathode, and the porous dissolution of the cement matrix serves as the electrolyte (Andrade *et al*., 2008; Bertolini *et al*., 2013).

Some authors highlight macrocell corrosion is produced together with microcell corrosion (Andrade *et al*., 1992; Ji *et al.,* 2013). The last one is due to heterogeneity of the material, creating small microcells between the different phases of the microstructure. In Figure 1, it is possible to see the difference between microcells and macrocells.

The macrocell current is measured with a Zero Resistance Ammeter (ZRA) (Andrade *et al*., 2008). Using ZRA in laboratory is possible due to specimens where anode and cathode have not electrical contact can be manufactured. However, measurements in real structures are impossible due to there are electrical contacts between rebars. In this case, it should be necessary to isolate one part of the reinforcements, becoming this measurement an invasive technique. Including isolated sensors and using electrical connections executed before casting would avoid destructive techniques and would facilitate the measurements.

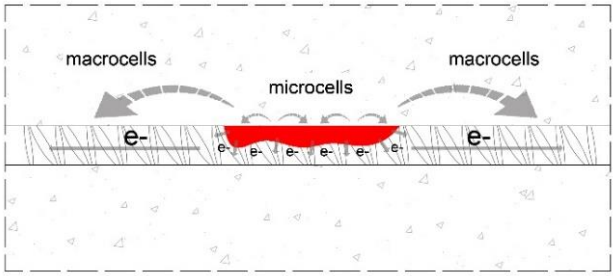

Figure 1. Macrocells and microcells.

2.1 Previous Work

Previously to this study, a macrocell analysis was performed using small specimens and different dosages (Lliso-Ferrando *et al*., 2019). During the first phase of this analysis, cylindrical test specimens where measured as it is shown in Figure 2. The corrosion process is slower than using impressed current, but it allows to observe the corrosion phenomena in a more natural way. The rebar works as anode and the stainless steel plates are the cathodes, which demand electrons to the carbon steel due to the oxygen availability in water.

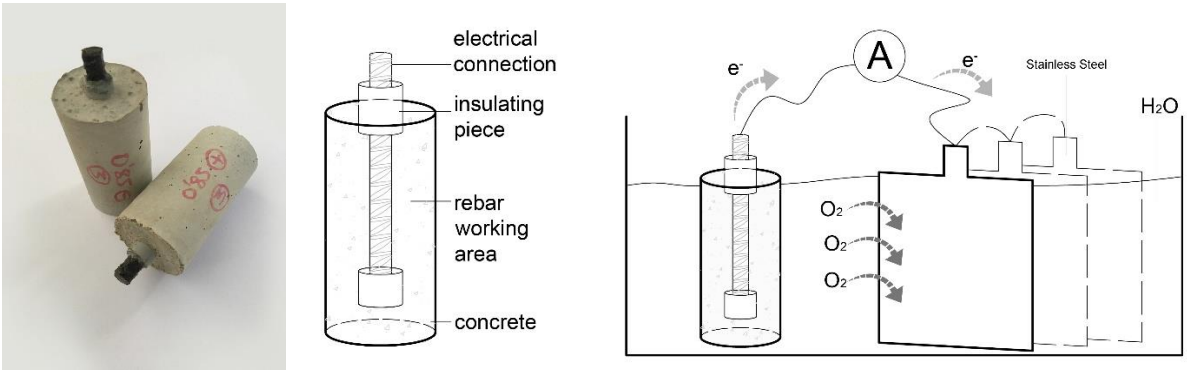

Figure 2. Test specimen and testing procedure.

The study allowed to analyse the influence between cathode-anode surface ratio in the corrosion intensities, as it is possible to see in Figure 3. Several specimens with different mixes were studied. The anode surface is always the same (specimen), and the cathode surface increase gradually (stainless steel plates). As shown in Figure 3, once the ratio between anode and cathode surface exceed 1/350, the macrocell intensity stabilizes because the anode is not able to provide more electrons. As it is possible to appreciate, depending on the concrete characteristics, the ratio can be lower if the concrete quality is better (lower water/cement ratio).

During the second phase of this study, the specimens were exposed in 24 hours' periods to different environments (Laboratory conditions (65% R.H. and 20ºC), Saturated, 100% R.H., dry (40ºC and 23% R.H.)). In every atmosphere, macrocell intensities were measured. It was found the cyclic tendency of this parameter. However, the cathode (stainless steel mesh) was joined to the specimen using a wet cloth. This situation simulated a hypothetic case.

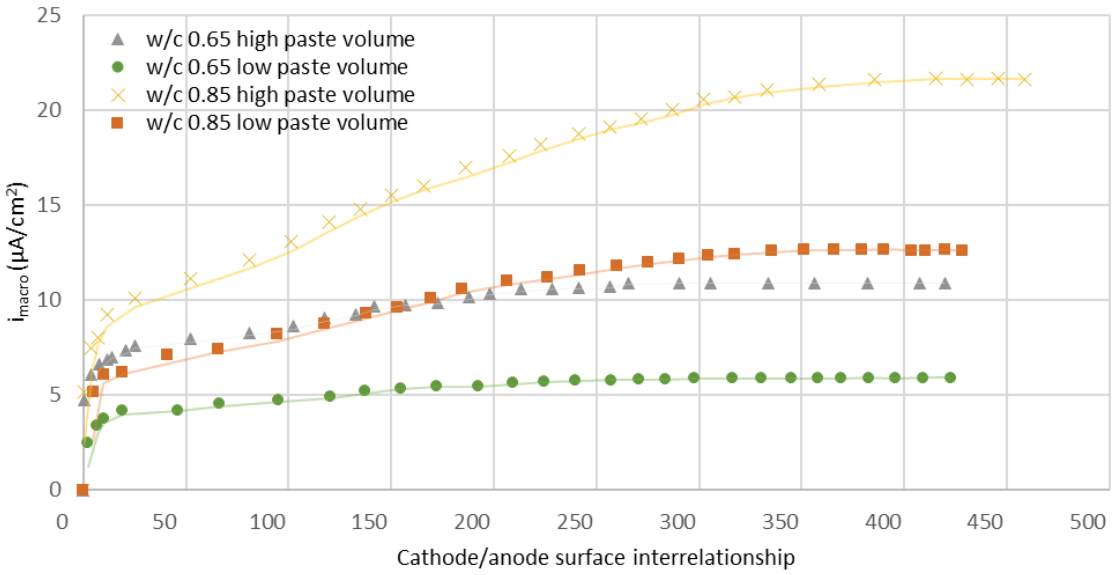

Figure 3. Cathode/anode surface ratio for several specimens with different W/C ratio.

In the present case study, the analysis is carried out on specimens where anode and cathode are embedded in concrete to simulate a real situation.

3 Experimental

3.1 Materials

Several concrete specimens were manufactured, using cement CEM I, and a water/cement ratio of 0.5. The table 1 shows the dosage and the compressive strength.

Table 1. Dosage of concrete per weight.

f_c	w/c	Cement*	Water	Superplasticizer	Sand
47.3 Mpa	0.5	360	180	1.1	1872

*CEM I 42.5.

3.2 Test Specimens

In Figure 4, test specimens' schemes and pictures are shown. The measurements were carried out on cylindrical specimens with a diameter of 100mm and a height of 200mm. Inside the specimen, a rebar was embedded (Ø1.2x16 cm) having electrical connection. A stainless steel mesh was embedded having a cable for electrical connection too. Using different steels, noblest metal is the cathode (stainless steel), while rebar is the anode (carbon steel), it is possible to create a macrocell when they are connected.

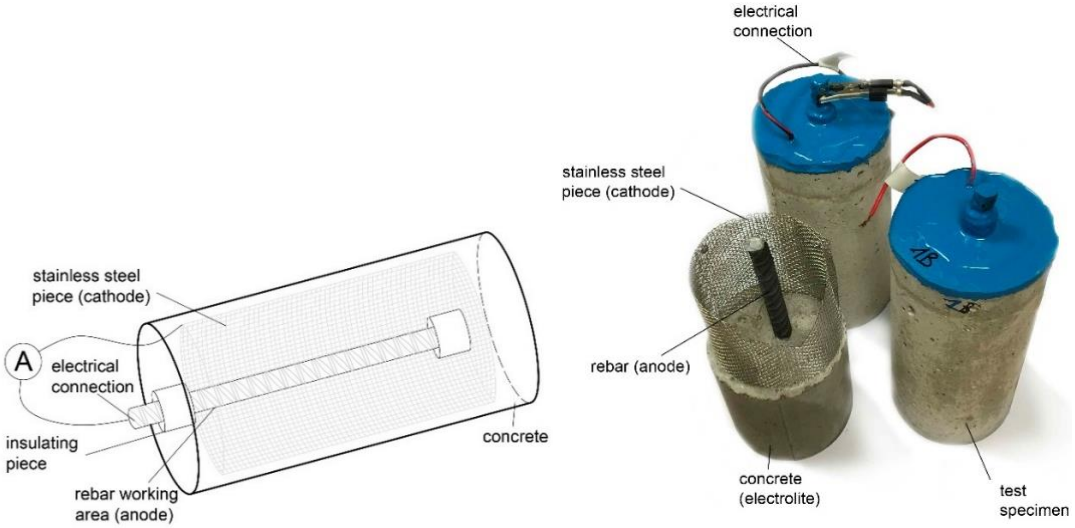

Figure 4. Test specimens.

3.3 Measurements

After 28 days of casting and curing, specimens were exposed to accelerated carbonation process. The chamber conditions were 20ºC, 65% R.H. and 30% CO_2. The specimens were located in the chamber until they were completely carbonated. This period lasted two months. This process allowed to work having higher macrocell and corrosion currents.

Once rebars were depassivated, the specimens were exposed to different atmospheres during 24 hours' periods. At the end of each cycle, resistivity, corrosion potential and macrocell and corrosion currents were measured. During all the process, anode and cathode were electrically connected and just for measuring they were disconnected.

The specimens were exposed to four different atmospheres: dry atmosphere (40ºC and 23% R.H.); saturated (3 hours in vacuum and 21 hours submerged); 100% Relative Humidity; and laboratory environment (approx. 65% R.H.).

Macrocell measurements were carried out with a ZRA.

4 Results

Figure 5 shows the macrocell and local corrosion currents evolution during the different cycles when concrete samples were exposed to different environments after carbonation process. As shown in Figure 5, macrocell currents have a cyclic tendency related to the changes in the environment where test specimens are located.

In addition, it is possible to appreciate how local corrosion intensity values also change depending on the atmosphere where specimens are located. This is due to the fact there are different humidity levels in each environment. On the one hand, when specimens are in a 40ºC and 23% R.H. atmospheres, there is barely enough humidity for let ionic transfer between anode and cathode, and intensities show lower values. Otherwise, when specimens are located in humid environments, presence of water allows the ionic transfer and intensity values doubled their previous ones.

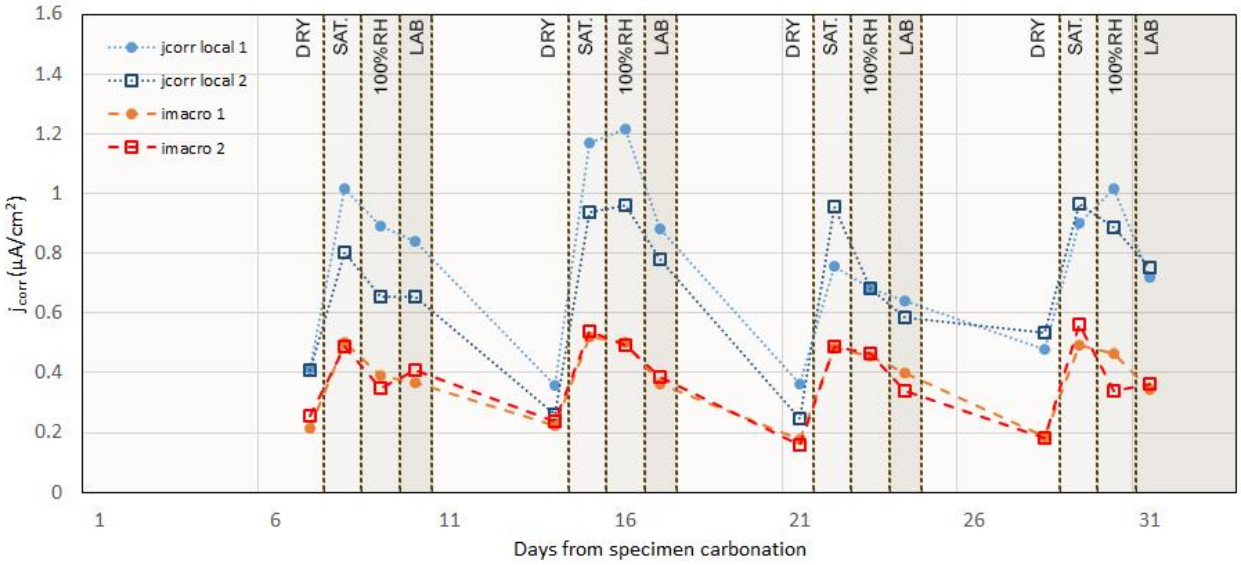

Figure 5. Macrocell current and local corrosion current cyclic variations.

Furthermore, we can appreciate there are not variations between macrocell intensities in specimens 1 and 2, despite having different cathode surfaces. As it was commented on Figure 3, depending on the concrete quality, the stabilization between cathode/anode surfaces can generate no differences between these currents. In this case, the ratio anode/cathode in specimen 1 was 1/10 and in specimen 2 was 1/20. However, as highlighted in Table 1, the concrete has a good quality (lower water/cement ratio) and these ratios are in the stabilized part.

Figure 6 shows the average values of macrocell and local corrosion intensities values. Also it is possible to appreciate the total corrosion intensity values.

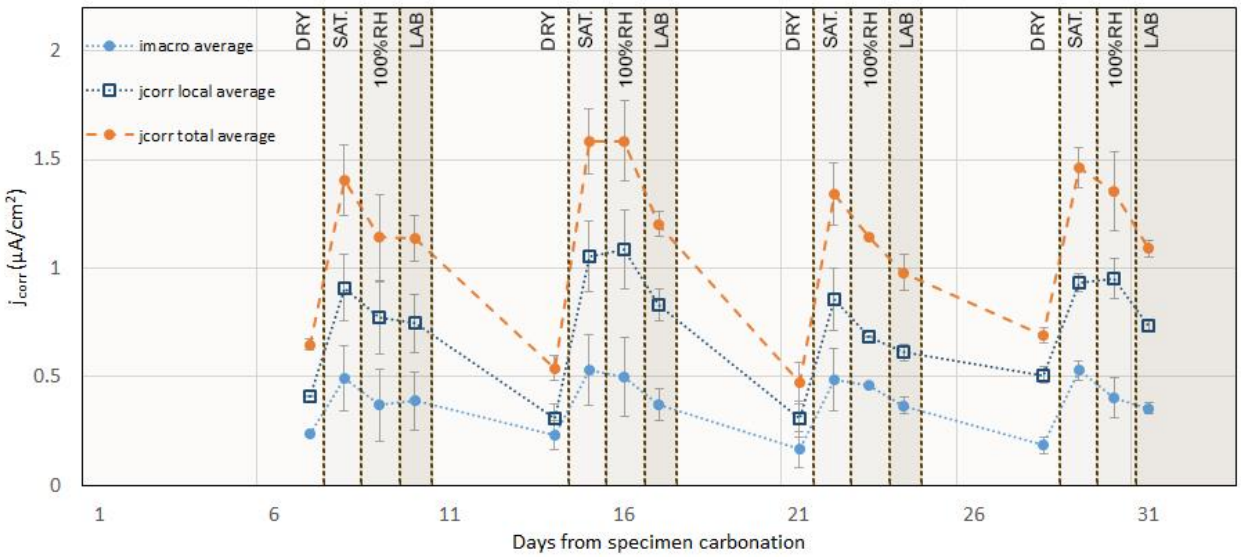

Figure 6. Macrocell and local corrosion intensities and the total corrosion intensity.

Total corrosion intensity has been obtained from the sum of macrocell intensity and local corrosion intensity. As shown in Figure 6, macrocell intensities ranged between 30%-40% from the total corrosion intensities. This fact highlights we mustn't underestimate the macrocell created in the reinforcements.

5 Conclusions

In this study, it has been shown the importance of analysing the macrocell currents in order to understand and know the real corrosion currents in rebars embedded in reinforced concrete structures. The experimental analysis has let to check the behaviour of macrocell and local corrosion intensities in different atmospheres. It has been possible to appreciate the relation of these parameters and the humidity/water presence in the cement matrix.

This study shows using sensors for analysing the local corrosion can lead to wrong results. Overlooking the macrocell currents it is possible to obtain corrosion values 30%-40% lower than the real corrosion intensities.

The main purpose of this study was understanding the macrocell currents in order to become possible the macrocell currents real-time monitoring in reinforced concrete structures. This fact can become an important tool in order to complement the corrosion analysis of the steel embedded in reinforced concrete structures.

6 Future Analysis

The next step for understanding better the macrocell current is the analysis using samples where rebars are not carbonated. This study was carried out using carbonated concrete specimens in order to get high corrosion and macrocell currents values. A variant of this study can be the analysis of corrosion and macrocell currents before the rebars depassivation and afterwards.
In addition, the analysis of macrocell currents in a real structure is an essential tool in order to understand the electrochemical processes and how they develop themselves in real cases. In the electrochemical laboratory of ETSIE, in UPV, a 20 meters long beam was manufactured two years ago. The beam is located in the campus gardens and it was exposed to the weather conditions. The piece includes several reinforcements embedded in order to observe the macrocell currents. The rebars are still passive and in a short-them period, the macrocell and corrosion intensities will be monitored and analysed in passive state and once they are depassivated.

Abstract. *Climate change and the request for better assets' energy performances are forcing the construction sector towards passive or even active buildings: assets with a positive balance between energy production and consumption. Building insulations play a crucial role in reducing energy demand. One of the most used technology to insulate new and refurbished buildings are the External Thermal Insulation Composite Systems (ETICS). Despite their thermal advantages, low cost, and ease of application, these systems may have serious problems if not well designed. Cracks on the coating layer are among the most common pathologies during ETICS service life. They have been studied using a Finite Element Method (FEM) analysis on two different types of ETICS in order to understand how cracks and the mechanical characteristics of materials used in the ETICS are related. The results show that errors during ETICS installation impacts on cracks occurrence as much as the mechanical performances of some layers. The FEM analysis have been complemented by the experimental study of the mechanical behavior of the coating layer under the effect of rainwater, in order to better understand ETICS behavior over their service life.*

Keywords: *External Thermal Insulation Composite Systems (ETCS), Finite Element Methods (FEM), Mechanical behavior, Durability.*

1 Introduction

Climate change and the request for better assets' energy performances given by the European Union (Directive EU 2018/844) are forcing the construction sector towards passive or even active buildings, *i.e.* assets with a positive balance between energy production and consumption. According to the (European Construction Sector Observatory, 2019) of the residential building stock in the EU Member States, on average 45.4% of the buildings were built before 1969 and 75.4% before 1990. This means that, not only designing and constructing energy efficient buildings should be targeted, but also retrofitting the building with energy efficient strategies to improve buildings performance through its lifespan should be considered (Sözer, 2019).

Building insulations play a crucial role in reducing energy demand. One of the most used technology to insulate new and refurbished buildings are the External Thermal Insulation Composite Systems (ETICS). According to (ETAG 004) an ETICS is "a system that comprises

a prefabricated insulation product bonded onto the wall, or mechanically fixed using anchors, profiles, special pieces, etc..., or a combination of adhesive and mechanical fixings. The insulation product is faced with a rendering consisting of one or more layers (site applied), one of which contains a reinforcement. The rendering is applied directly to the insulating panels, without any air gap or disconnecting layer".

ETICS, have often been used in Europe since the 1970s, both in new buildings and in retrofitting. The popularity of this technology grew due to its advantages regarding other techniques of insulation. ETICS guarantees the reduction of the thermal bridges and greater thermal comfort due to the preservation of interior thermal inertia, providing a finished appearance similar to the traditional rendering (Tavares, 2020).

The increasing and progressive use of ETICS has also resulted in a significant number of failure cases. Among these, the main defects found in literature can be classified into four main types (Tavares, 2020):

- staining/color or texture changes;
- joint defects;
- loss of continuity/integrity defects;
- loss of adhesion defects.

Examples of loss of continuity/integrity are oriented or mapped cracks and defects in corners that are usually caused by a combination of different causes. Cracks in ETICS are not only a serious aesthetic defect, they are also a weak point for the entry of rainwater into the facade. The consequences of the excessive presence of water inside an ETICS system are its accelerated degradation and a decay in the thermal resistance of the insulating layer. The latter compromises the performance of the entire system.

Thus, a study on the development of cracks in ETICS coatings is of utmost importance and understanding the causes may allow for better designed and longer life façades.

2 State of the Art

A research on the most common databases of scientific publications reveals how ETICS have been studied in relation to some of their characteristics and other performance of the building.

For example, Figure 1 shows a diagram obtained by searching SCOPUS and WebOfScience for the following research string: (ETICS OR "external thermal insulation composite systems") AND ("service life" OR durability OR (FEM OR "finite element method") OR crack* or "mechanical behavior"). This search string allows you to find articles that deal with ETICS and durability or service life, or ETICS and mechanical behavior, with attention to the occurrence of cracks.

It can be noted in Figure 1 (the biggest circle in picture) that ETICS have often been studied in relation to the thermal insulation requirement, which was easily foreseeable. For what is most relevant to the scope of this research, durability aspects of ETICS have been analyzed mainly in relation to moisture and, similarly, the keyword "degradation" has been often searched combined to "mold growth" and "biodegradation" especially on "housing". Nevertheless, some studies on cracks on ETICS can be found.

Durability of ETICS has been often associated to degradation of their coating layer due to mold growth (Kučeriková 2014, Stanaszek-Tomal, 2017). Although, ETICS generally perform satisfactorily if thoroughly designed and carefully erected, they are not very robust. Even minor

errors in design techniques and/or craftsmanship can lead to rendering defects (Kvande, 2018).

(Tavares, 2020) after a survey of 378 façade found that stains or aesthetic changes are the most common anomalies and were identified in practically all claddings. In contrast, anomalies associated with loss of adhesion were only identified in 10.5% of the sample set.

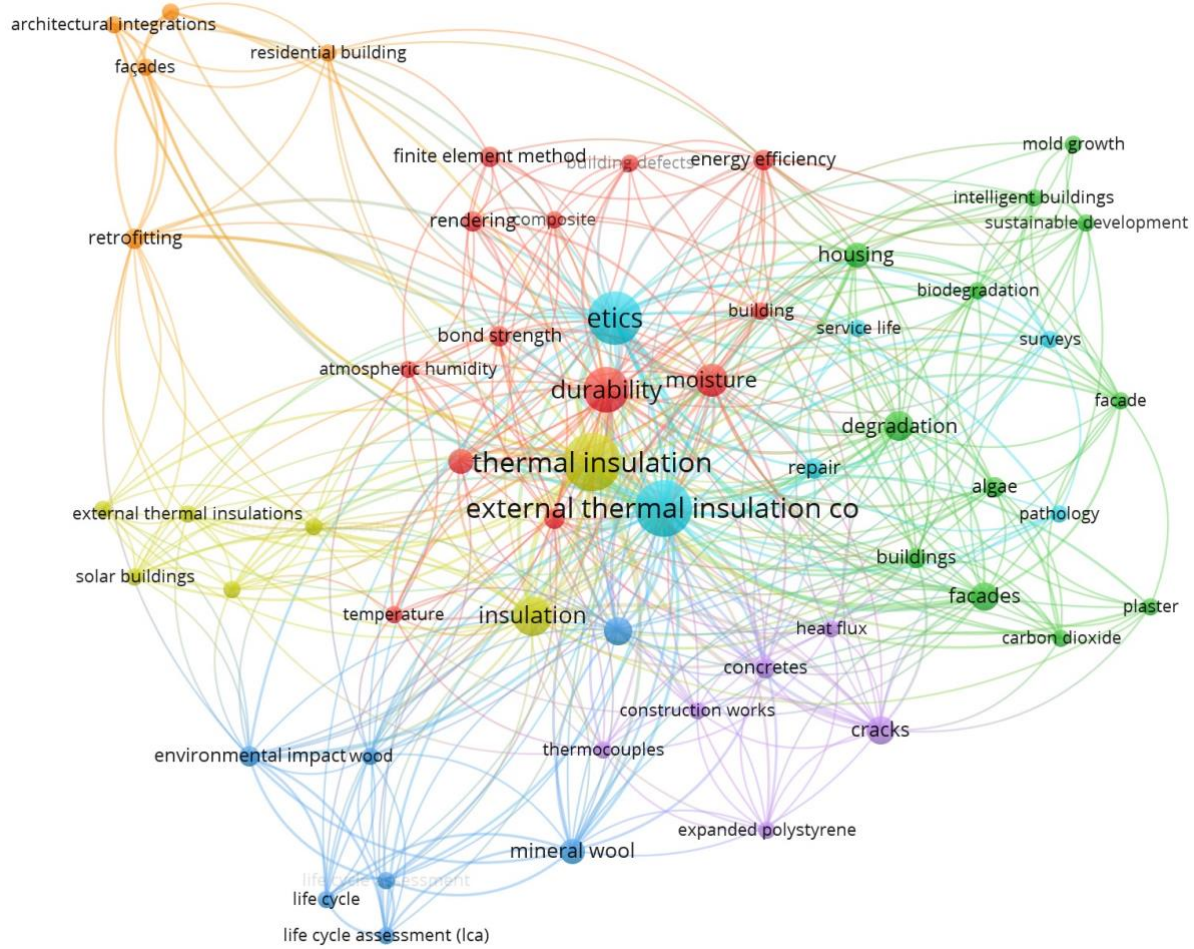

Figure 1. Network analysis of the keywords ETICS, external thermal insulation composite systems, service life, durability, FEM, finite element method, cracks, mechanical behavior.

In a survey of the facade defects with ETICS in a cold climate made by visual inspection (Liisma, 2016) found that most of the ETICS defects were material rupture (51%) and color/aesthetic defects (40%). Only a small proportion of defects were associated with flatness (9%).

3 Methods and Tools

The research is divided mainly into two great stages as pictured in Figure 2. The first one is dedicated to data gathering on both aging agents and materials' mechanical properties and to some pre-analysis needed to understand the behavior of the coating layer of ETICS. The second one is the actual FEM analysis and data post-processing for visualization.

Focusing on the first stage, an investigation of cracks in ETICS, conducted through

interviews with experts and some analyses of failure cases, has shown that temperature variations are one of the major stressing agents in this type of degradation. Noteworthy, researches (Künzel, 1999) prove that during the course of the day the surface of ETICS is exposed to thermal and hygric variations of up to 40 K and 80% RH.

Accordingly, the climate of some locations was analyzed in order to define the stress conditions to which the ETICS coat was subjected. In particular, when choosing the locations to be analyzed, attention was paid not only to the maximum air temperature but also to seasonal and day/night temperature variations. Eventually, the choice of locations was also influenced by the spread of ETICS on the market. Once the locations have been selected thermal stresses on ETICS have been computed using the model WUFI® (Künzel, 1994), which has been developed at Fraunhofer-IBP in Germany since mid of the 1990ies. In this model the relevant heat and moisture transport processes within hygroscopic porous media are described by two partial differential equations which are solved by the help of a finite volume procedure.

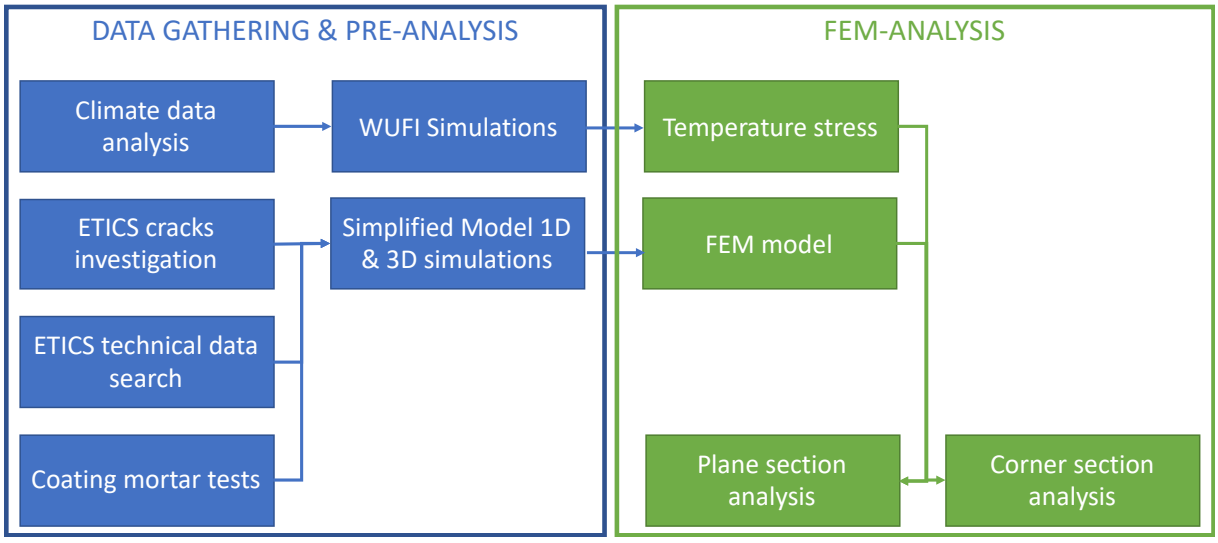

Figure 2. Research schema.

Alongside to the analysis of climate agents, simplified structural models have been created to better understand the phenomenon of the development of cracks on the external surface of ETICS. For example, a model was built by modelling the ETICS finishing layer as an elastic beam resting on a bed of springs whose rigidity is proportional to the compressive strength of the thermal insulation layer. These first analyses on simplified models have highlighted fundamental aspects for the prosecution of the research. It has emerged, for example, that in without imperfections in the installation phase or defects in the material such as the different thickness of the panels, the only thermal variations are not able to generate tension or compression stresses inside the coat that can cause the formation of cracks.

In the second stage of the research a nonlinear finite element model has been set-up for the mechanical analyses of ETICS. The model consists of seven insulating panels arranged in three rows so as to represent, considering the appropriate symmetries, the planar and central surface of the facade of a building. The chosen finite elements are of isoparametric kind, three-dimensional, with 8 nodes and incompatible shape modes. The total number of finite elements is about 70000, with about 75000 nodes.

On the ETICS bottom, *i.e.* where the system adheres to the supporting wall, fixed boundary conditions are imposed on surface parts physically glued. Boundary conditions, consistent with a periodic repetition of insulations panels, are set to the lateral surface.

FEM input is represented by the temperature distribution, along the ETICS thickness, computed by "WUFI" software in the first stage of the research. Non-linear kinematics has been adopted to perform the analyses.

Defects that may occur during the installation of the ETICS or imperfection in the thickness of the panels are modelled by a thickness reduction of the central panel. The onset of the fracture is checked by a Rankine criterion in the plaster.

In order to complete the finite element analysis and also to investigate particular configurations of the panels, different types of edge constraints have been imposed. The first stage of the research showed that in many cases the corners (edges of the facade, corners of doors and windows, corners in correspondence of balconies and loggias, ...) are places of frequent development of cracks. Thus, a second finite element model has been created to allow the analysis of these troublesome point in an ETICS façade.

Eventually, results FEM analyses were combined with some experimental investigation on the tensile strength of the coating made in the first stage of the research.

4 Results

The main research results are set out in this section. It should be noted that for all finite element models a double analysis has been made, one in the case of a polystyrene foam (EPS) insulation panel and another with the insulation panel made of mineral wool (MW).

The 1D preliminary analyses pointed out that a temperature increase cannot be the only cause of cracks (due to instability) on the base coat. If the coating is undamaged the critical (Eulerian) stress is σ_{cr} = 6.1 MPa and the corresponding critical temperature variation is ΔT_{cr} = 576 K. If the base coat is already cracked the same variables have the following values, σ_{cr} = 3.1 MPa, ΔT_{cr} = 288 K. On the other hand, a temperature drop may cause cracks on the base coat but only for a material with a medium to high Young modulus.

These preliminary results were confirmed by the 3D FEM analyses where a model made of seven insulation panel has been investigated using temperature distribution obtained from HMT analyses using weather data of the city of Milano. Even in FEM analyses, if the model has no imperfections, i.e. there are no errors in construction or insulation panels have no thick tolerances, then there are no signs of possible cracks. Otherwise, if errors or imperfection are modeled with one insulation panel (the central one in this case study) having a different thickness (1 mm thicker in this case study) then displacements are much bigger, as shown in Figure 3. Accordingly, in the coat significant stress concentrations at the joints of flanked insulation panels were found.

Figure 4 shows a comparison between stresses in the z direction, i.e. parallel to the longest side of the insulation panel, caused by a negative temperature variation may on ETICS made with two different materials for insulation layer: MS (a) and EPS (b).

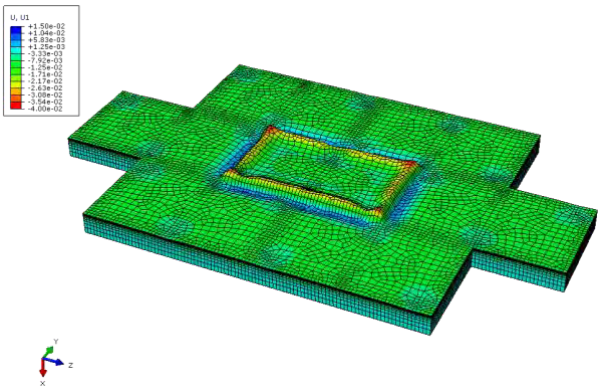

Figure 3. FEM Analysis results for the plane section of the MW ETICS. Displacements in x direction (thickness) [mm] for a positive temperature variation.

In both cases stresses in the coating layer were below the strength of the material. FEM analyses confirmed what had been found in the scientific literature and in the investigated fault cases: cracks on the coat of ETICS will develop if a) the external face of the insulation panels does not belong to a perfect plane; b) the coat has a high Young (elastic) modulus and c) there are high temperature variations.

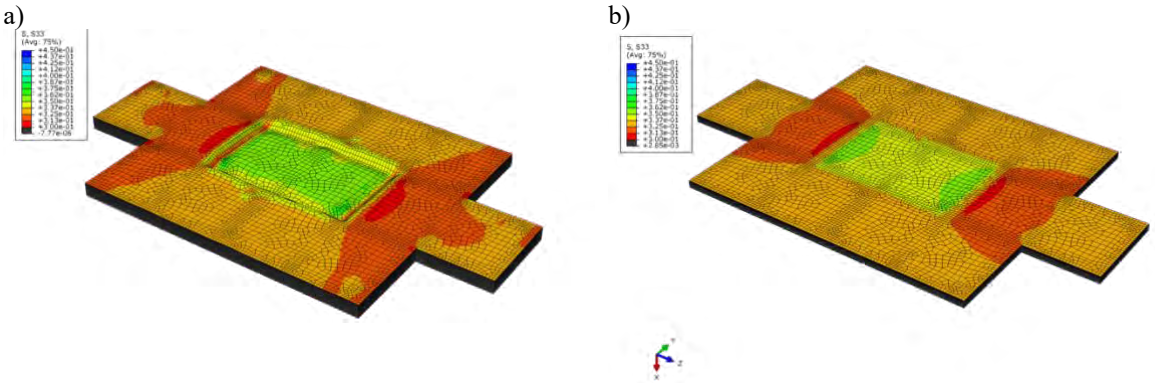

Figure 4. Comparison between mineral wool (a) and EPS (b). Stresses z direction [MPa] for a negative temperature variation.

In order to simulate the behavior of an ETICS near a corner some FEM analyses on a single insulation panel with two unconstrained edges have been done. An example of the results of these analyses is shown in Figure 5. The difference in the thermal expansion coefficient between the two insulation panel materials led to a huge difference in stresses in the coat layer, namely in the ETICS made of EPS stresses inside the coat are up to 6 times the stresses in ETICS made of mineral wool and with the given thermal stresses (city of Milano, medium dark color coat) are dangerously close to the strength of the coat.

Since the tensile strength of the coating play a crucial role in the development of cracks, 12 coat samples were tested to measure their tensile strength. Six of them were characterized by a high water content (immersed) and 6 with a standard water content (dry).

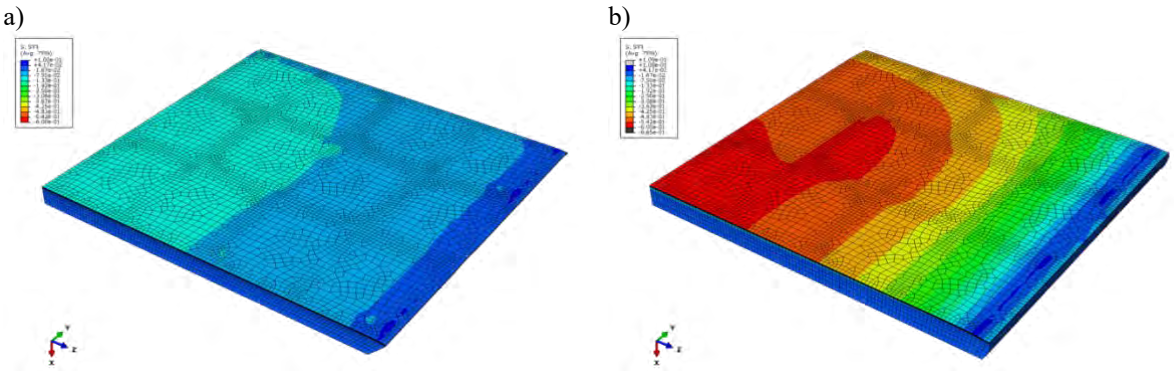

Figure 5. Comparison between mineral wool (a) and EPS (b). Stresses [MPa] when two edges of ETICS are unconstrained.

Experimental results proved that the average tensile strength applied to obtain a 2% strain varies significantly comparing the dry samples and the immersed ones with an average 42% reduction. By combining the results obtained in the two phases of the research, we can say that high water contents can easily halve the critical thermal variation, i.e. the thermal variation causing cracks on the ETICS coat. This high reduction is all the more dangerous as the elastic modulus of the insulating material increases.

5 Discussions and Conclusions

After a deep literature review performed to find the right values of material properties to be used in FEM simulation and some preliminary simplified analysis made to have a first feeling of the phenomena, two different kind of models were set up:

- one where ETICS is fully constrained to analyze the behavior of the system far from any singularity such as windows, doors, corner of buildings, etc…
- one where two side of the ETIC are unconstrained in order to investigate what happens away from the center of the façade (and of the ETICS)

In both cases thermal stresses were computed starting from a temperature distribution given by HMT simulations.

FEM simulations using the fully constrained model showed that cracks in the coat layer are mainly a consequences of steps in two near panels (a small step from one panel to the near one may be due even to a small tolerance in the thickness of the panel or to defects in the support layer and it's always present) and that a coat with high Young modulus suffers more than a rigid one high temperature variations. Simulations made with the unconstrained model highlighted that thermal expansion coefficient of the insulation panels and its compressive strength in the direction perpendicular to the main face are important factors for cracks development. An insulation panel with a low thermal expansion coefficient behave better in hot climate, the case studies showed, for example, that ETICS made with mineral wood insulation have stresses in the coat layer six times lower than the ones made with EPS. Some design principles can be deduced from FEM simulations:

- (if possible) always try to limit the thermal excursion of the coat layer of the ETICS using light colors in hot climate (or where there is a high sun radiation);

- use insulation panels with low tolerance in the thickness (small manufacturing errors) and fix them on a plaster layer (or be sure to have a very flat surface);
- in hot climate (or where there is a high sun radiation) use insulation panels with a low thermal expansion coefficient and a high compression resistance (in the direction perpendicular to the main surface);
- it is always better to protect ETICS from rainwater because the tensile strength of the coat decreases significantly in presence of water, thus lowering the threshold (temperature variation) of cracks.

Observations of Moisture Damages in Historic and Modern Wooden Constructions

Stephan Ott and Patrik Aondio

Department of Civil Geo and Environmental Engineering, Technical University of Munich, Arcisstrasse 21, 80333 Muenchen, Germany, ott@tum.de & aondio@tum.de

Abstract. *With the introduction of new building products made of planar glued board lamellas, the CLT, the restriction of load-bearing structures to linear and thus additively used load-bearing members was abolished. As a result, new, technically determined boundary conditions for moisture management in the interior of buildings have arisen. Due to the emergence of massive, planar wall and floor components as in concrete construction, the integration of building services technology in timber construction must now take place differently than was traditionally the case. In addition, it can be observed that the damage to building components is increasing, the detection of moisture damage is becoming more difficult and, ultimately, the consequences and risks are not yet foreseeable. The study focuses on the cause-effect relationship of increased water input and uses selected examples to reveal the problem of moisture exposure in the interior of buildings with planar load-bearing structures, the damage mechanisms and direct consequences set in motion. This paper shows the necessity for moisture protection measures in modern timber structures in comparison to traditional ways to construct with timber. It shows where moisture intake with modern structures must be considered and avoided from the engineering perspective in order to minimize the risk of moisture damage.*

Keywords: *Moisture Damage, Mass Timber Construction, CLT, Damage Mechanisms, Durability, Risk.*

1 Introduction

Wood is one of the oldest construction materials in our history. Due to its one-dimensional growth direction, it is mainly found in one-dimensional, linear components. This fact has significantly influenced the building with wood in the last centuries. Individual beams were used for load transfer, which worked alone or in combination with other beams. Only in the last decades a new building product has arisen by the emergence of the adhesive technology, which has created the breakthrough into our construction everyday life under the name *CLT*. In recent years, *CLT* has become one of the most popular building products for engineering timber construction. From today's point of view, its origins go back a very long way. In Central Europe, the first nailed *CLT* elements from the beginning of the 20th century are known under the name of construction method *Broda* (Kersten, 1926). In 1929 (Pohl, 1934), the Building Research Institute in Moscow had extensive investigations carried out on cylindrical shells made of nailed *CLT*. It was not until many years later (1992) that the company *Holzbau Merk*, *Aichach*, Germany, gained experience in the production of glued, large-format elements from crossed board lamellas. On this basis, the first general building authority approval (AbZ Z-9.1-354) was issued in 1998 under the name *Merk Dickholz*. Since this time, *CLT* production has shown a steady increase in production. According to the internet news portal *Holzkurier*, an annual

production output of 1.2 million cubic metres of cross-laminated timber is to be achieved in 2020 (Ebner, 2017).

The development of the cross-laminated timber construction product has massively changed the way walls and floor are designed. The once linear components of timber construction (beams) are increasingly being replaced by planar components made of cross-laminated timber. Construction times and construction heights can be reduced by constructing on the plane (see Figure 1), as the plane that encloses the room is combined with the load-bearing layer. The closed plane, which is formed by cross-laminated timber, is not only advantageous. If a building is to be constructed, different types of construction can be used for building floor. From a structural engineering point of view, the bending stiffness of the type of construction used is usually decisive, since it characterizes the serviceability limit state. If a 4-metre *CLT* floor is compared with a wooden beam floor, it can be seen that the *CLT* floor requires only 2/3 of the construction height of the beam floor with the same bending stiffness, cp. Figure 1.

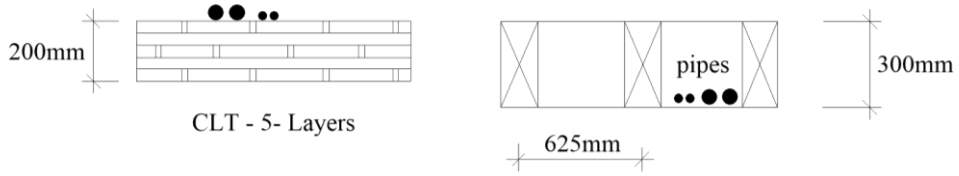

Figure 1. The two main different types of timber floor systems, a *CLT* plate with 2-axial structural span (left) and a traditional framed floor of joists with a 1-axial span (right). The installation of water pipes with respect of the type of construction is shown.

This article is intended to examine the problems of flat components with regard to their moisture resistance, special damage mechanisms as well as their causes and effects and the risks of repair, and to point out possible problem solutions and approaches for practical implementation.

Moisture damage generally poses a major problem in the construction industry and for wood components made of the renewable building material wood as well as most wood-based materials. Humidity usually does not destroy the building material suddenly, but slowly and gradually. What is the reason for this? On the one hand, wood itself has good resistance to short-term exposure to moisture. If the material can dry off quickly and the water content falls below 18% by mass again, then there are no concerns about durability. Even changing moisture contents of the material are in themselves harmless, although there are geometric changes in the cross-section due to shrinkage and swelling during moisture supply or removal. The geometrical changes are not to be classified as harmful if there are sufficient degrees of freedom of the component or a subcomponent. This shows examples, like wooden roof shingles from larch wood, which are to be found for example in the Alpine region frequently. Despite their constantly changing moisture content and additional exposure to wind and solar radiation, both of which promote drying, the material has a service life of 30 years or more in this application field.

In the case of moisture damage in the construction industry, most damage to wood only comes to light after a long period of time, apart from large and sudden damage events such as defects in water pipes. This type of defect is either concealed and is not noticed by anyone or the amount of moisture is small but constant and the damage mechanisms set in motion work slowly.

Damage mechanisms in wood and wood-based materials can be divided as follows: phenomena and damage mechanisms that do not damage the structure, directly damage the structure and indirectly damage it. Non-structural damaging mechanisms include the formation of mould on the material or component surface and blue stain fungi. These can be listed, however, as healthwise precarious and optically aesthetic lacks. The wood-destructive fungi (brown rot, dry rot) belong to the second damage-mechanism that leads to irreparable structure-damages in the material due to continuous high humidity. The last group of indirect damage mechanisms is triggered by moisture-dependent shrinkage and swelling and the reduction in strength due to high moisture. These two characteristics do not initially lead to damage to the material. However, shrinkage and swelling can lead to cracks in the cross-section along fibres and cause damage to entire components or adjacent components due to deformation of the cross-section, as the change in moisture can lead to large forces in the material. This can be observed in connection with internal stresses or settlement of components, but does not necessarily lead to damage to the material itself. By reducing the strength due to high humidity, deformations of the load-bearing component due to forces are possible and thus damage to the load-bearing or adjacent components is possible. The systematics of the damage mechanisms and their consequences are described in detail by (Ott *et al.*, 2017) in the report of TallFacades. The research project focused on moisture damage in the building envelope and the effects of weather and climate. It was already recognised that there are major risks of moisture damage inside buildings. The generally applicable damage mechanisms are not discussed in detail, nor are the direct consequences, since both can be read in the above-mentioned report on TallFacades. In principle, they also do not change in the event of damage inside buildings. In this article we get to the bottom of the following questions, following the damage and searching for the causal chain that leads to damp damage inside the building:

i) Which damage events can be observed inside buildings and how can the indirect consequences be linked with the overarching consequences of moisture damage?
ii) Which components are affected by moisture impacts and where have the damage mechanisms affected to what extent over time?
iii) How does the causal chain of damage mechanisms for the specific impact work?
iv) How much water and moisture has affected the wood.
v) Where does the impact (triggering event) come from?

Are there indications somewhere in the causal chain, either in the type of action or in the damage mechanisms or at the end in the direct and indirect consequences, which in particular are related to the aforementioned planar *CLT* structures?

In the discussion and summary, hints are given for the avoidance of impacts, elimination of damage mechanisms and minimization of consequences for the respective construction method (planar or linear). In addition, supplementary measures for the protection of the construction against excessive and continuous exposure to moisture are proposed through regular monitoring. Their final areas of application and application procedures, the testing and control of success are described in detail in a further paper.

2 Methods

2.1 Data

In order to analyse the relationships between the damage mechanisms and impacts, data from several damage surveys and expert opinions of the last five years are evaluated and compiled in Table 1. Specific information is taken from the sources in order to identify and further classify the damage to the construction methods and components.

Table 1. Data from evalutated multi-storey and mid-rise timber buildings.

Building and use	i) Construction type	ii) Structural part with damage	iii) Damage mechanism	iv) Water amount	v) Source of water
hotel	flat, 2-axial floor slab	top side *CLT* slab	top layers rotten	bathroom, leaking pipe	water on floor, below screed, not detectable
school	flat roof as warm roof, and beam structure	roof panelling, on bottom & top of beams	wood panels (OSB), rotten	construction moisture, no drying	tight roof top, vapour tight interior layer,
new office on top of existing parking, depot and heating plant	extension on RC-structure flat roof: beam flooring with timberframed panels	insulation inbetween beams, panelling	wet cellulose ins., beams, sills, and rotten panelling	construction moisture, high convective moisture input	neighbouring glass house, missing vapor barrier floor and edges, open shafts
daycare for children	nail laminated elements	nail laminated floor slabs and wall panels (1st floor and roof)	swelling of lamellas of elements, damage of connected elements	construction moisture, rain, high amount	missing protection during construction
pv-installation on tilted roof	beam structure	insulation inbetween beams, panelling	beams wet and dark coloured, wood panels rotten	rain water and convective moisture	small holes in roof cladding, penetration by pv-fixation

2.2 Procedure of Case Studies Analysis

The causal chain of the damage event and the damage mechanism, according to (Tietze et al. 2016), is evaluated and structured on the basis of the descriptions from the expert opinions and their categorization in Table 1. The following procedure is used: the primary influence of water damage on the position and size of the damage to the component is analyzed by the mutual investigation of the effect on the component and the damage resulting in the component. Information is evaluated to answer i) the general question about the occurrence of moisture damage in multi-story wooden buildings and ii) about the construction method and the affected

areas in the building components. The respective damage mechanism and the causal chain leading to the damage are determined in question iii) on the basis of the categorization of the damage patterns or according to the type of damage to the component. The trigger of too much moisture in the component is presented in question iv) according to the quantity and duration of the water impact. Finally, v) investigates the cause of excessive moisture ingress which leads to corresponding damage.

2.3 Systematization Results Case Studies

The systematization of damage mechanisms and their consequences is described in detail in the final report of the research project TallFacades (ibd.). The generally valid damage mechanisms are not discussed in detail, neither are the direct consequences, since both can be read in the report on TallFacades. In TallFacades the focus of the investigation was on moisture damage in the building envelope and the effects of the weather as a major cause and it has already been recognized in TallFacades that there are major risks for moisture damage inside buildings. These were only cursorily surveyed and the specific damage mechanisms were not dealt with either. As with the damage in the building envelope, the nature of the specific effects on internal components and the resulting indirect consequences in the building are explained in more detail. From this, initial findings on typical damage events will be summarized.

3 Results

3.1. Damage Incidents Inside

The evaluation of the results from the investigated case studies produces the following impact categories: Category of the size of the moisture input over time and the cause of the moisture input. The extracted subcategories are further specified in the explanations in the unexpected events in the interior of the building, mostly of great magnitude, which can be traced back to technical systems and which are paired with constructive characteristics. The primary damage mechanism is capillary water absorption. Another mechanism to be observed is the convective moisture input through unsealed components such as shafts or floor levels between different areas of use. The diffusive moisture input is hardly relevant. In addition, the loss of insulation properties and thus a building up effect of the humidity is not to be recognized in the present cases and unlikely, since the constructions lie predominantly in the interior and insulations are not necessary. With the few construction elements to the outside climate these are either completely unsealed or they show holes, which make the penetration of liquid water possible, which represents an unacceptable deficiency from the outset.

3.2 Construction Status (t=0)

As described in Chapter 1, *CLT* floors are becoming more and more popular as lower construction heights are required compared to beam floor with identical bending stiffness. However, with *CLT* floors, it is not possible to easily distort installations at the structural level. These must be installed in separate levels either above or below the *CLT* floor. This is different for beam floors, where pipes can also be routed between the beams, see Figure 1.

3.2 Unplanned Event = Damage (t=1 ... n)

Moisture damage is one of the most frequent types of damage in residential buildings. These are often caused by leaking pipes or design faults. In beam floor, the escaping water often migrates through the construction level and escapes at the underside and thus becomes visible quite quickly. Furthermore, the water inlet and outlet areas of beam floors are usually close to each other. If water is exposed to a closed surface such as *CLT*, the water moves to the deepest point of the structure where it collects, see Figure 2. Since the surface is usually closed and the water cannot pass unhindered through the construction level, it sometimes remains lying there for a long time and searches its way downwards along paths that are sometimes difficult to follow. Thus the place of the moisture entry and the place of the exit may be far apart. Furthermore, it can take a very long time until such moisture damage is detected. As an example the *CLT* floor of a hotel is shown here, where a damaged water connection was not found over 8 years, see Figure 3. From the once 220 mm thick *CLT* floor 100 mm have been decomposed by wood-destroying fungi. The floor structures originally did not suggest any damage, as the top of the floor and the underside of the floor were dry. In addition, the location of the maximum damage was several meters away from the cause of the damage (leaky water connection). Due to the very low construction height, the renovation was very costly. Auxiliary steel structures have to be used to replace the damaged *CLT* elements with new ones and to support the roof structure above.

Table 2. Categories of exposure and related reasons.

Scale & Time category	Reason	Explanation
large & suddenly	pipe burst, household applicance burst, sprinkler	- (unexpected event)
small & long-term (water source related)	pipe and fitting leakage, pipe connections	material damage, (quality management)
	complex and integrated installations	water leakage not detectable, continuous water supply (leakage)
small & long-term (construction technology related)	type of structures in mid-rise housing	large areas with flat slabs, thick slab dimensions, seldom beam structures
	ducts crossing different units without necessary barriers (air stops)	missing awareness & planning, expensive task, complex on-site work, no quality management, difficult maintenance
	type of indoor climate conditions	warm, humid, no or limited air-flow, no dry-out capacity

4 Discussion

4.1 Construction Technology Overview

The danger of moisture damage occurs wherever liquids are transported through pipe systems. Therefore, it is important to consider how structural measures can look like in order to avoid moisture damage as far as possible or to detect it as early as possible. If possible, pipes should be routed in such a way that they can be inspected. In addition, particularly vulnerable areas of

buildings such as wet rooms (bathrooms, toilets, washrooms, kitchens) should have special sealing systems that draw the user's attention to moisture damage and, for example, have overflows.

4.2 Outlook Repair (t=m)

If damage to the load-bearing structure is known, it must be repaired. In the case of the beam floor, the repair of damaged beams is relatively simple. In the simplest case, the damaged beams can be removed and replaced. Alternatively there are possibilities of lateral reinforcement by additional beams, construction materials or steel. As there is still space between the beams, this can be used for repair purposes. This is different for *CLT* constructions. Since the construction space is already completely occupied, *CLT* cannot simply be renovated or reinforced on the existing level. If a *CLT* floor cannot simply be replaced, complex constructions are often required to carry out the renovation. This is also reflected in the repair costs.

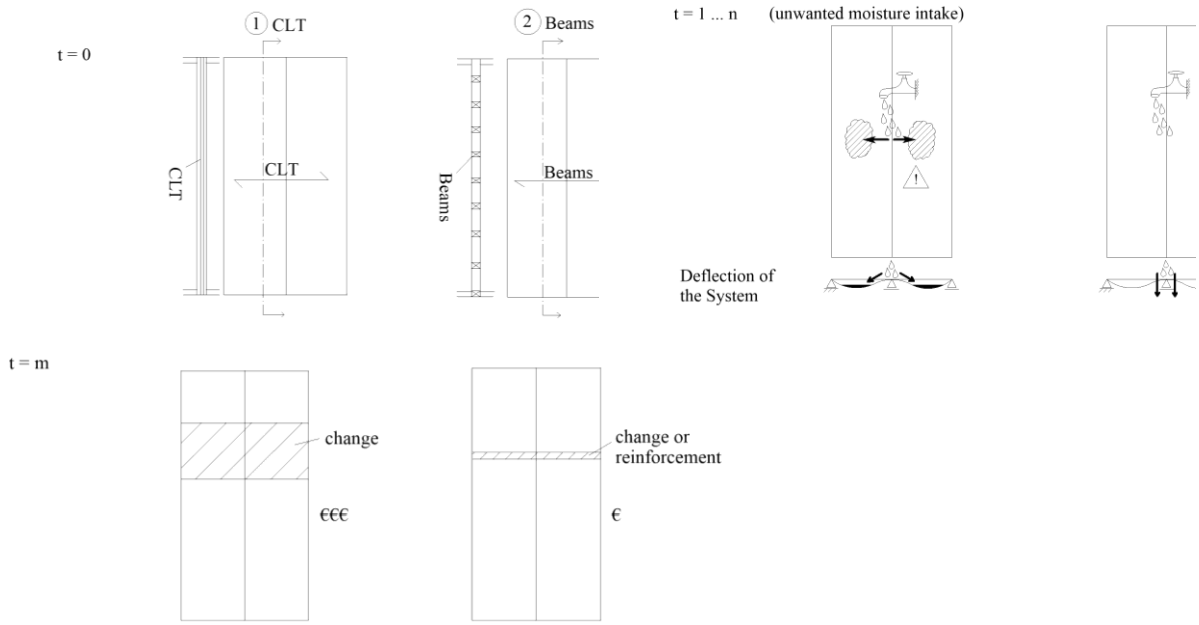

Figure 2. Timber floor systems 2-axial (left column) versus 1-axial during assembly t = 0, t = 1 …n with moisture intake and finally t = m with possible repair scenarios.

4.3 Outlook Monitoring

Since moisture leads to large damages in floor systems as discussed above, it is possible to set up appropriate monitoring systems. These can, for example, record the amount of water fed into and discharged from a building or room and issue a warning if the difference is too large. On the other hand, humidity sensors can also be installed directly at critical points. These humidity sensors would be particularly suitable for *CLT* floors, where water can wander along and is only discovered very late. This can be done by sensors placed close to the surface or in the wood.

5 Conclusion

The conclusions can be summarized as follows:

- Moisture damage with related wood decay inside buildings is a relevant problem,
- Such damages are difficult to detect because the damage mechanisms are acting slowly,
- Massive, planar structural components are particularly affected by slow decay mechanisms,
- Wood decay effects are mainly occurring due to defective water pipes on top of the floor.

In principle, the earlier an unexpected moisture penetration in timber constructions is detected, the smaller the damage and the lower the cost of restoration measures

Figure 3. Pictures of damaged *CLT* slab and wall elements in hotel room.

Abstract. *The durability of materials used in buildings has been widely studied and, in many cases, there are standards to assess it. However, studies on how pathologies affect the durability and comfort of the building users are not so common. The aim of this article is to explain different pathologies of the building envelope, considering glass as its main element and to analyze the causes of those pathologies, agents involved, and how they have affected durability. For that purpose, different cases of pathologies were analyzed on-site, both during the construction process and during the final use of the building. The effects of the different pathologies were also assessed. In each case, the technical data sheets available of the materials involved and the information on the design and the expected performance of the constructive solution were compiled. In some cases, the pathologies had caused an irreversible damage, so, the solution had to be drastic; while in other cases, they were detected early enough to propose remedial actions without affecting the final durability of the building. After having analyzed the different cases, the agents causing the pathology or those responsible for it and the phase in which the pathology occurred were identified. As a result, remedial actions were proposed to avoid the generation of pathologies during the design, construction and maintenance processes that affect the durability of the building and their user's comfort.*

Keywords: *Glass, Pathology, Sealant, Coating, Durability.*

1 Introduction

Since the industrial breakthroughs that allowed massive, high-quality production of glass for building in the 1960s, large glazed buildings have proliferated and along with them their associated pathologies. Additionally, the improvement of thermal performance of insulated glass units (from now on IGU) due to the importance of energy efficiency have resulted in premature failures in several cases (Hubbs *et al.*, 2015). Accordingly, studies on failure cases have also increased in the literature in order to understand the reasons and effects of glass failures (Honfi *et al.*, 2014; Loughran, 2003).

The pathologies of a glazed envelope may be of different natures. Glass breakage is one of the most known failure and have been widely studied using qualitative and quantitative methods (Overend *et al.*, 2007). However, there are other pathologies (such as sealing failure, yellowness or delamination) that have a direct impact on the durability of the building, since they affect the

functionality of the building and/or the comfort of the users. It should be borne in mind that the pathologies in this building element usually have the added complexity that the number of materials and elements that form the envelope solution are many and of a very different nature and function.

The pathologies of a glass building envelope can occur due to the following causes: chemical incompatibility, manufacturing failure/error or because of a product is not suitable for its intended use.

In a building envelope there are a lot of different organic materials and it is complicated to verify the chemical compatibility between all of them. In extreme cases it is not even necessary that both materials are in physical contact for a failure to occur.

Manufacturing failures, such an incorrect choice of materials or unsuitable manufacturing times and conditions, may also create pathologies. They are common in innovative and unique products or solutions as there is no previous experience.

Finally, an unsuitable glass product can also cause pathologies. The product is correctly manufactured, but its intended use has not been taken into account and this leads to a pathology, i.e. not all glass products can be used in all situations. For example, the building envelope may be subject to adverse environmental conditions that were not considered at the design stage.

Therefore, a pathology can occur in any of the following stages of the building work: design, manufacturing, assembling, on-site execution and while it is in service. In this article, we will only focus on the failure mechanisms that appears in the service period. All these failures have a direct impact on the durability of the building envelope. On the one hand, directly on the durability of the materials and on the other hand, indirectly on the durability of the building since the thermal, acoustic and optical performance are affected.

In the following sections we will give notions and analyze each of them deeper through real case studies.

2 Sealing Failure

In this first case study, degradation in the form of a slump of one or both sealing barriers of a IGU is noted (Figure 1). This pathology occurs in an office building with a large glazed surface that is two years old. The construction of all the glazing in the building is unique, large-format double insulating glass units filled with argon gas formed both externally and internally by laminated glass.

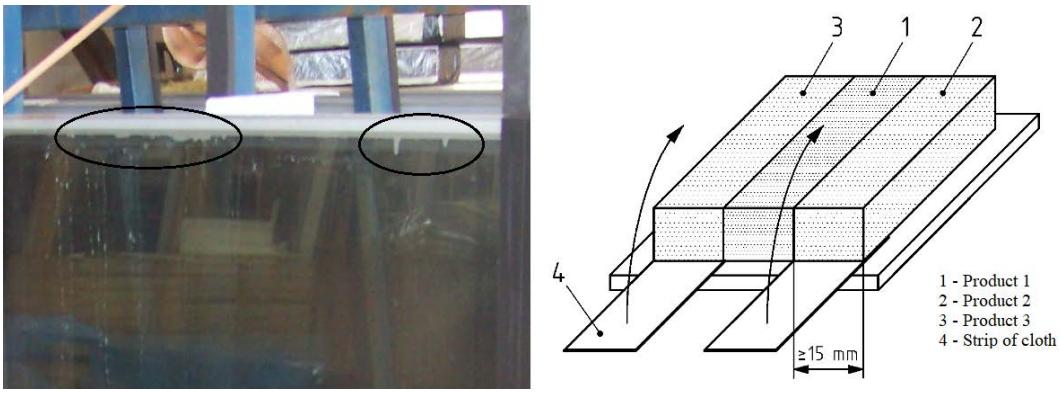

Figure 1. Sealant flowing (left) and test specimen for the chemical incompatibility test (right).

Degradation is detected in discrete areas of some of the IGUs. The concern with this pathology is firstly, the possible detachment of the outer sheet and its subsequent fall and secondly, if the property of thermal insulation is still preserved.

2.1 On-Site Inspection

When analyzing the units with pathology and their situation in the building, no pattern was detected due to their location in areas most exposed to solar radiation and therefore to a higher temperature. No water leakage was detected in the building envelope, i.e. the drainage system of the curtain wall seemed to be working correctly. All the glass units were exposed to equivalent UV radiation except for the differences due to the orientation of the building, however, no pattern showed that the failure was due to the orientation, height or degrees of exposure of those units and the pathology only appeared in some of them. Therefore, the influence of the environmental conditions such as temperature, humidity and radiation was dismissed early in the on-site inspection process.

When degradation of a sealant is observed, it is necessary to analyze which agents may be producing that degradation. Several IGUs were dismantled from the building and sent to the laboratory for a deep analysis, as only the on-site inspection couldn´t lead to a clear conclusion.

2.2 Laboratory Analysis

Once the samples were received in the laboratory, one of them was disassembled. Both sheets of glass were separated, and it was verified that the sealant was the one attacked. In this case, the degraded sealant was that of the first sealing barrier.

After this, all the polymeric products contained in the curtain wall were identified and gathered, such as sealants, adhesives, gaskets, supporting blocks... regardless of being in direct contact with each other or not. After this, sets of specimens containing adjacent materials were subjected to a chemical compatibility test using the UV method in accordance with section 7 of EN 15434:2007+A1:2010 Glass in building - Product standard for structural and/or ultra-violet resistant sealant (for use with structural sealant glazing and/or IGUs with exposed seals).

For performing the ageing, a laboratory weathering instrument ATLAS weather-ometer model Ci3000+ was used. The test specimens (Figure 1) were prepared with each two of the materials under study and they were exposed to UV solar radiation (by xenon lamps) for 504 hours and at 60 ºC temperature. After this UV exposure a peeling test was performed by means of strips of cloth or with cuts. A positive result in the test means that no visual discoloration appears and that no adhesive breakage occurs during the peeling tests.

After completing the compatibility test on the different combinations of adjacent materials, it was verified that the inner sealing barrier and the weathertightness gasket were highly incompatible.

Additionally, to this analysis, the building owner has made several measurements of the argon gas content of the glazing units, regardless degradation was present or not. Those measurements did not register a significant gas leakage on the units and a total detachment of the external glass pane has been dismissed up to now. The owner is performing regular controls to check the evolution of the pathology.

3 Luminous Transmittance Variation

The pathology studied in this second case occurred on two floors of a building that had not yet been occupied. There was no furniture or equipment that could alter human visual perception in any of the floors. However, a difference was noted by the owners in the perceived luminous radiation coming to the inside in each of the floors.

It was an office building with several floors where refurbishment was planned to be performed floor by floor. Refurbishment was integral, so affecting to the change of building envelope and interior furniture or equipment.

Refurbishment of the initial floor consisted in changing the carpentry and glazing of the complete envelope and after finishing there, works started in a new floor non adjacent to that first one.

First step of the pathology evaluation consisted in studying the type of glazing requested and checking delivery notes for the glazing of both floors. After that, an on-site visual inspection was carried out for a first approach. It was not so easy to visually quantify the difference in visual perception of the solar radiation, due to the great height gap between floors. This height gap means that shading due to adjacent buildings differs significantly and the influence on each floor is hard to quantify.

Therefore, the decision to remove two glazing units, one per each floor, and to measure their luminous and solar characteristics in the laboratory, was taken. IGUs were completely dismantled and luminous and solar transmittance and reflectance of all glazing panes were measured, in order to check whether those two glazing units were identical.

The IGU was composed by a laminated glazing (two annealed glass panes) on one side and a thermally toughened coated glass on the other side. For performing such measurements, a spectrophotometer UV-Vis-NIR Lambda 900 with a 150 mm integrating sphere was used.

As the laminated glass units were composed by annealed glass panes, they were cut into 100 mm x100 mm test specimens and transmittance and reflectance were measured from 280 to 2500 nm (Figure 2). In the case of thermally toughened coated glass though, it was not possible to prepare such test specimens and measurements were made with the equipment fully opened and the surrounding of the lab prepared to avoid external radiation getting inside.

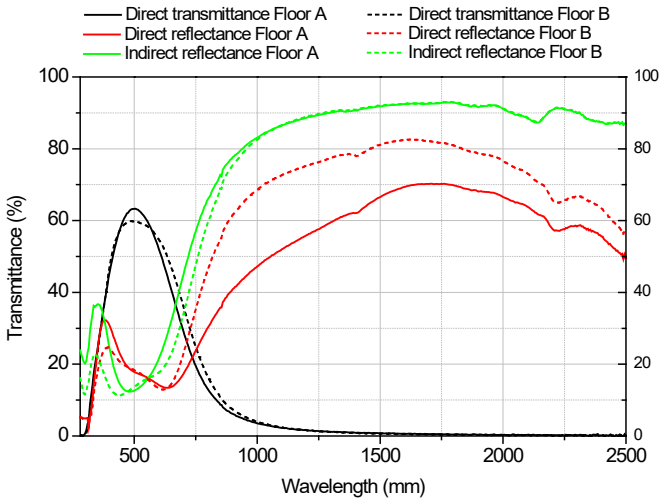

Figure 2. Transmittance and reflectance spectra of the coated glass.

After finishing the lab measurements, we noticed that laminated glass panes for both glazing units were the same but coated glass panes were not identical. Even though they were similar, differences were enough to be perceived by the human eye.

Considering manufacturing tolerances in the luminous/solar transmittance and/or reflectance, it could be concluded that both coated glass panes were not the same product.

Glass coatings are metallic oxides depositions that affect to the luminous, thermal or solar properties of the glass panes. Some coatings do not bear the thermal toughening process, so coatings are usually designed to provide similar properties, both for a toughened and a non-toughened version.

With the described measurements and collaboration from the manufacturer, we reached the conclusion that there was a manufacturing error, meaning that a coating not designed for the thermal toughening process, had been tempered by mistake.

4 Yellowness and Delamination

Pathologies are different for the sandwich products composed of glass and materials of different nature. An on-site inspection of the building of the third case showed colour change in glass products. Detachment of the exterior glass sheet was also detected in some cases. The inspection revealed that two types of glass solution with a similar external appearance had been used, one placed on the façade and the other on a sloping roof.

This case study refers to a semi-public building that has been in use for more than 10 years. For the study of pathologies, several affected units were disassembled and sent to the laboratory, along with stocked glass that had not been in use.

One of the solutions was a laminated glass unit consisting of an outer glass pane, an adhesive of an unknown nature, a marble pane, another adhesive similar to the previous one and an inner glass pane. The second solution was more complex and was composed of an exterior glass pane adhered to a pane of marble, which was in turn glued to an aluminium honeycomb panel.

Since the conditions of temperature and water presence are usually very different on the façade and the roof, it was concluded that ultraviolet radiation had been the main agent responsible for degradation. Nevertheless, the other agents –temperature and water in this case– had also played their role.

The durability of the material was evaluated by exposing two samples to ultraviolet radiation: a glass-marble-glass composition piece without defects and a glass-marble-honeycomb composition piece with colour degradation. Half of each piece was covered to avoid the degradation of that area. The test was carried out according to the procedure described in method A of section 7 of the standard EN ISO 12543-4:2011 Glass in building. Laminated glass and laminated safety glass. Part 4: Test methods for durability.

The test consisted in subjecting part of each panel to 2,000 hours of radiation. For this purpose, the panels were placed at 1,100 mm from 16 OSRAM ULTRAVITALUX lamps that formed an area of 1 m x 1 m. The radiation level on the panels was (900 ± 100) W/m^2. The radiation source used emits a spectrum similar to solar radiation and its spectral characteristics are as follows: UVB (280 - 315 nm) 3% ± 1%; UVA (315 - 380 nm) 8% ± 1%; Visible light (380 - 780 nm) 18% ± 1%; IRA (780 - 1400 nm) 24% ± 2%; IRB (1400 - 2600 nm) 27% ± 4%; and IRC (> 2600 nm) 20% ± 3%.

Three different areas of the exposed zone of each panel were selected and three luminous

reflectance measurements were made in each of them before and after the ageing. The luminous reflectance spectrum between 360 nm and 740 nm was measured using Minolta model CM2600d spectrocolorimeter in incidence d/8º. The colour coordinates L* a* b* for the observer at 10º and the illuminant D65 were calculated from the reflectance spectrum according to CIE76. Afterwards, the L* a* b* average colour coordinates of each area were determined and the ΔE*ab colour difference between the initial and final situation was calculated. The panels were also inspected for additional failures.

After 2,000 hours of exposure to simulated solar radiation, a considerable change in colour was observed between the exposed and unexposed areas of both panels (Figure 3). In the case of the glass-marble-glass composition, the difference in colour in the three selected areas before and after aging was less than 2.3 and in the case of the glass-marble-honeycomb composition the difference was greater than 2.3.

Figure 3. Exposed area of the panel (left) and unexposed area of the panel (right).

There is no requirement as to allowable colour difference after ultraviolet exposure for these innovative solutions. However, according to Sharma (2003) a colour difference ΔE*ab of approximately 2.3 is considered just noticeable difference. Therefore, in the case of the glass-marble-honeycomb composition the differences are clearly noticeable.

At the same time, the nature of the adhesives was analyzed by comparing the infrared spectra obtained by a Nicolet iS10 with the iD7 ATR accessory. Spectrum analysis was performed in transmittance mode, with 16 scans. Additionally, a thermogravimetric analysis was performed with a TG-DTA92 thermobalance in order to check the proportion of the different components. It is concluded that the nature of all adhesives used between glass and marble is the same regardless of the composition of the panel.

During the inspection of the building it was observed that the roof area was more degraded than the façade area. Even so, it is proved that in both cases the solution chosen was not suitable for the intended use. In order to avoid this pathology that directly affects durability, the suitability of both solutions should have been verified in the design implementation phase, considering the environmental conditions to which they would be exposed.

5 Interlayer Failures

In line with the latter case, bubbles, cloudiness, delamination or colour variations can be appeared in laminated glass compositions. The compositions of glass-glass with some other material embedded in the organic interlayer that joints both glasses are especially prone to failure. Therefore, those compositions are cases to be studied. In this regard, there are examples of the ageing behaviour of interlayer in the literature (Weller *et al.*, 2011).

The study of these kind of products should be carried out in the design implementation phase in order to validate the durability of the final product before being installed on site.

The procedures of the EN ISO 12543-4:2011 standard are used as a basis to assess the durability of this type of unique solution. This standard contemplates three possible exposures to attacks (high temperature, humidity and ultraviolet radiation) to which the laminated glass product must not present defects or must not vary its luminous transmittance.

5.1 High Temperature

In the case of high temperature exposure, test specimens are subjected to 100°C in an oven for 16 hours or by immersion in boiling water for 2 hours. In this way, it is checked whether the air between the two glasses was completely eliminated during the lamination process. It is not easy to eliminate this residual air when a metallic or plastic mesh type element is included in the interlayer and depending on its nature.

When this laminated glass is subjected to high temperatures, bubbles may appear in the mesh area. Different tests were carried out with different interlayers and it is easier to laminate this type of material with polyvinyl butyral intercalary. However, on certain occasions this type of interlayer is not suitable as it does not comply with certain mechanical aspects of the project and both the mechanical requirement and the durability must be assessed as a whole.

5.2 Humidity

In the case of exposure to moisture, the nature of the interlayers is decisive for studying the durability of the final product. Polyvinyl butyral and ionomer interlayers usually perform well in the presence of moisture, although this is not the case with liquid water. In the case of ethyl vinyl acetate interlayers, the humidity penetrates through the perimeter if this is not protected and, consequently, the interlayer become cloudier in the edges. If that laminated glass is no longer exposed to moisture, it migrates back to the outside and the laminated glass recovers its transparent appearance.

If there are embedded materials, special care must be taken if they reach the edge and how they react to moisture. The most obvious case is when the material placed between the two glasses is hygroscopic, since if the perimeter is not protected the moisture can migrate to the interior and produce a pathology that leads to lack of adhesion between materials, for example between marble and glass.

5.3 UV Exposure

The third attack on laminated glass to verify its durability refers to the ultraviolet exposure for 2,000 hours, after which the variation in luminous transmittance of the test specimens is limited. In this test, defects relating to delamination or bubbles do not usually occur, but the requirement for variation in luminous transmittance may not be met. The durability of laminated glass can also be verified by other standards, but the basis in all is similar. In the case of ANSI Z97.1-2015, for example, in addition to limiting the variation in luminous transmittance, the variation in yellowing index, the haze variation and the colour difference is also limited.

If there are additional embedded elements in the laminated glass, it must also be checked that there are no defects in that embedded material or in the interlayer, as it may happen that the two materials work well separately but not together.

Therefore, it is advisable to determine the variation of luminous reflectance or the variation of the colour coordinates of that embedded material –although the regulations do not contemplate it– in order to fully assess the degradation that the laminated glass is going to suffer.

6 Conclusions

- The pathologies of the glass building envelope may be different in nature and due to different causes, but they can be summed up in three main groups: chemical incompatibility, manufacturing failure/error or because of a product is not suitable for its intended use.
- After having analyzed the different cases, the design phase has been identified as the main stage of the building work in which the pathology could be avoided, followed by the product manufacturing phase. Accordingly, architects/project management or product manufacturers are the main agents causing the future pathology or those responsible for it. It should be added that a wrong assembly does not usually generate a pathology but contributes to its manifestation.
- As a result, two main remedial actions that can be implemented during the design, construction or maintenance processes are proposed to avoid the generation of pathologies that affect the durability of the building and their user's comfort. On the one hand, testing the selected products taking into account their intended use is the way to avoid failures before the construction of the building envelop. Most of the pathologies of the glass building envelope can be avoided if the durability of the chosen solution is verified during the design phase, considering the type of use and exposure to which the element will be placed. These previous checks are of particular interest in innovative or unique products or solutions, such as laminated glass products with organic interlayers. On the other hand, factory production controls became essential to avoid failures/errors that can occur in the product manufacturing stage.

Abstract. *Resilient flooring is a popular choice in healthcare facilities, given its durability, comfort, low maintenance and cost. However, anomalies that occur in vinyl and linoleum floorings (VLF) often do not fulfil the expectations of a flooring with good performance and durability. In fact, studies show that pathological phenomena in VLF occur more often in the first years in service, indicating a probable connection with the design and execution stages. These stages are crucial to the quality of VLF, since, if not given adequate attention, pathological symptoms are likely to increase, hence decreasing service life. The authors developed an inspection, diagnosis and rehabilitation system for VLF in healthcare facilities, including: the classification of anomalies, their probable causes, in situ diagnosis methods and repair techniques; anomalies - causes, inter-anomalies, anomalies - diagnosis methods, and anomalies - repair techniques correlation matrices. The same system was validated through the visual inspection of 101 compartments in six health infrastructures in Lisbon, Portugal, and the respective descriptive statistics analysis of the collected data. That analysis showed, for instance, that the summed contribution of "design errors" and "execution errors" to "faulty welding joints" was 59%. Making an effort to change the situation diagnosed in the mentioned inspection sample, some design and application stages' recommendations are highlighted, according to the main sensitive issues of the flooring system during its service life. The sensitiveness of VLF highlights the importance of a suitable maintenance plan to minimise susceptibility to various degradation mechanisms.*

Keywords: *Building Pathology, Design and Execution Recommendations, Healthcare Infrastructures, Inspection System, Vinyl and Linoleum Floorings, Maintenance.*

1 Introduction

Apart from their durability, comfort, low maintenance and cost, vinyl and linoleum floorings (VLF) have ideal properties for health infrastructures, such as static control, slip resistance and antibacterial characteristics. However, without adequate maintenance of VLF, these properties can lose their effectiveness and anomalies may appear, hence decreasing performance levels and life expectancy.

With the recent rise of awareness towards decreasing the ecological footprint of the construction sector, recycling and using more environmental-friendly products have increased. In this context, considering life-cycle assessments, the expectation of extending the service life of the building elements brings new attention to maintenance programs (Ayçam *et al*., 2017; Harris and Fitzgerald,

2013). To avoid the development of pathological phenomena in VLF, an adequate maintenance program must be implemented from the beginning of their life-cycle, even before the application of the flooring. Therefore, it is of high importance to study the durability of VLF in sets of buildings in various locations, subject to different actions, in order to understand the pathology according to the characteristics of VLF. Inspections can be systematised and should be included in a maintenance plan, to prevent degradation of the flooring and its substrate.

Regarding the health sector, several studies emphasise the importance of adequate maintenance, in order to prevent hospital-acquired infections (Brito, 2017; Carling *et al.*, 2010; Harris *et al*., 2010; Harris and Detke, 2013; Harris, 2017). However, apart from maintenance manuals, there is hardly any literature regarding the maintenance of VLF.

An inspection, diagnosis and rehabilitation system for VLF in healthcare facilities (Carvalho *et al*., 2018) was developed, including: the classification of anomalies, their probable causes, in situ diagnosis methods and repair techniques; anomalies - causes, inter-anomalies, anomalies - diagnosis methods, and anomalies - repair techniques correlation matrices. This system was validated through the visual inspection of 101 compartments in six health infrastructures in Lisbon, Portugal, and the collected data were analysed with descriptive statistics (Carvalho *et al*., 2019).

The purpose of this paper is to gather the maximum of information available on "Maintenance Recommendations Guides" from several manufacturers, supporting the presented information with the statistical data acquired during the inspection and validation campaign of Carvalho *et al*. (2018, 2019). Regarding the design and execution stages of VLF, a complete analysis can be found in Carvalho *et al*. (2018, 2019).

2 Installation

Regarding the installation of VLF, the instructions given by the manufacturer must be strictly followed. However, there are some general preliminary actions that are necessary (Armstrong, 2019; Construction, 2013; Ovation, 2013; Polyflor, 2019; Tarkett, 2012), such as: (i) the materials must be kept in the room where they will be installed for at least 24 hours before application, at room temperature, to adapt to the ambient conditions; (ii) the layout should be designed for the lowest number of joints; (iii) the substrate must be dry, clean and level; (iv) if not level, a levelling screed must be applied; (v) before installation, the flooring must be unrolled, measured and pre-cut according to the areas to be coated to minimise waste; (vi) when cutting the material, extra 15-20 cm must be considered, depending on the length; (vii) after the installation of the flooring with adhesives, it will require a drying period, so it should not be walked on, washed or scrubbed within this period.

The preparation of the substrate is the same for vinyl and linoleum, whereas the application varies according to the type of adhesive and drying period. As for the preparation of the substrate, a 10 cm thick screed is usually applied. However, in rehabilitation works, due to ceiling height limitations, it is not always possible to ensure the minimum screed thickness. In such cases, a glass-fibre reinforced screed should be used. Also, on ground floors, a vapour barrier should be applied over the screed.

A levelling compound should be applied over the screed in two cross coats. Silica sand may be added to the second coat to improve adhesion. After drying, any loose sand is vacuumed, the floor is buffed and any dust is cleaned. Next, the coves, with varying heights, usually around 10 cm, are placed on the wall with contact glue. After drying, the pre-cut rolls are placed aligned

on the floor. The roll is folded in half and the adhesive is carefully applied on the floor (Figure 1a), with a specific comb, and on the coves, with a brush (Figure 1b). To avoid adhesive excess, it must be well spread. The drying period varies and depends on the weather, as humidity will delay drying. After drying, half the roll is placed on the adhesive and the press roller is used.

In order to be well laid, the VLF must be heated, to become flexible and follow the curve of the cove, and then compressed, to ensure adhesion. Therefore, a welding machine is used, without the welding tool, to make the vinyl more ductile (Figure 1c). If this step is skipped, detachment of the coving may occur. In the corners, 45º cuts must be made (Figure 1d) using a utility knife, which is also used to make straight cuts in vinyl. The curved-tip knife (banana knife) is used to remove excess vinyl on the cove, before fitting it to the upper housing.

Before welding the joints, a half-moon shaped tool is used to create the necessary spacing to place the string. The welding string is then applied using a welding machine or a robot. After the string has cooled, the excess must be removed either by using two tools separately (Figures 1e) or one tool, with a single cut. Then, a transition profile, made of PVC or aluminium, should be placed at each room entrance to ensure a smooth transition between different floorings of similar thickness. Optionally, a silicone string may be applied in the joint between the coving and the wall, to minimise the risk of possible water ingress.

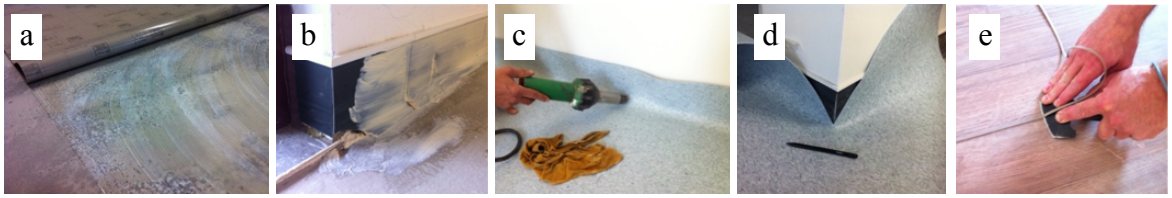

Figure 1. Installation of vinyl flooring: a) application of adhesive on the floor; b) application of adhesive on the footers; c) heating of the flooring; d) corner detail; e) removal of the string excess.

3 Maintenance

Floorings are selected for many reasons including colour, design and sometimes special properties, such as static control or slip resistance. Without regular maintenance, dust and soiling build up quickly, changing aesthetic properties and making special features practically useless. Moreover, dirt and soiling usually harbour bacteria, making the flooring a health hazard. Also, dust and grit underfoot can act as an abrasive, which, if left uncontrolled, will shorten the service life of the flooring, causing premature replacement.

Regular and well-planned maintenance keeps the flooring in pristine condition and can enhance its original appearance. It can also reduce wear and ultimately prolong the service life of the flooring. Adequate maintenance (daily/regular and periodic) may lead to high costs in the long run, but the lack of adequate maintenance means higher costs in the future with localised or total replacements. By defining a maintenance programme, real savings can be made without compromising appearance, hygiene and cleanliness requirements.

3.1 Factor Points to Consider

Before establishing a maintenance programme, some variables should be considered, as they affect the method, frequency and hence the cost of maintenance. So, the floor location, type and volume

of traffic, and the existence of dirt barriers should be taken into account. The location of the flooring in the building is one of the main factors, since entrance and reception areas will require more intensive and frequent cleaning than upper floors or low traffic corridors. The types of traffic, density and frequency in the given location also play an important part, since the density of traffic and type of footwear used in common corridors differs from the ones in operation rooms. The expectation of the client for a given location also plays an important part. If a high level of hygiene is required, like in the health department, the maintenance regime must be able to provide it. Finally, the type of cleaning equipment conditions the programme, since manual methods may be time-consuming in large areas and incompatible with the periodicity requirement. However, large machines used in confined spaces can take longer than manual methods (Polyflor, 2019). Additionally, the colour of the flooring is important, since, in general, light colours show soiling more easily and need more frequent cleaning, whereas dark colours more easily show loss of gloss.

3.1.1 Assessing the location

The first part of the maintenance programme process is to break down areas to be cleaned into a series of independent locations. Then, each one should be assessed before a particular maintenance strategy is employed to provide a clear indication as to where the effort and therefore the cost should be applied best.

The assessment should establish the following: type of cleaning; frequency of cleaning; cleaning products and equipment; the level of labour required; and time to be allocated. It is of high importance to regularly assess the different locations and be flexible about the planned maintenance. If the floor in a particular place needs more attention, then it must be ensured that it is addressed as soon as possible. On the other hand, if some areas seem over-maintained (*e.g.* with polish build-up in the non-walked on areas), then the maintenance level should be adjusted, but the situation must always be monitored to ensure it remains within control.

According to Carvalho *et al*. (2019), anomalies "staining/dirt/colour changes" and "brightness changes" resulted exclusively from causes in groups "environmental actions" and "maintenance errors", the latter represented only by "insufficient/incorrect cleaning of the flooring". In both "staining/dirt/colour changes" and "brightness changes", the predominant environmental causes were "biological action/chemically aggressive agents" (50% and 94%, respectively). Such frequencies were expected, as the use of inappropriate cleansers or spilling of aggressive substances, such as antiseptic drugs, causes blemishes, changes in brightness, or indelible stains.

3.1.2 Dirt barrier systems

The dirt barrier systems (DBS) play an essential role in VLF maintenance, as most dirt, grit and moisture are carried into a building by users. By reducing the amount of these elements that are brought in, not only would this cut the cost of its removal, but it would also cause less abrasive action on the flooring. Also, with less moisture, there would be less potential for slipping. An effective "passive" DBS has both scraping and absorbing qualities and is sufficiently large to perform these actions on both feet during normal walking (Polyflor, 2019).

An exterior and an interior mat should compose the DBS. The exterior scraper mat should be at least two paces long, set into a mat well and have enough height to allow grit to fall below. Inside the building, an interior grade combination of scraper and moisture mat of two to three metres long should be installed, as it removes most moisture and any fine abrasive particles.

However, to keep the effectiveness of DBS, they must also have adequate maintenance and be cleaned regularly; otherwise, they can increase the soil intake by creating a "soil reservoir" at the entrance of the building.

It is highly important to invest in high-quality floor mats for an extra layer of protection. The mats should be placed at entrances and exits to collect and trap corrosive substances that can be tracked in, such as dirt, sand, oil, grit, asphalt, among others.

3.2 Types of Maintenance

The best way to maintain the product characteristics for long-term use is to perform regular cleaning and proper maintenance. In this context, two factors contribute to the decrease of a VLF life-cycle: the lack of maintenance or an inadequate one. The first scenario includes the permanent accumulation of dust, loose dirt and other corrosive materials (such as hand disinfectant). The second scenario includes the use of aggressive cleaning agents, which remove the superficial protection barrier of these floorings, or excessive waxing.

According to Harris (2017), the most common resilient floorings used in patient rooms are rubber, linoleum and vinyl roll and tiles. Tiled vinyl is considered to be the most durable and cost-effective at initial costs, though it requires continuous maintenance at high long-term costs. As for vinyl roll, it is less stable and durable than tiles, but its welding joint mitigates the risk of contamination of the bedding layer. Finally, linoleum derives from natural resources, having antistatic and antimicrobial constituents. However, it is susceptible to water damage, usually requiring a surface protector that inhibits antimicrobial properties.

Before the flooring installation, the site must be adequately cleaned, otherwise some anomalies may arise immediately. Therefore, all loose dirt, dust and grit must be removed by mopping, sweeping or vacuuming. Also, all traces of adhesive on the surface of the flooring must be removed.

Harris and Fitzgerald (2015) identify the procedures for adequate maintenance of resilient floorings exposed to heavy traffic in healthcare facilities. Daily cleaning should be performed with a dry and wet mop; weekly, localised cleaning; quarterly, scrubbing and polishing cleaning; and semi-annually a surface protector should be applied.

According to Carvalho *et al*. (2019), anomalies "scratches/wear", "staining/dirt/colour changes" and "faulty welding joints" occurred in more than half of the inspected floorings. The most frequent anomaly was "scratches/wear", which was expected considering how easy it is to scratch a VLF (Douglas, 2011), since careless dragging of equipment is enough to leave a scratch, and the wheels of most trolleys have inadequate or worn-out material. The second most frequent anomaly is "faulty welding joint". The absence or deficiency of the welding joint, allied with inadequate cleaning, creates a singularity where water may enter, triggering detachment of the flooring. This shows the importance of timely maintenance interventions at welding joints to guarantee the expected service life of the VLF. In general, dirt can be eliminated by cleaning, whereas for indelible stains and colour changes in linoleum floorings, they can only be removed by stripping. In vinyl or recent linoleum floorings, they can be removed by polishing. In these cases, the VLF is only replaced when the affected area is of exceptional aesthetic value.

As for the location of anomalies, in some situations, a specific type of anomaly is predominant. For example, anomaly "scratches/wear" is often seen in poorly executed transition areas or at the rooms' entrance (Figure 3a and b). It is also the case of anomaly "brightness changes", which often occurs immediately below the alcohol-based disinfectant dispensers (Figure 3c).

According to Carvalho *et al*. (2019), there are some repair techniques that should be adopted in the maintenance program, according to the different types of anomalies detected in the regular flooring inspections. For example, the application of a surface protector is a technique widely used for scratches/wear, staining/dirt/colour changes and brightness changes, to reduce its aesthetic impact by smoothing the surface. When scratches exist, partial or total replacement of the flooring should only take place when the area has a high aesthetic value. Stripping is a technique exclusively used in linoleum floorings, being less associated with stains than with brightness changes. In some cases, the floorings are cleaned and waxed regularly, but stripping is only partial and not in the required timings, often resulting in alternated areas with different wax thicknesses, as seen in Figure 3d.

Figure 2. Anomalies: (a) scratches; (b) wear; (c) brightness changes; (d) brightness changes on a linoleum flooring due to inadequate maintenance.

Anomaly prickles/punctures was only not associated with repair techniques "glue injection" and "repair of anomalies in footers". The application of the repair techniques depends on the area affected by the anomaly. For small areas, cleaning and applying a sealant or a welding string is sufficient. For linoleum floorings, they can be stripped, or the punctures can be covered with a mixture of white glue and linoleum scraps.

3.2.1 Routine/regular/daily maintenance

The following recommendations are provided as guidelines. However, the periodicity of each operation depends on the amount and type of traffic, the provision of adequate DBS and the maintenance equipment available.

For daily vinyl cleaning, the flooring should be mopped, swept or vacuumed to remove dust and loose dirt. Stains can be easily removed with detergent and subsequently rinsed. If required, to remove persistent black marks, the floor may be damp mopped with a neutral cleanser—the label must always be read to ascertain suitability, and the manufacturer's instructions for application must be followed. It is highly important that the flooring is washed with nonabrasive cleaners. When rinsed, the floor must be allowed to dry. All smooth floorings can be slippery when wet. If necessary, the floor may be buffed with a dry soft mop or cloth. The appearance of the flooring should be assessed weekly.

Once a week or, if necessary, more often, the floor should be cleaned with a damp cloth or a mop soaked in warm water and a neutral cleaner. Light scuffing is executed with a buffing machine with a suitable dry and clean pad.

3.2.2 Periodic maintenance

The appearance of the floor should be periodically assessed. If the floor has dirt build–up, it should be machine scrubbed with a scrubber dryer fitted with a suitable clean pad, using neutral detergent.

Then, it should be rinsed thoroughly and allowed to dry. To restore the finish, it may be dry buffed.

Regarding the stripping and resealing of a linoleum floor, according to Gorrée *et al*. (2002), stripping should be done six times in 20 years (approximately every three years) in public buildings.

3.2.3 Preventive measures

To prevent damage, some precautions should be taken. For example, spills should be cleaned immediately, since the longer spilt materials are left on the floor, the higher the risk of irreversible staining. Regarding the furniture, it should always be lifted and carried, instead of pushed, pulled, or dragged over the floorings. According to Carvalho *et al*. (2019), cause "dragging of equipment" was the most frequent, being indicated in approximately 28% of anomalies, probably due to a close correlation with the occurrence of scratches. This cause represents the use of improper wheel material, which easily leaves a mark in VLF, or moving of furniture without adequate protections. Furthermore, heavy furniture or appliances that are not moved often should be equipped with flat, non-staining floor protectors, to avoid indentation from heavy furniture or sharp furniture feet. The heavier the furniture, the wider the protectors should be (Seeley, 1985). Vacuum cleaners with beater bars should be avoided, as they can damage the flooring. Black rubber wheels and rubber feet can cause discolouration. Strong detergents must be avoided, as they may wear the protective layer. Cleaning and maintenance training courses from manufacturers, including both practical and theory work, should help facilities maintenance staff get the best from vinyl floorings by using adequate cleaning methods and products (Polyflor, 2019; Tarkett, 2012).

4 Conclusions and Future Developments

Several difficulties were found during the research, mainly the scarce scientific literature about VLF, both in general and in health infrastructures. Therefore, the recommendations stem from different sources, namely supplier guidelines, site assessment and statistical evaluation from site assessments (Carvalho *et al*., 2018 and Carvalho *et al*., 2019).

This paper contributes to the dissemination of knowledge on the maintenance of VLF, specifically in health infrastructures, as the presented information may be used to improve and increase the effectiveness of maintenance plans. Additionally, it may also be useful at the application stage, as some defects with substrate origin, for instance, may be prevented with adequate cleaning of the substrate. Moreover, at the design stage, a maintenance manual or a concise user's manual of the flooring may be developed and delivered to the client. Furthermore, the consideration of efficient dirt barriers, with scraping and absorbing qualities, should take place early at the specification stage, and not afterwards, when there are rarely enough funds or space to do the job correctly.

To avoid defects at the application stage, several measures may be implemented, always starting with the use of specialised labour and better communication between contractors. Specialised labour is more likely to apply floorings according to the best practices, hence avoiding defects caused by execution errors. In terms of maintenance, regular cleaning is more beneficial and cost-effective to the flooring than occasional heavy cleaning.

Regarding future developments to increase the life cycle, cleaning and maintenance training courses given by the manufacturers should be mandatory. It is essential to train the cleaning staff since inadequate maintenance directly contributes to accelerating the degradation of VLF. Moreover, regular inspections are also necessary to ensure the quality control of the VLF application. It is

also expected that the efficiency and effectiveness of maintenance in VLF increase if the inspection system proposed by Carvalho *et al*. (2018) is used. In the future, to improve the system, a wider inspections campaign should be made.

Abstract. *Alkali–silica reaction (ASR) is a major concrete durability problem. The occurrence of ASR results in significant maintenance and reconstruction costs to concrete infrastructures all over the world. Ever since Stanton (1940) discovered the expansive characteristics of ASR in 1940, there has been much speculation as to the cause and actual mechanism of expansion. Current market solutions are not always sustainable, such as hauling non-reactive aggregates or fly ash from long distance; or use of Li-based chemical admixture that is facing challenge of raw material's availability. The current article will present a patent pending technology which provides a commercial solution for mitigating the ASR. The ASR mitigating effect of this technology is compared with lithium, calcium, and aluminum salts, and densified silica fume.*

Keywords: *Alkali–Silica Reaction (ASR), Durability, Silica Fume, Metakaolin, $LiNO_3$, $Ca(NO_3)_2$, $Ca(NO_2)_2$, $Al(NO_3)_3$, Expansion, Slurry, Solution.*

1 Introduction

Since Stanton (1940) demonstrated that reaction between high-alkali cements and certain aggregates could cause disintegration of concrete, a large amount of research has focused on the alkali aggregate reaction. An annotated bibliography containing over 1300 references pertinent to the phenomenon of alkali silica reaction (ASR), was compiled by Diamond (1992). ASR has remained a subject of much research and discussion because of the necessity of employing marginal aggregates in many areas, as well as the limited availability of low alkali cement, class F fly ash, slag, and lithium. Szeles *et al.* (2017) estimated that by 2030, the supply of fly ash in the United States will be approximately 14 million tons, but the demand will exceed 35 million tons. Lithium-based chemical admixtures face limited raw material availability and

rising price. Tesla and other electric-vehicle makers dominate lithium consumption, a lightweight element that some call "white petroleum" for its use in lithium-ion batteries that power electric cars. 'In order to produce half a million cars a year…we would basically need to absorb the entire world's lithium-ion production,' Elon Musk said in March 2016 according the Wall Street Journal (2016).

Densified silica fume has been used to increase ASR resistance. Due to low volume demand, concrete manufacturers do not normally install a silo for densified silica fume. The two main issues of densified silica fume are: (1) it might cause ASR due to agglomeration (Pettersson 1992), and (2) densified silica fume in bags are difficult use in concrete manufacturing. Clearly, the concrete industry is looking for alternative chemical admixtures, which are easily dispensed into a central mixer or concrete truck in ready mix concrete or precast plants, for mitigating ASR.

Six pumpable products, which are three salt solutions and three slurries were selected in this study. The three salt solutions are Calcium Nitrate ($Ca(NO_3)_2$), Calcium Nitite ($Ca(NO_2)_2$), and Aluminum Nitrate ($Al(NO_3)_3$). The three pumpable slurries are based on densified silica fume, metakaolin, and Z silica fume (a by product from zirconia oxide manufacture). The technology of manufacturing these slurries is patent pending. A screening test method was developed based on ASTM C1567 (2018) to evaluate the ASR mitigating effects of these six products.

2 Experimental

2.1 Materials and Test Method

An ASTM C150 Type I/II portland cement with alkali content of 0.93% equivalent Na_2O was used throughout the study. The reactive aggregates are recycled borosilicate glass granules from Vitro Minerals. Commercial Solutions of $LiNO_3$, $Ca(NO_3)_2$, and $Ca(NO_2)_2$ were used. The $Al(NO_3)_3$ solution was prepared from analytical reagent grade of $Al(NO_3)_3 \cdot 9H_2O$.

2.2 Accelerated ASR Test Method

To evaluate the ASR mitigation effects of the selected materials, an accelerated test method based on ASTM C1567 (2018) was developed. The key for developing an accelerated ASR test method is to determine the pessimum amount reactive aggregate (borosilicate granules) in the mortar mixture. The pessimum amount of borosilicate is about 25% of total fine aggregate, which caused the maximum ASR expansion under the current test condition. Therefore, the screening test for evaluating potential candidates for ASR mitigation was designed as follows:

- Mortar with pessimum amount of reactive aggregate (25% borosilicate).
- Follow the ASTM C1567 test procedure.
- The expansion results are an average of four measurements.

3 Results and Discussion

3.1 Effects of $LiNO_3$, $Ca(NO_3)_2$, $Ca(NO_2)_2$, and $Al(NO_3)_3$ on ASR

The alkali silica reaction (ASR) is primarily one of OH^- ions rather than of alkali cations; nevertheless, the latter are of critical importance. Both sodium and potassium ions cause distress; lithium apparently not, and its presence tends to inhibit distress. In an attempt to find

a compound that would effectively inhibit ASR, McCoy and Caldwell (1951) carried out a vast number of mortar tests with a representative selection of many types of possible additive materials. The most significant facts that emerged from this study was that lithium compounds (LiCl, Li_2CO_3, LiF, Li_2SiO_3, $LiNO_3$, and Li_2SO_4), in some unexplained way, reduced mortar expansion. Even almost insoluble lithium salts, such as LiF, seemed to be beneficial. Ong (1993) demonstrated that these insoluble lithium salts, such as LiF and Li_2CO_3 were quickly converted to LiOH in pore solution of cement paste. Due to its high solubility in water, $LiNO_3$ has been commercially used as a chemical admixture for mitigating ASR. The mechanisms of ASR mitigating by $LiNO_3$ was recently studied by Feng *et al.* (2010) and Guo *et al.* (2019). The formation of Li-Si crystal (Feng 2010) or Li-Si amorphous structure (Guo 2019) act as barrier surface on the reactive aggregate surface and prevent ASR.

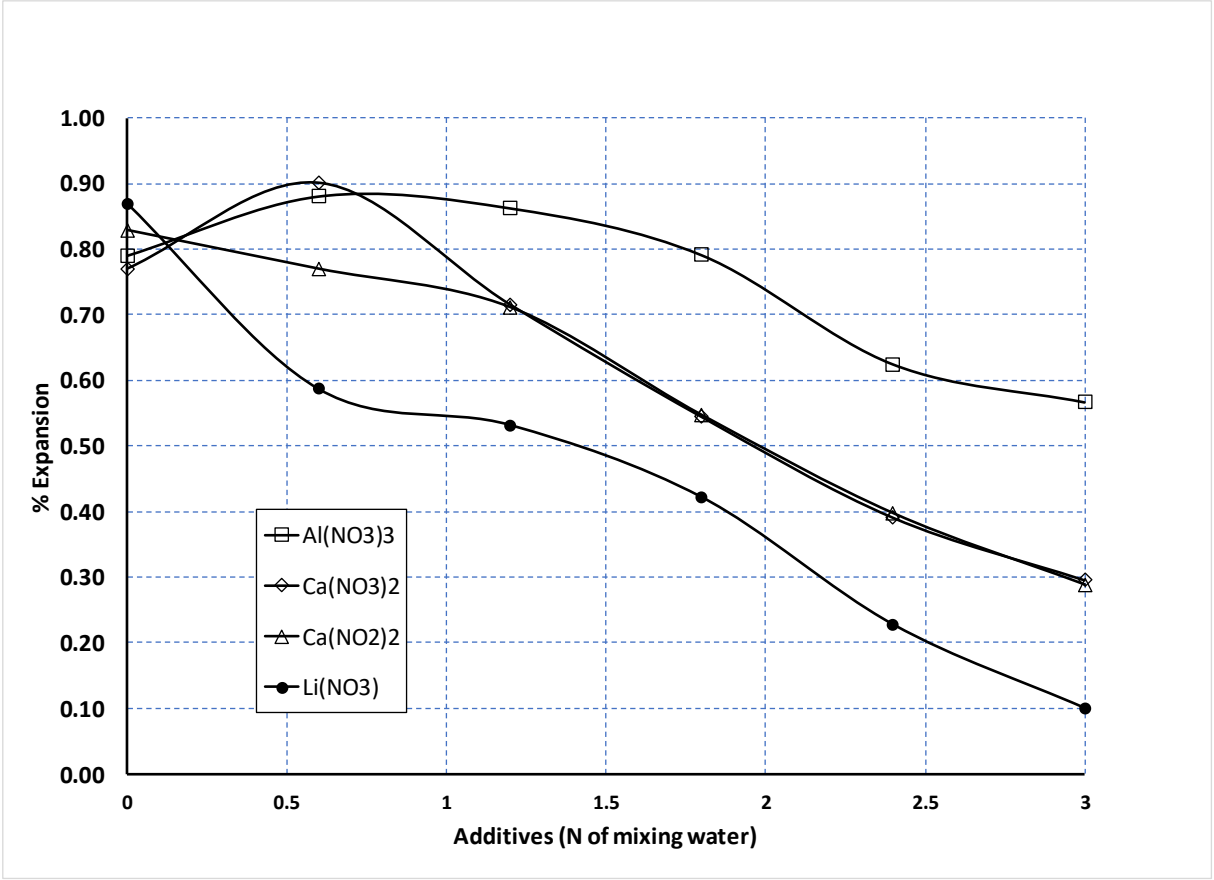

Figure 1. The comparison of ASR mitigating effects of $LiNO_3$, $Ca(NO_3)_2$, $Ca(NO_2)_2$, and $Al(NO_3)_3$.

The role of calcium ions in ASR have been investigated and debated for many years. Powers and Steinour (1955) suggested that ASR gel with a low-calcium content was expansive, while ASR gel with a high-calcium content was not expansive. Hudec and Banahene (1993) indicated that calcium ions mitigated ASR. Concrete with some free calcium ions in pore solution did not expand as much as one without. On the other side, many studies (Kawamura *et al.*, 1998, Aquino *et al.*, 2001, and Feng *et al.*, 2010) suggested that calcium ions are vital for

deleterious ASR expansion to occur. Without calcium ions, silica dissolves by OH^- and remains in solution (Thomas 1998).

Even though there are limited studies directly on the effect of aluminum on ASR, a good review on the beneficial effects of aluminum in mitigating ASR was provided by Rajabipour *et al.* (2015). The proposed explanations for Al benefits are:

- Reducing silica dissolution by Al adsorption on the surface of reactive aggregate.
- Removing OH^- ions by the formation of C-A-S-H.
- Removing $Ca(OH)_2$ to form calcium aluminate phase.

The above hypotheses were further investigated by studying the effect of $Al(OH)_3$ on ASR expansion with ASTM C1293 concrete prisms (Szeles *et al.*, 2017). It was found that the replacement of 20% cement with $Al(OH)_3$ significantly reduced silica dissolution and prevented ASR expansion.

The ASR mitigating effects of lithium, calcium and aluminum salt solutions were compared at five dosages: 0.6, 1.2, 1.8, 2.4, and 3.0 N of the initial mixing water. Figure 1 compares the ASR mitigating effects with different salts, at 14-day expansion as a function of additive normality of initial mixing water. The results in Figure 6 are summarized as following:

1. $LiNO_3$ solution has the most ASR mitigating effect in term of expansion reduction, among the four salt solutions tested. The addition of 0.6N of $LiNO_3$ significantly reduced ASR expansion, however this dosage was not enough to suppress the ASR. The 14-day expansion was still 0.59%. With increasing dosage of $LiNO_3$, ASR expansion was continuously reduced. At the highest test dosage of $LiNO_3$ investigated (3.0 N), the 14-day expansion was reduced to 0.10%.
2. At higher dosages (1.2N), the effectiveness of ASR mitigating with $Ca(NO_3)_2$ and $Ca(NO_2)_2$ are almost identical. With addition of 3N of Ca^{2+}, the 14-day expansion was still 0.3%, which is much higher than the 0.1% limit.
3. $Al(NO_3)_3$ solution has a slight ASR mitigating effect at dosages higher than 1.8N, and causes increased ASR expansion at lower dosages.

3.2 Effects of Silica Fume and Metakaolin Slurries on ASR

Silica fume is an ultrafine powder collected as a by-product of the silicon and ferrosilicon alloy production with a very light bulk density of 130 kg/m^3. Densified silica fume is produced by treating silica fume to increase the bulk density up to a maximum of about 400 to 720 kg/m^3. This increase in bulk density is usually accomplished by tumbling the silica fume particles in a silo, which causes surface charges to build up. One harmful consequence of the densification is that significant contents of undispersed grains of the order of several hundred microns are found in cementitious materials treated with densified silica fume (Diamond 1997). The grain can react with OH^- which may give rise to ASR distress. The agglomeration of silica fume particles is illustrated in the low and high magnification SEM images shown in Figure 2. At low magnifcation, the silica fume was clustered in grains of a few microns to several hundred microns, as shown in the left side image in Figure 2. The original size of the silica fume particles were in the range of a few nanometers to several hundred nanometers, as shown in the high magnification image on the right side of Figure 2.

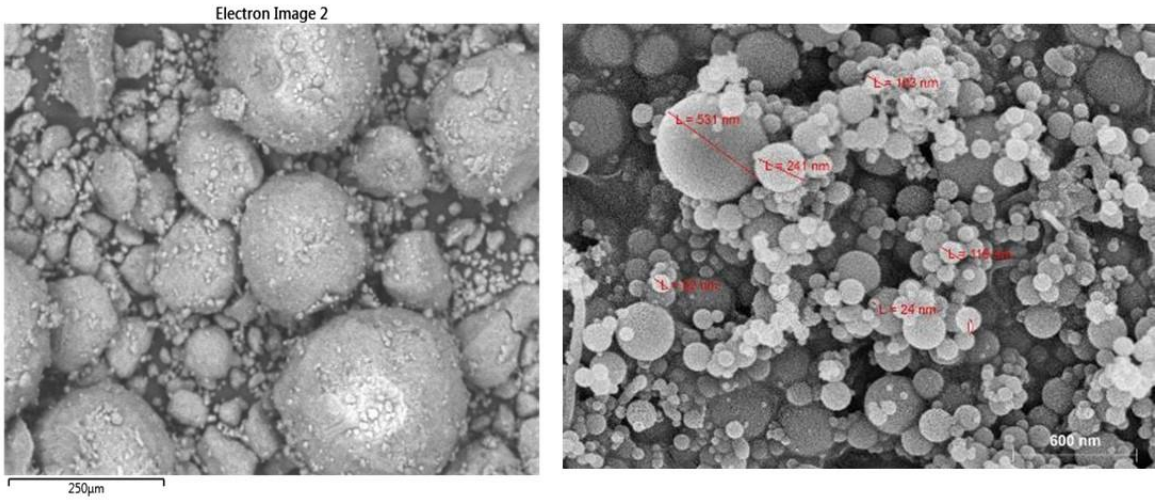

Figure 2. The SEM images of densified silica fume with low and high magnifications.

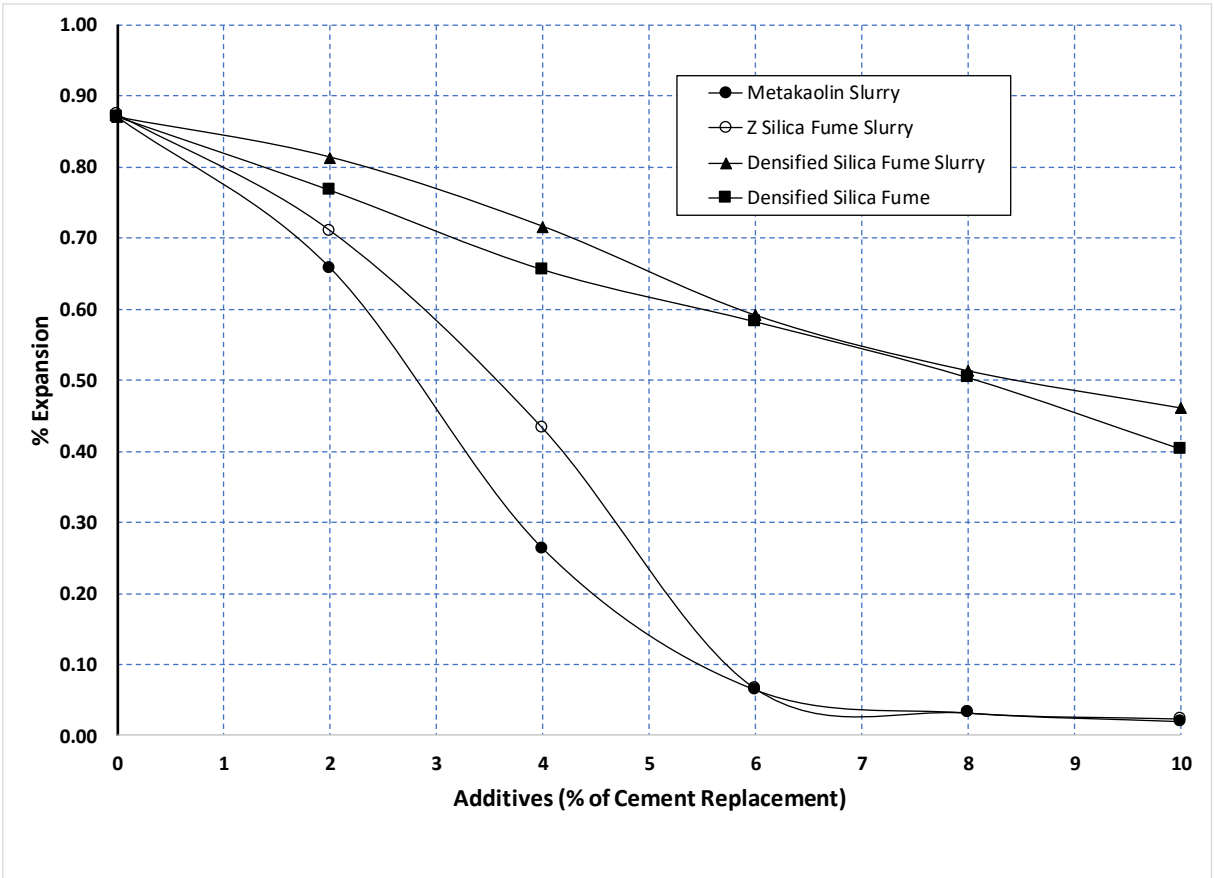

Figure 3. The comparison of ASR mitigating effects of different slurries and densified silica fume.

A direct comparison of the ASR mitigating effects of densified silica fume and the three slurries, at 14-day expansion, as a function of additive percentage by weight of cement replacement, are compiled in Figure 3. The results in Figure 3 are summarized as following:

1. Densified silica fume has the lowest ASR mitigating effect in term of expansion reduction, among the four products tested.
2. Converting densified silica fume to a slurry form only slightly improves the ASR mitigating effect.
3. Metakaolin and Z silica fume slurries have almost identical ASR mitigating effect. When the dosages of both slurries were increased to 6% (dry basis), the ASR was almost stopped, resulting in only 0.07% expansion at 14.

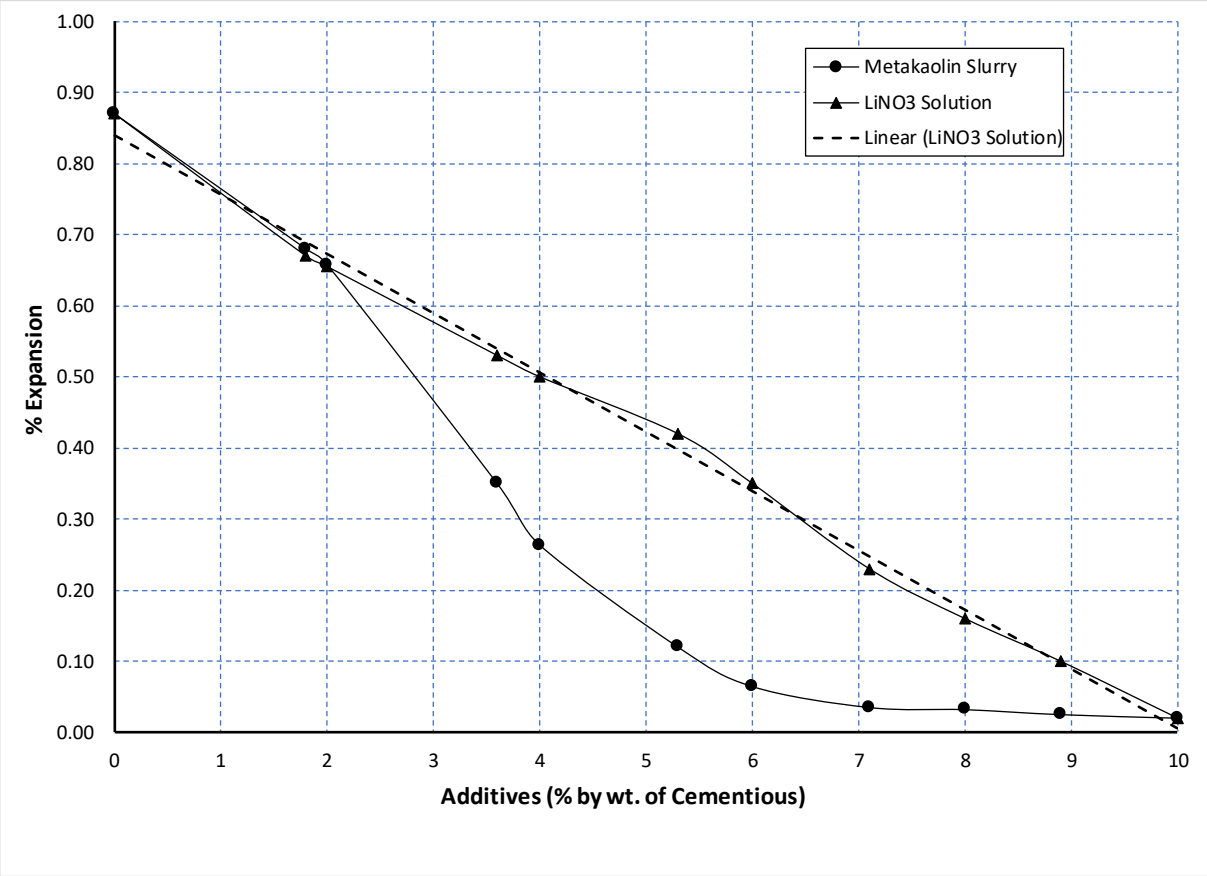

Figure 4. The comparison of ASR mitigating effects of $LiNO_3$ solution and metakaolin slurry.

The ASR mitigating effects of $LiNO_3$ solution and metakaolin slurry are compared in Figure 4. Dosages are expressed as percentage of total cementitious materials on a dry basis. The results in Figure 4 are summarized as following:

1. At low dosages (less than 2%), both $LiNO_3$ solution and metakaolin have similar ASR mitigating effect.
2. The reduction of ASR expansion by $LiNO_3$ solution is increased almost linearly with increasing dosage. To achieve a 14-day expansion less than 0.1%, the dosage of $LiNO_3$ exceeded 8.9% by weight of cement in the current testing condition, whose soak solution is not buffered with $LiNO_3$.

3. At a dosage greater than 2%, the reduction in ASR expansion by the metakaolin slurry is accelerated away from linear. A metakaolin dosage of 6% by weight of total cementitious materials is enough to suppress the ASR.

4 Conclusions

Due to a critical shortage of lithium raw material and difficulty with using densified silica fume, an effort was made to develop an alternative chemical admixture for mitigating ASR. Six dispensible materials were tested as potential candiates to replace $LiNO_3$ and densified silica fume. Based on the results of ASTM C 1567 expansions of mortar bars, the following conclusions can be made:

- For salt solutions, $LiNO_3$ is the best choice for ASR mitigating.
- Solutions of $Ca(NO_3)_2$ and $Ca(NO_2)_2$ have the same ASR mitigating effect, but are not effective enough to stop ASR. Therefore, $Ca(NO_3)_2$ or $Ca(NO_2)_2$ solution itself can't not be the candidate to replace $LiNO_3$ as chemical admixture for mitigating ASR.
- $Al(NO_3)_3$ solution has a weak ASR mitigating effect and a negative effect on workability. It will not be recommended as chemical admixture for mitigating ASR.
- The densified silica fume slurry has only slighly better ASR mitigating effect than densified silica fume. The slurry manufacturing procedure was unable to break-down clustered silica fume particles.
- Both pumpable slurries of metakaolin and Z silica fume have an excellent ASR mitigating effect.

An Experimental Evaluation of the Thermal Performance of Felt Type Vegetated Facade System

Elif Özer Yüksel[1] and Nil Türkeri[2]

[1] Department of Architecture, Faculty of Architecture, Gebze Technical University, Kocaeli, Turkey, e.yuksel@gtu.edu.tr

[2] Department of Architecture, Faculty of Architecture, İstanbul Technical University, Kocaeli, Turkey, sahal@itu.edu.tr

Abstract. *Vegetated facade systems (VFS) have been used as green building envelope systems in recent years. Using VFS for ecological strategies and evaluating thermal performance of these sytems are not a new concept. However, there is not any experimental study in literature which evaluates thermal performance of felt type VFS applied on an insulated existing building wall which is located in Csa climate during cooling and heating periods. Hence, an experimental study was conducted to measure thermal performance of felt type (type which used felt material as growing media) VFS in Kocaeli (under Csa climate). Test results indicate that in day time with high amount of solar radiation, felt type VFS decreased exterior surface temperatures of an insulated existing wall by maximum of 30°C. Also, interior surface temperatures of vegetated facade were lower than interior surface temperatures of reference facade with the maxiumum difference of 1.8°C. Although high differences between exterior surface temperatures of vegetated and reference walls were observed, there was no significant difference between interior surface temperatures of vegetated and reference walls. This is due to the fact that existing building exterior wall assembly includes 5 cm thickness expanded thermal insulation material which enchance thermal performance of brick wall. In addition, indoor air temperatures behind both facades were close to each other, and were not suitable according to ISO 7730 and ASHRAE 55 Standards comfort range for representative summer days with high ambient air temperatures. Nevertheless, indoor air temperatures behind vegetated facade were in the comfort range in the fall representative day which required cooling, while indoor air temperatures behind reference facade were not in the comfort range in summer representative day.*

Keywords: *Vegetated Facade System, Thermal Performance, Field Measurement, Surface Temperature, Sustainability.*

1 Introduction

Fourth Assessment Report of Intergovernmental Panel on Climate Change indicates that average temperature on earth has increased by 0.75 °C from the beginning of the 20th century until today (IPCC, n.d.). Additionally, it is predicted that average air temperature on earth will increase by 1.8-4°C at the end of 21th century (MCCAR, n.d.). Also it is claimed that annual average air temperature in Turkey will rise by 2.5-4°C in following years (Turkey's National Climate Change Adaptation Strategy, 2011). Urbanization causes reduction of huge amount of green areas and replaces them with buildings and surfaces with low albedo value (Cheng *et al*., 2010; Koyama *et al*., 2013; Wong *et al*., 2010). These changes cause a significant rise of urban temperature known as heat island effect, which is responsible for the increase of ambient air temperatures (Wong *et al*., 2010; Alexandri and Jones, 2008). Use of vegetated

surfaces and vegetated facade systems plays an important role to reduce urban heat island effect (Koyama *et al*., 2013; Alexandri and Jones, 2008; Olivieri *et al*., 2014). Greenhouse effect plays also an important role in the increase of ambient air temperatures. Building sector is responsible of 40% of the CO_2 and other greenhouse gases emissions. With improvements in economic development, energy use in building sector has increased (Perez *et al*., 2017; Technology Roadmap, 2013). In order to decrease greenhouse gases emissions it is essential to use renewable energy sources instead of fossil fuels and/or reduce energy consumptions. Energy consumption caused by building sector can be reduced by several sustainable design strategies. One of them is covering walls with vegetation, that is called as vegetated facade systems (VFS). "Greeney" is a common term in literature, hovewer in the present study it is prefered to nomenclature these systems as "vegetated facade systems" because of the reason that main components of these system are vegetation and growing media. Literature review reveals that vegetated facades minimize heat gain through building facade, decrease surface temperature and increase energy efficiency of buildings (Perez *et al*., 2017; Safikhani *et al*., 2014; Raji *et al*., 2015; Konteleon and Eumorfopoulou, 2010; Haggag *et al*., 2014; Feng and Hewage, 2014; Perini *et al*., 2011). Studies in Köppen subgroup "Csa" (mild with no dry and hot summer climate) indicate that vegetated facade systems reduce the maximum exterior surface temperature of reference building surface up to 25°C in cooling period (Olivieri *et al*., 2014; Akbari *et al*., 1997). Aim of the present paper is to evaluate thermal performance of felt type VFS in Csa climate conditions during cooling period in summer and fall seasons. Also, by means of the results of the present study it is aimed to fill the gap in literature regarding data of thermal performance of VFS applied on insulated wall and lack of data for thermal performance of felt type VFS. Initially, design of vegetated facade, instrumental setup and measurement parameters are presented. Subsequently, solar radiation and surface temperature results are given and values of both vegetated and reference facades are comparatively assessed.

2 Materials and Methods

Thermal performance monitoring was conducted at a building located in Gebze Technical University, Gebze, Kocaeli. Gebze Technical University is located at 40°48'41"N, 29°21'19"E (GTU, 2017). Kocaeli is classified as "Csa" (mild with dry and hot summer climate) according to Köppen climate classification. Vegetated facade system and instruments were installed in the first week of September 2016. Trial tests were done during 5 months after installation of experimental setup. Monitoring including whole parameters are started on 04 February 2017.

2.1 Experimental Building

An existing office building located on Gebze Technical University Campus was chosen as experimental building, two facade surfaces of the building were determined to be used as vegetated and reference facades. Both facades are oriented to the south. They are exposed to solar radiation for the majority of the day (especially hours when solar radiation reaches high values) and there are no obstructions in front of the facades. Also, there is no opening in the respective south oriented walls, both facades are fully opaque and have same dimensions. Window to wall ratio (WWR) of east oriented exterior wall of room which south wall was

fully vegetated is 20%, while WWR of east oriented exterior wall of room which south wall was non vegetated is 13%. Spaces behind both facades are office rooms which have approximately similar conditions. Both of them have the same heating and cooling systems, which is air conditioning. It operates between 08:00 and 17:00 during week days and doesn't operate during weekends. Existing wall system of the building is composed of the following components from inside to outside: 19 cm brick wall with 2 cm thickness interior plaster and 5 cm thickness expanded polystrene heat insulation material and 3 cm thickness exterior plaster. This wall system is considered to be reference wall system. Most widely used VFS in Turkey is "felt system" (Yüksel and Türkeri, 2016a). Additionally, there is no previous experimental study in literature in which the thermal performance of a felt type VFS under Csa climate region has been measured during neither cooling period nor heating period (Yüksel and Türkeri, 2016b; Yüksel and Türkeri, 2017). Therefore felt type was chosen as vegetated facade system. Also, "euonymus japonica" was selected due to its well adaptation to survive in temperate and mediterranean climates. The vegetated facade is composed of two main components: existing wall system and vegetated system. Vegetated system consists of following components from inside to outside: 40x40x2mm galvanized steel frame mounted on the wall, PVC panel of 1 cm thickness fixed on this frame, first and second layers of geotextile felt attached on it and vegetation layer embedded the felt pockets.

2.2 Instrumental Setup for Monitoring

An instrumental setup was designed and installed at the reference and vegetated facade systems to measure solar reflectance, surface and air temperatures (Figure 1a,b). Local meteorological data (air temperature and humidity, atmospheric pressure, wind direction and wind velocity) was measured by a weather station installed on the roof parapet of existing building (Figure 1c).

(a)

(b)

(c)

Figure 1. Image of VFS (left) and RFS (middle) and image of the weather station on the roof parapet (right).

Figure 2 designates sections of reference facade and vegetated facade test assemblies. Three pyranometers were used to measure solar radiation incident and solar reflectance. A pyranometer ("I" in Fig. 2b) was installed vertically in front of the vegetated facade to measure solar irradiance reflected from the vegetated facade. Two pyranometers were installed in front of the reference facade vertically and mounted back to back symmetrically. One of these pyranometers, ("D" in Fig. 2a) was used to measure solar radiation incident on reference and vegetated facades and the other ("E" in Fig. 2a) measures solar irradiance reflected from the reference facade. Only one pyranometer was decided to measure incident

solar radiation since solar radiation values reaching each both facades are accepted as identical. Infrared non-contact thermometers were used to measure surface temperatures of exterior wall of reference facade ("F" in Fig. 2a), exterior wall of vegetated facade ("N" in Fig. 2b), back ("M" in Fig. 2b) and front ("L" in Fig. 2b) side of the PVC panel, second layer of felt ("K" in Fig. 2b). Contact thermometers were used to measure surface temperatures of interior walls of reference ("G" in Fig. 2a) and vegetated ("O" in Fig. 2b) facades. Also, indoor temperature and humidity sensors were placed 20 cm in front of the interior wall surface of the reference ("H" in Fig. 2a) and vegetated ("P" in Fig. 2b) facades in order the measure indoor air temperature of the rooms behind the vegetated and reference walls. Additionally, a temperature sensor ("J" in Fig. 2b) was placed inside the leaves to measure the air temperature among leaves (Yüksel and Türkeri, 2017).

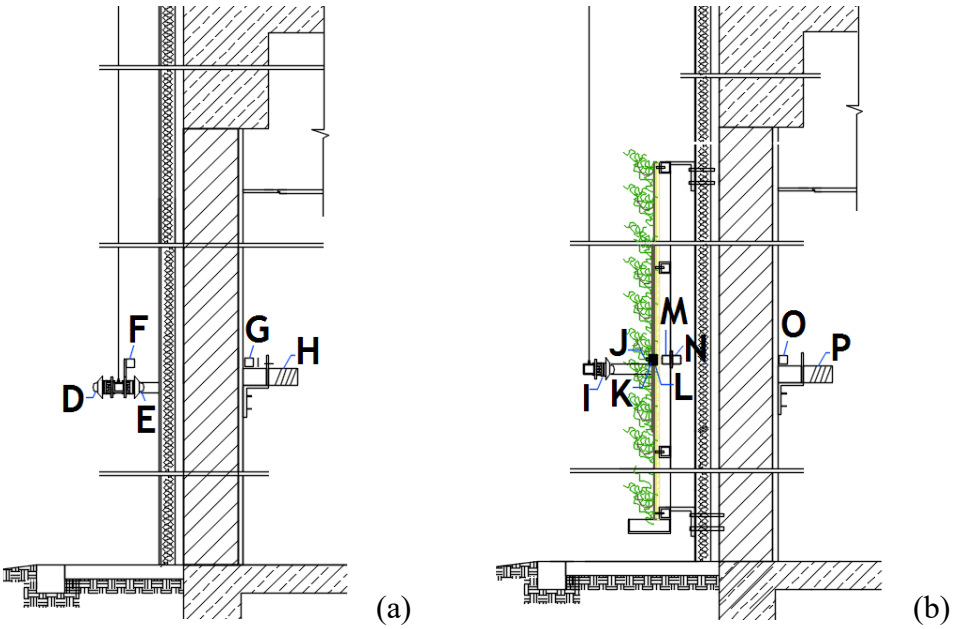

Figure 2. Section of reference facade (left) and vegetated facade (right) test assemblies.

Monitoring periods included months representing summer and fall seasons of the year 2017. Data regarding each parameter was recorded every 10 minutes during these periods. Nevertheless, user behaviours were found to be different in office rooms during weekdays behind vegetated and reference rooms. Hence, representative weekend days were selected for the summer and fall periods when high solar radiation was observed and exterior surface temperatures of reference facade reached maximum values.

3 Test Results

Exterior and interior surface temperatures and indoor air temperatures of vegetated and reference facades were compared with each other. Also, indoor air temperatures were evaluated according to comfort temperature range identified in ISO 7730 and ASHRAE 55 Standards. Additionally, solar reflectance ratio of reference facade and vegetated facades were compared with each other. Solar reflectance ratio were calculated according to ASTM E

1918:2006 (ASTM E1918:2006). For each representative day and for both facades, the ratio of reflected solar irradiance values to total solar irradiance values was calculated between 09:00-15:00. August 12, 2017 and September 24, 2017 were chosen as representative days for the summer and fall periods, respectively, because of the reason that high solar radiation values occured and exterior surface temperatures of reference facade reached maximum values in that hot days. Test results regarding that days such as microclimate values, solar reflectance values of reference and vegetated walls and maximum exterior surface temperatures of reference and vegetated facades are shown in Table 1.

Table 1. Microclimate, solar reflectance and maximum exterior surface temperature values observed on August 12, 2017 and September 24, 2017.

Ambient air temp. ranges	Relative humidity ranges	Max. solar radiation reaching to facades	Max. solar radiation reflecting from RFS	Max. solar radiation reflecting from VFS	Solar reflectance of RFS	Solar reflectance of VFS	Max. exterior surf. temp. of RFS	Max. exterior surf. temp. of VFS
22.4°C - 33.1°C	29% -93%	454W/m^2 (at 14:10)	364W/m^2	54W/m^2	0.88	0.12	53.2°C (at 14:40)	30°C (at 16:40)
13.1°C - 25.6°C	39% -93%	642W/m^2 (at 14:10)	448W/m^2	73W/m^2	0.80	0.10	53.3°C (at 15:00)	23.6°C (at 15:50)

Exterior surface temperatures of vegetated wall were extremely lower than exterior surface temperatures of reference wall for both periods during the day time (Figure 3 and Figure 4).

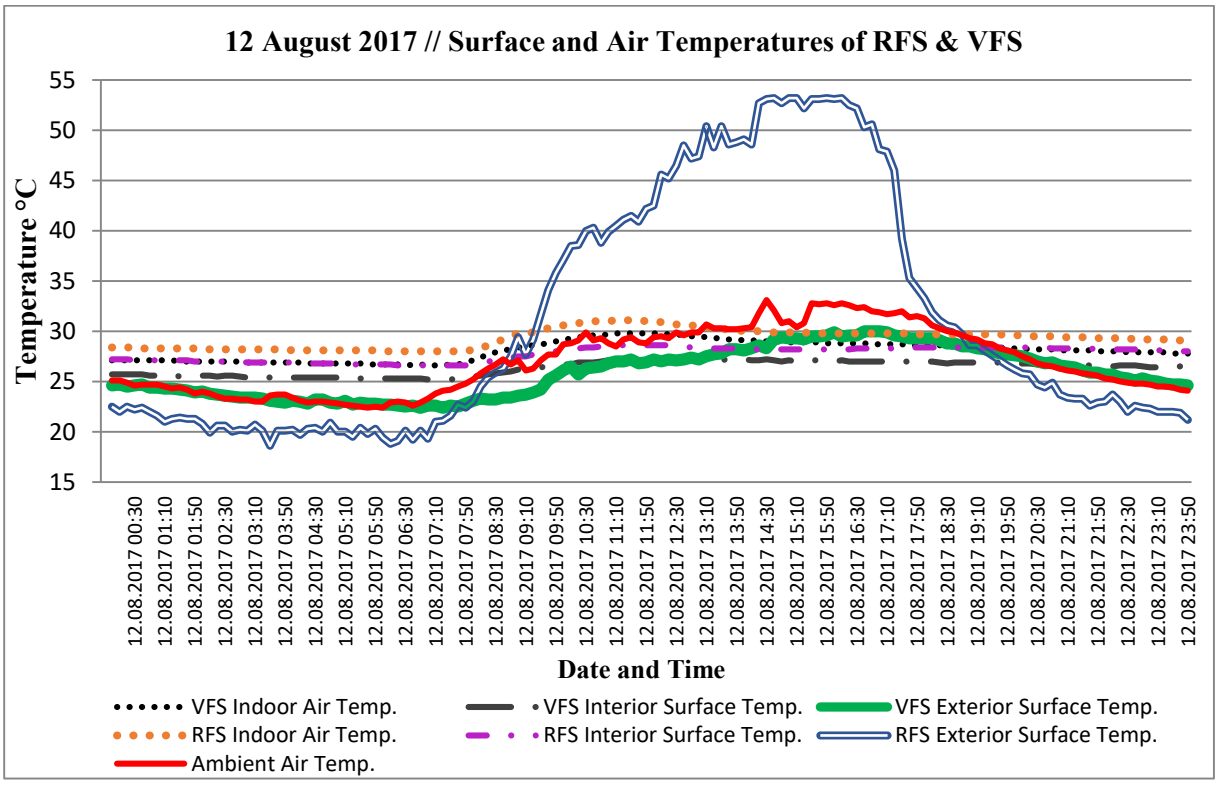

Figure 3. Exterior and interior surface and indoor air temperatures of RFS and VFS on August 12, 2017.

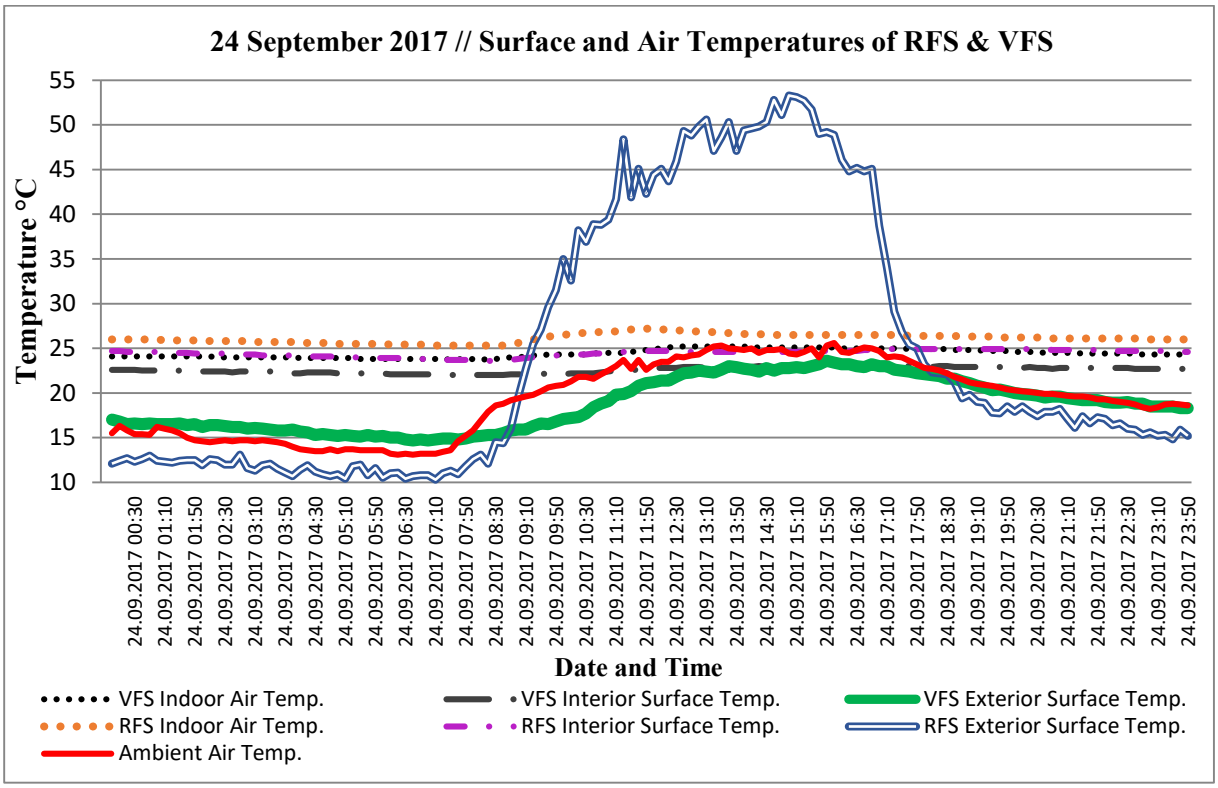

Figure 4. Exterior and interior surface and indoor air temperatures of RFS and VFS on September 24, 2017.

Differences between maximum exterior surface temperatures of reference and vegetated facades were 24°C and 30.5°C for representative days of summer and fall periods, respectively. Also, during the night time, exterior surface temperatures of vegetated wall are higher than exterior surface temperatures of reference walls for both periods. Interior surface temperatures of reference facade were also higher than interior surface temperatures of vegetated facade along the day time. Differences between maximum interior surface temperatures of reference and vegetated facades were 1.3°C and 1.8°C for representative days in summer and fall periods, respectively (Fig. 3 and Fig. 4). Additionally, Fig. 3 presents that on August 12, indoor air temperatures behind both facades were not in the range of 23-26°C which is recommended as a comfort range for cooling period in ISO 7730:2005 Standard and ASHRAE Standard 55-2010. Nevertheless, on September 24, max. indoor air temperature (25°C) behind vegetated facade is lower than upper limit value of 26°C, while maximum indoor air temperature (26.5°C) behind reference facade is higher than 26°C (Fig. 4).

4 Discussion

Although high differences between exterior surface temperatures of vegetated and reference walls were observed, there was no significant difference between interior surface temperatures of vegetated and reference walls. Also, there was no significant difference between indoor air temperatures behind vegetated and reference walls. The results regarding indoor air temperature differences between vegetated and reference facade showed similarities with the results of the study conducted under a different climate condition

(Cfa:humid subtropical climates) by Chen et al., (2013) which revealed that cooling effect of VFS on the indoor environment is relative small because of the high heat resistance of the wall. If the existing exterior wall was designed without any thermal insulation, it is obvious that the VFS would present greater passive cooling effect. In addition, indoor air temperatures behind both rooms were not suitable according to comfort temperature ranges indicated in standards for representative summer day. Nevertheless, indoor air temperatures behind VFS were in the comfort range in the fall representative day in day time which required cooling, while indoor air temperatures behind reference facade were not in the comfort range. Also, it can be claimed that indoor air temperatures of both rooms were not only affected by exterior surface temperatures of south oriented walls, but also by the surface temperatures of interior walls, ceeling, slab and east oriented exterior walls. Also, it can be assumed that vegetated room gained and lost more heat through windows due to higher WWR compared with reference room. It can be claimed that if east facades of both rooms had same WWR, vegetated room would show greater performance in terms of indoor air temperatures compared with reference room.

5 Conclusions

It can be concluded that felt type VFS decreases exterior surface temperatures of an insulated existing wall located in Csa climate. In addition, most remarkable results were observed in fall period, and in that period the differences between exterior surface temperatures of reference and vegetated facades reached to 30.5°C. These results suggest that VFS has a positive contribution on thermal performance of building wall during cooling period. In addition, solar reflectance of reference facade was 3-8 times higher than solar reflectance of VFS. Although solar reflectance of reference facade was higher than solar reflectance of VFS, exterior surface temperature of vegetated facade was significantly lower than exterior surface temperature of reference facade. That is because VFS transfers less energy to exterior wall of building even though VFS absorbs more solar radiation compared with reference facade system. Thus, it can be claimed that VFS uses most of energy reaching on its surface and so transfers less amount of energy to the exterior wall surface of building wall. Also, lower solar reflectance values of VFS indicate that these systems have positive impact on reducing urban heat island effect.

An Experimental Study on the Thermal Conductivity of Concrete Containing Coal Bottom Ash Aggregate

In-Hwan Yang, Jihun Park and Hoe-Won Jung

Kunsan National University, Department of Civil Engineering, Jeonbuk 54150, Kunsan, Republic of Korea, ihyang@kunsan.ac.kr

Abstract. *Thermal conductivity plays a significant role in efficient energy usage, especially in the construction field. Low thermal conductivity is preferable because lower thermal conductivity will increase the thermal insulation provided by the concrete and reduce the heating and cooling costs for residential and commercial buildings. To accomplish this goal, porous materials can be considered for use in concrete. Additionally, researchers have had challenges producing high-strength concrete with low thermal conductivity. Therefore, this study aims to investigate the effects of replacing crushed fine aggregates with coal bottom ash (CBA) on the thermal conductivity and mechanical properties of high-strength concrete. The concrete properties, including unit weight, compressive strength, and thermal conductivity, were measured. The experimental results revealed that the thermal conductivity of the CBA concrete decreased as the unit weight of the CBA concrete decreased, and the thermal conductivity also decreased as the compressive strength decreased. Finally, the relationships between the thermal conductivity, unit weight, and compressive strength of the CBA concrete were also examined.*

Keywords: *Coal Bottom Ash, Thermal Conductivity, High-Strength Concrete, Porosity.*

1 Introduction

Currently, the demand for energy-efficient buildings is increasing to optimize the internal temperature of buildings (Najjar *et al.,* 2019). One of the key factors for optimizing energy efficiency is thermal conductivity. When a building is constructed from materials with higher thermal conductivity, to ensure the internal temperature of the building, a greater amount of energy must be consumed for cooling and heating. To address this issue, materials with low thermal conductivity are recommended during construction. Thus, considering concrete with low thermal conductivity is the most suitable choice.

To produce concrete with low thermal conductivity, Aghdam *et al.* (2019) carried an experimental study to estimate the effects of carbon nanotubes on the thermal conductivity of steel fiber-reinforced concrete. Their test results indicated that the agglomeration of carbon nanotubes caused a decline in the concrete thermal conductivity. However, the use of carbon nanotubes is expensive, and high-strength concrete is not considered.

Currently, coal-fired thermal power plants create a substantial amount of bottom ash and fly ash. Bottom ash is industrial waste produced at the bottom of coal furnaces. To develop concrete

doi:10.23967/dbmc.2020.172

with low thermal conductivity for energy efficiency, an experimental study to investigate the effects of partial or total replacement of crushed fine aggregates with coal bottom ash (CBA) on the thermal properties of concrete is vitally necessary.

Therefore, in this experimental study, the thermal conductivity and mechanical properties of high-strength concrete specimens containing 25, 50, 75, and 100% replacement of crushed fine aggregates with CBA were investigated at a curing age of 28 days. The compressive strength, unit weight, and thermal conductivity of these specimens were measured. The relationships between the thermal conductivity, unit weight, and compressive strength of the CBA concrete were also examined.

2. Experimental Program

2.1 Materials

Figure 1. CBA aggregate.

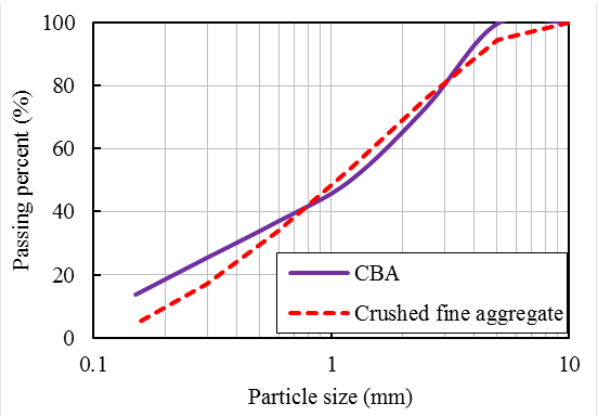

Figure 2. Grading curve of CBA and crushed fine aggregate.

Table 1. Physical properties of fine, coarse and coal bottom ash aggregate.

	Fineness modulus	Water absorption (%)	Unit weight (g/cm^3)
Crushed fine aggregate	3.17	0.69	2.60
Coarse aggregate	6.77	1.44	2.61
CBA	3.83	6.87	1.84

The coal bottom ash used in this study was collected from a thermal power plant company in Korea. The CBA aggregate was screened to remove particles greater than 5.0 mm and to retain the particles greater than 0.15 mm. The CBA used for this study is presented in Figure 1, and the particle size distribution of the CBA is also presented in Figure 2. The test results of the density and water absorption of the CBA are shown in Table 1. The particle size distribution of the crushed fine aggregates is illustrated in Figure 2. The unit weight, water

absorption and fineness modulus results of the crushed fine and coarse aggregates are also shown in Table 1.

2.2 Mix Proportions

A concrete mix was designed with a target compressive strength of 60 MPa at a curing age of 28 days. The mixing proportions of the control concrete and coal bottom ash concrete are indicated in Table 2. The crushed fine aggregate was replaced with five different volume fractions (0, 25, 50, 75, and 100%) of coal bottom ash in the concrete.

Table 2. Mixing proportions of the coal bottom ash concrete.

Mixtures	Replacements of CBA (%)	W/C	Water	Unit content (kg/m^3)				
				Cement (OPC)[a]	Coarse aggregate	Fine aggregate	Coal bottom ash	HWRA[b] (0.6% × cement)
CBA00	0	0.3	178.5	595	878.5	663	0	3.6
CBA25	25	0.3	178.5	595	878.5	497.2	117.7	3.6
CBA50	50	0.3	178.5	595	878.5	331.5	235.3	3.6
CBA75	75	0.3	178.5	595	878.5	165.7	353	3.6
CBA100	100	0.3	178.5	595	878.5	0	470.7	3.6

a: OPC: ordinary Portland cement.
b: HRWA: high water reducing agent.

2.3 Specimens and Test Procedures

Cylindrical specimens with dimensions of 100 mm × 200 mm were cast to measure the unit weight, compressive strength, and thermal conductivity of the different samples. The unit weight, compressive strength, and thermal conductivity of the CBA concrete were measured at a curing age of 28 days. The thermal conductivity of each specimen was measured using a transient plane source (TPS) measurement system, as shown in Figure 3.

3 Test Results and Discussion

3.1 Unit weight

The unit weight results of the concrete specimens with different coal bottom ash ratios are shown in Figure 4. The figure indicates that the unit weight of the CBA concrete decreased as the replacement of crushed fine aggregate with CBA increased in the concrete. At a curing age of 28 days, the unit weight of the control mixture was 2,370 kg/m^3, whereas the unit weights of the coal bottom ash concrete mixtures CBA25, CBA50, CBA75, and CBA100 were reduced by 2.1, 3.2, 5.3, and 7.6%, respectively. The decrease in the unit weight of the CBA concrete mixtures is due to the replacement of coal bottom ash, which is a lighter fine aggregate than crushed fine aggregate, as shown in Table 1.

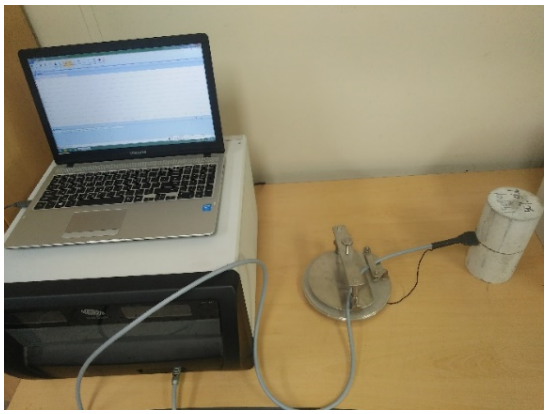

Figure 3. Test setup for thermal conductivity measurements.

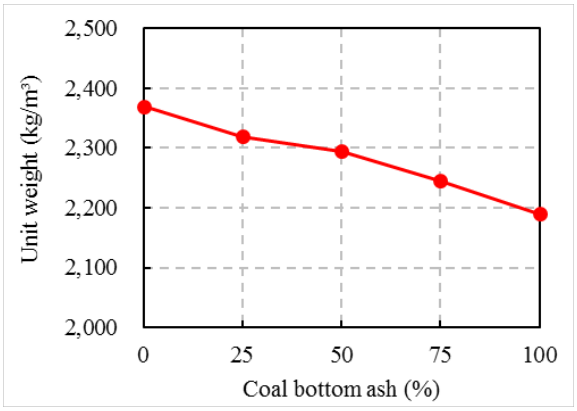

Figure 4. Effect of CBA replacements on unit weight of concrete.

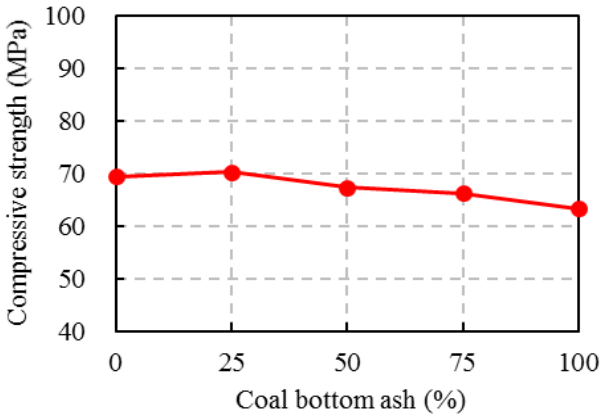

Figure 5. Effect of CBA replacement on compressive strength.

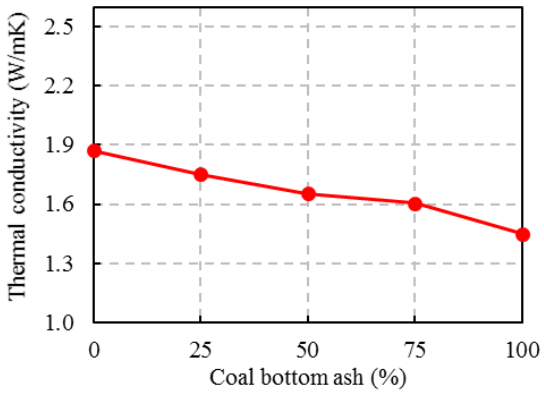

Figure 6. Effect of CBA replacement on thermal conductivity.

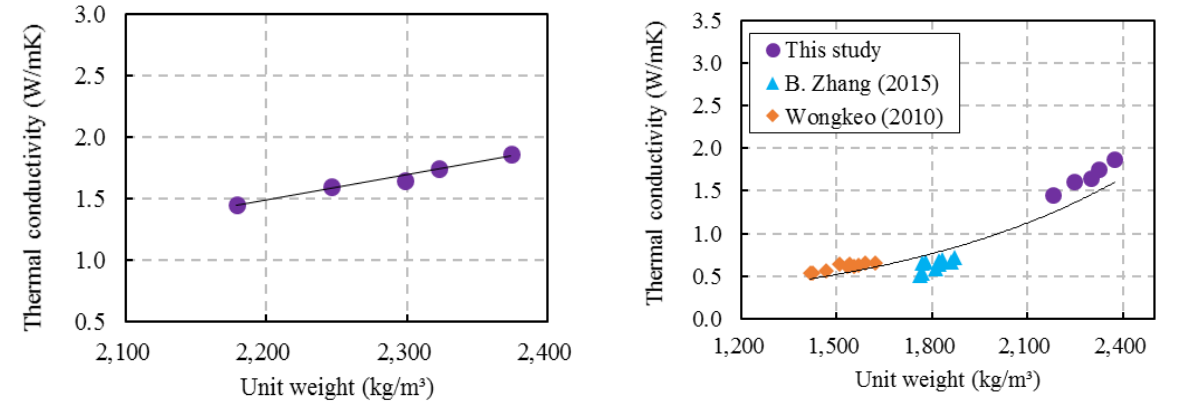
3.2 Compressive Strength

The test results of the compressive strength of the concrete specimens with different coal bottom ash contents are summarized in Figure 5. Generally, at a curing age of 28 days, the compressive strength of the CBA mixtures decreased as the CBA replacement increased. The compressive strength of the coal bottom ash concrete mixtures CBA50, CBA75, and CBA100 were 3.0, 4.6, and 8.8% less than that of the control concrete mixture (69.4 MPa), respectively. However, the compressive strength of the coal bottom ash concrete mixture CBA25 was insubstantially higher (1.2%) than that of the control concrete mixture. The compressive strength loss could be explained by the increase in the porosity of the concrete. These porosities cause negative impact on concrete matrix and reduce the compressive strength of the CBA concrete specimens [Singh *et al.,* 2014].

3.3 Thermal Conductivity

The thermal conductivities of the concrete specimens with different CBA contents are presented in Figure 6. At a 28-day curing age, the thermal conductivities of the CBA mixtures decreased as the CBA content increased. The thermal conductivities of the CBA concrete

mixtures CBA25, CBA50, CBA75 and CBA100 were 6.4, 11.7, 14.2, and 22.5% less than that of the control concrete mixture (1.87 W/m·K), respectively. The thermal conductivity of the CBA concrete with a 100% CBA content was significantly less than that of the control concrete mixture. It is known that thermal conductivity highly depends on the lightweight aggregate pore structure, the concrete density and the cement paste. Hence, the pore structure was one of the key elements affecting thermal conductivity (Tasdemir *et al.,* 2017). For that reason, the observed decline in thermal conductivity could be explained by the increase in the CBA concrete in the concrete. As the CBA content increased, the total volume of porosity of the concrete increased, and the thermal conductivities of the concrete decreased. Reducing the thermal conductivity would increase the thermal insulation provided by the concrete and reduce the heating and cooling costs for buildings.



(a) Test results of this study

(b) Comparison between this study and previous studies

Figure 7. Relationship between the thermal conductivity and unit weight.

The relationship between the thermal conductivity and unit weight of the CBA concrete is demonstrated in Figure 7. As the unit weight of the CBA concrete increased, the thermal conductivity of the CBA concrete increased. Moreover, the thermal conductivity of the CBA concrete is nearly linearly proportional to the unit weight. Increasing the air voids or lightweight aggregate in concrete is a method to reduce unit weight and thermal conductivity. A similar trend was found when analyzing the test results of Wongkeo *et al.* (2010) and Zhang *et al.* (2015), in which the unit weights ranged from 1417 to 1621 kg/m^3 and from 1760 to 1870 kg/m^3, respectively, as shown in Figure 7(b).

The relationship between the thermal conductivity and the compressive strength is demonstrated in Figure 8. This relationship is similar to the relationship between the thermal conductivity and unit weight of the CBA concrete. Additionally, the thermal conductivity has a direct relationship with the compressive strength of the CBA concrete. Figure 8(b) shows a similar trend between the test results in the present research and those of other authors.

(b) Comparison between this study and previous studies

Figure 8. Relationship between the thermal conductivity and compressive strength.

4 Conclusions

In this research, an experimental study was performed on the low thermal conductivity of high-strength concrete specimens with different CBA replacement ratios. The research findings are summarized hereafter:

- The thermal conductivity of the CBA concrete is highly dependent on the porosity in the concrete specimens. For that reason, as the CBA content increased, the thermal conductivity of the CBA concrete decreased gradually. Remarkably, when replacing all the crushed fine aggregate with CBA, the thermal conductivity of the CBA concrete was 22.5% less than that of the control mixture.
- As the coal bottom ash content in the CBA concrete increased, the compressive strength of the CBA concrete decreased. In particular, the compressive strength of mixture CBA100 was 8.8% less than that of the control mixture CBA00.
- As the compressive strength of the CBA concrete decreased, the thermal conductivity of the CBA concrete also decreased.

Abstract. *Surface chloride concentration (Cs) is one of the parameters that feed models used to simulate chloride ingress into concrete. Therefore, understanding its behaviour over time is important for a more accurate forecasting. This work is part of a larger researcher project that aims to analyse the transport of chlorides into concrete in marine atmosphere zone based on long-term field exposures. The present paper focuses on the behaviour of Cs along 12.5 years. Prismatic concrete specimens with three different mixtures were exposed at places located at four different distances from the sea. Climatic variables and chloride deposition on the wet candle were parameters used to characterise the environment. Periodically, samples from concrete surface were extracted from the specimens and chemically analysed. Results show that Cs increases along the years and suggests a tendency of stabilisation over time, although this level could not be reached in the present exposure period. The relationship between Cs and chloride deposition rate on the wet candle was analysed and it was observed that the function* $Cs = C_0 + k_{cs}.(Dac)^n$ *is the one that best fits to experimental data.*

Keywords: *Concrete, Corrosion, Marine Atmosphere Zone, Surface Chloride Concentration.*

1 Introduction

Surface chloride concentration (*Cs*) is one of the main parameters to feed models used to simulate chloride penetration into concrete structures. It has been observed that *Cs* tends to increase over the years (Costa and Appleton, 1999; Yang *et al.*, 2017). However, this increase tendency weakens along time reaching a stabilisation, which can be observed after about ten years of exposure time in some cases (Andrade *et al.*, 2000). This behaviour can be represented by some mathematical models, which are presented in Table 1, that shows functions proposed in literature to represent the behaviour of *Cs* in concrete structures exposed in marine atmosphere zone.

It can be observed that there are not many studies aimed on the behaviour of *Cs* and that most of functions are power or exponential functions, with a predominance of first one.

Analysing the results presented by the studies referenced in Table 1 it can be observed that, in general, *Cs* sharply increases in the first years and, in the following years of exposure, this trend gives way to a more understated increase. Depending on the function adopted to represent

data behaviour, its final part can assume a more asymptotic shape, which denotes a stabilisation trend along the years. Moreover, in some cases *Cs* presents some fluctuation, which can be a result of the environmental interaction (Andrade *et al.*, 2000; Meira, 2004).

Table 1. Literature models to represent surface chloride concentration behaviour in marine atmosphere zone.

Source of data	Exposure time (years)	Function	Authors	Year
Japan	23 - 58	$Cs=a.t^{0,5}$	Uji *et al.*	1990
Portugal	0.5 - 5.5	$Cs=a.t^{b}$	Costa and Appleton	1999
United States of America	2 - 16	$Cs=a.(1-e^{b.t})$	Kassir *et al.*	2002
South Corea	0.7 – 48.7	$Cs=a.Ln.(b.t+1)+c$	Pack *et al.*	2010
Data from literature	0 – 3	$Cs=a+b.t^{0,5}$	Zhou *et al.*	2016
Data from literature	0 - 5	$Cs=a.(1-e^{b.t})$	Yang *et al.*	2017

Cs = surface chloride concentration *t* = exposure time

Regarding the shape of *Cs* curve, the continuous cement paste hydration along time is one of the aspects that may influence its behaviour. As hydration of cement paste advances, the concrete surface becomes less porous and less chloride ions can be captured in this region (Maheswaram and Sanjayan, 2004; Pack *et al*., 2010). As a consequence, the rate of Cs increase weakens. Besides that, the concrete ability in capturing chlorides decreases with the chloride concentration increase, which also contributes in the same way.

Another aspect to be considered in this analysis is the aggressiveness of the environment to which concrete structure is subjected. At places with a higher availability of chlorides there is a stronger increase of *Cs* in the first years with a subsequent attenuation with time (Sandberg *et al*., 1998; Costa and Appleton, 1999). However, along the years, *Cs* may present some fluctuation, which can be related to the ions movement towards bulk concrete or to effects like surface chloride removal due to rainfall.

Although there are some proposals to represent *Cs* behaviour along time in marine atmosphere zone, they are still scarce and there is no consensus related to the best function to represent *Cs* behaviour. This work contributes to this discussion and analyses the behaviour of *Cs* in concretes exposed along 12.5 years at a marine atmosphere zone located in northeast of Brazil. This is part of a project that studies the long-term chloride transport into concrete under natural exposure in marine atmosphere zone.

2 Experimental Work

Experimental work was based on environmental characterisation and chloride concentration measurements in concrete surface.

2.1 Environmental Characterization

The environmental characterization was done on temperature, relative humidity, rainfall, wind characteristics and sea-salt data. Climatic data were collected by a Brazilian Government weather station located in the region where the research took place. Sea-salt data was collected

at places 10, 100, 200 and 500 m far from the sea (Figure 1 and Table 2) using the wet candle method, according to ASTM standard G140 (ASTM, 2014).

Figure 1. Region where wet candle devices and concrete specimens were exposed.

Table 2. Geographical coordinates of exposure sites in northeast of Brazil.

Distance from the sea (m)	Latitude	Longitude
10	7º1'42.9''	34º49'50.1''
100	7º1'42.2''	34º49'52.8''
200	7º1'41.0''	34º49'55.8''
500	7º1'47.2''	34º50'13.1''

2.2. Surface Chloride Concentration in Concrete

Prismatic concrete specimens (0.15 x 0.15 x 1.40 m) were cast using a filler-modified Portland Brazilian cement, which chemical and physical properties are presented in Table 3. Concrete mixtures, with w/b ratios between 0.65 to 0.50, and physical properties are presented in Table 4. They are identified as C65, C57 and C50. Considering that these mixtures were performed a long time ago, they considered w/b that are not usual nowadays.

Table 3. Chemical and physical properties of used cement.

Composition (%)	SO_3	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Na_2O	K_2O	Insoluble residue (IR)	Loss on ignition (LI)
	3.21	18.11	4.31	2.27	59.87	3.61	0.21	1.51	1.45	5.50
Property	Specific surface (cm^2/g)			Specific density (g/cm^3)						
	3650			3.06						

Table 4. Concrete mixtures and properties.

Concrete	C50	C57	C65
Mixture			
Cement (kg/m^3)	406	356	320
Sand (kg/m^3)	769	812	840
Coarse aggregate (kg/m^3)	947	947	947
Plasticiser (kg/m^3)	1.22	1.06	-
w/b	0.5	0.57	0.65
Property			
Slump (mm)	80	80	80
Compressive strength (MPa – 28 days)	31	27	20

The specimens were cured in a wet chamber for 7 days and afterwards they were painted with a waterproof film at those surfaces thorough which chloride penetration should be avoided. Then, the specimens were placed at the same monitoring stations used for wet candle devices. After 6, 10, 14, 18, 46, 78 and 150 months of exposure, samples were extracted from the specimens to obtain chloride profiles in concrete. Although chloride profiles were obtained at each sampling period, here only surface chloride contents are analysed. These samples were extracted in the first millimetre of the exposure surfaces of specimens. The total chloride content was determined by potentiometric titration, following the procedures of the International Union of Laboratories and Experts in Construction Materials, Systems and Structures (RILEM, 2002).

3 Results and Analysis

Climatic results show that temperature ranged between 16 and 33.6 ºC along this period, with an average value of 27 ºC. The relative humidity presented a fluctuation between 55 and 99 %, with an average value of 76.6 %. Higher values were reached during the winter (rainy season) that takes place mainly between May and August. Wind speed data ranged between 1.5 and 7.6 m/s, with average value in this period around 3 m/s. Predominant wind directions were south (S), southeast (SE) and East (E), with a preponderance of SE winds. This is a typical behaviour for the studied region (Meira *et al*., 2006).

Average chloride deposition data are presented in Figure 2. This figure shows a strong salinity decrease in the first meters far from the sea, which may affect reinforced concrete structures in different levels. This drop in salinity is a consequence of the removal of marine aerosol salt particles due to gravimetric effect joined with other removal mechanisms (obstacles, rain, etc.).

Results of the surface chloride concentration are presented in Figure 3, considering the three different concretes and the four exposure sites and their distances from shoreline. Regarding the general aspects of the data, they show some fluctuation in the first exposure months, followed by a period of significant increase and afterwards a tendency of increase at lower rates, which suggests a tendency of reaching a maximum along time, but that was not possible to be observed in these 12.5 years of exposure. The initial fluctuation of chloride concentration in concrete surface can be attributed to the environmental interaction, where the rainfall can play an important role, due to the wash-out effect [Meira 2004, Chen *et al.*, 2013].

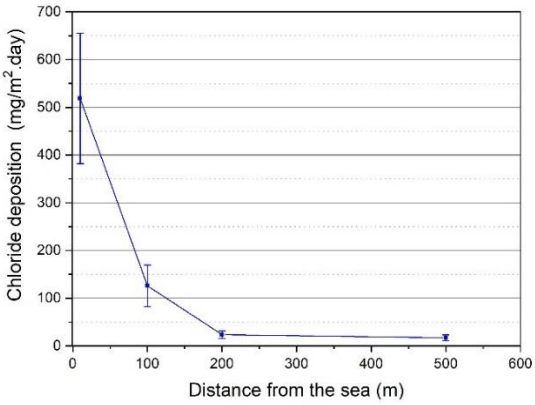

Figure 2. Average chloride deposition data during the research period.

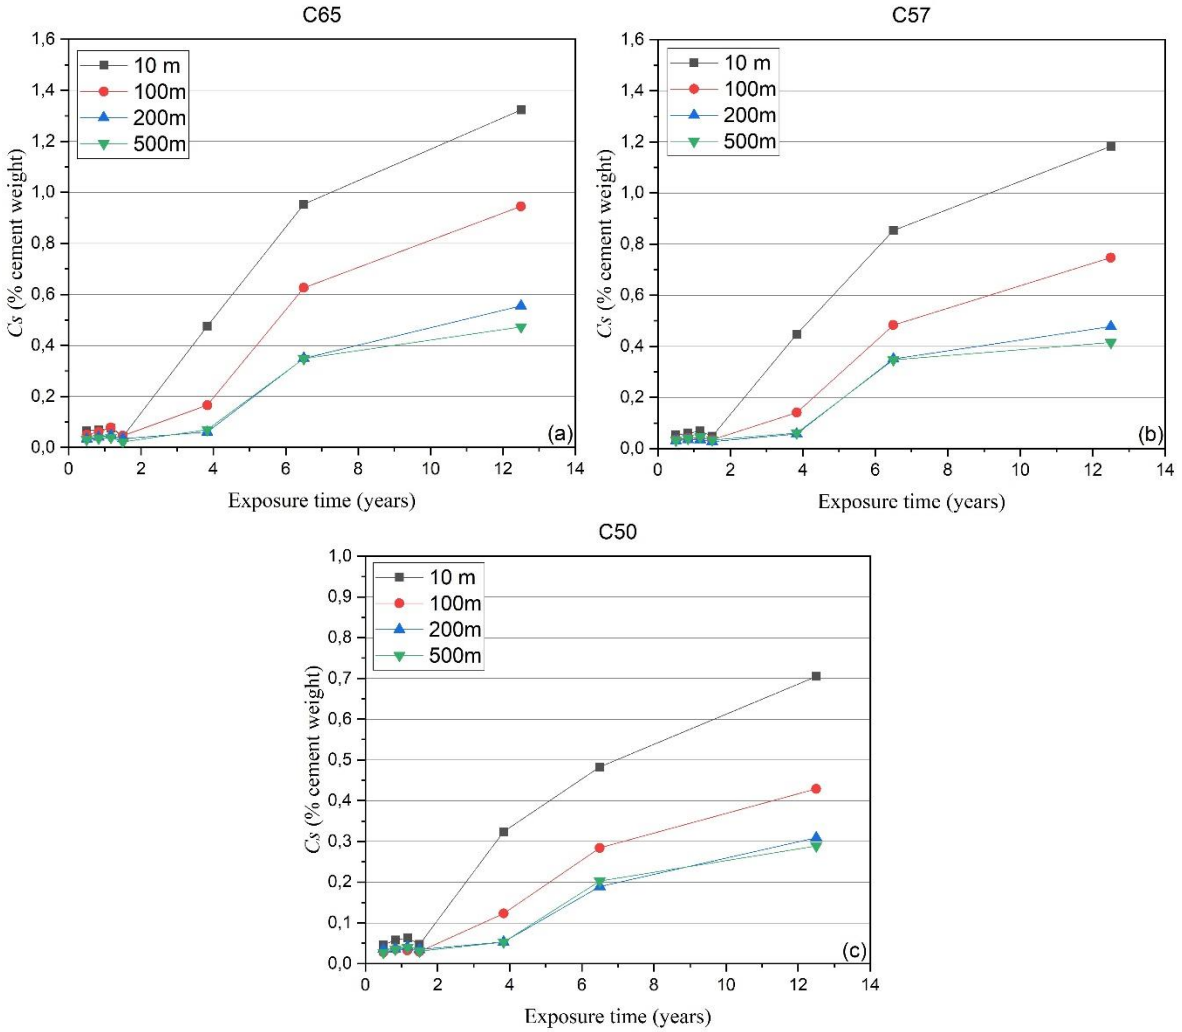

Figure 3. Behaviour of *Cs* along time for concretes C65 (a), C57 (b) and C50 (c).

Regarding the influence of concrete characteristics, it is clear the higher accumulation of chlorides in concrete surface as concrete porosity increases (higher w/b). Moreover, taking into account the distance from the sea, it is noticeable the chloride concentrations decay as going far from the sea, which is a consequence of the aggressiveness decrease at sites far from the shoreline due to the lower availability of chlorides in atmosphere.

Considering that the time is not the main variable that influences *Cs* increase, but the availability of chlorides in atmosphere, it seems quite reasonable to analyse the relationship between *Cs* and the accumulated deposition of chlorides on the wet candle (*Dac*), which is obtained summing month-to-month the chloride deposition on the wet candle (Figure 4).

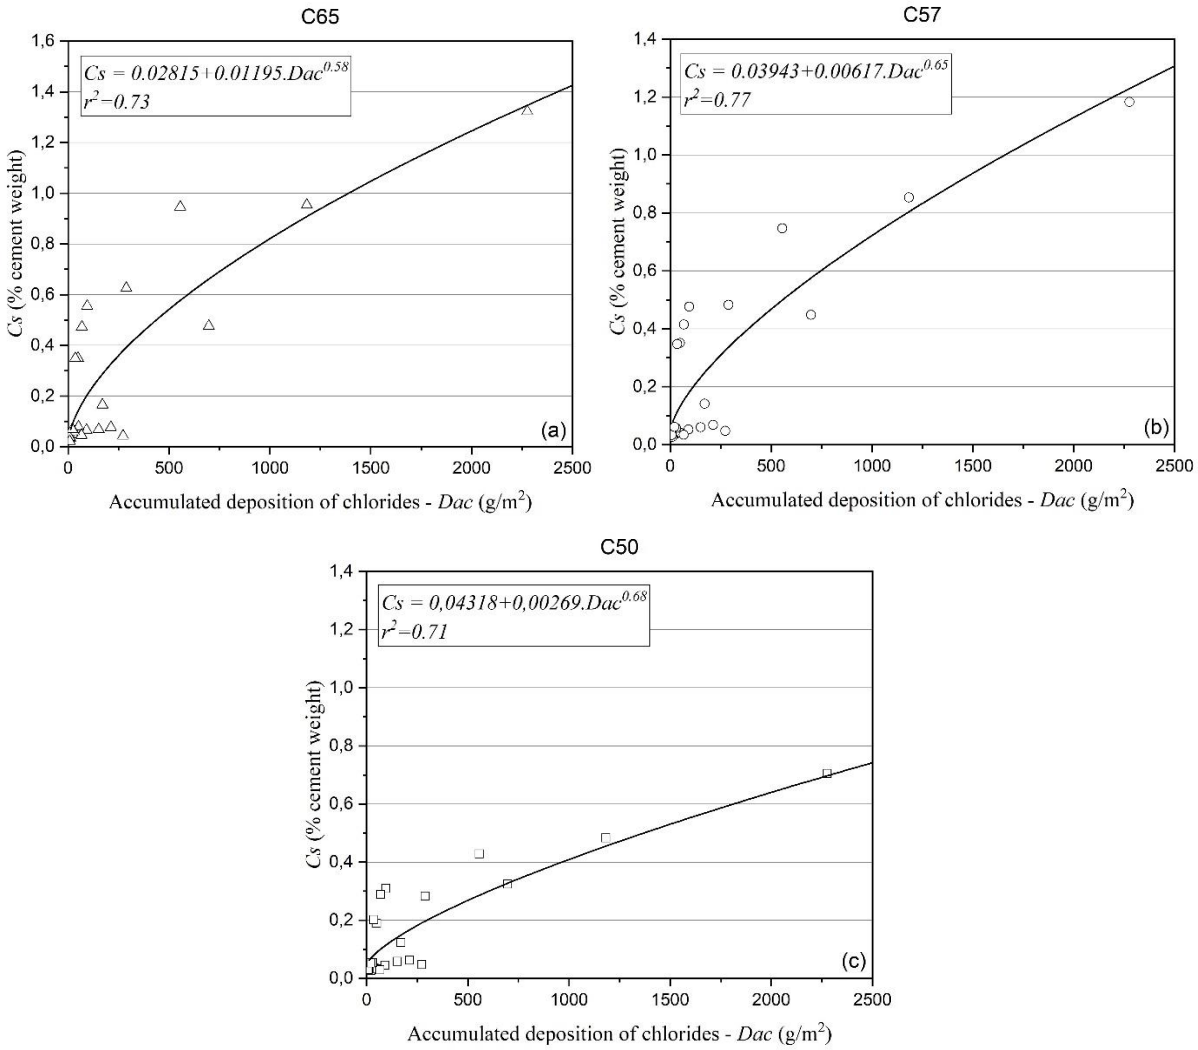

Figure 4. Relationship between *Cs* and accumulated deposition of chlorides (*Dac*) for concretes C65 (a), C57 (b) and C50 (c).

As can be seen in Figure 4, the relationship between *Cs* and *Dac* can be represented by the Equation (1), where *Cs* is the surface chloride concentration, C_0 is the initial chloride concentration in concrete, k_{cs} is a coefficient associated to the concrete ability in capturing

chlorides from atmosphere, *Dac* is the accumulated deposition of chlorides and *n* is a coefficient associated to the rate of *Dac* increase along time.

$$Cs = C_0 + k_{cs}.(Dac)^n \quad (1)$$

This Equation follows a similar way of some previous studies when considered the influence of time on *Cs* increase (Uji *et al*., 1990; Costa and Appleton, 1999; Zhou et al., 2016). However, it has the advantage of taking into account the direct relation between the chlorides present in atmosphere and those captured in concrete surface.

4 Conclusions

The main conclusion that can be drown up from the present analysis are:

- *Cs* increases along time and although tends to reach a maximum, this moment was not reached in 12.5 years of exposure time.
- Concrete porosity influences on *Cs* behaviour in a direct way. Concretes with higher w/b present a faster increase of *Cs* values.
- The availability of chlorides in atmosphere plays an important role in *Cs* behaviour. Higher availability of chlorides means higher *Cs* values. However, this relationship does not follow a linear function.
- The best function to represent the relationship between *Cs* and the availability of chlorides in atmosphere is $Cs = C_0 + k_{cs}.(Dac)^n$, where *Cs* is the surface chloride concentration, C_0 is the initial chloride concentration in concrete, k_{cs} is a coefficient associated to the concrete ability in capturing chlorides from atmosphere, *Dac* is the accumulated deposition of chlorides and *n* is a coefficient associated to the rate of *Dac* increase along time.

Carbonation Effect on the Chloride Profile

Carmen Andrade

International Center for Numerical Methods in Engineering (CIMNE), Universitat Politècnica de Catalunya - BarcelonaTECH, Campus Nord UPC, 08034-Barcelona, Spain, candrade@cimne.upc.edu

Abstract. *In natural marine exposures, the chloride profile may have a maximum in the concrete surface (surface concentration) or this maximum may appear some mm or even centimeters, in depth. This fact has been attributed to a) a "washing effect" due the continuous action of the sea water, b) the wet and dry "convection" induced by the action of the sea water waves c) the leaching of the hydroxide ions or d) the carbonation of the external layer of concrete. In a test in the laboratory, the profile resulting in a diffusion chloride test in most of the cases presents the maximum in the surface of the specimen but seldom has this maximum beyond the surface. This behaviour in natural and in laboratory conditions, although noticed, has not been satisfactorily explained. The author has addressed the problem in a previous communication. In present one shows evidences on the role of the carbonates/bicarbonates in the water of the testing solution. It can be deduced from the analysis of the profiles obtained with de-carbonated solutions that the carbonates/bicarbonates ions compete with the chlorides in the binding with the hydrated cement phases, which results in a modification of the chloride profile and a different diffusion coefficient. The maximum seems to be produced by the higher mobility of the chloride with respect to the carbonate/bicarbonate. The bound chlorides are displaced by the carbonation and the free chlorides move inside forward. In the external parts less total chlorides are noticed because the free chlorides are function of the bound chlorides.*

Keywords: *Concrete, Chlorides, Profile, Maximum, Carbonate.*

1 Introduction

In marine environments, chlorides penetrate trough the pore network of concrete. This ingress is usually modelled, through the so named "error function equation", assuming pure diffusion, a constant external chloride concentration and a constant diffusion coefficient, in spite that wet-dry cycles are produced in the atmospheric and tidal zones. The chloride profiles obtained can have a decreasing shape from the concrete surface or can present a maximum some mm inside the concrete (Andrade *et al*., 1997; Andrade *et al.,* 2015). This "anomalous" profile departing from the fickian behaviour has been attributed to four main causes (Baroghel *et al.,* 2012; Qiang *et al.,* 2011; Lianfang *et al.,* 1999; Ngala *et al.,* 1997; Galan *et al.*, 2015): a) convection due to wet and dry cycling b) leaching of calcium and hydroxides, c) carbonation of the concrete skin or d) that the concrete "skin" has a different microstructure than of the concrete bulk. All these processes may overlap with the pure diffusion. The reasons and the interaction of several of them remain without experimental confirmation. The consequence of this lack of description of the process is one of main limitations for the accuracy of the prediction of concrete service life because the error can be of decades.

Present work contributes to study the effect of carbonation in the production of the profile maximum and in particular, analyses the impact in the chloride testing by pure diffusion (ponding test), because it is studied the effect of de-carbonating the external salt solution by boiling the water. The results show that the carbon dioxide dissolved in the solution

influences the profile shape giving different diffusion coefficient that could explain part of the scatter in the testing. The results also show that the previous carbonation does not prevent completely the chloride binding, that also impacts in the value of the diffusion coefficient deduced from fitting of the error function equation.

2 Experimental

The cement used was an OPC of low C_{3A} content (CEM I 52.5 N-SR). Its chemical composition is shown in Table 1.

Table 1. Chemical composition (%) of CEM I 52.5 N-SR 5.

SiO_2	Al_2O_3	CaO	Fe_2O_3	K_2O	MgO	Na_2O	SrO
19.868	3.751	64.356	4.052	0.65	0.624	0.65	0.051

The specimens were of paste in order to avoid the influence of the aggregate proportion in the further analysis. The w/c ratio was of 0.4. Three cylindrical paste specimens of 200 mm height and 150 mm diameter were moulded. After setting and hardening for 24h, the specimens were cured in the humid chamber with humidity higher than 95% and temperature about 23^{o}C for 6 further days. After removing the specimens from the curing chamber, the three specimens were cut horizontally by its half, in order to have the tests by duplicate exposing the same surface (the cut one) to the salt solution.

The following conditions were tested:

1. Normal salt solution of 30 g/l of NaCl
2. De-carbonated: salt solution of 30 g/l de-carbonated by boiling the water before adding the salt in order to expel out the dissolved gases (air)
3. Pre-carbonated: the specimen was first carbonated and then submitted to the 30 g/l NaCl solution.

When the specimens were cut to have the duplicate samples, two of the set (1 and 2) were sealed on all faces except the exposure surface and a pond was placed on the top (cut surface): in set-1 non-de-carbonated and in set 2 the solution was previously de-carbonated.

The other two duplicates of the set-3 were introduced in a carbonation chamber at 100% CO_2 during 30 days. Then, the pond was placed on the cut surface with a normal solution of NaCl for 90 days. The pond was covered with a plastic film in order to minimize the progressive uptake of air by the solution during the exposure time.

Finally, when removing the pond, chloride profiles were made by grinding the specimens mm-per-mm and analysing the chlorides (total and water soluble) (Castellote *et al*., 2002; Castellote *et al.,* 2002a; Cen 12390-11 2009). In the powder samples it was also determined the portlandite and carbonate contents by Differential Thermal Analisys (DTA).

3 Results

The chloride profiles of the three set of specimens are given in Figure 1. The three profiles differ significantly, mainly when the sample was previously carbonated. Each profile is the average of the duplicate samples, which gave very similar ones. The symbols here and in the rest of Figures are: Set-1 (NaCl), set-2 (Cl+CO_2), set-3 (CO_2).

All the profiles of the three set show a maximum some mm far from the concrete surface. Contrary to what was expected the highest chloride concentration is shown by the set-2 with non-de-carbonated solution. The smallest chloride concentration is logically given by the sample previously carbonated, although the high difference between total and water-soluble chlorides indicates that there is significant amount of bound chlorides.

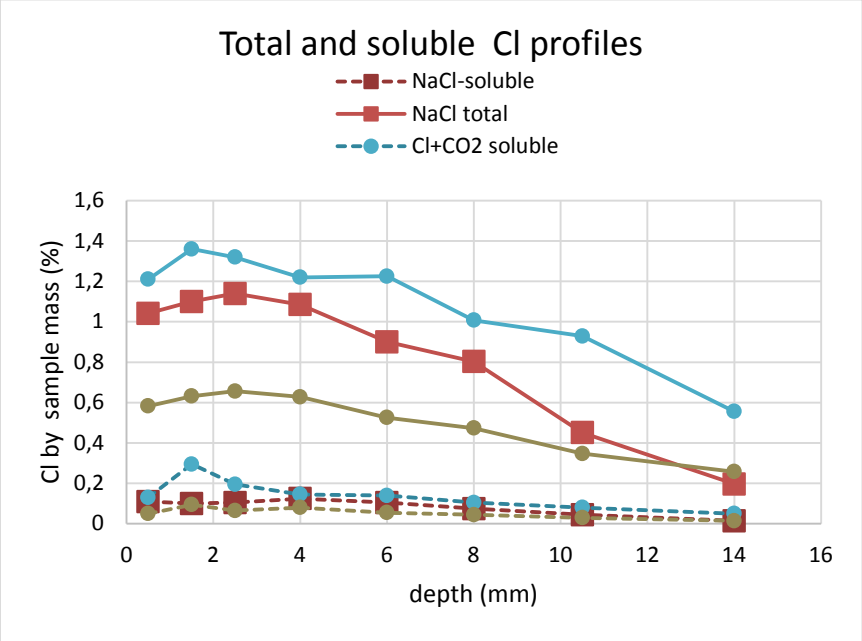

Figure 1. Chloride profiles of total and water soluble chlorides (average of the duplicated samples) of the three set of tests. The symbols here and in the rest of Figures are: Set-1 (NaCl), set-2 ($Cl+CO_2$), set-3 (CO_2).

In Figure 2 is given the relation between the soluble chlorides (named free in the Figures) and the total chlorides in function of the depth of penetration. All the relations are around 0.1% denoting very high binding ability of the cement, in spite of its low C_3A content. This binding is attributed to the chloride adsorption in the C-S-H gel and in the portlandite (Florea and Brouwers, 2012). It is interesting to notice that the relation is not constant because it decreases with the depth and it is a bit smaller in the case of the carbonated specimen. Finally, it is important also to notice that the highest value of soluble chlorides appear in the case of normal salt solution (non-decarbonated set-2) in the depth where the maximum appears and that, therefore, it is the reason of the higher total value.

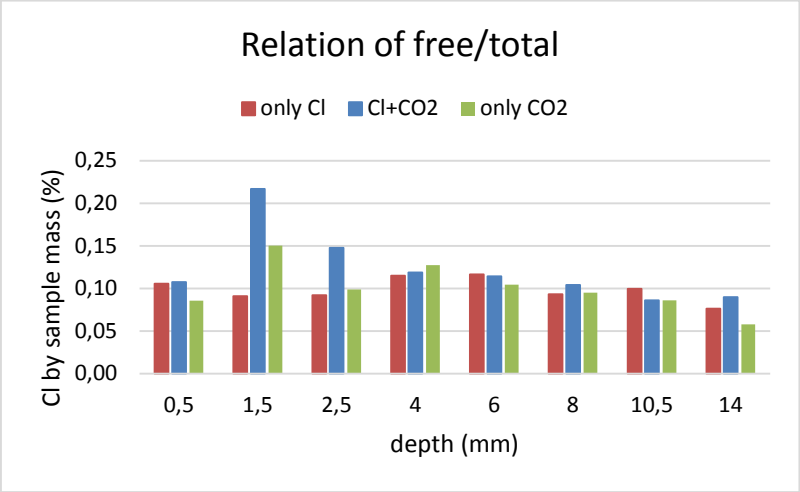

Figure 2. Ratios of free/ bound chlorides in the three set of specimens.

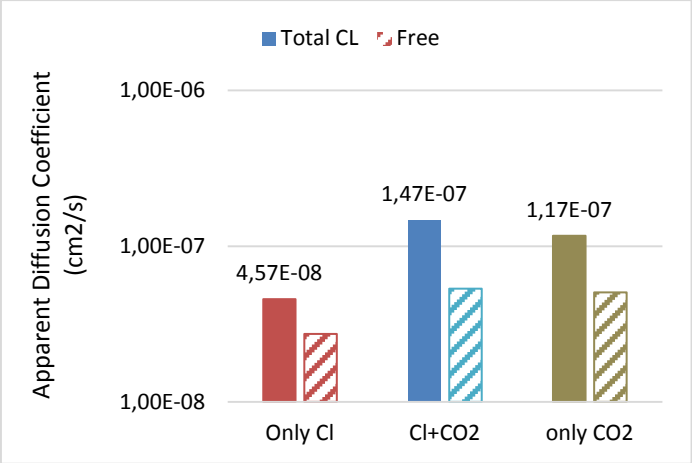

Figure 3. Apparent Diffusion Coefficient calculated through the fitting of the error function equation into the profiles of Figure 1.

The diffusion coefficient and the surface concentration deduced from the fitting of the error function equation into the profiles, are given in Figures 3 and 4 respectively. The diffusion coefficients, D_{ap}, differ between the three set and also between fitting into the soluble and total chloride profiles, being smaller if fitted into the soluble chloride profile. The highest value of both parameters is given by the normal salt solution (set-2) and the smallest surface concentration but highest D_{ap}, in the case of the pre-carbonated specimen (set-3).

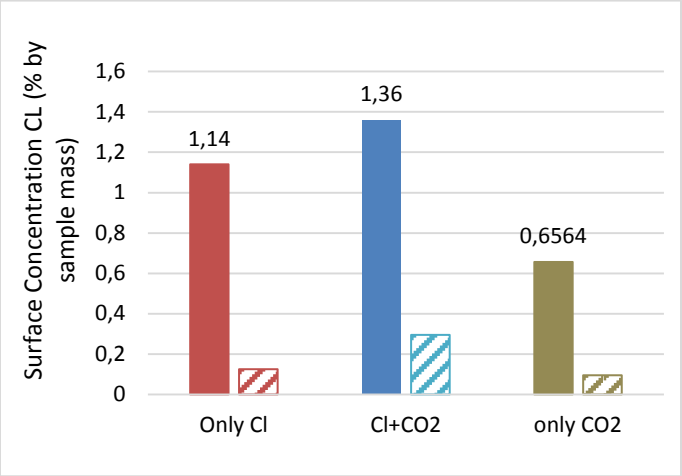

Figure 4. Chloride surface concentration calculated through the fitting of the error function equation into the profiles of Figure 1.

The results of the Portlandite and Calcite contents calculated from DTA analysis are shown in Figure 5 to 7 together with the chloride profiles. One first surprise is that the content of calcite in the surface of the concrete is a bit higher in the sample with de-carbonated solution, which indicates that the carbon dioxide has been uptake during the exposure of the 90 days in spite of the covering of the pond. Other observation is that the calcite profile is decreasing towards the interior and the portlandite, on the opposite, is increasing. Then, the carbon dioxide is reacting at least with the portlandite and carbonation is produced. The pre-carbonated specimen shows logically the highest proportion of calcite, but it is also decreasing towards the interior, which means that the specimen was not homogeneously pre-carbonated and it shows the maximum Calcite content (around 12%) in the surface.

The presence of calcite seems to have a direct relation to the production of the maximum in the chloride profile.

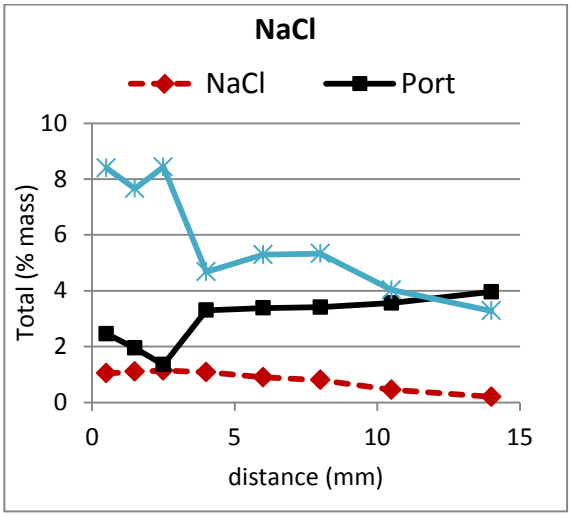

Figure 5. Profiles of calcite, portlandite and total chlorides in set-1.

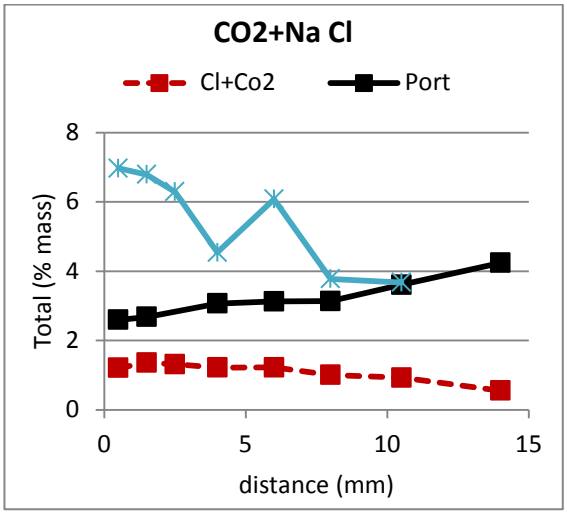

Figure 6. Profiles of calcite, portlandite and total chlorides in set-2.

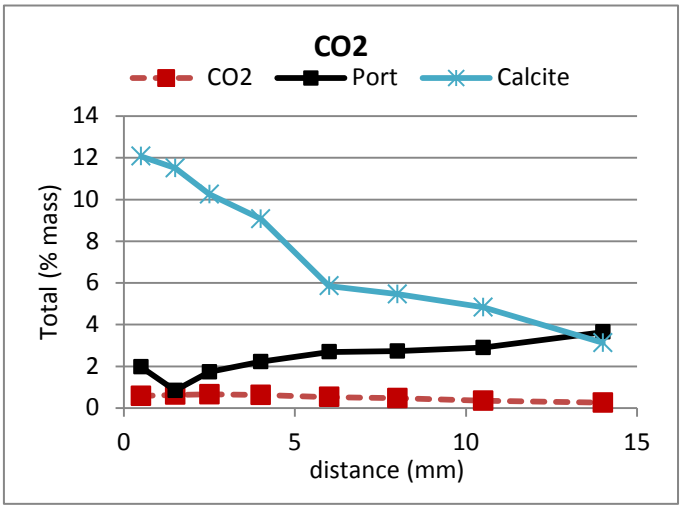

Figure 7. Profiles of calcite, portlandite and total chlorides in set-3.

4 Discussion

The results enable to emphasize that carbonation is not only produced in unsaturated conditions, but it is also produced by the air dissolved in the water in contact to a saturated concrete.

With respect to the mechanism of production of the maximum in the profile, there will be commented further the pre-carbonated sample (set-3) and first the other two cases (set 1 and 2). In set-2, the salt solution has "free" CO_2 gas and bicarbonates due to its neutral pH value. The bicarbonate will be transformed into carbonate ion as soon as it entries in contact to the high alkalinity of the pore solution leading into the precipitation of calcium carbonate, while the calcium bicarbonate is soluble and does not precipitate. There is a buffer of carbonate/bicarbonate at pH = 10.4. The bicarbonates can diffuse inside the sample producing again $CO_3^{=}$ ions. The pH value (OH^- content) simultaneously decreases, also because its leaching out due to the external pH value is neutral.

In set-2 with the standard salt solution, the chlorides and the bicarbonate entry simultaneously but the chlorides have higher ionic mobility. They penetrate first and bind with the hydrated phases (Afm phases, C-S-H gel and portlandite). The bicarbonate arriving later, on one hand, exchanges with the chloride in the hydrated phases releasing free chlorides to the pore solution, which move inwards again. They cannot move backwards due to the concentration gradient. On the other hand, the bicarbonates become carbonate ion due to the high alkalinity, precipitating $CaCO_3$. The $CaCO_3$ nucleation will physically cover the pore walls, decreasing the reactive sites for the chloride in the hydrated phases. Consequently. The total chloride decreases in the carbonated zone.

The maximum is produced because the pushing inside of the released Cl by the carbonation from the bound ones. The CO_2 in the salt solution acts as an intensifier of the chloride penetration. The profile advances due to the gradient between the maximum and its farther front inside the concrete. All the profile moves a step forward. New chlorides have to penetrate from outside to maintain the equilibrium with the bound chlorides to fulfil the so called chloride isotherm (Tang and Nilsson, 1993), all along the profile. That is, the

progressive carbonation of the skin decreases its bound and total chloride content, but does not stop the chloride penetration due to the need to maintain the Bound/ free chloride equilibrium, although this carbonation perhaps reduces with the time the amount of penetrating chlorides and it is one of the reasons of the "aging" effect (decrease with time of the diffusion coefficient). The external carbonated zone acts as a "filter" by the progressive decreasing the chloride flow.

In set-1 with the de-carbonated salt solution, the profile shape is similar than in set-2, but the total amount of chlorides is smaller. If the bicarbonates are in smaller amount, the carbonation will be less intense and the amount of exchanged chlorides in the interior of the pores will be smaller, and so the released free chlorides. The maximum in the profile is produced, but the total chlorides are smaller.

In the case of the pre-carbonated specimen (set-3), the profile shape is different than the other two set, because it is flatter. The total chloride is even smaller than in set-2 due to the reactive sites, from the beginning, are in much smaller amount. Also less chloride amount penetrate perhaps due to the smaller porosity produced by the carbonation. In addition, the pH of the pore solution is neutral, and then the bicarbonate will not be converted into carbonate when entering in the pore network. The neo-formed calcite will be in less amount. The specimens have more calcite due to the previous carbonation.

In this set-3, the pre-carbonation has not being complete enough to stop binding and then, it is remaining Afm, C-S-H and portlandite that are able to adsorb chlorides (Figure 1). This behaviour helps to conclude that the carbonation influences in a different manner the chloride penetration when it is produced previously, than when it is simultaneous to the chloride penetration. One main difference found is the pH value, because while the accelerated carbonation previously decreases the pH of the pore solution towards neutrality, similar to that of the salt solution, in the case of the CO_2 in the solution (set-2), the pH value of the pore solution is initially alkaline.

In summary, not only the carbonation itself, but the equilibrium carbonate/bicarbonate, which is pH dependent, seems to have a key role in the production of the maximum in the chloride profile. This evidence indicates the need to continue the understanding of the process by studying the diffusion of the bicarbonate ion into the pore network, because it seems that the HCO_3^- as being soluble, is a competitor of the chloride to be bound in the reactive sites and because it is evolving to carbonate at high pH level, inducing the precipitation of calcium carbonate, physically affecting the contact area of the pore solution and the reactive hydrated phases.

5 Conclusions

- The air (CO_2) content of the salt solution influences the chloride profile and in consequence, the calculated diffusion coefficient.
- The most aggressive condition (enabling higher chloride penetration) opposite to what was the hypothesis, is that of the standard salt solution (non-de-carbonated). This enables to confirm that present testing conditions for natural diffusion, are the most convenient ones.
- The pre-carbonation of the specimen leads into smaller amount of penetrated chlorides and a flatter profile.

- The production of the maximum in the chloride profile is attributed to the higher ionic mobility of the chlorides with respect to the carbonate/bicarbonates. Chloride binding is produced before the advance of the $CO_3^{=}/HCO_3^{=}$. When carbonation is produced behind the chloride penetration, chlorides are released that move forward making the profile to advance.
  - In the external layers of concrete the bound chlorides are smaller due to the carbonation. This mechanism may contribute to the known as "aging effect".
  - Bound chlorides have to be in equilibrium with the free chlorides given by the corresponding isotherm.
- Previous carbonation decreases the amount of reactive sites for the chlorides although may not fully exhaust them.
  - A maximum is also noticed in the pre-carbonated specimen attributed to the same mechanism than the non-carbonated, as in the material remain sites for chloride adsorption.

Detailed Modelling of the Masonry Unit-Mortar Interface Using Hygrothermal Simulation

Michael Gutland, Scott Bucking and Mario Santana Quintero

Department of Civil and Environmental Engineering, Carleton University, Ottawa Ontario, Canada,
michaelgutland@cmail.carleton.ca

Abstract. *Hygrothermal models are important tool for assessing the risk of moisture-related decay mechanisms in historic masonry structures. However, there are significant uncertainties in the process related to material properties, boundary conditions and quality of construction that effect confidence in the model's predictions compared to measured values. This paper examines one potential source of uncertainty; the imperfect nature of mortar joints in masonry walls, exemplified by such things as open joints, hairline cracks and imperfect bonds at the interface between mortar and unit. These are rarely considered in hygrothermal modelling in detail, where perfect interfaces are typically inferred. The premise is that at this interface, liquid transport behaviour is more similar to that of a fracture than that of a bundle of capillaries. These fractures of varying heights (or aperture) can affect transport into and out of the plane of the wall (perpendicular plane) and impede the liquid transport between mortar and the masonry unit (in-plane). This could lead to the "effective" moisture transport being different than what would be predicted using measured bulk material properties. A more detailed method for modelling this interface, borrowing techniques from the field of geohydrology is presented which demonstrates the effect that detailed modelling of the mortar joint has on moisture transport in masonry. A brick wall with cement mortar is studied. A two-dimensional hygrothermal model was created to demonstrate the effect of increased liquid conductivity into the wall cause by fractures.*

Keywords: *Masonry, Hygrothermal Simulation, Moisture Transport, Calibration, Mortar.*

1 Introduction

Hygrothermal models are an important tool for assessing the risk of moisture-related decay such as biological growth (mould and wood rot fungi), corrosion and freeze-thaw action in building envelopes. There are several gaps in our understanding and application of hygrothermal modelling involving uncertainty of material properties, boundary conditions, two-dimensional interactions and quality of construction. This can make it difficult to calibrate hygrothermal models to in-situ measurements and without calibration, our confidence in a hygrothermal model's predictions is lessened.

This paper examines one potential source of uncertainty; namely, the imperfect interface between mortar and the masonry unit. Imperfections may take the form of open joints (mm range), hairline cracks (μm range), or an imperfect bond between the mortar and the unit (**Figure 1**). These can be caused by structural displacements, shrinkage, decay/maintenance or inherent from its construction. It is intuitive to assume that a large presence of these openings will increase moisture transfer into the wall caused by wind-driven rain. The question is how much

and how do we properly account for this in hygrothermal simulations?

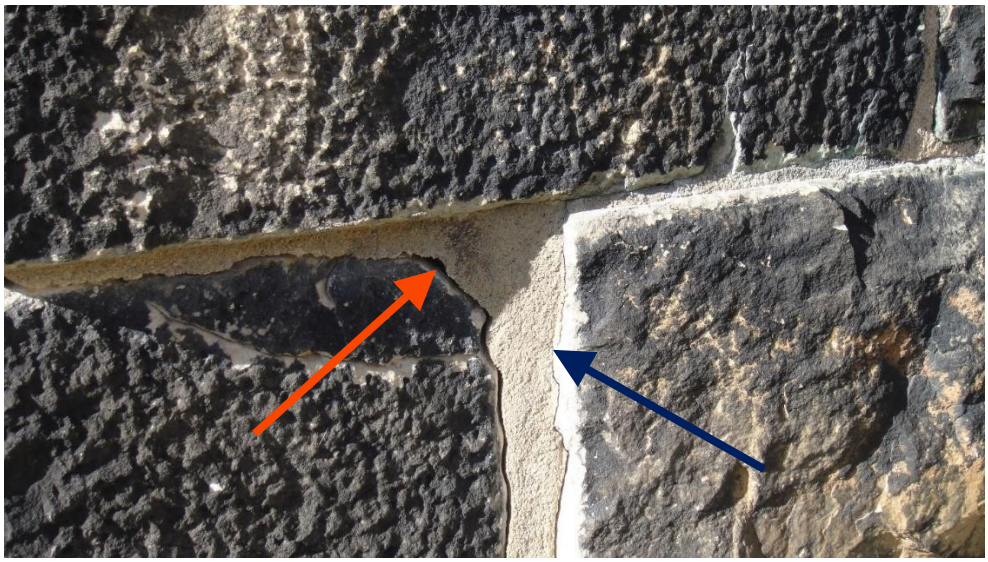

Figure 1. Sandstone masonry wall with open joint (Orange arrow) and hairline crack (dark blue arrow) between stone and mortar.

This paper proposes a methodology for explicitly modelling imperfections at the masonry interface by modelling this region as a fracture. The models assume a varying crack width (also called aperture). Material properties of the fracture are derived from fundamental principles for moisture retention and liquid conductivity.

2 Literature Review

Hygrothermal modelling software simulates the coupled heat and moisture flow (vapour and liquid) through building envelopes and assemblies using finite-element methods. The coupled heat and moisture equations are given in Equations 1 and 2:

$$\frac{\partial H}{\partial t} = -\nabla[\lambda \nabla T + h_v(k_v \nabla P_v) + h_l(k_l \nabla P_c)] \tag{1}$$

$$\frac{\partial w}{\partial t} = -\nabla(k_v \nabla P_v + k_l \nabla P_c) \tag{2}$$

Of particular interest to this paper is the term for liquid conductivity k_l. This controls the rate of liquid water ingress into a material by a capillary pressure gradient. Liquid conductivity is a function of moisture content and can be estimated from water absorption tests or pressure plate apparatus.

2.1 Masonry Interface

Previous studies have looked at moisture transfer at the interface and have shown that there is an interface resistance (R_{IF}) which inhibits transfer from one material to the other. This is analogous to contact resistances in the heat transfer of electronics. The presence of an interface resistance is caused by one of two reasons. The first is an imperfect contact between the two materials which forces water to travel across the interface through vapour diffusion instead of

the faster capillary method. The second reason is migration of fine particles toward the mortar joint during the curing stages (Brocken, 1998). The fine particles form smaller pores near the interface, and this reduces liquid flow.

Laboratory testing has measured the interface resistance between 1.0E08 and 1.0E12 m/s (Calle, De Kock, Cnudde, and Van den Bossche, 2019; Derluyn, Janssen, and Carmeliet, 2011; Qiu, Haghighat, and Kumaran, 2003). Simulations have demonstrated the effect that the interface resistance have on moisture uptake (Vereecken and Roels, 2013; Zhou, Desmarais, Vontobel, Carmeliet, and Derome, 2018). These methods only consider moisture transfer across the interface and not parallel to it.

2.2 Fractures in Masonry

There have been previous studies exploring water uptake in fractured building materials. Roels (2003) examined water uptake in a fractured brick sample and Rouchier (2012) modelled a detailed 2D crack network in a sample of concrete. Both studies required a detailed geometry of the fracture to be defined and meshed into a finite – element model. This is time and computationally expensive. It is also highly unfeasible to do on anything greater than a small sample. Modelling with an assumed fracture width will remove this need.

These simulations were also done on homogenous materials, meaning that the material was the same either side of the fracture. In a masonry interface that is not true as the material properties of the two adjacent materials may be quite different. These studies also looked primarily at water uptake and did not consider the drying phase.

2.3 Capillary Mechanics

Hygroscopic materials are often idealized as a bundle of round capillaries or pores of varying sizes. With knowledge of the pore size distribution though porosimetry or other means, it is possible to infer many of the important hygroscopic material properties required to model moisture transport. This includes the moisture retention, liquid conductivity and vapour diffusion curves. The Young-Laplace equation relates capillary pressure to pore radius:

$$\Delta P = \frac{2\gamma cos\theta}{r} \tag{3}$$

If the capillary suction pressure is greater than this, a capillary with this radius will not be filled. The Kelvin Equation describes the relationship between vapour pressure and condensation inside the capillary:

$$\mathrm{LN}\left(\frac{p}{p_{sat}}\right) = \frac{2\Gamma \mathrm{V_M}}{\mathrm{RRT}} \tag{4}$$

These equations combined with the pore size distribution allow for construction of the moisture retention curve, describing the relationship between saturation and capillary suction pressure. Narrower pores retain moisture longer and larger pores catch and release moisture more easily.

Moisture retention curves can be measured in the laboratory or estimated with the Van Genuchten equation, where α and n are material- specific parameters (van Genuchten, 1980).

$$P_c = \frac{1}{\alpha}\left[S_{eff}^{-\left(\frac{n}{n-1}\right)} - 1\right]^{\frac{1}{n}} \tag{5}$$

Liquid Conductivity is also a function of the capillary radius and can be calculated through the Hagen-Poiseuille equation:

$$k_l = \frac{\rho r^2}{8\eta_l} \tag{6}$$

Liquid transport only occurs when capillaries are filled. Therefore, liquid conductivity is a function of saturation and exponentially increases with saturation. The moisture-dependent conductivity $k_l(\theta_l)$ can be estimated by integrating the Hagen-Poiseuille over the range of active capillaries or by using the Burdine relative permeability approach (Burdine, 1953).

$$k_l(\theta_l) = \frac{\rho}{\tau} \int_{R_{min}}^{R} \frac{\pi r^4}{8\mu_l} \frac{dn}{dr} dr \tag{7}$$

The theoretical curve will not match the measured liquid conductivity curves (Scheffler, Grunewald, and Häupl, 2004). Tortuosity (τ) is included in this equation to account for the reduction in flow due to tortuosity, pore shape and the degree of interconnectivity of pores. Likewise, vapour diffusion can be estimated from fundamentals, but is not discussed here.

Determining the hygroscopic properties of a fracture is similar to the process for determining those of capillary materials. To begin, we need to determine the size of the aperture with which liquid is flowing, similar to what is learned from the pore size distribution. Aperture (h) is the distance between the boundary surfaces of the fracture. Apertures are not constant in real-world applications because it widens and contracts along its path and generally follows a tortuous path. There are two methods for determining an "effective" aperture. The first is to use the average aperture ($\overline{h}$), and the other is to use the hydraulic aperture (h_H) which is the value which would make the cubic law true (Zimmerman and Bodvarsson, 1994).

Typical apertures in subterranean rock are reported to be in the 0.001-0.1 mm range (Pyrack-Nolte, Myer, Cook, and Witherspoon, 1987). Fractures in building materials range are in a similar range ((Roels *et al*., 2003; Rouchier, 2012). Anything much smaller than this and liquid transport is greatly reduced.

The hygroscopic material properties of the fracture can be calculated with a few distinctions to that of capillary materials. The liquid conductivity is calculated with the cubic-law or Reynold's Equation, the difference being a change in the denominator.

$$k_l = \frac{\rho_h{}^2}{12\eta_l} \tag{8}$$

Fractures can also have a much higher porosity with few obstructions. A smooth moisture retention curve can be created if an aperture distribution is assumed. The larger the aperture the further to the left the curve will be.

3 Methodology

DELPHIN 6.0 was used for hygrothermal simulations (Bauklimatik Dresden, 2018). DELPHIN allows input of custom material properties including direction-dependent properties, detailed moisture retention curves, and moisture-dependent liquid and vapour transfer coefficients.

3.1 Material Properties

The first step was to define material properties of the masonry. Typical bulk material properties for brick and cement mortar were determined by the taking median values for all materials of its class in the DELPHIN library. The moisture retention curve for each material was estimated using a unimodal Van Genuchten with parameters n and α where calculated using least-squares regression.

Table 1. Bulk material properties used in hygrothermal simulations.

Position	Clay Brick	Cement Mortar
θ [--]	0.294	0.2296
λ [W/m-K]	0.682	0.723
μ [--]	20.2	25.6
$k_{l,\,eff}$ [s]	2.21E-09	9.053E-12
n [--]	1.55	1.48
α [1/Pa]	1.00	2.172

The approach for creating the liquid conductivity curve was to use the theoretical curve (Equation 7) below the capillary water content (θ) scaled by the tortuosity (**τ**).

$$\tau = \frac{k_l(\theta_{cap})}{k_{l,eff}} \tag{9}$$

The liquid conductivity above the capillary suction curve was held fixed at $k_{l,eff}$. For simplicity, sorption hysteresis, temperature or moisture-dependent thermal properties and air permeability were neglected for the purposes of this experiment.

The fracture material properties were calculated based on apertures in a range from 0.25μm to 10μm. The fractures were modelled as a normally distributed curve with standard deviation of (h/2). This was done to smooth the moisture retention curve and help the numerical calculations. At high degrees of saturation, the liquid conductivity of the fracture is several orders of magnitude greater than the brick and mortar. It is less pronounced at lower degrees of saturation. Even though the exposed area of the fracture is small it can contribute to an increase in overall moisture transport.

3.2 Finite-Element Model

There are three materials in the finite element model shown in Figure 2: unit, interface and mortar. The dimensions of the model (taking advantage of symmetry) are 5mm thick mortar, *x* mm aperture and 28mm brick. The width of the assembly is 92mm.

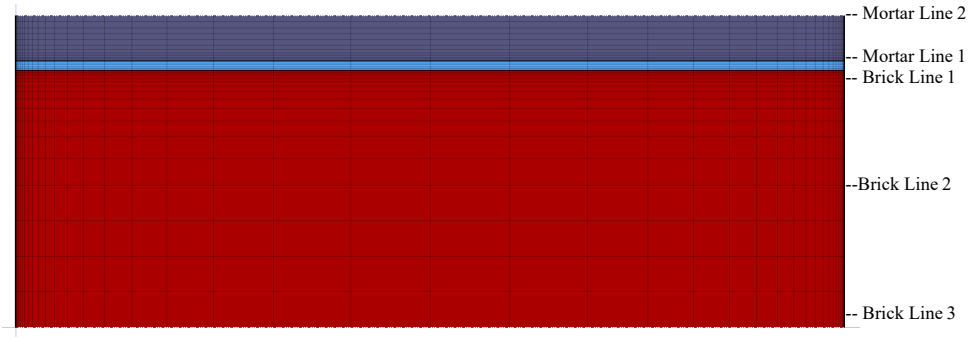

Figure 2. Finite Element Model (interface is not drawn to scale).

3.3 Boundary and Initial Conditions

The simulation was performed under the following boundary conditions:

1. Water Uptake – All materials set to 50%RH and exposed to a capillary pressure of -0.025m on one side only. This was done to mimic a water absorption experiment.
2. Drying – All materials are set to 99.99%RH and exposed to an RH of 30% on one side.

All other sides are adiabatic and there is no temperature gradient, sources/sinks in the model.

4 Results

A sample of the results are shown in **Figure 3** and **Figure 4** for the moisture content of the brick

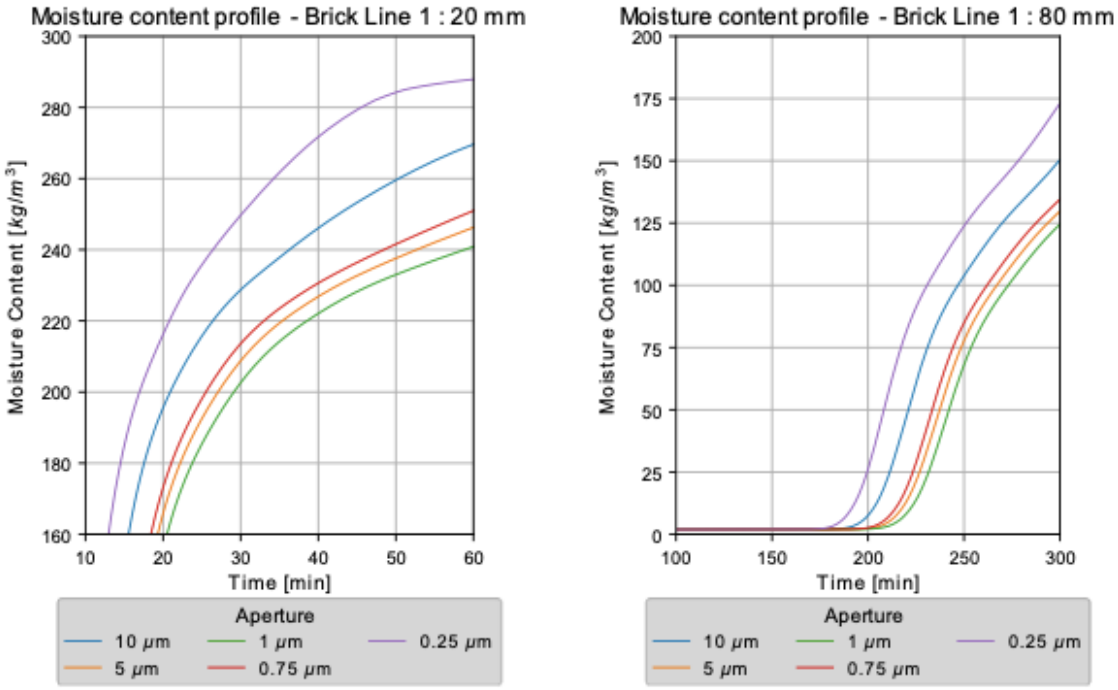

Figure 3. Moisture content of the brick adjacent to the fracture at 20mm depth (left) and 80 mm depth (right).

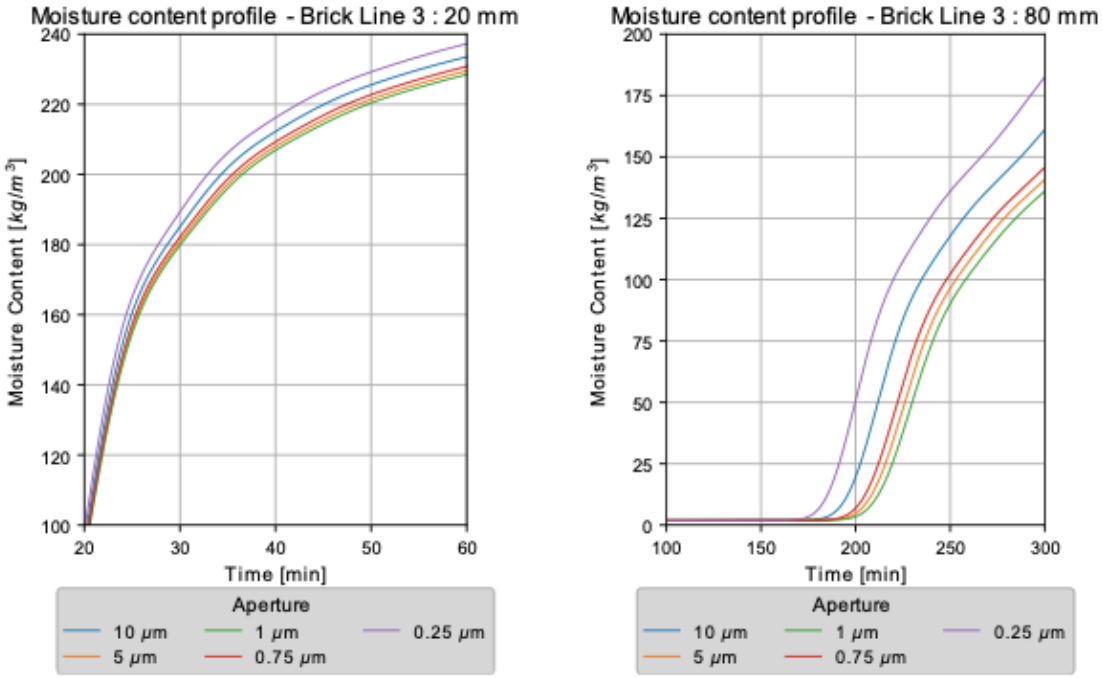

Figure 4. Moisture content of the brick at centreline of brick at 20mm depth (left) and 80 mm depth (right).

adjacent to the fracture and at the centreline of the brick. The results show that there is a significant change in moisture content depending on the aperture height. What is interesting to note is that there does not appear to be a linear relationship between moisture absorption and aperture, in fact it appears to be parabolic. Both sets of graphs show that a 1 µm aperture (green) has the minimum uptake while both smaller apertures (purple and red) and larger apertures (blue and orange) have increased absorption. The smaller apertures, while having a lower maximum flow rate are easier to fully wet and become active at higher capillary pressures. The larger apertures need extremely low (and in the reality of building walls, extremely rare) capillary pressures to become active and allow liquid to flow. The effect was noticeable adjacent to the fracture and the centre of the unit.

The simulation was performed on a sandstone/lime mortar combination with roughly twice the material dimensions. The results were not as pronounced as the case of brick/cement mortar combination. The impact of the fracture appears to be dependent on bulk material properties and the relative area density of the interfaces.

The drying simulation was performed over the course of one calendar year. The effect of the fracture was found to be minimal with a reduction in RH of less than 1% at the centre of the brick. It was determined that any enhancement to vapour diffusion out through the fracture was minimal.

5 Conclusion

The results of the DELPHIN simulations show that modelling imperfections at the masonry interface explicitly as fractures can affect simulation results compared to using only bulk material properties. The presence of fractures greatly increases the liquid conductivity locally

in a fashion similar to a thermal bridge. Future work will look at incorporating an anisotropic model into the fracture interface to account for interface resistances across the fractures as well as under more realistic boundary conditions such as typical meteorological years. Further research needs to be done to determine what the range of apertures are common in masonry walls and correlate the models to experimental data. The goal is to determine "effective" moisture transport coefficients which take into consideration imperfections and two-dimensional interactions which can be used by practitioners.

Drying Potential of Wood Frame Walls Subjected to Accidental Water Infiltration

Marijke Steeman, Nathan Van Den Bossche and Klaas Calle

Building Physics research group, Ghent University, J. Plateaustraat 22 B-9000 Ghent, Belgium, Marijke.Steeman@UGent.be

Abstract. *Wood frame construction is the most widespread building method. In Belgium the number of wood frame buildings has grown in the last years: in 2018 over 10% of all new built dwellings were wood frame buildings. This increase can be partly attributed to the growing attention for energy performant buildings with a low environmental impact. In contrary to masonry construction, wood frame is more vulnerable to moisture problems, mould growth and wood rot. An important risk is water infiltration through imperfections in the building envelope as a result of driving rain. Therefore it is important for the design to be resilient and allow drying without consequential damage. To analyze the drying potential, an experimental set-up with 8 wood frame compartments was built. The compartments differ in the type of insulation material (mineral wool or cellulose) and the type of vapour retarder (OSB or smart vapour retarder) that were used. In this way 4 types of compartments were obtained, each having a different combination of insulation and vapour retarder. Of each combination there are 2 identical compartments. This allows to insert water in one of both, to mimic rain water infiltration from the outside into the compartment. Temperature, relative humidity and moisture content were measured on different locations in the construction (in total 92 sensors). In this way, the hygrothermal performance of the compartments with and without water infiltration can be analyzed, as well as the drying rate.*

Keywords: *Wood Frame Construction, Measurements, Drying, Water Infiltration.*

1 Introduction

Though masonry is the most common construction method in Belgium, wood frame construction is gaining more popularity. On the one hand this can be attributed to the stricter energy requirements and the associated thicker insulation layers. On the other hand, there is also a growing attention for sustainable construction, *i.e.* CO_2 captured in wood. In 2018, over 10% of all new dwellings were wood frame buildings and that number has increased over the last years. Also for renovations and extensions to existing buildings, wood frame is interesting due to its limited weight (Houtinfobois, 2019).

Scandinavian countries or countries such as Canada where wood frame is the main construction type, are characterised by a cold climate that limits the conditions for mould growth. In contrast to that, Belgium has a moderate maritime climate with a dominant wind-driven rain from south-west orientation. It is therefore crucial to design constructions in a resilient way to guarantee drying without consequential damage in case of accidental water infiltration.

This paper therefore investigates the hygrothermal performance and the drying potential of different wood frame wall constructions subjected to water infiltration, using in-situ measurements on a test wall.

2 Experimental Set-up

2.1 Pavilion and Test Wall

A test pavilion (6,60m x 4,37m) called “STEAMlab21” was built in Kortrijk and consists of two adjacent rooms. Figure 1 shows the floor plan and a vertical section of the pavilion.

The exterior north-west facing wall is replaceable and used as a test wall. The test wall is a wood frame wall with 8 compartments. The compartments consist of I-joists filled with insulation material, wood fibre board and a ventilated wooden cladding at the outside. At the inside a service cavity with a gypsum fibreboard finishing is installed. All other exterior walls of the pavilion are constructed with SIP panels.

The test pavilion and the test wall were built about one year prior to the measurements described in this paper and therefore subjected to the outdoor climate.

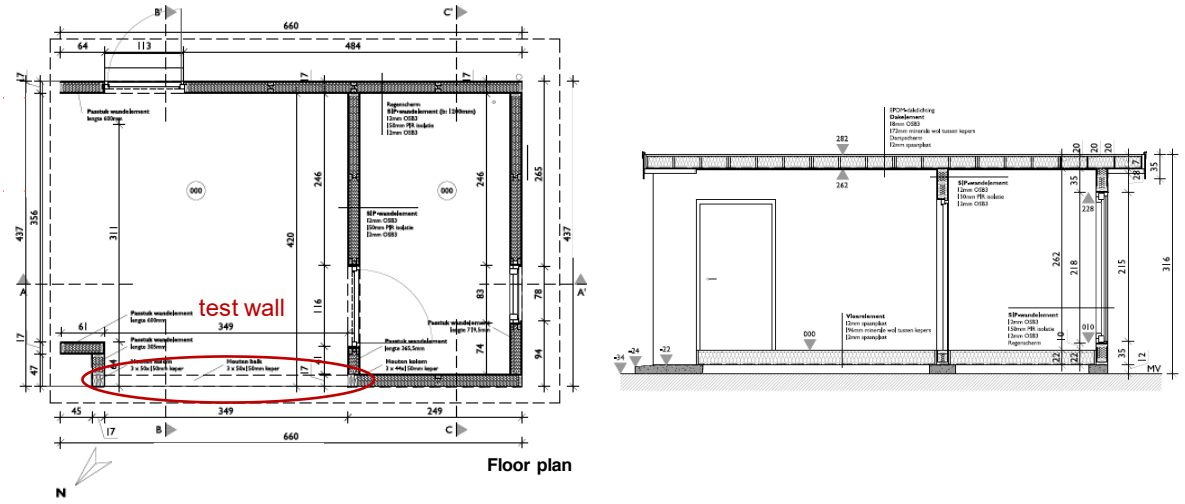

Figure 1. Floor plan (left) and section AA’ (right).

Each compartment of the test wall measures 34,4 cm width and 266 cm height. The compartments differ in the type of insulation material and the type of vapour retarder that were used. Two types of insulation material were used: mineral wool and cellulose; and two types of vapour retarder: a smart vapour retarder (SVR) and oriented strand board (OSB). In this way 4 types of compartments were obtained, each having a different combination of insulation and vapour retarder. Two identical compartments of each combination of insulation type and vapour retarder were available.

Water is added from the outside in one of the two identical compartments, mimicking rain water infiltration. In order to avoid mutual influence between the compartments, a vapour tight coating was applied to the I-joists between the compartments. Figure 2 lists the characteristics of each wall compartment, while Table 1 shows an overview of the most important material properties. The U-value of the test wall was 0,10 W/m²K for the compartments with mineral wool and 0,11 W/m²K for the compartments with cellulose.

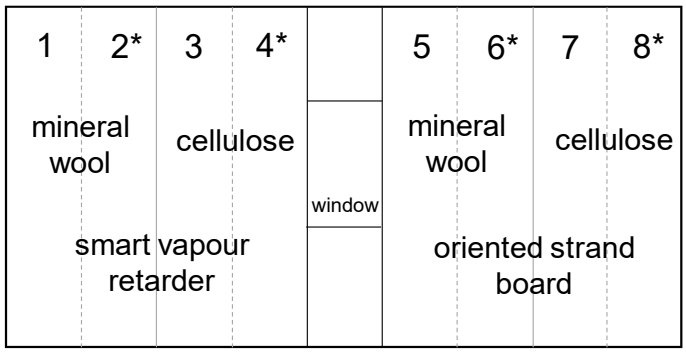

Figure 2. Schematic overview of the test wall with 8 compartments. Compartments with water injection are marked with *.

Table 1. Characteristics of the materials used in the test wall.

Material	Thickness (m)	Thermal conductivity (W/mK)	Vapour diffusion resistance factor (-)
Wooden cladding	0,026	0,090*	-
Ventilated cavity	0,022	-	-
Wood fibre board	0,022	0,048	5
Glass wool (blown in)	0,300	0,034	1
Cellulose (blown in)	0,300	0,038	1-2
Smart vapour retarder	0,0004	0,170	Sd 0.25 → 25 m
OSB3 board	0,015	0,130	175
Service cavity	0,06 - 0,072	-	1
Gypsum fibre board	0,0125	0,320	13

All data are based on technical specifications, (*) data based on the material database in WUFI.

2.2 Measurement Equipment

Temperature, relative humidity and moisture content were measured on different locations in the test wall. In total 92 sensors were installed. At the following locations, also indicated in Figure 3, thermocouples type K (accuracy ±0,1°C) and RH sensors (HIH-40000 Series Humidity Sensors, accuracy ±3,5% RH) were installed:

- On the inner surface of the wall at two locations: in the middle of the left and right wall side, at half height
- In the service cavity of each compartment at ± 1,80m height (illustrated in Figure 4, left photo)
- On the interior side of the insulation layer for each compartment, at two heights: at ± 0,80m and at ± 1,80 m height
- On the exterior side of the insulation layer for each compartment, at ± 1,80 m height
- In the ventilated cavity of the wall at two locations: in the middle of the left and right wall side, at ± 0,80m and at ± 1,80 m height (illustrated in Figure 4, photo on the right)

All sensors were connected to a data logger that registers the measurements every 15 minutes. Additionally, in each compartment of the test wall two moisture pins were installed and connected to the data logger: one in the bottom plate and one in the I-joist to measure the

moisture content of the wood. Unfortunately, the results of these moisture content measurements showed to be unreliable and therefore they are not included in this paper.

Furthermore the temperature and relative humidity of the indoor and outdoor climate were monitored. A HOBO U12-013 was used to monitor the indoor temperature (accuracy ± 0,21°C) and relative humidity (accuracy ± 2,5 % RH). A HOBO U23 Pro v2 logger was located outside shielded from direct sun irradiation and precipitation for measuring temperature (accuracy ± 0,21°C) and relative humidity (accuracy ± 2,5 %RH).

A convector was installed in the test room to control the indoor climate. The set point was 20°C. Furthermore, a fan was used to ensure well-mixed air conditions.

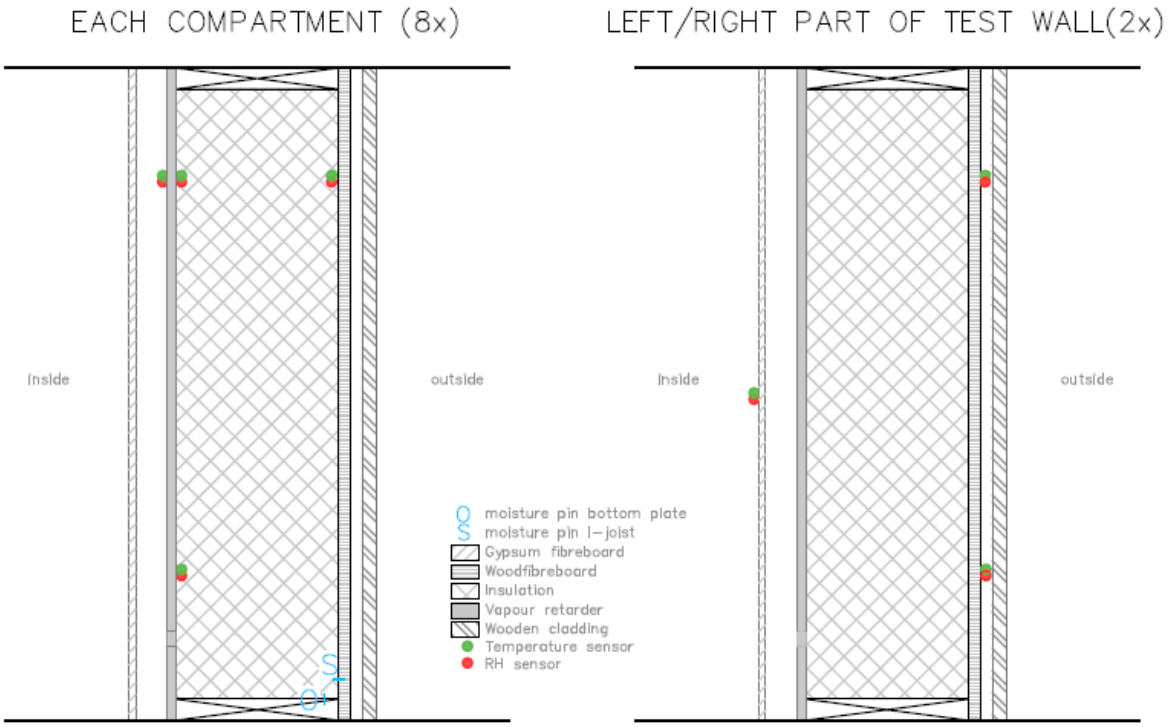

Figure 3. Scheme with location of the sensors in the test wall.

2.3 Water Infiltration

In 4 compartments (2, 4, 6 and 8) 0,2323 l water was injected into the insulation layer. Figure 4 (photo on the right) shows the outside of the test wall with the infiltration tubes at half height. The tubes were installed in such a way that the water is infiltrates between the wood fibre board and the insulation layer.

The amount of water was calculated based on the horizontal rain load during a heavy rain shower with a duration of 4 hours in Belgium (rain load 72,4 mm or 18,1 mm/h based on data from RMI), the measured wind speed during a realistic rain event (based on Van Goethem, 2014) and a worst case infiltration percentage of 0,6% of the incident rain that infiltrates in the construction. The latter was based on water infiltration measurements in a typical cavity wall construction (Geldof, 2016). In this way, a rather high amount of rain water infiltration was obtained, based on the maximum rain load.

Figure 4. View on the compartments from the inside (photo left) and view on the outside with water infiltration tubes, indicated with a red circle (photo right).

3 Measurement Results

Measurements were carried out for 30 days from April 28th to May 27th 2019 every 15 minutes. Water was injected on April 30th 2019 at 2 pm. After the water was injected, measurements ran for 27 days.

3.1 Moisture Buffering Effect

Figure 5 shows the course of the relative humidity in the insulation layer for a compartment filled with mineral wool (compartment 5) and a compartment filled with cellulose insulation (compartment 7). In both compartments, there was no water infiltration.

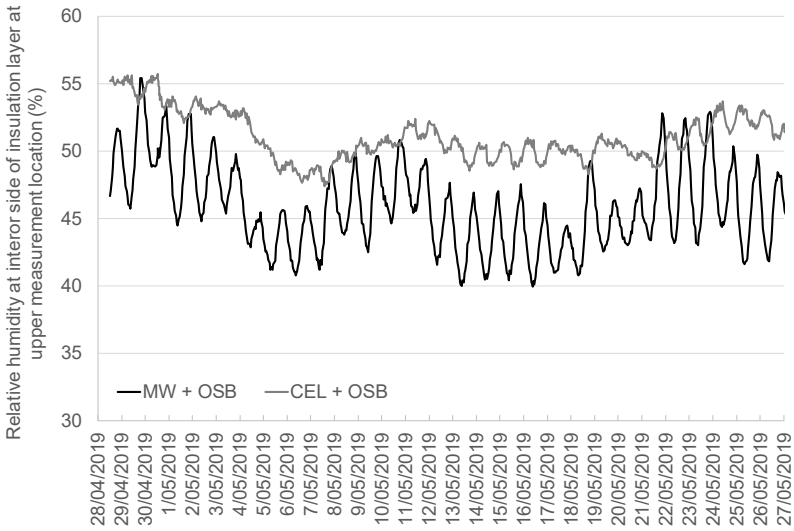

Figure 5. Course of the RH measured at the inside of the insulation layer (upper measurement location) for a compartment with mineral wool (comp. 5) and cellulose (comp. 7), both without water infiltration.

Figure 5 shows that the relative humidity fluctuates a lot more in the compartments filled with mineral wool compared to the compartments filled with cellulose insulation. This observation is expected and can be explained by the hygroscopic characteristics of cellulose. The oriented strand board has similar moisture buffering characteristics, but because the

thickness of the layer is limited (0,015m), this effect is rather small.

3.2 Moisture Increase and Drying Rate

When the measurement results were analyzed it was clear that the injection of water was mainly visible at the interior side of the insulation (lower measurement location). The relative humidity clearly increases when water is injected.

Figure 6 compares the relative humidity of the wall compartments with and without water infiltration for each combination of insulation and vapour retarder. The moment water is injected into the construction can be clearly read from the graphs (also indicated with a black arrow). The graphs show that the relative humidity increase is higher for the compartments with mineral wool than for the compartments with cellulose insulation. This can again be attributed to the hygroscopic characteristics of cellulose.

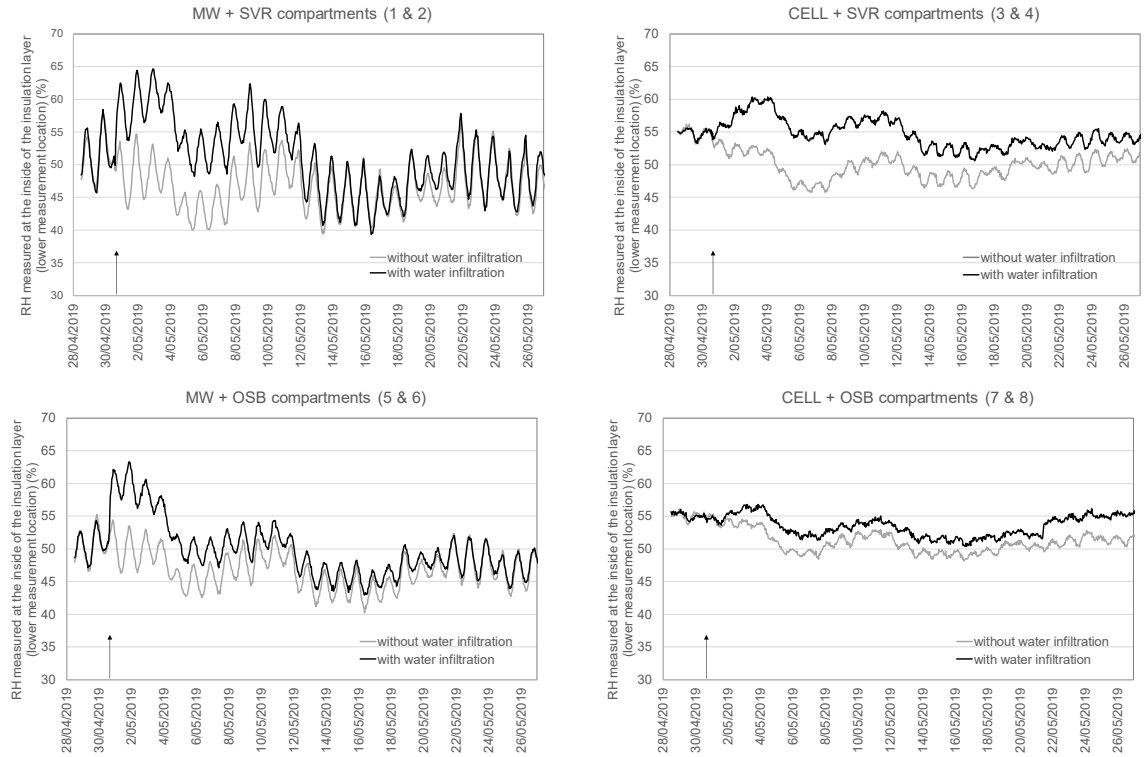

Figure 6. Course of the RH measured at the inside of the insulation layer (lower measurement location) for all compartments, with and without water infiltration.

Figures 7 and 8 show the relative humidity course measured at the interior side of the insulation (upper measurement location) and at the exterior side of the insulation for compartments 1 and 2, and 3 and 4 respectively. It is clear that the water injection is harder to observe from these measurement locations. For the compartments with mineral wool (Fig. 7) the relative humidity of the dry compartment is slightly higher than the relative humidity of the wet compartment, although the difference is still within the accuracy of the sensor. For the compartments with cellulose insulation (Fig. 8) the relative humidity of the wet compartment is slightly higher than the relative humidity of the dry compartment, but the difference is very

limited. For the other compartments, similar observations were made. This suggests that the injected water mainly runs down at the interior side of the insulation layer, especially for the compartments with mineral wool because the moisture buffering capacity of mineral wool is very low.

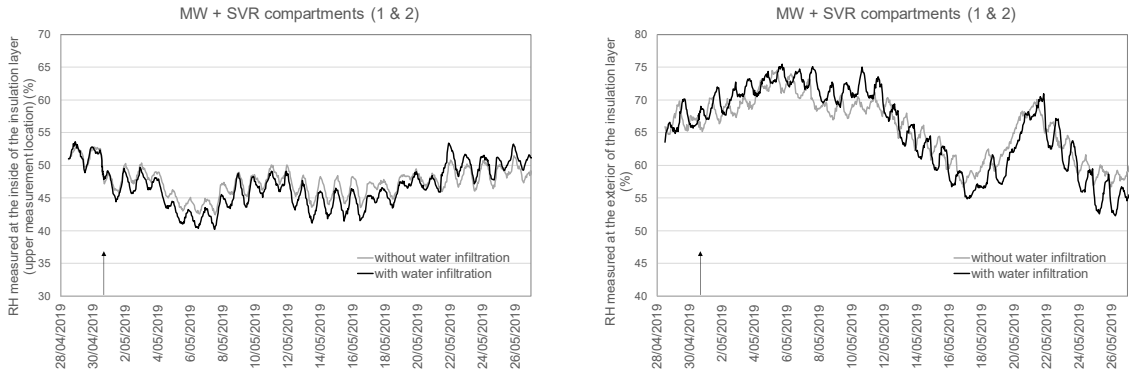

Figure 7. Course of the RH measured at the inside of the insulation layer (upper measurement location) (left) and at the exterior side of the insulation layer (right) for the compartments with mineral wool and SVR (1 & 2).

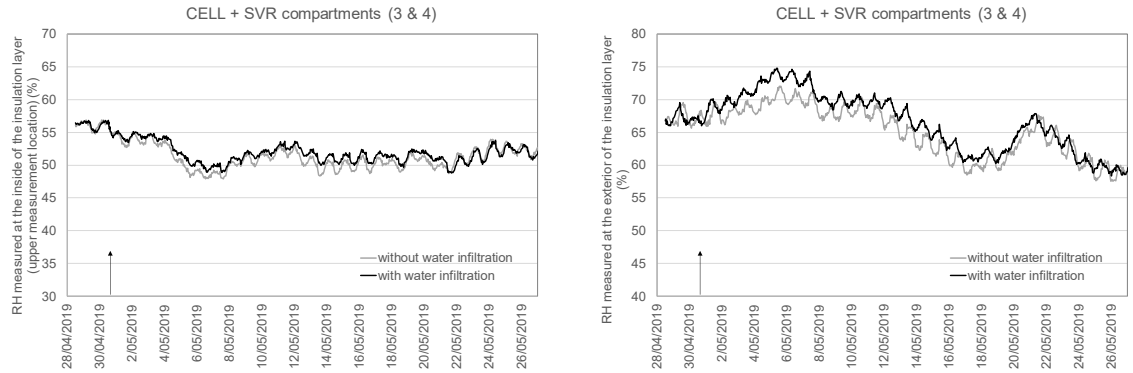

Figure 8. Course of the RH measured at the inside of the insulation layer (upper measurement location) (left) and at the exterior side of the insulation layer (right) for the compartments with cellulose and SVR (3 & 4).

In order to estimate the drying rate of the test compartments, the relative humidity of the wet and dry compartment of each construction type are compared (lower measurement location at interior side of insulation) in Figure 9 (graph left). The relative humidity difference increases faster in the compartments filled with mineral wool compared to the compartments filled with cellulose. Similarly, the drying rate of the compartments with cellulose is lower.

For the compartment with mineral wool and SVR (compartment 2) and with mineral wool and OSB (compartment 6), the drying period is ± 14 days and ± 21 days respectively. For the compartments with cellulose (compartments 4 and 8), the drying period is considered longer then the measurement period (> 27 days). For compartment 8 an increase in RH is noted after 21 days (May 21th), but no explanation for this observation could be found.

Drying out is considered mainly towards the inside of the construction. Figure 9 (right-hand graph) compares the measured vapour pressure in the insulation layer (interior side, lower measurement location) with the vapour pressure in the service cavity. For compartment 2 with mineral wool drying starts immediately after water infiltration, while for compartment 4 with

cellulose there is a time delay and drying starts later. During measuring, there were no internal moisture loads.

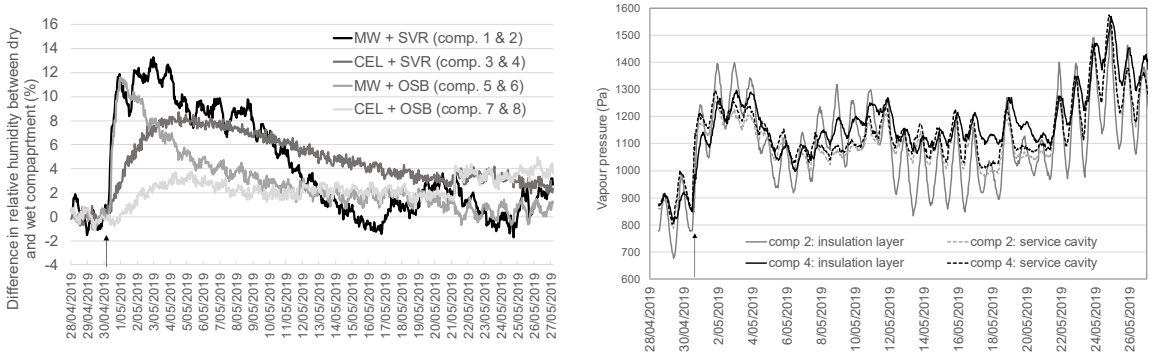

Figure 9. Difference in RH between wet compartment and the dry compartment (left) and vapour pressure in the insulation layer and service cavity for compartments 2 (MW + SVR) and 4 (CELL + SVR).

4 Conclusions

The aim of the study was to analyze the hygrothermal performance of wood frame construction subjected to accidental water infiltration. The results showed that the drying rate was faster for the compartments with mineral wool, and for the compartments where a smart vapour retarder was used. Also moisture buffering in the cellulose was clearly observed. In all cases, the construction dries out and no moisture damage is expected at first glance. However, further research should give insight in the moisture content of the wooden elements (bottom plate, I-joists) when water runs down. In the experiment water was injected at only one moment in time. In reality, water could leak into the construction in a more contentious way. This was not taken into account here. Also, parameters such as the moment of water injection, orientation of the test wall and boundary conditions (*e.g.* presence of internal moisture loads) will have an effect on the resulting drying rate and should be studied in more detail.

Acknowledgements

The test pavilion was built in cooperation with the VTI in Kortrijk, the authors highly appreciate the support of the staff. The authors also would like to thank MSc-students M. Veraeverbeke, J. Lagniau, B. Gryson and L. Dewachter for their help with the experiments in the context of their Master thesis.

Abstract. *Hemp and Recycled Aggregates Concrete (HRAC) is a sustainable concrete where coarse aggregates are partially replaced with industrial hemp fibers and recycled concrete aggregates (RCA). This replacement has two main benefits: it saves on natural resources and it recycles and reuses waste material. Previous studies showed that the mechanical performance of HRAC is satisfactory. On the other hand, concrete's durability is also an important criterion to evaluate concrete's performance and HRAC's durability can be affected by the presence of both RCA and hemp fibers in the concrete's alkaline environment. This paper aims at investigating the durability of HRAC concrete mixes by comparing the mechanical performance of HRAC specimens at the ages of 2 and 28 days. Furthermore, the performance of HRAC under freeze/thaw cycles is evaluated and compared to that of regular concrete. Results showed that the mechanical performance of HRAC improves at older age and the resistance of HRAC mixes to freeze-thaw cycles is similar to that of control mixes.*

Keywords: *Sustainable Concrete Materials, Recycled Aggregates, Hemp Fibers, Durability, Mechanical Properties.*

1 Introduction and Background

Sustainability has become an essential issue on a global scale in the recent years. Therefore, construction, among other sectors, is reviewing its practices to make them more environmentally friendly and reduce their negative effect on the planet as a whole.

Concrete production consumes large quantities of natural aggregates causing significant damage to the environment. To reduce the amount of natural aggregates used in concrete HRAC is proposed. This is a concrete mix where hemp fibers are incorporated in the mix, the amount of natural coarse aggregates (NCA) is reduced by 20%, and where 50% of NCA are replaced by RCA.

HRAC also helps in reducing the problem of construction and demolition wastes (CDW) which are a mixture of surplus materials generated during new construction, renovation, and demolition of buildings, roads, bridges, and other structures (Cheng *et al.,* 2013)

A sustainable concrete should be also durable; therefore, it is important to study the effect of the incorporation of hemp fibers and RCA on the durability properties of concrete.

Ramli *et al.* (2013) studied the durability of coconut-fiber-reinforced concrete in aggressive environments. Results showed that the damaging effects of aggressive environments on concrete can be lowered with fiber-reinforced concrete since the fibers play a role in restraining the development of cracks. Awwad *et al.* (2014) investigated the long-term behavior of concrete incorporating hemp fibers and concluded that at an age of 1.5 years

hemp fibers did not have a negative effect on concrete strength. Vázquez et al. (2014) found that the presence of RCA in concrete can improve the resistance to chloride penetration since C-S-H gels that exist in higher amounts in RCA assist in chloride binding. Also, the resistance of high-performance concrete with RCA to freezing can be similar to that of normal concrete (Ajdukiewicz *et al.,* 2002). The carbonation depth increases with the increase of RCA replacement ratio, but Lei *et al.* (2008) found that when the percentage replacement of NCA with RCA was higher than 70%, the carbonation depth decreased, which may be due to the adhered mortar on the RCA which increases the total cement content and slows down the carbonation rate.

In this paper, the durability of the proposed HRAC is investigated by evaluating its mechanical performance at the age of 2 years and by studying its resistance to freeze-thaw cycles.

2 Materials and Experimental Procedures

Sixteen different mixes were prepared and are identified in Table 1. The mixes are divided into two groups: Group 1 with MSA of 10 mm and Group 2 with MSA of 20 mm. The control mixes with no hemp fibers and no coarse aggregate reduction are referred to as N10 (NCA with MSA = 10 mm) and N20 (NCA with MSA = 20 mm), and were designed to achieve a concrete compressive strength of 30 MPa. R10 and R20 are two mixes with 50 percent replacement of NCA with RCA, no hemp fibers, and also no reduction of coarse aggregate content.

The other twelve mixes with hemp fibers are identified by a three-part notation. The first part is N (100% NCA) or R (50% replacement of NCA with RCA) and 10 or 20 mm are the MSA. The second part of the notation refers to the length of the hemp fibers (H20 is 20 mm and H30 is 30 mm). The third part is the type of fiber treatment where T1 is alkali treatment and T2 is acetyl treatment. A total of 7 HRAC mixes were used.

Based on the reported studies of Awwad *et al.* (2014), hemp fibers in mixes with fibers were added in a volumetric percentage of 0.75% of the volume of concrete. The weight of the fibers was then calculated based on the average density of the fibers determined to be 1,400 kg/m^3. The weight of the coarse aggregates for these mixes was also reduced by 20% of the concrete volume.

To study the long-term mechanical performance of HRAC, compressive strength tests, flexural strength tests and modulus of elasticity tests were performed at an age of 2 years for 14 of the 16 mixes and the results were compared to the results at 28 days presented in previous studies (Ghosn *et al.,* 2019). The tests were done according to ASTM C39 (2017), ASTM C78 (2016) and ASTM C469 (2014) respectively. For each test, 2 replicates were made for each mix.

The resistance to freeze-thaw cycles was conducted according to ASTM C666 (2015). For each mix, one prismatic specimen (75x100x405 mm) was cast and cured in water for 28 days. Each specimen was then brought to a temperature of -18 °C and tested for fundamental transverse frequency. Then, the specimens were exposed to 144 cycles of freezing and thawing. Each freezing-and-thawing cycle consisted of lowering the temperature of the specimens from 4 to -18 °C and raising it from -18 to 4 °C in a period of 4 hours and 40 minutes.

Table 1. Identification of the concrete mixes.

	Mix No.	Mix ID	MSA (mm)	% Replacement of NCA by RCA	Fiber Length (mm)	Fiber Treatment
Group 1 MSA = 10 mm	1	N10 (Control10)	10	0	-	-
	2	R10	10	50	-	-
	3	N10-H20-T1	10	0	20	Alkali
	4	R10-H20-T1	10	50	20	Alkali
	5	R10-H20-T2	10	50	20	Acetyl
	6	N10-H30-T1	10	0	30	Alkali
	7	R10-H30-T1	10	50	30	Alkali
Group 2 MSA = 20 mm	8	N20 (Control20)	20	0	-	-
	9	R20	20	50	-	-
	10	N20-H20-T1	20	0	20	Alkali
	11	R20-H20-T1	20	50	20	Alkali
	12	N20-H20-T2	20	0	20	Acetyl
	13	R20-H20-T2	20	50	20	Acetyl
	14	N20-H30-T1	20	0	30	Alkali
	15	R20-H30-T1	20	50	30	Alkali
	16	R20-H30-T2	20	50	30	Acetyl

The specimens were tested for their fundamental transverse frequency each 36 cycles. The fundamental transverse frequency (n) was determined according to ASTM C215 (2008) using Humboldt HC-3177 Resonance Test Gauge. The relative dynamic modulus of elasticity (RDME) was then calculated as follows:

$$P_c = \frac{n_1^2}{n^2} \times 100 \quad (1)$$

Where: P_c = Relative dynamic modulus of elasticity (RDME) after c cycles of freezing and thawing (%), n is the fundamental transverse frequency before proceeding freezing and thawing cycles, and n_1 is the fundamental transverse frequency after c cycles of freezing and thawing.

For each test two groups of specimens were tested: Group 1 with MSA of 10 mm and Group 2 with MSA of 20 mm. In each group, normal and recycled aggregate mixes (N and R mixes) with or without hemp fibers and with different fiber lengths and fiber treatments were tested and compared.

3 Results and Discussion

3.1 Long-Term Mechanical Performance

3.1.1 Compressive strength

The results of the compressive strength test are presented in Table 2.

Table 2. Compressive strength test results.

	Mix ID	28 days Compressive Strength Value (MPa)	28 days Compressive Strength Ratio*	2 years Compressive Strength Value (MPa)	2 years Compressive Strength Ratio*	Ratio (2 years /28 days)
Group 1; MSA = 10 mm	N10 (Control10)	38	-	42	1.00	1.11
	R10	34.25	0.9	37.75	0.90	1.10
	N10-H20-T1	23	0.61	29.5	0.70	1.28
	R10-H20-T1	24.5	0.64	29.25	0.70	1.19
	R10-H20-T2	24.5	0.64	26.5	0.63	1.08
	N10-H30-T1	24	0.63	26.25	0.63	1.09
	R10-H30-T1	24	0.63	27.5	0.65	1.15
Group 2; MSA = 20 mm	N20 (Control20)	39	-	44	1.00	1.13
	R20	35	0.9	38	0.86	1.09
	N20-H20-T1	28	0.72	34	0.77	1.21
	R20-H20-T1	25	0.64	31.5	0.72	1.26
	N20-H30-T1	32	0.82	34	0.77	1.06
	R20-H30-T1	26	0.67	31.25	0.71	1.20
	R20-H30-T2	25	0.64	32.75	0.74	1.31

**Ratio = Mechanical property value for the mix divided by that of the control mix N10 in Group 1 and by that of the control mix N20 in Group 2.*

In general, the results at the age of 2 years were consistent with results at the age of 28 days; when the hemp fibers are incorporated in the mix, the compressive strength decreases since aggregates which are the hardest elements in a concrete mix are replaced by fibers which are weak in compression. Furthermore, all mixes showed an improved compressive

strength at the age of 2 years as compared to those at the age of 28 days. This increase ranges from 6 up to 31% for the HRAC mix R20-H30-T2.

3.1.1 Flexural strength

The results of the flexural strength test are presented in Table 3.

Table 3. Flexural strength test results.

	Mix ID	28 days Modulus of Rupture Value (MPa)	Ratio*	2 years Modulus of Rupture Value (MPa)	Ratio*	Ratio (2 years /28 days)
Group 1; MSA = 10 mm	N10 (Control10)	5.1	-	6.87	-	1.35
	R10	4.8	0.94	6.78	0.99	1.41
	N10-H20-T1	4.95	0.97	5.75	0.84	1.16
	R10-H20-T1	4.35	0.85	5.43	0.79	1.25
	R10-H20-T2	4.2	0.82	6.07	0.88	1.45
	N10-H30-T1	4.8	0.94	6.71	0.98	1.40
	R10-H30-T1	4.2	0.82	6.43	0.94	1.53
Group 2; MSA = 20 mm	N20 (Control20)	5.25	-	7.71	-	1.47
	R20	4.57	0.87	7.30	0.95	1.60
	N20-H20-T1	5.1	0.97	6.05	0.78	1.19
	R20-H20-T1	4.65	0.89	5.77	0.75	1.24
	N20-H30-T1	4.95	0.94	6.71	0.87	1.35
	R20-H30-T1	4.5	0.86	6.68	0.87	1.48
	R20-H30-T2	4.5	0.86	6.19	0.80	1.38

**Ratio = Mechanical property value for the mix divided by that of the control mix N10 in Group 1 and by that of the control mix N20 in Group 2.*

The variation of the flexural strength at the age of 2 years is consistent with that at the 28 days; the incorporation of hemp fibers and recycled aggregates leads to lower flexural strength. However, this decrease is less significant as compared to that in the compressive strength as some HRAC mixes have a flexural strength of 94% compared to the that of the control mix at the age of 2 years. In addition, the flexural strength shows a significant increase at the age of 2 years with increases around 50% in some of the HRAC mixes.

3.1.1 Modulus of Elasticity

The results of the flexural strength test are presented in Table 4.

Table 4. Modulus of elasticity test results.

	Mix ID	28 days Modulus of Elasticity Value (MPa)	Ratio*	2 years Modulus of Elasticity Value (MPa)	Ratio*	Ratio (2 years /28 days)
Group 1; MSA = 10 mm	N10 (Control10)	34.2	1.00	30.8	1.00	1.11
	R10	34.1	0.94	28.8	1.00	1.18
	N10-H20-T1	28.6	0.72	22.2	0.84	1.29
	R10-H20-T1	27.7	0.74	22.8	0.81	1.21
	R10-H20-T2	26.8	0.74	22.9	0.78	1.17
	N10-H30-T1	28.3	0.74	22.7	0.83	1.25
	R10-H30-T1	28.8	0.73	22.5	0.84	1.28
Group 2; MSA = 20 mm	N20 (Control20)	36.3	1.00	33.2	1.00	1.09
	R20	34.5	0.95	31.4	0.95	1.10
	N20-H20-T1	30.3	0.78	26	0.83	1.17
	R20-H20-T1	28.9	0.71	23.7	0.80	1.22
	N20-H30-T1	28.6	0.82	27.2	0.79	1.05
	R20-H30-T1	25.5	0.73	24.3	0.70	1.05
	R20-H30-T2	25.7	0.71	23.7	0.71	1.08

**Ratio = Mechanical property value for the mix divided by that of the control mix N10 in Group 1 and by that of the control mix N20 in Group 2.*

Similar to the compressive strength, the MOE is also higher at the age of 2 years than at the age of 28 days. The increase ranges between 5 and 28% for HRAC mixes.

3.1 Resistance to Freeze/Thaw Cycles

Results of Pc or RDME after each 36 cycles of freezing and thawing are presented in Table 5. Group 1 with MSA of 10 mm, had a good resistance to freeze-thaw cycles for all tested specimens with Pc ranging from 77% to 90.4% after 144 cycles. While Pc for the recycled aggregate mix R10 was the lowest in the group (77%), mixes with hemp fibers had a Pc ranging between 77 and 90.4, a value which is even higher than the control mix (83.5%).

Group 2 mixes with MSA of 20 mm, had a lower resistance to freeze-thaw cycles than that of Group 1 mixes. Pc decreased more quickly to reach values ranging between 31% and 56.5% after 144 cycles. Similar to Group 1, 50% replacement of NCA with RCA but without hemp fibers incorporation (R20) led to the lowest value of Pc after 144 cycles (31%). This poor resistance of Group 2 to freeze-thaw cycles can be due to the fact that when the MSA increases from 10 to 20 mm, the cement matrix contains less entrapped air bubbles. During the freezing phase of a cycle, the water present in the matrix freezes and expands causing pressure that may lead to cracks and to the deterioration of the concrete. The more entrapped air bubbles present in the 10-mm matrix relieves the pressure by providing more space for water to expand into when it freezes. As for the effect of incorporating hemp fibers in the mix, the four mixes with hemp fibers had values ranging between 42 and 56.5% as compared with 51% for the control mix N20.

Table 5. Relative dynamic modulus of elasticity (RDME) values of all mixes after each 36 cycles.

	Mix ID	Relative Dynamic Modulus of Elasticity P_C (%)				
		c = 0	c = 36*	c = 72	c = 108	c = 144
Group 1 MSA = 10 mm	N10 (Control10)	100	94.1	90.2	86.2	83.5
	R10	100	98.2	89.5	87.5	77.0
	N10-H20-T1	100	93.8	87.2	81.6	77.0
	R10-H20-T1	100	90.5	90.5	90.5	88.5
	R10-H20-T2	100	90.2	88.5	83.7	79.5
	N10-H30-T1	100	95.2	93.0	93.0	90.4
	R10-H30-T1	100	95.2	93.0	90.4	90.4
Group 2 MSA = 20 mm	N20 (Control20)	100	93.2	79.2	62.4	51.0
	R20	100	92.7	70.2	57.8	31.0
	N20-H20-T1	100	88.1	79.2	70.8	42.0
	N20-H20-T2	100	83.2	75.3	63.7	55.5
	R20-H20-T2	100	85.8	78.3	69.5	53.2
	R20-H30-T1	100	87.7	77.2	70.5	56.5

**c = number of freeze-thaw cycles.*

4 Conclusion

This paper studies the durability and long-term performance of HRAC, a "green" concrete material where natural aggregates are partially replaced by recycled concrete aggregates and industrial hemp fibers. Results showed that at the age of 2 years, HRAC mixes have an improved mechanical performance as compared to the age of 28 days, The compressive strength, the flexural strength and the modulus of elasticity improved by up to 31%, 53% and 28%, respectively. The variation in the mechanical performance between HRAC mixes and control mixes was also consistent at the age of 28 days and the age of 2 years. Furthermore, the resistance to freeze-thaw cycles of HRAC was similar to that of normal concrete mixes after 144 cycles.

Based on these results, it can be concluded that HRAC is a durable concrete that has a reliable long-term mechanical performance and it can be used in cold climates as it has a freeze/thaw durability performance comparable to that of ordinary concrete mixes.

Abstract. *This study examined durability of mortar after repairing crack using alginate gel films (1.5 wt.%) mixed with healing agents under seawater splayed condition. The healing agents consist of Bacillus subtilis (natto) as an aerobic microorganism and glucose as an organic carbon source, thereby producing insoluble calcium carbonate in the gel films in the presence of calcium ions. In this study, repaired mortar was dried under room condition for half year and exposed at seawater splayed condition for another half year. After that, surface condition, elastic wave velocity was measured. In addition, the inside situation in the crack was observed by X ray computed tomography. Based on the results of elastic wave velocity, the property of repair material in mortar was improved under the seawater splayed condition. Additionally the substance in crack derived from healing agents was remained even after seawater splayed exposure.*

1 Introduction

Recently, repair materials associated with microbial induced calcium carbonate precipitation (MICCP) have been intensively studied in the field of self-healing concrete *e.g.* (Jonkers et al., 2010). We proposed a liquid based repair system comprising dry yeast, organic carbon sources, calcium sources mixed with Tris alkali buffering solution (Kawaai *et al*., 2016; Putri *at el*., 2016). The grout used for repairing cracks in concrete is supposed to seep into deeper zones in cracks, joints and gaps spatially distributed in larger areas. Then, calcium carbonate precipitation mainly contributing to the sealing effect can be formed in the cracks well before 24 hours (Kawaai *et al*., 2016). It has been reported that the precipitation rate was largely dependent on the concentration of constituents, pH levels, and ambient environment such as temperature. The effect of temperature is significant in facilitating the precipitation process (Putri *et al.*, 2016), thus leading to a larger amount of precipitates formed compared to those tested in normal room conditions.

Apart from the grout system, the activity of Bacteria added to mixing water was observed to be limited owing to the pore solution with highly alkaline environment (Jonkers, 2011). In order to protect them from corrosive agents and the severe environment, much research has been carried out in the development of encapsulation techniques including expanded clay particles, glass tubes, superabsorbent polymer, more recently alginate-based systems (Jonkers, 2011; Tittleboom *et al.*, 2011; Wang *et al.*, 2014; Palin *et al.*, 2016).

doi:10.23967/dbmc.2020.053

According to past research reported by Kawaai *et al.*, (2017), precipitation of calcium carbonate in alkaline environment has been confirmed by precipitation tests using aerobic Bacillus subtilis (natto) encapsulated in calcium alginate capsules. Sodium alginate extracted from brown seaweed could provide viscosity in aqueous solution, which varies depending on the concentrations. When sodium alginate dissolved in a liquid is used for repairing cracks in concrete, there is a strong possibility that the alginate reacts with calcium ions available on the cracked surface, thus forming a polymer comprising calcium alginate via ion-link on the cracked surface. This could result in in-situ encapsulation for the microorganism and nutrients in the cracks. Generally, there are two types of microorganisms, anaerobic and aerobic microorganisms. The former can metabolize an organic carbon sources in an oxygen-free environment. On the other hand, the latter requires oxygen for the metabolic activity. In this study, we selected Bacillus subtilis (natto) as an aerobic microorganism. The liquid-based mixture is supposed to be applied to concrete structures in tidal zones under marine environment. Dissolved oxygen is expected to be available during the wet and dry cycles. Based on the above background, this study examines the durability of repaired mortar under seawater splayed environment.

2 Experimental Programs

2.1 Materials

First, culture solution of Bacillus subtilis (natto) containing sodium alginate is stirred using a stirrer for 30 minutes until the sodium alginate dissolves. Subsequently, Tris buffer solution or glucose is added. The concentrations of each constituent of the mixtures are shown in Table 1. The experimental parameters include the presence (N1 mixtures) and absence (W mixture) of Bacillus subtilis (natto), the concentration of sodium alginate is specified as 1.5 wt.% for all the mixtures tested. The use of Tris buffer solution with concentrations of 0.1 mol/L is also considered as a testing parameter. In this study, three mixtures were totally prepared.

Table 1. Concentrations of each constituent of mixtures.

	Mixtures	Sodium Alginate (%)	Glucose (mol/L)	Tris buffering solution (mol/L)
N1	N1-G1-T0	1.5	0.4	-
	N1-G1-T1	1.5	0.4	0.10
W	W -G0-T0	1.5	-	-

2.2 Cultivation of Bacillus Subtilis (Natto)

In this study, Bacillus subtilis (natto) was cultivated using culture media mainly comprising NH_4Cl, NH_4NO_3, Na_2SO_4, $MgSO_4$, $CaCl_2$, K_2HPO_4, KH_2PO_4 in this study. The round rod shape of Bacillus subtilis (natto) forms a spore per a bacterial cell in the bacterial body.

Spores are formed when it becomes an environment not suitable for growth such as oxygen, water and nutrient sources. And then, they become dormant and inactive. However, if the environment is set, the spore dormancy state ends, and germination begins. And then it becomes vegetative cell and the activity starts. Therefore, the Bacillus subtilis (natto) has higher resistance to environmental fluctuation compared to other microorganisms. In this study, the culture solution of the Bacillus subtilis (natto) after 24 hours was used as repair mixtures. Before preparing the mixtures, the dissolved oxygen concentration in the culture solution was measured to confirm the metabolic activity of Bacillus subtilis (natto) without an aeration apparatus.

2.3 Specimen Preparation and Exposure Tests

In this study, a mortar specimen with a water cement ratio of 0.5 and unit water content of 316 kg/m^3 and unit weight of crushed sand 1264 kg/m^3 was prepared using a cylindrical mold of ϕ 50×100 mm. Specimens were demolded after 24 hours and sealed curing was carried out until the age of 28 days. In order to simulate the cracks generated in the concrete member, split cracks were induced using a loading machine. The experimental set-up is similar to tensile strength test. The crack width was targeted around 0.5 mm. And then, the repair mixtures were poured into the cracks. After 1 week, exposure tests were carried out either through wet conditions (12 hours) and dry conditions (12 hours) or only wet conditions (24 hours). Wet cycles were executed using distilled water containing NaCl (3%) for both cases.

2.4 Measurement of Crack Width and Sealing Rate

The crack width and sealing rate by MICCP are measured using microscope (Dino-Lite Edge AM7915, ANMO) as shown in Figure 1. The five points highlighted in the figure are consistently measured using two specimens subjected to each exposure condition. The sealing rate is calculated based on the ratio of widths occupied with the precipitates over crack widths at each measurement point.

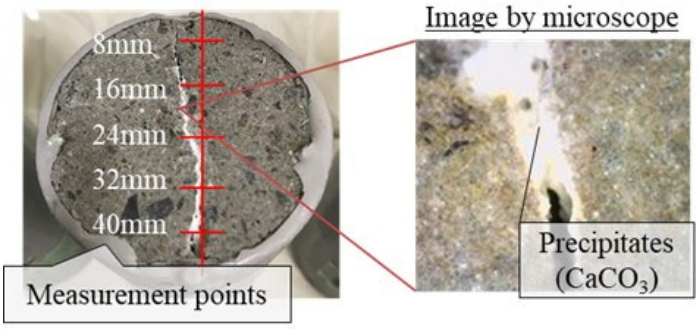

Figure 1. Measurement of crack width and sealing rate by microscope.

2.5 Exposure Condition after Repairing

The specimen after repairing was exposed to seawater splayed condition. The seawater was pumped up from Kurihama bay and splayed to specimens as shown in Figure 2. Seawater was splayed twice in a day and specimen was exposed for 6 months.

Figure 2. Seawater splayed environment.

2.5 Measurement of Elastic Wave Velocity

In order to evaluate the crack filling effect of self-healing material, the elastic wave velocity was measured every 1 month after exposure test. Elastic wave velocity can evaluate the connectivity of materials at crack part and the value increase with the crack filling due to deposition of healing materials produced by the metabolic activity of Bacillus subtilis. The schematic figure of measurement was illustrated in Figure 3. The sensors were set at the side surface of specimen and the elastic wave velocities against vertical direction along the crack were evaluated.

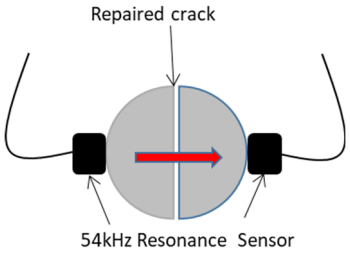

Figure 3. Measurement outline of elastic wave velocity.

3 Experimental Results and Discussion

3.1 Results of Elastic Wave Velocity

The elastic wave velocity of each specimen exposure to seawater splayed condition after 0, 30, 90, 180 days is shown in Figure 4. Before exposure to seawater splayed condition, the specimens were exposed to experimental room (20 degree centigrade and 60 % R.H.) and specimens were dried. Therefore the results of all of elastic wave velocity of specimens before exposure were equivalent to cracked mortar. After exposed to seawater splayed environment,

the elastic wave velocities of mortar with crack were increased. Especially in the cases of specimen with Bacillus subtilis, the elastic wave velocities of specimen were clearly increased.

It was assumed that the repair substance inside of crack remained and the elastic wave penetrate that part. Figure 5 show the result of X ray CT in crack after 180 days exposure. From this figure, it can be said that the substance produced by Bacillus subtilis were remained inside of crack even after exposed to seawater splayed condtion.

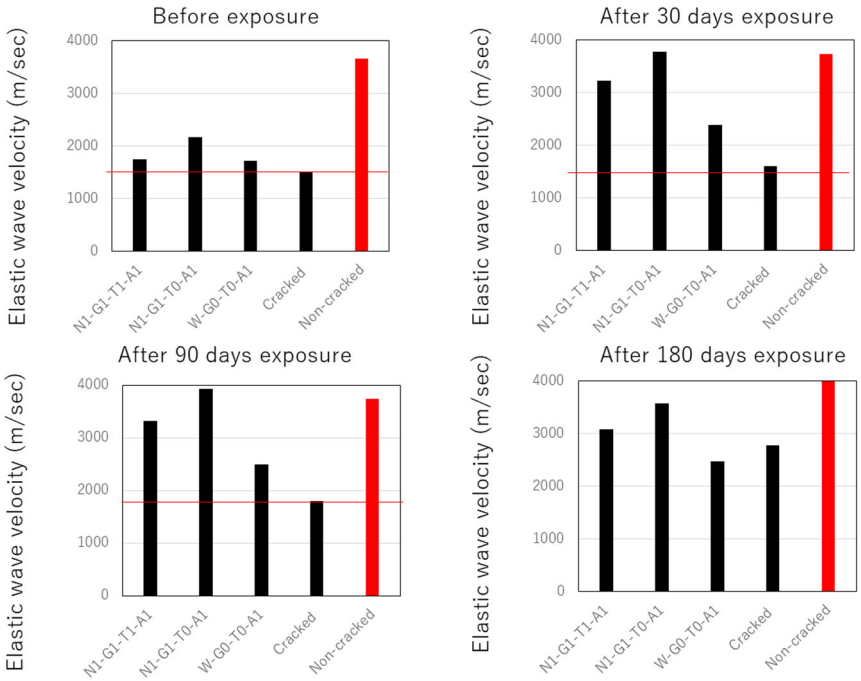

Figure 4. Elastic wave velocities before and after exposure.

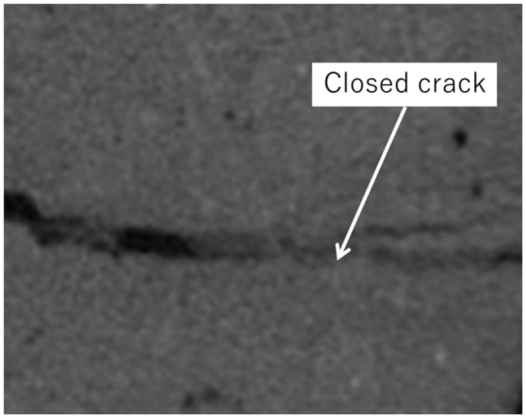

Figure 5. Crack closure situation after exposure for 6 months under seawater splayed condition.

4 Conclusions

- Based on the observations made on the sealing rate of crack repair, the presence of gel films remained intact on the cracked surface under exposure conditions could contribute to higher sealing effect in the cases of the N1 mixtures.
- The results suggest that the repair effect of crack produced by Bacillus subtilis would be kept even after exposed to seawater splayed condition.

Effect of Vapor Diffusion Port on Drying of Wood-Frame Walls

Ben Zegen Reich[1], **Hua Ge**[1] **and Jieying Wang**[2]

[1] Department of Building, Civil and Environmental Engineering, Concordia University, Montreal, Canada, hua.ge@concordia.ca

Abstract. *Vapor diffusion ports (VDP) that are drilled in the exterior sheathing of wood-frame walls are commonly used in wood-frame construction in the coastal region of British Columbia with the intention to improve the drying capacity of wood-frame exterior walls. This practice was originated following the systematic building envelope failures due to rain penetration that occurred in this region around 1985-1995. A previous laboratory study carried out by FPInnovations found that the diffusion ports provided substantial improvement in the drying rates of Oriented Strand Board (OSB) sheathed walls, but not for plywood sheathed walls (Hazleden and Morris, 2001). A more recent laboratory test (Wang, 2018) using wood-frame walls with higher insulation levels in compliance with the current more stringent energy code found that VDPs did not significantly improve the drying rates; On the other hand, the provision of VDPs may allow moisture ingress into the wall assembly instead in a damp environment. The difference in these two studies in terms of test wall sizes, moisture sources, and test conditions may have attributed to the different findings. To provide a more comprehensive and systematic evaluation of the effect of VDPs, hygrothermal simulations using Wufi-2D are carried out in this study. The Wufi-2D model is firstly validated by comparing simulation results to the test results provided by Wang (2018), which tested the effect of VDPs under laboratory conditions by using a wetted wood block installed inside each wall assembly as a simulated moisture source. The simulation results agree well with the measurements. The Model is then used for sensitivity analysis with different levels of rain leakage with and without VDPs using yearly weather data. The variables included are types of exterior insulation, types of sheathing (OSB versus Plywood), and types of sheathing membrane. This paper presents the validation of the model and simulation results under transient conditions with rain leakage. General conclusions on the effect of VDPs are provided.*

Keywords: *Vapor Diffusion Ports, Wood-Frame Walls, Hygrothermal Simulations, Durability.*

1 Introduction

Moisture content (MC) of various elements of a building's wall assembly greatly influences its durability. In areas with high seasonal wetting potential such as the coastal region of British Columbia (BC), a practice of providing vapor diffusion ports (VDP) in the exterior sheathing of wood-frame exterior walls to encourage drying was introduced in the late 1990's and gained popularity in the region. However, little research has been done to investigate the effect of VDPs on building assembly durability. There are mainly two laboratory experiments. Hazleden and Morris (2001) compared drying rates of larger wood-frame assemblies with framing wetted to high level of moisture contents initially using a large environmental chamber under laboratory conditions with the addition of VDPs. The moisture contents of sheathing were measured. It was found that for OSB sheathed walls, VDPs had a substantial effect on drying of sheathing, with typical MC levels in the sheathing being 34%-36% MC without a VDP and 22%-25% MC with a VDP after the drying process. For plywood sheathed walls, VDPs had

doi:10.23967/dbmc.2020.160

very little effect on drying performance. Wang (2018) tested the VDPs applied on more recent but smaller wall assemblies and materials, including deep cavity walls and exterior insulated assemblies under laboratory conditions. The moisture contents of an initially wetted wood blocked placed over the bottom plate were measured. The study concluded that VDPs had insignificant effects on drying of the wet wood block simulating a rain leakage scenario for assemblies sheathed in OSB or plywood.

These two previous studies focused on laboratory testing under simulated environmental conditions. This study aims to provide a more comprehensive and systematic evaluation of the effect of VDPs through transient hygrothermal simulations representing more realistic climatic weather conditions and moisture loads.

2 Methodology

The program chosen for hygrothermal simulation is Wufi-2D, a transient 2D heat and mass transfer program that is capable of simulating the effect of VDPs on the hygrothermal performance of the wall assemblies. The model is firstly validated by comparing simulation results with the measurements from the recent experiment conducted by Wang (2018) under laboratory conditions. The validated model is then used to evaluate the effect of VDP on the hygrothermal performance of a typical 2x6 wood-frame wall, defined as a baseline wall, under real weather conditions with rain leakage assumed to the exterior surface of sheathing as a moisture source. A parametric study is carried out on the baseline wall to investigate the effect of various parameters including wall orientation, sheathing materials, and exterior insulation.

2.1 Hygrothermal Model Setup

The experiment by Wang (2018) was carried out for a variety of wall assemblies and an initially wetted wood block placed above the bottom plate was used as the moisture source. The moisture content of the wet wood block was measured during the drying process at two depths, 5 mm and 12 mm, and 18 readings were taken on a weekly basis over the test period of 127 days. The hygrothermal model is set up to represent the test configuration as close as possible. The wet wood block is divided into two layers, surface and center, for a better comparison of measurements at two depths. The VDP has a diameter of 50 mm and placed 100 mm above the wet wood block. The VDP is represented by a 50 mm slot in the hygrothermal model. The initial MC of each layer is set to match the experiment readings on day 0, which vary among test assemblies. The experiment was conducted in an outside shed that was open to the environment but covered from solar radiation and rain events, and the simulation model uses temperature and relative humidity (RH) data measured on-site but no rain or solar inputs. Figure 1 shows the simulation model in Wufi-2D and the experiment test setup.

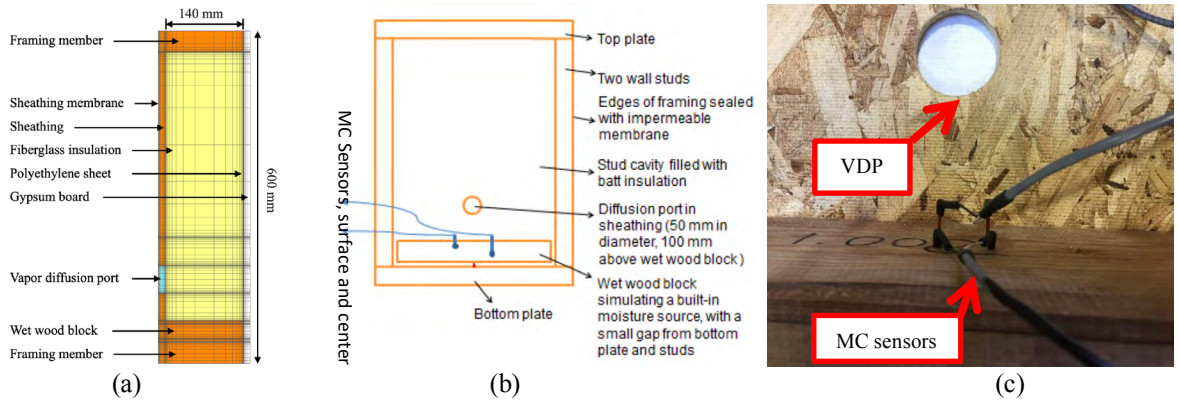

Figure 1. (a) Wufi-2D simulation model for validation (b, c) Experiment assembly (Wang, 2018).

2.2 Hygrothermal Model Validation

Sixteen of these wall assemblies are simulated, with OSB and plywood sheathing, with and without exterior insulation, with and without VDPs, and the MC of the wet wood block from the simulations are compared to the experiment results. As an example, Figure 2 shows the comparison between experimental and simulation results for the case of an OSB sheathed 2x6 wall with no VDP and the case of OSB sheathed wall with VDP. In general, the simulation results agree well with the measurements. The simulation results have a better agreement with the measurements for the center location than that for the surface layer. The main discrepancy occurs during the initial drying period. This may have attributed to the initial moisture content set in the model as only two measurements, at 5mm and 12mm depth, are available and also the model's limited capacity in modeling moisture transport in wood at moisture content level above its fiber saturation. The comparison between the simulation and experiment results is made by root-mean-square error (RMSE), which is the root of the sum of the differences squared, divided by the number of measurements. Of 16 simulation cases compared to the experiment, the RMSE ranges from 0.81 to 3.77 with a median value of 1.65 for the surface layer, and ranges from 0.38 to 4.72 with a median value of 1.30 for the center layer.

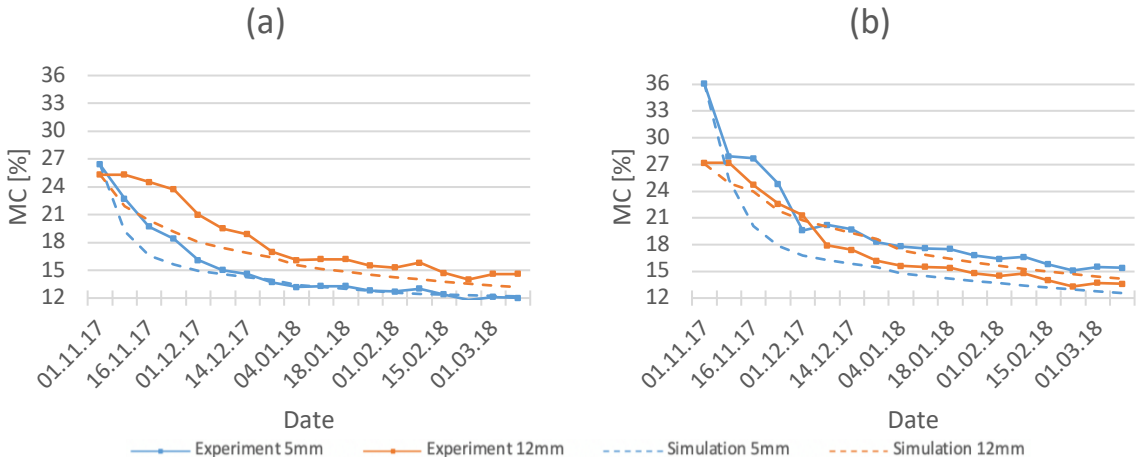

Figure 2. MC of wet wood block for an OSB sheathed 2x6 wall with no exterior insulation, surface and center layers, experiment and simulation results, without (a) and with (b) VDP.

2.3 Parametric Study

The baseline assembly is a 140 mm deep and 600 mm high wall cavity filled with fiber glass insulation, a polyethylene vapor barrier and gypsum board towards the interior, sheathed in OSB and protected with a spun bonded-polyolefin (SBPO) membrane. Cladding assumed is a 13 mm fiber cement layer with a 20 mm ventilated air space behind it with a 100 air changes per hour to the exterior air assumed. To evaluate the role of VDPs under more realistic conditions, the validated model is adapted with the removal of the wet wood block and the addition of rain penetration to the sheathing as an ongoing moisture source, aligned with the ASHRAE 160 standard. 1% fraction of driving rain is applied uniformly on the sheathing material. The initial MC of the sheathing and framing is set to 10%.

The weather data used is for Vancouver, BC. The baseline weather data corresponds to the most severe year concerning moisture damage to building envelopes out of a measured period of 10 years, as published in ASHRAE RP-1325 by Salonvaara, Zhang, and Karagiozis (2011). Orientation is East, the prevailing wind-driven rain direction. The rain model used is for buildings up to 10 meters in height. Interior conditions are set using ASHRAE-160 model, heating only. The simulation time period is two years, starting November 1st, 2017 at 1-hour intervals.

Following the baseline simulations, the effect of wall orientation is investigated by facing the wall to south instead of east for the maximum solar exposure instead of maximum rain deposition. Plywood sheathing is simulated to compare with the OSB baseline. Mineral wool exterior insulation is added and compared to the baseline with no exterior insulation.

3 Results and Discussion

3.1 MC Analysis

The simulated MC of the sheathing below the VDP and the bottom plate is used for a comparison of assemblies with and without VDPs.

3.1.1 Baseline case

3.1.1.1 Sheathing Figure 3 presents the MC of the OSB sheathing below the VDP and of the bottom plate for the baseline simulations. The simulation begins Nov. 1st, the beginning of the winter which is the rainy season in Vancouver, and so in the beginning of the simulation there is quick intake of MC from the environment and rain penetration. The moisture intake is slightly more rapid for the assembly with a VDP by a maximum difference of 0.63% MC that happens on Nov. 11th. Both assemblies reach a similar maximum MC after the first winter, with the VDP assembly reaching 27.5% MC on Feb. 28th and the assembly without the port reaching 28.3% MC on the same day. On following winters, when the starting MC is higher, the VDP assembly reaches 28.8% MC and the assembly without the port reaches 30.4% MC, also on Feb. 28th. Thus, the maximum MC value for the assembly without a VDP is 1.6% higher than that with VDP.

From beginning of the spring until end of the summer (beginning of Mar. until end of Aug.), the assemblies dry out to the exterior, and the assembly with the VDP has MC by up to 3.8% lower than the assembly without VDP at times.

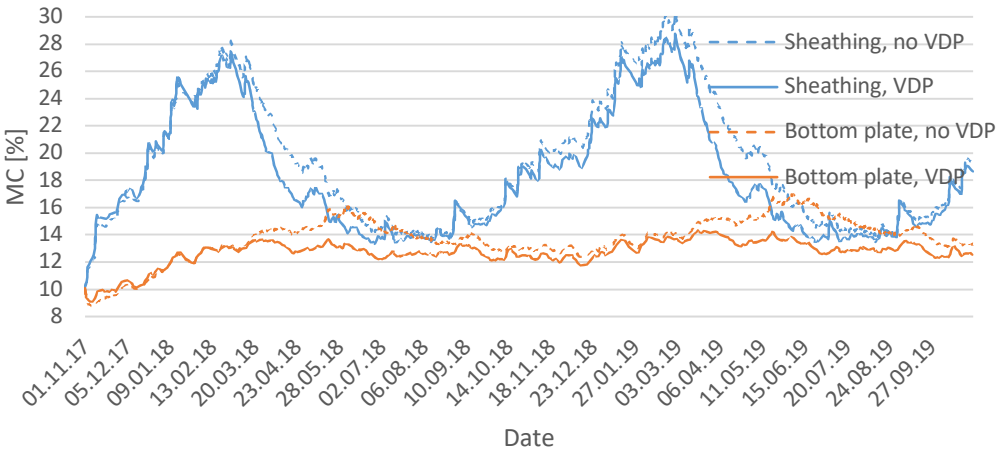

Figure 3. MC of OSB sheathing and bottom plate for the baseline rain infiltration simulations.

The time to dry from the maximum MC to under 20% MC is 34 days for the VDP assembly, occurring on April 4th, compared to 56 days for the assembly with no port, occurring on April 26th. The autumn period (Sep. to Nov.) is similar to the winter period with slightly decreased wetting.

Other than the beginning of the first winter, the assembly with the VDP has a lower value of MC for the rest of the simulation duration. During dryer periods the OSB sheathing MC with and without VDP is similar, and there is no observed effect of moisture intake from the environment due to the VDP.

3.1.1.2 Bottom plate. In order to investigate the effects of the VDP on other components in the wall assembly that are further away from the port, MC is displayed in Figure 3 for the top 5.3mm of the bottom plate, which is the portion of the bottom plate that would be more susceptible to durability issues including mold growth when conditions allow it.

After an initial phase of water intake from the environment and redistribution in the assembly, the bottom plate shows a relatively low variance in MC values throughout the year. During periods of wetting, which occurs to the sheathing, there is little difference between the MC with and without the VDP. Contrarily, during drying periods, the MC of the bottom plate for assemblies with a VDP is by up to 3.3% lower. This can be explained by the quick redistribution process within the assembly, which makes the MC difference in the bottom plate follow the MC difference in the sheathing.

For the bottom plate, similar to the sheathing, no undesired effects of the VDP are observed, except for the beginning portion of the simulation where the VDP allows for quicker moisture intake. Overall, it is found that the MC of other components in the assembly follows closely the differences in MC in the sheathing.

3.1.2 Effect of wall orientation

Two assemblies with the same parameters but facing south instead of east for maximum solar exposure instead of maximum rain deposition are simulated. Figure 4 presents these results compared to the baseline. Due to the lower rain exposure on south orientation, the MC values of sheathing are significantly lower, with a maximum value of below 20% MC as opposed to a

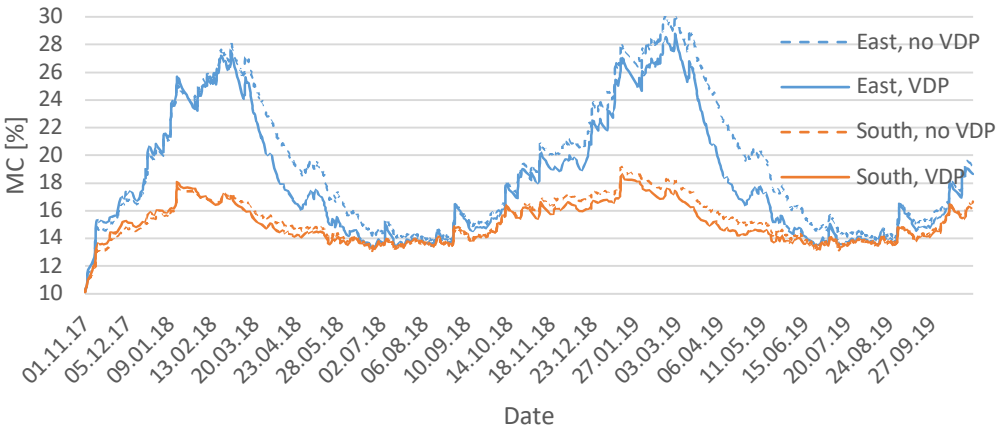

Figure 4. sheathing MC for east and south orientations, with and without a VDP.

value of 30% MC for the baseline simulation facing East. The effect of the orientation change is significant because it directly affects the amount of driving rain that is deposed on the sheathing. The VDP assembly compared to the one without shows a more moderate improvement of 1% lower MC facing south compared to 3.8% facing east at most. Same as with the baseline simulations, there are no adverse VDP effects except for a faster moisture intake during the first transient phase of moisture equilibration in the beginning of the simulation.

3.1.3 Effect of sheathing materials

Figure 5 shows the comparison in MC between plywood and OSB. Overall, MC behavior is similar to the OSB assemblies, as are drying times to reach under 20% MC. The maximum difference between values with and without a VDP is 4.8% MC for plywood compared to 3.8% in OSB, and occurs at the same time. This can be explained by the plywood assemblies reaching higher MC values and being able to dry further than the OSB assemblies, with or without the presence of a VDP. It shows that for high load of wetting, VDPs can be beneficial in plywood too.

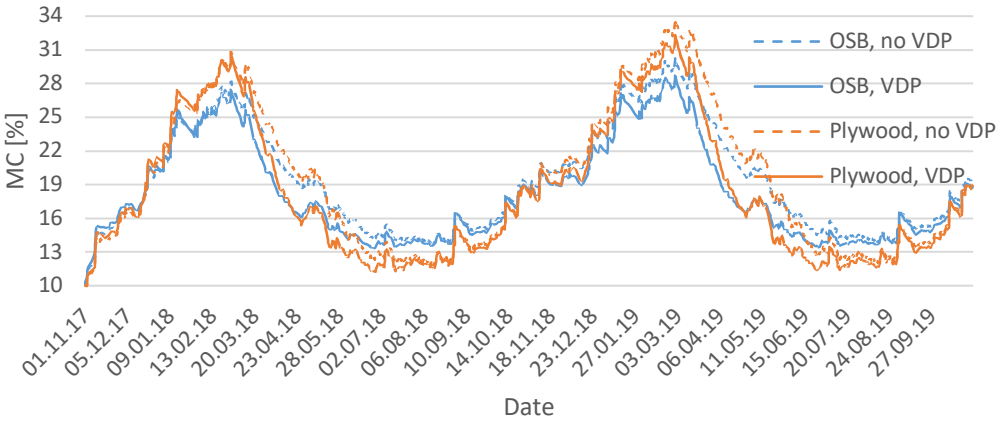

Figure 5. MC in sheathing (OSB vs. plywood), east orientation, with and without a VDP.

3.1.4 Effect of adding exterior insulation

An exterior insulation layer of 75 mm mineral wool is added to the baseline assembly. Figure 6 presents the sheathing MC for the assemblies with and without mineral wool exterior insulation, with and without a VDP. MC is significantly lowered and so the VDP effect is reduced. The MC behavior stays similar to the baseline simulation. For the baseline simulation with no VDP compared to the assembly with mineral wool exterior insulation and no VDP, the maximum MC is reduced by 7.5%, from 30.5% to 23%, while the minimum MC values do not change. The VDP maximal effect is reduced from maximum relative drying of 3.8% to 2.2% MC, and there is no moisture intake from the environment.

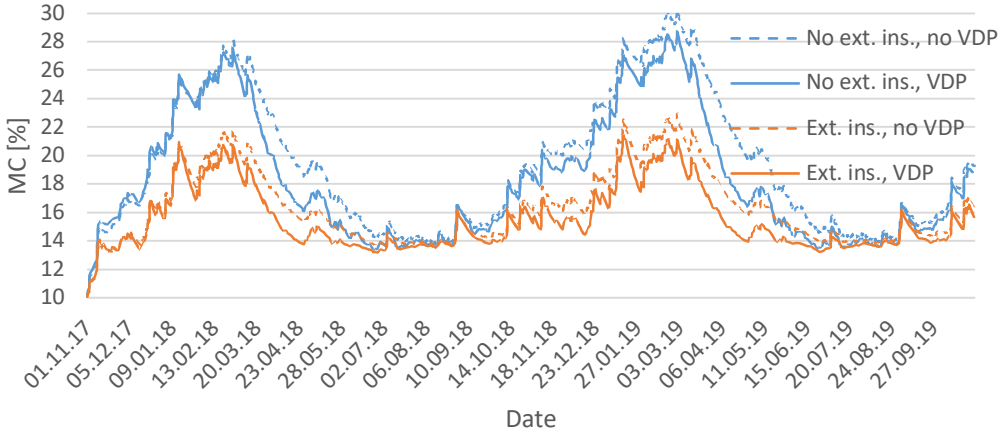

Figure 6. MC of OSB sheathing with and without mineral wool ext. insulation, with and without a VDP.

3.2 Mold Index

In addition to the examination of resulting MC in the assembly, mold index is calculated following ASHRAE standard 160-2016. Mold growth index is calculated and compared for two sensitivity classes: “Sensitive” class, corresponding to wood-based boards such as plywood and OSB, and “Very sensitive”, usually used for untreated wood and used here as a worst-case scenario for mold growth potential. The mold growth index calculation uses hourly temperature and relative humidity data extracted from the simulations following the procedure prescribed in ASHRAE 160. The standard states that in order to minimize problems related to mold growth, the mold growth index should not exceed a value of three.

The maximum mold growth index over the simulation period is summarized in Table 1. The mold growth index is slightly higher for the assemblies with a VDP, in spite of the lower MC values on the sheathing. The explanation for this phenomenon is that during the beginning of the simulation there is a short period during which the MC and RH are rising quicker in the assemblies with a VDP, and therefore a higher maximum mold growth index in the VDP assemblies. Later in the simulation RH levels are lower in the assemblies with the VDPs and the difference in mold index reduces, but the 2-year simulation period is not enough to close the initial gap in mold index for most simulations. For the assemblies examined, no improvement in mold index was found, even though MC values did show improvement. According to ASHRAE 160 criteria, there is mold growth risks only when “very sensitive” class is assumed for both OSB and Plywood sheathed wall assemblies.

Table 1. Maximum mold growth index over the simulation period.

Simulation inputs			Mold index, Sensitive		Mold index, Very sensitive	
Sheathing	Exterior insulation	Orientation	without VDP	with VDP	without VDP	with VDP
OSB		East	1.38	1.39	4.41	4.43
OSB		South	0.02	0.02	0.02	0.02
Plywood		East	1.00	1.12	3.47	3.84
OSB	Mineral wool	East	0.03	0.07	0.11	0.21

4 Conclusions and Discussions

Vapor diffusion ports have an ability to modestly improve the rate of drying for wall assemblies with an on-going moisture source of rain infiltration on the sheathing layer based on the hygrothermal simulations of this study. Table 2 summarizes the improvement due to VDP effects of MC (max and root mean square difference), mold index, and number of days to dry to under 20% MC. The higher the MC of the assembly, the greater the potential contribution of the VDP to drying. For the East-oriented wall, the maximum MC difference in OSB sheathing is 3.85% with an average difference of 1.5%, while for the south-oriented wall the maximum MC difference in OSB sheathing is 1% with an average difference of 0.4%. Similar trend is found for plywood-sheathed wall. With the addition of exterior insulation, the temperature of sheathing is elevated and therefore improved drying capacity. Consequently, the contribution of VDP to drying is reduced. The provision of VDP also reduces the time for OSB sheathing to dry to below 20% MC. For example, an OSB sheathed wall with no exterior insulation oriented to the east will take 22 less days to dry to under 20% MC due to the presence of a VDP. However, the effect of VDP on the mold growth risk is negligible.

Table 2. Summary of improvement in MC and mold index due to VDP effects (comparison between assemblies with VDP and without VDP).

Simulation inputs			MC - Max [%]	MC- RMSD [%]	Mold index	Time to dry under 20% MC [days]
Sheathing	Exterior insulation	Orientation				
OSB		East	-3.85	-1.50	0.02	-22
OSB		South	-1.09	-0.44	0.00	NA
Plywood		East	-4.85	-1.84	0.37	-38
OSB	Mineral wool	East	-2.19	-1.07	0.10	-17

Abstract. *The purpose of the present study is to evaluate pore structure of hardened cement paste immersed in sodium sulfate solutions and to experimentally examine the relation between the change of pore structure and hydration products. Cement paste specimens were immersed in sodium sulfate solutions and ion-exchanged water for two weeks. Since oxygen gas can pass through the pores having micro scale, it is possible to evaluate the effect of the pore structure on the oxygen transport in cement pastes. Thus, the oxygen diffusion coefficient (D_{O2}) of the specimens after immersion were measured, and the pore volume and the pore size distribution were also measured. In addition, the phase compositions of the specimens were acquired. As a result, D_{O2} of the specimens immersed in the sodium sulfate solutions decreased as compared to the specimens immersed in the ion-exchanged water. The tortuosity of the specimens immersed in the sodium sulfate solutions increased due to decreasing of the pore volume having a diameter larger than 20 nm. There was a correlation between the volume of ettringite and the pore volume having a diameter larger than 20 nm. According to the above results, it was considered that the decreasing of D_{O2} in the case of sulfate immersion can occur as a result of the complication of the pore structure owing to filling of the pores by ettringite.*

Keywords: *Sulfate Attack, Oxygen Diffusion Coefficient, Pore Structure, Tortuosity, Ettringite.*

1 Introduction

The sulfate attack is known as a chemical reaction caused by sulfate and causes the fragility and tissue fragility in hardened cement paste by generating a large amount of ettringite. Although there are not many cases of sulfate deterioration in Japan, there is a high potential risk of sulfate attack in Japan because it is revealed that the marine clay layer producing sulfates is widely distributed (Matsushita *et al.,* 2010). In addition, it is considered that cement-based materials are used for building of radioactive waste processing facilities.

Generally, in order to predict the deterioration phenomenon, it is necessary to grasp the ion transfer characteristics affecting the degradation of hardened cement paste. Furthermore, the ion transfer in the hardened cement paste is known to be greatly affected by the pore structure. Thus, in order to predict the progress of sulfate attack, it is necessary to grasp the pore structure as a transferring field of sulfate ions. However, the pore structure and mass transfer characteristics are significantly changed when the sulfate ions penetrate the hardened cement paste. Sulfate ions causes a reaction with cement hydrate constituting the solid phase and generates ettringite in large quantities, that is considered the cause of change, but there are few

examples of experimentally examined changes of pore structure and mass transfer characteristics when affected by sulfate attack.

Therefore, we evaluated the oxygen transfer characteristics affected solely by pore structure to clarify the change in the pore structure of the hardened cement paste immersed in sodium sulfate solutions.

2 Specimens and Methods

2.1 Preparation of Specimens

In this study, ordinary portland cement was used. Table 1 shows the chemical compositions of the cement, and Table 2 shows the density and specific surface area. The mineral compositions calculated by Bogue equation is shown in Table 3. Three types of cement paste specimens having water to cement ratio of 45%, 55% and 65% were prepared. The size of the specimens was 3 × 4 × 0.5 cm. It was demolded at 1 d, and it was wet-sealed curing until 28 d at 20 °C.

2.2 Sodium Sulfate Immersion and Ion-Exchanged Water Immersion

The specimens were immersed in sulfate solutions. Sodium sulfate and ion-exchanged water (electrical conductivity 0.055μS/cm) were used for sulfate solutions. The concentrations of sodium sulfate solutions were 0.5 and 5 mass%. The specimens were immersed in solutions with the liquid-to-solid ratio of 5.0 at 20 °C for 2 weeks. The specimens were also immersed in the ion-exchanged water for comparison with the case of sodium sulfate immersion.

2.3 Analysis

The pore volume of each specimen was measured by Archimedes method. Each specimen after immersion was crushed into small pieces, after which 3 pieces (about 3 g) were immersed in ion-exchanged water and reduced pressure for 30 min. The mass of the specimens under water and the mass of the surface-dried condition were subsequently measured. Thereafter, the specimens were dried at 50 °C in a drying oven until the specimens mass no longer changed. The pore volume was calculated by the following equation (1)

$$V = \frac{m_s - m_{50d}}{m_s - m_W} \tag{1}$$

where V is the pore volume (m^3/m^3), m_s is the mass of the surface-dried condition (g), m_{50d} is the mass of the dried condition at 50 °C (g), and m_w is the mass of the specimen under water(g).

Pore size distribution was measured by mercury-intrusion-porosimeter. The crushed samples (about 5 mm) were immersed in acetone for 2 d to prevent further hydration. These specimens were subsequently placed under vacuum to remove the acetone and stored in a desiccator in the presence of silica gel until the mass no longer changed. The pressure range was 0.1 kPa to 400MPa. The measurement range of the pore diameter is approximately 4 nm to 120 μm.

Kikuchi *et al*. (2010) was measured the oxygen diffusion coefficient of the hardened cement paste, which is capable of grasping the complexity of the pore structure. Therefore, in order to grasp the pore structure of the specimens immersed in sodium sulfate solutions, the oxygen diffusion test was performed. The specimens after immersion were dried in a desiccator containing silica gel until the mass no longer changed. The oxygen diffusion test was carried out with reference to the method of Shirakawa *et al*. (1999). The oxygen concentration was recorded, when the change in oxygen concentration in the nitrogen gas side cell became constant. The oxygen diffusion coefficient was determined using the formula (2)

$$D_{O_2} = \frac{R_N \cdot (C_N - C_b) \cdot (L + \delta_N + \delta_O)}{\left\{1 - \frac{R_N}{R_O} \cdot \left(\frac{M_O}{M_N}\right)^{\frac{1}{2}} \cdot (C_N - C_b) - C_N\right\} \cdot A_C} \tag{2}$$

where D_{O_2} is the oxygen diffusion coefficient (cm^2/s), C_N is the oxygen concentration in nitrogen gas (%), C_b is the oxygen concentration in nitrogen gas cylinder (%), R_N and R_O are the nitrogen and oxygen gas flow rates (cm^2/s), M_N and M_O are the nitrogen and oxygen molecular weight (g/mol), L is the specimen thickness (cm), A_C is the cross-sectional area of the specimen (cm^2), and δ_N and δ_O are the boundary film thickness of the nitrogen gas side and oxygen gas side (mm).

Phase composition of the crystal phase of the sample was quantified by XRD / Rietveld analysis. The samples after immersion were immersed in acetone for 2 d and subsequently placed under vacuum to remove the acetone for 2 d. The samples were crushed and dried at 20 °C and 11% RH until the sample mass no longer changed. In this study, corundum was used as a standard sample, and the amount of the amorphous phase was quantified by the external standard method (Sagawa *et al.,* 2014). The compositions of amorphous phase and CaO/SiO_2 molar ratio of C-S-H (C/S ratio) were calculated by mass balance calculation (Maruyama *et al*., 2010) using the composition of each hydrate in 11% RH reported by Suda *et al*. (2014).

3 Results and Discussion

3.1 Effect of Sodium Sulfate on Oxygen Diffusion Coefficient

Figure 1 shows the oxygen diffusion coefficient of the sample immersed in sodium sulfate and ion-exchanged water. The oxygen diffusion coefficients of the specimens immersed in sodium

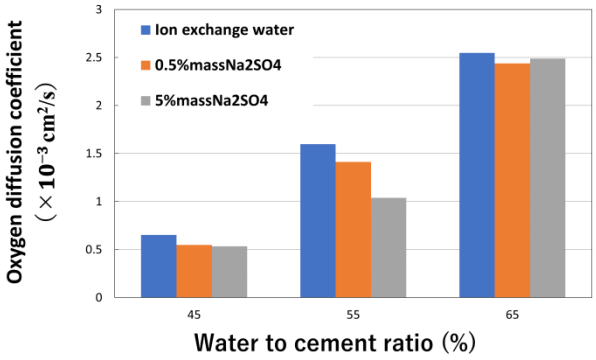

Figure 1. Oxygen diffusion coefficient of hardened cement pastes after immersion.

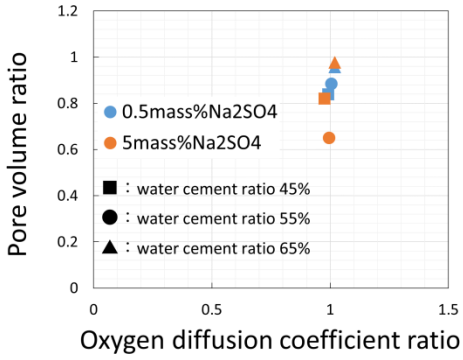

Figure 2. Relationship between oxygen diffusion coefficient ratio and pore volume ratio.

sulfate were reduced regardless of the water-to-cement ratio as compared with the case of ion-exchanged water. However, the degree of decreasing in the oxygen diffusion coefficient varies from water-to-cement ratio. The water-to-cement ratio 55% is large reduction degree, on the other hand, the degree of decreasing was reduced at the water-to-cement ratio 65%.

3.2 Change in Pore Structure by the Effects of Sodium Sulfate

The relationship between the decreasing in the oxygen diffusion coefficient affected by sodium sulfate and the change in the pore structure of the specimens was examined. First, the effect of the change in the pore volume was examined to quantify the change caused by the effect of sodium sulfate. The oxygen diffusion coefficient ratio R_{O_2} was calculated by the equation (3) using the value of the sample immersed in ion-exchanged water $D_{O_2\_water}$, which is not affected by sodium sulfate. Similarly, the pore ratio was calculated.

$$R_{O_2} = \frac{D_{O_2\_Na_2SO_4}}{D_{O_2\_water}} \tag{3}$$

Figure 2 shows the relationship between the oxygen diffusion coefficient ratio and the pore volume ratio. From the figure, the pore volume ratio is almost unchanged at 1.0 while the oxygen diffusion coefficient ratio is greatly changed in the range of 1.0 to 0.6. Thus, the decreasing in the oxygen diffusion coefficient caused by the effect of sodium sulfate could not be explained by a change in the pore volume.

Because it has been reported that the tortuosity is an index representing the complexity of the pore structure (Saeki *et al.*, 2014), the tortuosity of the oxygen diffusion in the hardened cement paste was calculated in this study. The tortuosity of the oxygen diffusion was calculated using the formula (4), with reference to the past studies (Kikuchi *et al.,* 2010; Saeki *et al., 2014*)

$$D_{O_2} = \frac{1}{{\tau_{O_2}}^2} \cdot D \tag{4}$$

where τ_{O_2} is the tortuosity of the oxygen diffusion, and D is the effective diffusion coefficient in the pore (cm^2/s).

In this study, the parallel pore model was adopted, and the effective diffusion coefficient in the pore was calculated by equation (5)

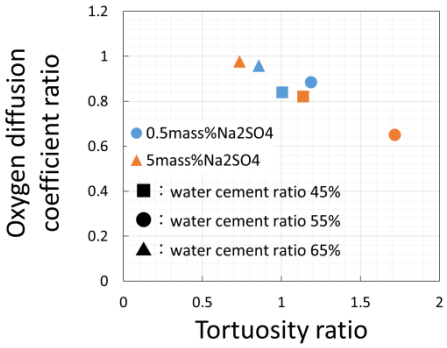

Figure 3. Relationship between oxygen diffusion coefficient ratio and tortuosity ratio.

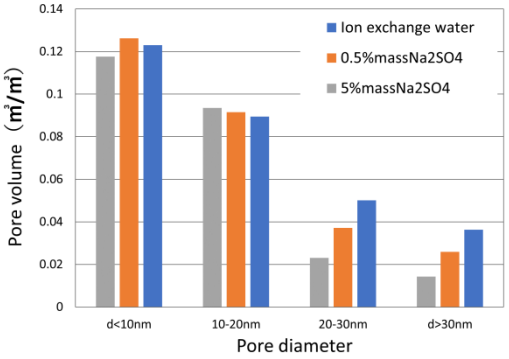

Figure 4. Pore volume of each pore diameter (water to cement ratio of 45%).

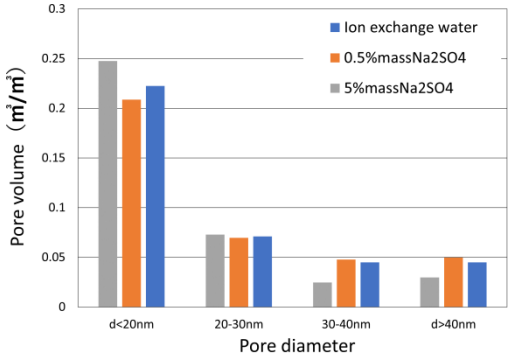

Figure 5. Pore volume of each pore diameter (water to cement ratio of 55%).

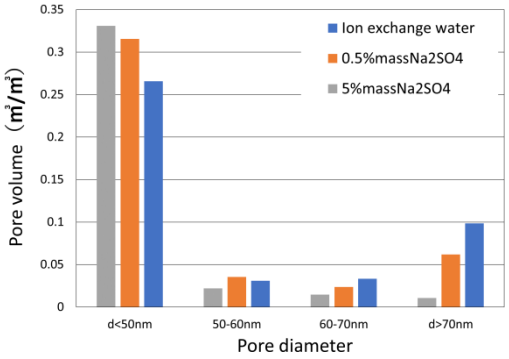

Figure 6. Pore volume of each pore diameter (water to cement ratio of 65%).

$$D = \left(\frac{\varepsilon_a}{\frac{1}{D_{Ka}} + \frac{1}{D_{ON}}} \right) + \left(\frac{\varepsilon_b}{\frac{1}{D_{Kb}} + \frac{1}{D_{ON}}} \right) \quad (5)$$

where ε_a is the pore volume having a diameter < 50 nm (cm^3/cm^3), ε_b is the pore volume having a diameter > 50 nm (cm^3/cm^3), D_{Ka} is the Knudsen diffusion coefficient of the average pore diameters < 50 nm (cm^2/s), D_{Kb} is the Knudsen diffusion coefficient of the average pore diameters > 50 nm (cm^2/s), D_{ON} is the molecular diffusion coefficient of nitrogen and oxygen (cm^2/s). The tortuosity ratio was calculated in the same manner as the oxygen diffusion coefficient ratio described above.

Figure 3 shows the relationship between the oxygen diffusion coefficient ratio and the tortuosity ratio. The oxygen diffusion coefficient ratio is reduced with increasing of the tortuosity ratio. These results suggest that the decreasing of the oxygen diffusion characteristics in the hardened cement paste affected sodium sulfate was caused by the increasing of the complexity of the pore structure due to sodium sulfate immersion.

Subsequently, in order to investigate the increasing of the pore structure complexity, we focused on changes in the pore size distribution. Figure 4 to 6 shows the pore volume of each

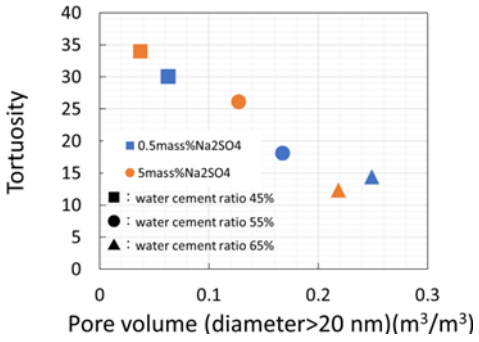

Figure 7. Relationship between tortuosity and pore volume (d > 20nm).

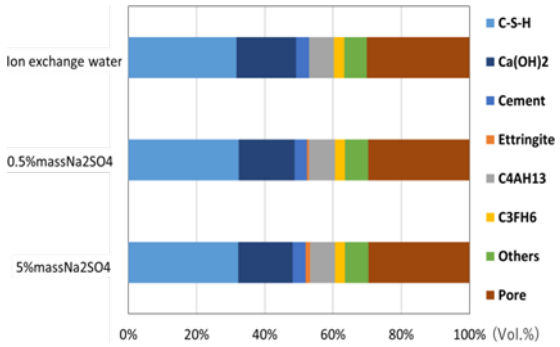

Figure 8. Phase compositions of the specimens after immersion (water-to-cement ratio of 45%)

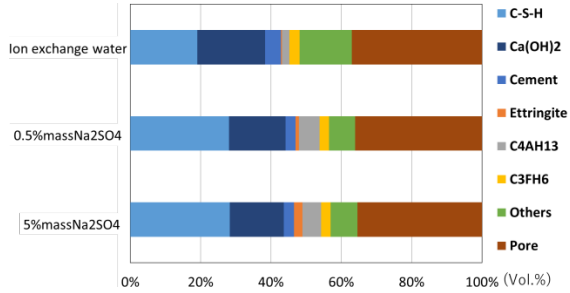

F igure 9. Phase compositions of the specimens after immersion (water-to-cement ratio of 55%)..

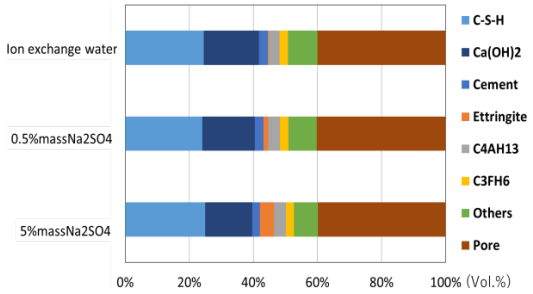

Figure 10. Phase compositions of the specimens after immersion (water-to-cement ratio of 65%).

pore diameter. From Figure 4, in the case of water-to-cement ratio of 45%, in the division of the diameter < 20nm, it was confirmed that the pore volume of the sodium sulfate immersion sample was slightly larger than that of the ion-exchanged water immersion sample. On the other hand, in the division of diameter > 20nm, the pore volume of the sodium sulfate immersion sample is reduced as compared to the ion-exchanged water immersion sample. It was confirmed that the diameter of 20 nm is the boundary of the trend change.

Figure 7 shows the relationship between the tortuosity and the pore volume having a diameter > 20 nm. From the figure, the tortuosity increased with decreasing of the pore volume having a diameter > 20nm. These results suggest that because the pore volume having a diameter > 20 nm in the specimen immersed in sodium sulfate decreased, the pore structure was complicated and the oxygen transfer was suppressed.

3.3 Effect of Hydration Products on the Change of Pore Structure

Figures 8 to 10 shows the phase compositions of the specimens after immersion having each water-to-cement ratio. In the case of the ion-exchanged water immersion, which is not affected by sodium sulfate, the C-S-H occupies most of the solid phases. In the case of sodium sulfate immersion, the C-S-H also occupies most of the solid phase at any water-to-cement ratio. Furthermore, the higher the water-to-cement ratio and the higher the sodium sulfate concentration, the amount of ettringite was increased. Therefore, we examined the relationship

between the pore volume having a diameter > 20 nm and the generation of C-S-H and ettringite.

In order to calculate the volume of C-S-H, which is affecting the pore volume, the amount of C-S-H was calculated using equation (6)

$$M_{C-S-H} = m_C \cdot \left(\frac{m'_{C-S-H}}{100}\right) \tag{6}$$

where M_{C-S-H} is the amount of C-S-H per unit volume (g/m^3), m_C is the amount of cement paste per unit volume (g/m^3), m'_{C-S-H} is the amount of C-S-H (cm^2/s). The volume of C-S-H V_I (m^3/m^3) was calculated by dividing the M_{C-S-H} by ρ_{C-S-H}, which is the density of C-S-H (g/m^3) as shown in equation (7).

$$V_I = \left(\frac{M_{C-S-H}}{\rho_{C-S-H}}\right) \tag{7}$$

Because the density of C-S-H changes depending on the C/S ratio, it was calculated from each C/S ratio using the equation (8) of Suda *et al*. (2014).

$$\rho_{C-S-H} = 0.45(C/S) + 1.36 \tag{8}$$

Furthermore, as shown in the equation (9), the volume of C-S-H was calculated

$$V_{C-S-H} = \frac{V_I}{P} \tag{9}$$

where V_{C-S-H} is the volume of C-S-H (m^3/m^3), P is the capillary pore volume (m^3/m^3).

Figure 11 shows the relationship between the C-S-H volume and the pore volume having a diameter > 20 nm. In both of the sodium sulfate solution concentration, the pore volume having a diameter > 20 nm decreased with the increasing of the volume of C-S-H. However, when a regression line was drawn for each sodium sulfate solution concentration, there was a slight error between the two lines. Since different linear relationships were shown for each solution concentration, it was considered that there were other factors besides the volume change of C-S-H in the change of the pore volume having a diameter > 20 nm. Therefore, the volume of ettringite was considered, in addition to C-S-H.

The volume of ettringite (V_{Ett}) was calculated using the same calculation as in equations (6), (7), and (9). The density of the ettringite was 1.78×10^6g/m^3 (Suda *et al*., 2014). As shown in equation (10), the total volume (V_{C-S-H_Ett}) was obtained by adding the V_{Ett} to the V_{C-S-H}.

$$V_{C-S-H\_Ett} = V_{C-S-H} + V_{Ett} \tag{10}$$

Figure 12 shows the relationship between the pore volume having a diameter > 20 nm and the volume of C-S-H and ettringite. In this case, the regression line drawn for each sodium sulfate solution concentration showed almost no error. These results suggest that the decreasing of the oxygen diffusion coefficient of the specimens affected by sodium sulfate was caused by the formation of ettringite, which is filling the pores having a diameter > 20 nm and the complication of the pore structure.

4 Conclusions

The purpose of this study was to investigate the effect of sodium sulfate on the oxygen transfer characteristics and the pore structure of hardened cement paste. The conclusions derived from this study can be summarized as follows.

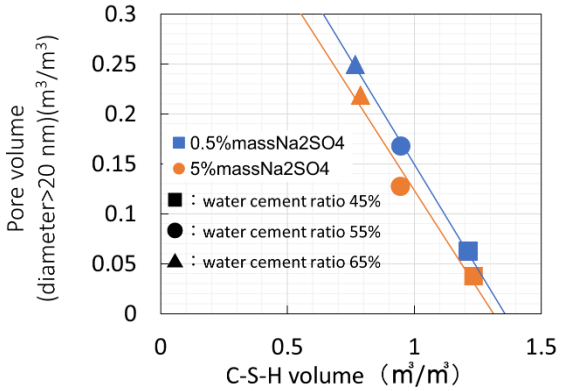

Figure 11. Relationship between pore volume (d > 20nm) and volume of C-S-H.

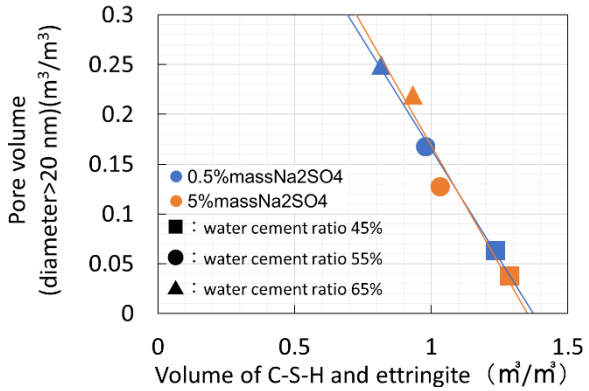

Figure 12. Relationship between pore volume (d > 20nm) and volume of C-S-H and ettringite.

When the cement paste was affected by sodium sulfate, the oxygen diffusion coefficient decreased compared to the case immersed in ion-exchanged water.

The decreasing of the oxygen diffusion coefficient affected by sodium sulfate was due to the increasing of the tortuosity owing to the decreasing of the pore volume having over 20 nm in diameter.

The decreasing of the oxygen diffusion coefficient of the specimens affected by sodium sulfate was caused by the formation of ettringite, which is filling the pores having over 20 nm in diameter and the complication of the pore structure.

Abstract. *Cemented sand is a common way for soil stabilization or ground improvement. Tortuosity is an important parameter that has a significant impact on flow and transport characteristics of porous media and related to permeability and diffusion coefficient. This study aims to quantitatively investigate the tortuosity of the cemented sand with different cement content using X-ray computed tomography (CT) based random walk simulation. The cemented samples were scanned using micro-CT and converted to 3D pore space through image processing. Random walk simulation was applied to the reconstructed 3D pore space to calculate the tortuosity. Higher cement content gave an increase in tortuosity and a decrease in porosity. This indicates that the addition of cement makes pore space more tortuous and decreases both permeability and diffusion coefficient which are being treated as important parameters for durability of construction materials.*

Keywords: *Cemented Sand, Tortuosity, X-Ray Microtomography, Random Walk Simulation.*

1 Introduction

Soil stabilization by cement mixing is one of the common methods to improve natural soil. Generally, cemented sand which is produced by mixing cement, sand, and water, has greater strength than natural soil. Ordinary Portland Cement is widely used in soil stabilization and many researches were carried out to investigate its mechanical (Consoli, Viana da Fonseca, Cruz, and Heineck, 2009; Wang and Leung, 2008). Pore network in cementitious material is an important factor that affects many mechanical properties including strength and stiffness as well as durability. However, it is difficult to quantitatively analyse due to its complexity thus several experimental parameters like porosity, permeability, and diffusivity are frequently being used to understand pore network and resulting durability, indirectly. Therefore, the knowledge of tortuosity for cemented sand is strongly required for designing not only the cement content for soil stabilization but also evaluating life span of cementitious materials under various environments.

X-ray Computed Tomography (CT) has been utilized to examine the microstructure of porous media. X-ray CT is a non-destructive technique that allows X-rays to pass through the material at different angles and measures the attenuation using the director. The key advantage of X-ray CT is that it is a unique way to obtain three-dimensional microstructure at specific resolution. This study aims to investigate the tortuosity of the cemented sand with different cement content from the X-ray CT based random walk simulation.

doi:10.23967/dbmc.2020.206

2 Background of Definition of Tortuosity

Tortuosity is a meaningful parameter that has a significant impact on flow and transport characteristics of porous media. The classic definition of tortuosity (τ) is given as the ratio of the average lengths of the actual paths that fluid or electric particles migrate from one point to the final point through the pore space of a porous medium to the corresponding straight and shortest distance between these points. In this regard, tortuosity is always greater than or equal to 1. The importance of tortuosity can be observed in various engineering applications (*e.g.*, diffusion, mass transfer and separation of mixtures) (Boudreau, 1996; Champoux and Allard, 1991; Thorat *et al.*, 2009).

In this study, tortuosity is treated as a property of the porous media which can be calculated from 3D micro-geometry of the pore structure. For instance, the tortuosity in cementitious materials has been evaluated by random walk simulation in the 3D pore structure obtained by X-ray microtomography (Promentilla, Sugiyama, Hitomi, and Takeda, 2009; Provis, Myers, White, Rose, and Van Deventer, 2012).

Diffusion tortuosity is defined as a ratio of the self-diffusion coefficient (D_0) of non-sorbing walkers in free space to the long-time self-diffusion coefficient (D_∞) of these walkers in pore space. The self-diffusion coefficient is estimated from mean square displacement (MSD) from the movement trajectories these random walkers as a function of time. The time-dependent diffusion coefficient D_t associated with the random Brownian motion of molecules in porous media. If diffusion time is great enough, it will be a non-zero value that can represent the entire pore characteristic because walkers can travel all of the pore space, but it approaches zero in a closed pore space. Thus, the long-time self-diffusion coefficient of molecule only in a connected pore structure divided by the one in the free space can be defined as the diffusion tortuosity.

The formation factor (F) can be calculated from the tortuosity and interconnecting porosity.

$$F = \frac{\tau_D}{\emptyset} \tag{1}$$

By Nernst–Einstein relation, the relative diffusibility, formation factor, porosity and tortuosity are related to each other.

$$\frac{D_e}{D_f} = \frac{1}{F} = \frac{\emptyset}{\tau_D} \tag{2}$$

where D_e is the intrinsic diffusion coefficient by using Fick's law, and D_f is the diffusion coefficient in the free fluid (Promentilla *et al.*, 2009).

3 Materials and Methods

3.1 Sample Preparations and Image Acquisition

The specimens of cemented sand used in this study were prepared by mixing Jumunjin standard sand and ordinary Portland cement Type 1. The sand/cement ratio of each specimen is 0%, 1%, 3%, 5%, 7% and water content which means the ratio of mass of water to solids (includes both sand and cement) is 0.1. The mix design is shown in Table 1. Samples are prepared in PVC molds and cured at 20℃ for 7days. One specimen per each mix was

analyzed by the CT and one volume of interest (VOI) per specimen was selected for image processing as described below.

Table 1. Mix design of cemented sand.

.

Sand (g)	Cement (g)	Water (g)	w/c ratio
1000	0	100	-
1000	10	101	10.1
1000	30	103	3.43
1000	50	105	2.10
1000	70	107	1.53

The X-ray imaging of specimens was performed by the Skyscan micro-CT (Skyscan1272, Bruker, Belgium). Acquired reconstructed image from tomographic data has 4904×4904 pixels and pixel size is 5 μm by 5 μm. 3280 layers of X-ray projection image are obtained with exposure time of 5000ms and an angle step of 0.1°.

3.2 Construct of 3D Pore Space

The VOI which is the portion of the full data set chosen for segmentation is necessary due to some limitations of memory during computation. The size of VOI should also be large enough to eliminate the introduction of errors resulting from the cropping images (i.e., the finite size). It has been suggested in previous literature that the minimum VOI should be at least 100 μm^3, or 3 to 5 times larger than the size of the largest distinct feature of the sample for hardened OPC pastes, to eliminate finite size error (Garboczi and Bentz, 2001; Provis *et al.*, 2012). In this study, 1000×1000 pixels of region of interest applied to each images and then it merged to 1000^3voxels of VOI which is equal to 3D pore space which satisfies the size requirement in image analysis. Hence, the raw images were cropped to 1000×1000 pixels in the center of the specimen (Figure 1).

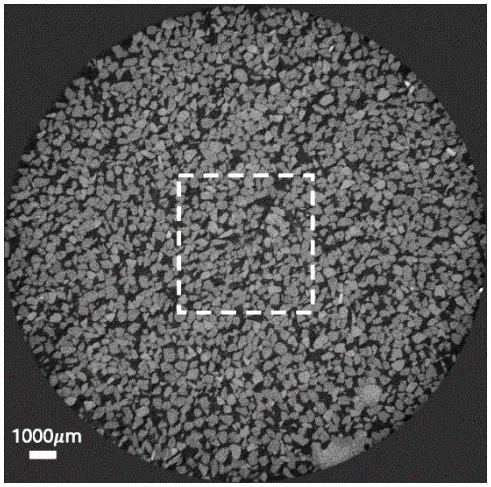

Figure 1. A slice through the full tomographic reconstruction of the 7-day 1% cemented sand specimen. White dotted area shows the size of the VOI selected.

First, Gaussian blur and anisotropic diffusion were adjusted in sequence in order to smooth the raw images while remaining the narrow pore space between sand particles. This procedure enhances the accuracy of watershed algorithm applied later. Then, segmentation is carried out to separate pore and solid due to the difficulty of distinguish sand phase and cement phase in X-ray image at a resolution lower than 1μm/pixel. Thresholding value in grayscale is selected as 5 greater than the value calculated by Otsu method in entire dataset due to eliminate the noises in pores space (Otsu, 1979). In addition, the narrow pores between sand particles containing lots of noises could be converted to pore after segmentation. Sand and pore phase are modified to white and black, respectively.

After pore segmentation, 1000 slices of 2D images are merged to 3D pore space to

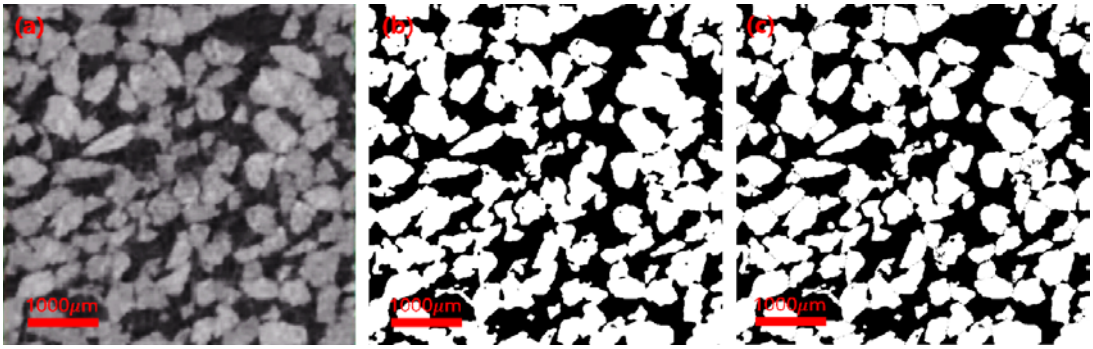

Figure 2. Application of watershed algorithm to separate the connected sand particles (2D images of 1% cement content): (a) filtered greyscale image, (b) binary segmented image, (c) binary image after applying watershed algorithm.

implement further processing at 3D pore space directly. The white closed particles of which size is smaller than the realistic sand particle is removed and the black closed particles that has smaller size than one that exists in the sand particles are also removed. In Figure 2(b), sand particles connected to each other in filtered greyscale image need to be separated because in actual cemented sand, sand particles cannot adhere completely to other due to roughness of surface. In addition, the narrow pores located near sand are transformed into solid phase. Eventually, watershed algorithm is applied to binary segmented image for severing connected sand fragments and restoring narrow pore surrounded by sand particles.

3.3 Particle Size Distribution of Sand

Particle size distribution (PSD) of sand is considered to verify the used image processing method. Sieve analysis was performed for the identical sand to gain PSD data following ASTM D422. In 3D pore space after applying watershed algorithm, all of the sand particles exist independently. It allows to calculate the volume of each separated sand particles by using cluster labeling. PSD is also obtained from these volume data by calculating equivalent diameter. Therefore, the accuracy of segmented 3D pore structure can be evaluated by the comparison of the PSDs obtained from the sieve analysis and image processing.

3.4 Tortuosity Calculation From Random Walk Simulation in 3D Pore Space

A 3D random walker simulation (Nakashima and Kamiya, 2007) implanted in MATLAB was used to compute the MSD of random walkers in the segmented pore space. Mirror image

boundary conditions were employed to the original pore space, resulting to an infinitely expanded pore structure where simulations are performed with preserving the continuity of inter-connected pore network. The average displacement of the walkers was plotted as a function of the number of the timesteps and the tortuosity was calculated from the inverse of the slope of this curve.

To execute the random walker simulation, a random pore voxel in the inter-connected pore network is chosen as the initial position of each walker. In each timesteps, the one was selected among the six voxels which are face-to-face connected with the random walker. Then the random walker migrates to the selected voxel when it has been identified as pore space. The diffusion tortuosity is defined as the ratio of the self-diffusion of a walker in free space to the self-diffusion of a walker in the pore space such that:

$$\tau_D = \frac{D_0}{D_\infty} = \left[\lim_{t\to\infty} \frac{\mathrm{d}\langle r^2(t)\rangle}{\mathrm{d}t}\right]^{-1} \tag{3}$$

where D_0 is the self-diffusion coefficient of a walker in free space, D_∞ is the self-diffusion coefficient of a walker in the pore space, and $\langle r^2(t)\rangle$ is the average of MSD as a function of a time. By using Eq. (3), restricted diffusion that reflects the geometry of the entire pore space can be defined as the diffusion tortuosity. On such time scales, the MSD starts to increase linearly with the number of timesteps due to an ample time for random walkers to travel the entire pore space, leading to constant calculated tortuosity.

4 Results and Discussion

An example of the results from image analysis of the VOI is shown in Fig. 4. Segmented solid phase is corresponding to the sand and cement particles including both hydrated and unhydrated

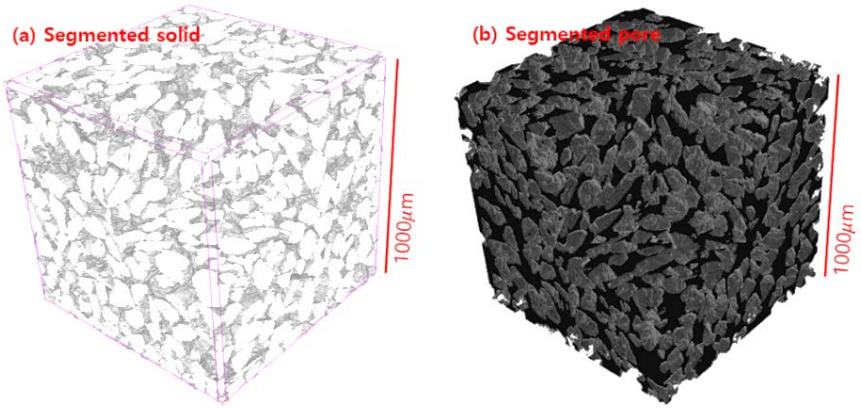

Figure 3. Visualization of pore space from microtomographic images of the 1% cemented sand sample ($\mathbf{1000^3}$ voxels). (a) binary image of segmented solid phase. (b) binary image of segmented pore phase.

4.1 Porosity

The data presented in Figure 4 shows that the segmented porosity decreases as the cement content increases. This trend holds for all samples with one exception of 0% cement sample. It showed a lower porosity than 1% cement sample. The 0% cement sample has only two phases which are sand and pore besides other samples have three phase including cement hydrate. This different number of phases can introduce the difference in overall shape of the greyscale histograms that affects to the threshold value selection in segmentation process and results underestimated porosity in the 0% cement sample. As cement content increases, porosity decreases because cement particles fill more pore space which are formed by packing of sand particles. The inter-connected porosity is completely equal to general porosity. This implies that all pores found in cemented sample are connected.

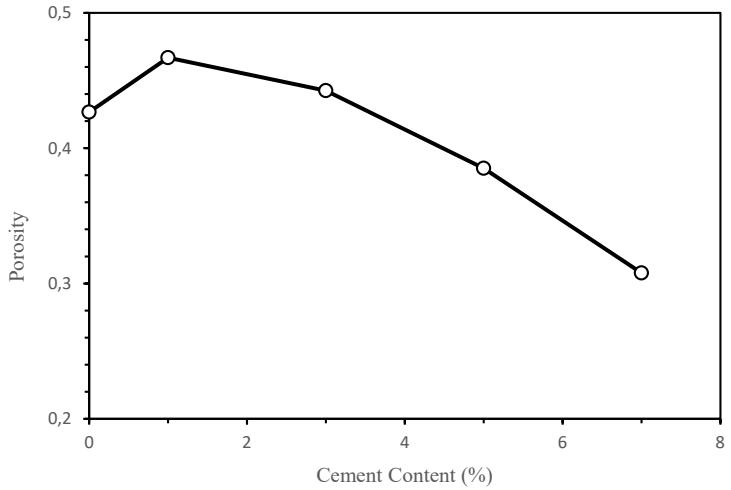

Figure 4. Relationship between the porosity and cement content for all samples.

4.2 Particle Size Distribution of Sand

Figure 5 compares the PSD of raw sand from sieve analysis and those of segmented solid obtained by image analysis. The 0% cement sample and sieve analysis are subject to investigate the accuracy of the microtomographic data in compare with actual data (*i.e.*, sieve result). There is a consistent horizontal shift between PSDs. The constant horizontal shift can be introduced due to the discrepancy of the diameter used to plot. For instance, volume-equivalent diameter was applied to generate PSDs for all cemented sand samples, whereas the diameter used for sieve analysis was a maximum diameter that a sand particle had to pass through the specific sieve.

For the 1%, 3%, 5%, and 7% cemented sand samples, the size of segmented solid particles increased as the cement content increased. This is expected because cement hydrate adheres to sand particles. The size of segmented particle size is the largest for 7% cemented sand sample because of the largest amount of cement used.

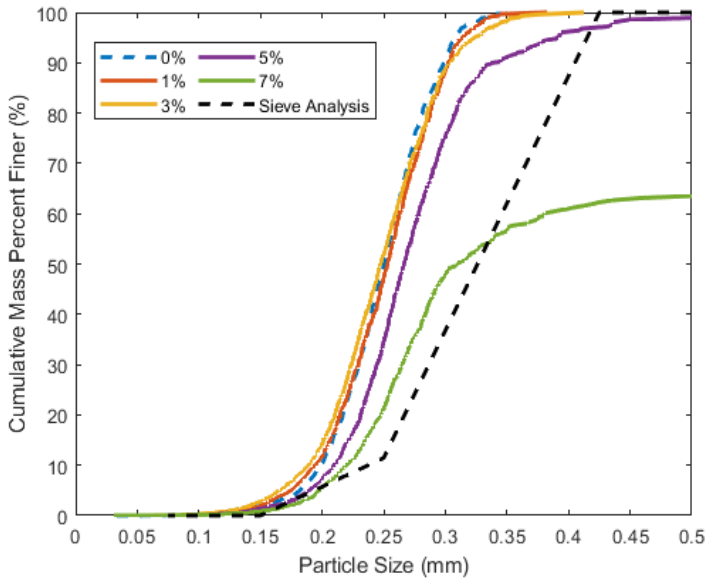

Figure 5. Particle size distribution of sand particles for all cemented sand sample and the data obtained by sieve analysis.

4.3 Tortuosity

Figure 6 shows the diffusion tortuosity of each sample calculated by random walker simulation on the segmented pore space (*i.e.*, interconnected pore). The diffusion tortuosity increased with cement content increased. This implies that the pore space is being more tortuous as cement added in the system. Cement hydration mainly occurs on the surface of the existing sand structure. Therefore, cement hydrates adhere to the surface of sand particles partially and make surface rough. At the same time, pores become narrower due to the adsorption of cement hydrates resulting the increase of tortuosity.

Figure 7 presents the formation factor as a function of cement content. The formation factor increased as cement content increased except for 0% cement sample which has intrinsically different solid system (*i.e.*, two phases vs. three phases) as previously discussed. Nevertheless, obtained trends of increasing tortuosity and formation factor clearly suggest that permeability and diffusion coefficient should decrease with cement addition. Thus, it can be quantitatively inferred that the addition of cement in cemented sand is an effective way for controlling permeability and diffusion.

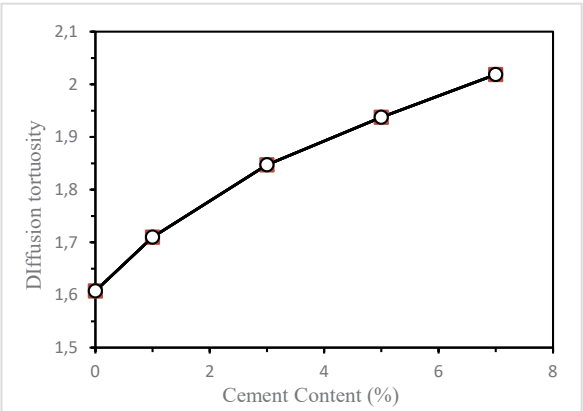

Figure 6. Relationship between the diffusion tortuosity and cement content for cemented sand sample.

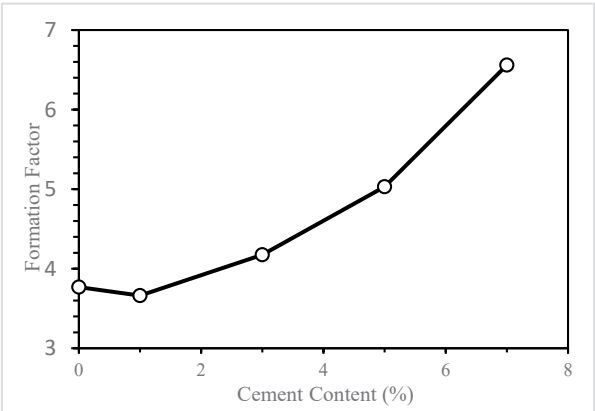

Figure 7. Relationship between the formation factor and cement content for cemented sand sample.

5 Conclusion

The porosity and tortuosity parameters obtained from the tomography data here provide an indication of the pore network geometry and microstructure of cemented sand. Higher cement content gave an increase in tortuosity and a decrease in porosity. This indicates that the small addition of cement hydrate in compacted sand, makes pore space more tortuous.

This study has provided the methodical three-dimensional analysis of cemented sand by X-ray microtomography. There remain difficulties in the accurate identification of pore and solid regions in cemented sand due to the low X-ray absorption. Phase contrast tomography proposes the potential in this area, but there is integral limitation due to microscale VOI which is small to represent intrinsic parameters of cemented sand. Nevertheless, the data presented in this study provide invaluable information regarding pore network, porosity and tortuosity, and suggest the novel method for future developments which can be led to further understanding on durability of solid materials.

Abstract. *Polyurethane waterproofing membranes are constructed at building sites by applying liquid material to substrate. The membrane thickness is related to the durability of the waterproof material, so quality control during construction is important. However, the membrane thickness is likely to be unstable because it is affected by various factors, such as the environment, substrate conditions, method of waterproofing material application, and construction skills. Therefore, a reduction in thickness variation is extremely important to secure the quality of the waterproofing membrane.*
To examine which construction conditions can ensure a uniform and appropriate thickness, we examined the combination of allocation method of the suitable construction area and application tools as an example of process control during construction. The construction area width and length were important, and a comparatively uniform and appropriate thickness could be ensured, when construction was carried out over an area with a 1.4-m width and length of 5.15 m by using the trowel and squeegee.

Keywords: *Waterproofing Membrane, Polyurethane, Thickness of Membrane, Construction Area, Application Tool.*

1 Introduction

Waterproofing membranes that are generally used in Japan are a liquid material that is applied to a base in a construction site, and a waterproof layer is formed by its hardening. The most important quality control item is to ensure the appropriate membrane thickness, which is related directly to the performance and service life of the waterproof layer. However, the membrane thickness tends to become unequal, because it is affected by the construction environment, foundation conditions, material, application method, and skill. Standard Japanese specifications state that the thickness of the waterproof urethane coating membrane is confirmed by the quantity used per unit area. However, there is no more detailed description of the concrete construction method except for "In order to secure the thickness of membrane, the coating amount per set of waterproof material is divided." Therefore, in many cases, concrete construction is achieved by the judgment of the constructor, and as a result, waterproof layers do not always reach the prescribed membrane thickness.

In this study, waterproofing membrane formation during construction was studied, and the effect of area on the membrane thickness was examined as an example of the quality control technique. The waterproof layer construction must be carried out over an appropriate time, and this paper aims to show the optimum construction area by considering these. By using a

doi:10.23967/dbmc.2020.158

concrete repair site floor and indoor laboratory, we carried out experiments by combining the partition shape and sprinkling method of the waterproof material and construction equipment as factors.

2 Effect of Observation of Waterproofing Membrane Work and Construction Area on Membrane Thickness

2.1 Experimental Outline

The experiment was carried out by using the roof of a multiple-dwelling house to observe the work content during waterproofing membrane construction and the effect of construction area on the membrane thickness. The plain field with a comparatively small gradient was selected as the waterproofing underlayer, and the area was made to be 14.0 m^2 (4.0 m × 3.5 m) by converting 27 kg of waterproofing material in one set into a target membrane thickness of 1.5 mm for one layer. As shown in Figure 1, two areas were prepared: area A in which the area line was indicated clearly, and area B in which a mark was provided at each of four corners. The waterproof material used was a two-component hand-kneaded type for flat field based on the Japanese Industrial Standard.

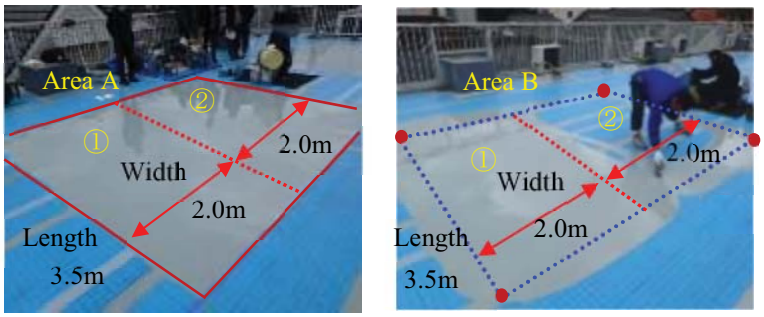

Figure 1. Application of polyurethane material in the two areas.

2.2 Experimental Methods

The construction procedure was as follows. A ventilation buffer sheet was attached to the entire roof. Then, three rows of 50-mm-wide aluminum tape were installed at 1.0-m intervals on the base surface because the membrane thickness is measured by a nondestructive inspection method (eddy current-type thickness membrane meter). The abovementioned area was prepared, and the waterproof layer was constructed with a target membrane thickness of 1.5 mm. The constructor was a technician with more than 20 years of experience, and a trowel was used as the construction application tool. The outside air temperature was 12 °C and the humidity was 45%.

2.3 Work Observation and Thickness of Membrane-Measurement Methods

During the experiment, moving image photography was carried out from the work start to the end, and the work content of the constructor was observed. After confirmation of the hardening of the waterproof layer on the following day, the membrane thickness was measured by using an eddy current-type thickness membrane meter. The measurement points were placed at 45 locations on the aluminum tape in each construction area.

2.4 Work Contents of Contractor

The waterproofing membrane was constructed as follows. The constructor divided the 4.0-m wide × 3.5-m long area into a 2.0-m width in which work was possible. A two-component waterproof material was kneaded with a main agent and a hardener in the field. The kneaded waterproof material was halved (13.5 kg) to fit the divided width of 2.0 m × 3.5 m length and poured using a container. The waterproofing material that was poured in the construction area was spread right and left by using a trowel. The other half of the plots was subjected to similar work. Observation indicated that the waterproofing membrane construction is composed of work where material was poured on the base and work where material was spread. The construction area in the field was divided by the width in which the spreading work was easy, and the amount of waterproof material poured was calculated in proportion.

2.5 Effect of Construction Area

The measured membrane thickness is shown in Figure 2 and it varied across both construction areas. In construction area A in which the area was strengthened, the average membrane thickness was 1.2 mm. In construction area B, which was constructed without much attention given to the area, the waterproof material protruded from the area. Therefore, the coating quantity in the area was insufficient compared with construction area A, and the average membrane thickness decreased to 0.9 mm.

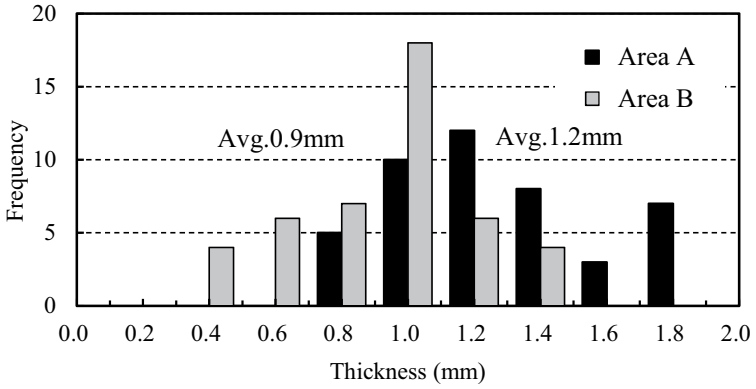

Figure 2. Measured thickness of areas A and B.

3 Effect of Pouring Waterproofing Membrane Material on Variation of Membrane Thickness

3.1 Experimental Outline

The work observation indicated that it is necessary for the constructor to pour waterproof material evenly from the container to the prescribed area, and to spread it uniformly by using the construction tool. The waterproofing membrane thickness, "Area Length" appears to be related to the pouring of the waterproof material, and the "Area Width" appears to be related to the work of pushing and spreading. Therefore, the experiment was carried out by using these as variables. A concrete floor (< 3/1000 accuracy) in an indoor laboratory was used as a base.

In the confirmation experiment of the preceding section, the partition width was divided into

2.0 m to facilitate the spreading. This experiment was carried out at three section-length levels of 9.0 m (0.8 m wide), 5.15 m (1.4 m wide), and 3.6 m (2.0 m wide), with a 7.2 m^2 construction area. To omit mixing in the field, the waterproof material of one component type for a flat field based on the Japanese Industrial Standard was used.

3.2 Experimental Methods

The construction procedure was as follows. First, a polyethylene film sheet was laid on the working surface because the waterproof material after curing was peeled from the base and the mass was measured. The division was carried out and waterproof material (14.0 kg) that was suitable for a target film thickness of 1.5 mm was poured linearly in the center of the division width by using a pail can as shown in Figure 3. These operations were carried out in an environment at a room temperature of ~23 °C and a 60% relative humidity by technicians with more than 20 years of experience. After confirming the hardening of the waterproof layers the following day, the spread waterproof material was cut into 10 pieces and its mass was measured.

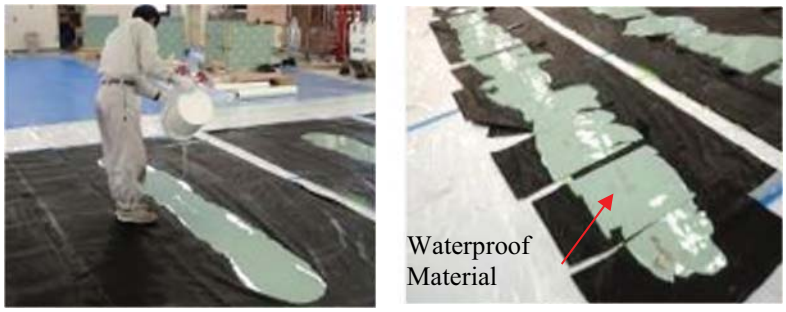

Figure 3. Pouring works (left) and cut membrane to measure their mass (right).

3.3 Area Length Effect

When the pouring work was observed, the waterproofing material appeared to flow out uniformly from the container. However, the variation after curing was large, wide, and narrow portions were intermingled. The mass standard deviation per unit length is shown in Figure 4.

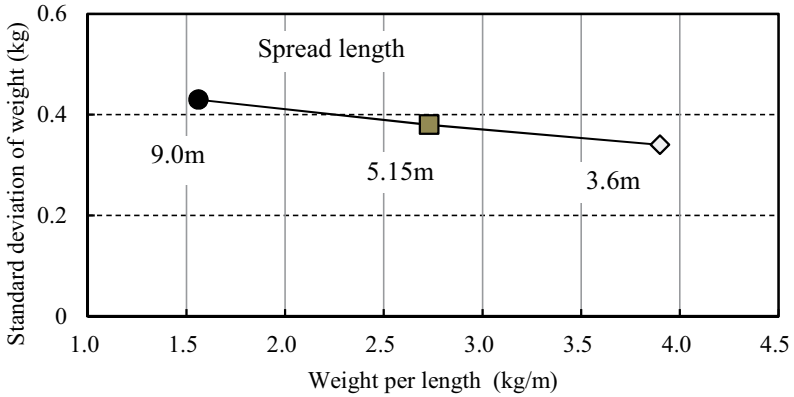

Figure 4. Relationship between material masses in three areas and their standard deviations
Polyurethane material and standard deviation of mass.

based on the measured mass of the waterproof material. The standard deviation of the area length of 9.0 m was 0.43 kg, that of 5.15 m was 0.38 kg, and that of 3.6 m was 0.34 kg. This information shows that the material tended to be poured unevenly, when the length from which the waterproof material was poured was lengthened.

4 Effect of Spreading Urethane Coating Waterproof Material on Membrane Thickness

4.1 Experimental Outline

To confirm the effect of the "Area Width" on the film thickness, the experiment was carried out with the same concrete base and construction area as used previously. The division width was made to be three levels of a width of: 1.4 m (5.1 m long), which allows for a natural trowel movement to the left and right; a narrower 0.8 m (9.0 m long); and a wider 2.0 m (3.6 m long).

As shown in Figure 5, the construction tool was a trowel, which was a standard construction tool, and a polyethylene patterned squeegee with a 5-mm groove depth and a 600-mm width. The target waterproof layer membrane thickness was 1.5 mm for the first layer and 1.5 mm for the second layer, which totaled 3.0 mm. The waterproofing material was used in a commercial one-component-type flat field, and the regulated quantity was measured for each construction area.

These tasks were performed by technicians with more than 20 years of experience in an environment of ~23 °C and a 60% relative humidity.

4.2 Experimental Methods

The construction procedure was as follows. At first, a ventilation buffer sheet that was treated with aluminum alloy thin film was laid on the entire surface of the base because the membrane thickness was measured in detail by using the eddy current-type thickness membrane meter.

The area was divided by the above-mentioned area width. To evaluate the effect of spreading the waterproof material accurately, a frame was made in the central part of the area by a 10-mm foamed polyethylene material, and a specified amount of waterproof material was poured uniformly into the frame. The waterproof material was spread with each construction tool. After confirming the hardening of the waterproof layer, the thickness of the first layer was measured.

The second layer was constructed by the same construction method, and the total membrane thickness was measured on the next day. The membrane thickness was measured at 105 positions

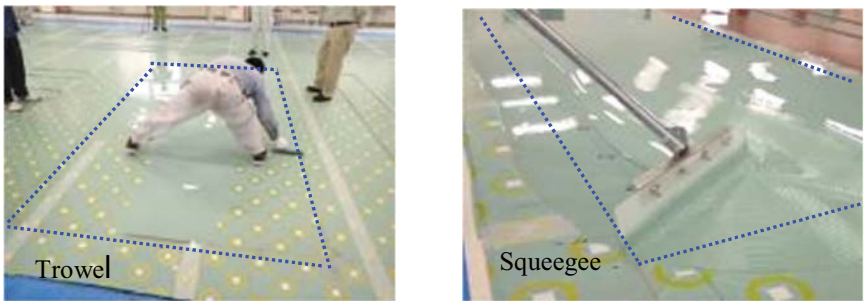

Figure 5. Spreading work using a trowel (left) and using a squeegee (right).

from the center of the partition width at 0.3-m intervals on the left and right sides, respectively. The time required from the start to the end of the spreading work was also measured.

4.3 Effects of Area Width and Application Tools on Membrane Thickness

The relationship between the mean membrane thickness and the standard deviation is shown in Figure 6. The membrane thickness distribution from the spreading work tends to be larger in the second layer. The average membrane thickness from the trowel was 1.3–1.4 mm in the first layer and 2.8 mm in the second layer. The value tended to be close to the target membrane thickness, which indicates that the target membrane thickness is approached regardless of the partition shape when the specified amount of waterproofing material is sprayed by specifying the partition. The membrane thickness distribution increased as the area width increased and was 1.1–1.9 mm in the first layer and 1.9–3.5 mm in the second layer. This occurs because, when the area widens, the distance required to move the trowel to the right and left increases, and it becomes difficult to push and expand the waterproof material uniformly. The average squeegee membrane thickness was 1.3 mm in the first layer, it became 2.7–2.5 mm in the second layer, and it decreased with an increase in area width.

When the construction area was observed, the waterproof material stuck out from the area by back and forth application by the tool. Therefore, the coating quantity in the construction area is believed to be insufficient, and the film thickness was affected. The membrane thickness dispersion decreased as the area width increased. The membrane thickness of the first layer was 0.9 mm and that of the second layer was 1.3–1.5 mm, which was more uniform than that achieved with the trowel.

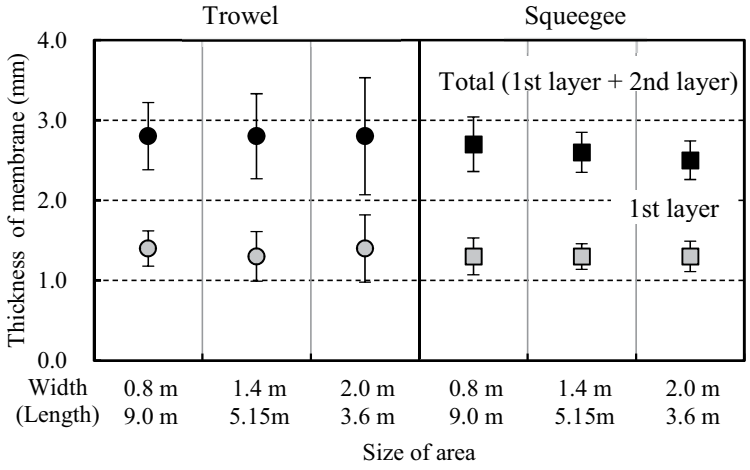

Figure 6. Average thickness of membrane and standard deviation of three.

4.4 Effect of Area Width and Application Tools on Work Time

Figure 7 shows the relationship between the shape of the construction areas and the work time for each construction application tool. The work time for the trowel decreased as the area width increased, especially in the second layer. For the squeegee, the work time lengthened as the area widened. This tendency is opposite to that for the trowel because a large amount of waterproofing materials can be pushed out at one time when the area width increased. The squeegee is efficient when the area length is long because it requires application tools to carry

out the spreading work while pulling in the advancing direction. However, it is necessary to turn the application tools back and forth at a considerable frequency, when the area width widens like this experiment, and these appear to affect the work time.

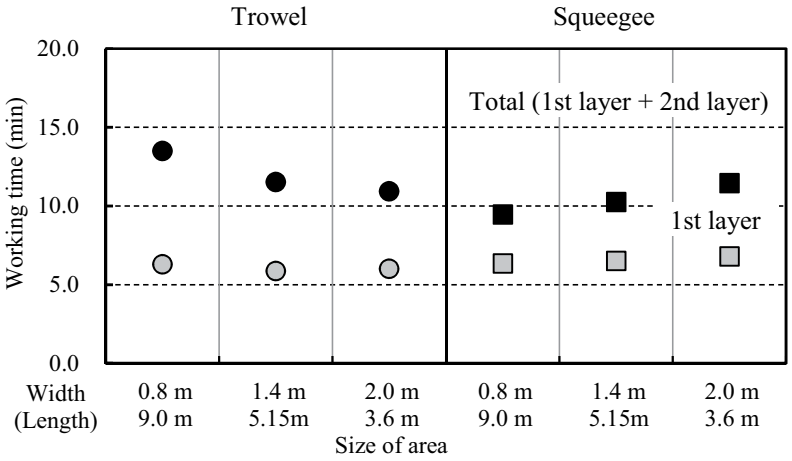

Figure 7. Working time in spreading work of three areas.

4.5 Consideration of Optimal Construction Area from the Viewpoint of Securing Membrane Thickness

The standard deviation of the membrane thickness for the trowel and squeegee area and the pouring and spreading work are shown in Figure 8. To ensure a stable membrane thickness, an area with a wide width and a short length should be used in the pouring work. On the other hand, the spreading work differs depending on the application tools and a narrow partition is desirable for the trowel. In a squeegee, the standard deviation tends to decrease as the area width increases and the area length shortens, and a trade-off relationship exists. The squeegee appears to be an effective application tool when the application quantity is easy to control compared with the trowel because the edge of the tip is a combed shape, and when the construction area is wide. The work time is reduced, and the productivity is improved when the area width increases. However, a reciprocal relationship exists with the quality, and the membrane thickness

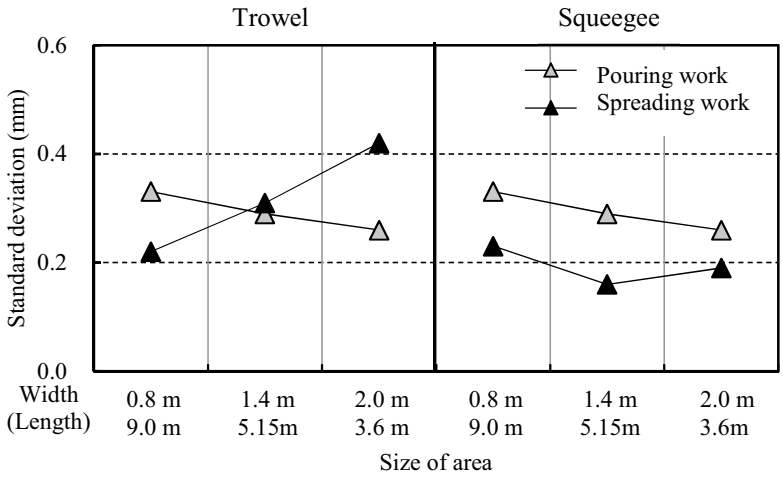

Figure 8. Standard deviation of membrane in pouring and spreading work.

distribution increases, when the time is shortened excessively. The area and cure time of materials at the construction area and the work quantity and productivity must be considered and judged synthetically.

Although this experiment was a prerequisite construction area of 7.2 m^2, it appeared to be a well-balanced construction area where the width of 1.4 m and the length of 5.15 m made it easy to prepare a suitable membrane thickness, when the time required for both application tools was considered.

5 Conclusion

We obtained the following conclusions from this study.

- To secure the waterproofing membrane thickness, a clarification of the construction area and the area shape are important in addition to the management of the application amount.
- During the waterproof material pour, the dispersion is smaller in the shorter area length. The length of the pouring waterproofing material increases and tends to be scattered unevenly.
- The area width of the spreading work differs according to the construction application tools. The membrane thickness distribution tended to be small; the partition width was narrow for the trowel and was widened with the squeegee.
- The work time differed significantly according to the construction application tool. The work time decreased when the area width widened with the trowel and became narrower for the squeegee.
- The partition width and length are important to ensure an appropriate membrane thickness. In this experiment, an area width of 1.4 m and a length of 5.15 m appeared to provide a comparatively well-balanced construction area shape for the trowel and squeegee.

KU Leuven, Department of Civil Engineering, Building Physics Section, Kasteelpark Arenberg 40, 3001 Leuven, Belgium, Evy.Vereecken@kuleuven.be

Abstract. *This paper presents a field study on the hygrothermal performance of hydrophobised masonry walls, provided with vapour tight or capillary active interior insulation. As a reference, also non-hydrophobised and non-insulated walls are analysed. To study the hygric performance, apart from traditional relative humidity sensors, in-house made moisture pins are embedded in the walls and are shown to yield valuable information in the high moisture range. Attention is given to the hygric performance of the wooden beam heads, the impact of wind-driven rain on the moisture conditions in the masonry wall, as well as to the impregnation depth of the water repellent agent. For the latter, the field study is supplemented with X-ray and liquid droplet measurements on a small semi-duplicate test wall. During the hydrophobisation process, an increased moisture level was induced. A drying period was needed to again reduce this level. After this period, a hydrophobic treatment showed a positive impact on the wall's hygric performance. The non-hydrophobised wall with a vapour tight interior insulation system showed the highest moisture level, especially deeper in the wall and thus where the wooden beam ends are located.*

1 Introduction

Driven by energy concerns and stricter energy regulations, wall insulation gains increasing importance. When dealing with renovation projects, three post-insulation techniques make a thermal upgrade of existing walls possible, i.e. cavity wall insulation, exterior insulation or interior insulation. For massive masonry walls with a valuable exterior facade, however, interior insulation remains as the only option. Unfortunately, interior insulation often leads to higher moisture contents in the wall, increasing the risk on wood rot of embedded wooden beam ends, frost damage, etc. (Vereecken *et al.*, 2015). These damage patterns are to a large extent caused by an exterior moisture source such as wind-driven rain (WDR), and therefore the application of a hydrophobic treatment is often pushed forward. To correctly estimate the effectiveness and potential side effects of a hydrophobic treatment, however, more insight on the moisture transport in hydrophobised walls is required. Thereto, this paper presents the results of a field study on the hygrothermal performance of hydrophobised internally insulated masonry walls.

Both walls with a vapour tight and with a capillary active interior insulation system are studied. As a reference, non-hydrophobised and non-insulated walls are analysed. The paper is organised as follows. Section 2 first describes the field test setup and the applied measurement techniques. Next, in Section 3 a selection of the logged data is presented and analysed. In Section 4, a special focus is put on the impregnation depth in the masonry. Finally, in Section 5 the main conclusions are drawn.

2 Field Test Setup

2.1 Test Walls

To study the impact of hydrophobisation on internally insulated walls, six 1.5-stone thick masonry test walls of approximately 32 cm thick, 0.6 m wide and 2.7 m high were constructed in two south-west oriented wall frames of the VLIET test building of KU Leuven (Figure 1a).

The masonry assemblies were masoned by use of Vandersanden Robusta bricks ($A_{cap} \approx 0.61$ kg/(m^2.s$^{0.5}$)) and lime mortar (ratio: 12.5 kg Saint-Astier NHL3.5, 50 kg River sand 0/2, 10 litres water; $A_{cap} \approx 0.26$ kg/(m^2.s$^{0.5}$) for mould cured mortar). Between the different test walls a barrier was provided, such that the hygrothermal behaviour of the test walls was not affected by the adjacent test walls. The construction of the test walls was finalised by the end of August 2017, after which a drying period took place. On October 23th 2018, three of the six test walls (Figure 1b) were hydrophobised by use of Silres® SMK2100 from Wacker Chemie AG. An impregnation depth of 3 cm in the bricks was pursued, for which per m^2 wall 6.9 litres of a 10 vol% hydrophobic agent solution was applied by spraying. The rain load on the test setup was measured via two wall-mounted WDR gauges (Figure 1b,c), with a collection area of 0.2 m x 0.2 m, as used by Blocken and Carmeliet (2006). To ease a comparison between the wall's hygrothermal performance and the WDR, the WDR load measured by the top WDR gauge is shown together with the results (Figure 4a).

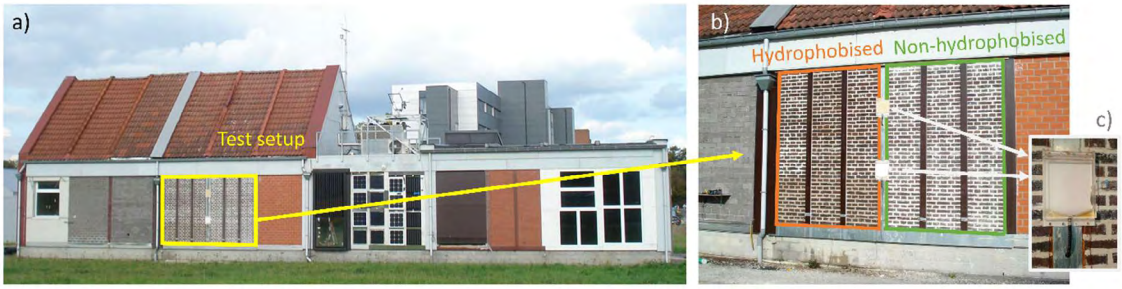

Figure 1. Outside view of the field test setup: (a) south-west oriented side of the VLIET-test building, (b) hydrophobised and non-hydrophobised masonry test walls with (c) wind-driven rain gauges.

On the inside, two test walls were provided with a vapour tight XPS interior insulation system, while two other test walls had a capillary active calcium silicate (CaSi) interior insulation system. Both systems were built up of a 10 cm thick insulation board which was fully adhered to the masonry by use of a glue mortar. As an interior finish, the XPS-system and the CaSi-system were provided with a gypsum board and plaster layer, respectively. The application of the interior insulation systems was performed in the second half of December 2018. The remaining two test walls had no interior insulation system, and thus acted as reference walls. An overview of the six test cases is given in Table 1. In each of the test walls, two wooden beam ends were embedded in the masonry (Figure 2). The upper wooden beam ends were in contact with a mortar layer, whereas for the lower wooden beam ends an air gap was present at all sides except for the bottom of the wooden beam end. At the room side, the end of the wooden beams were covered with bituminous paint, avoiding vapour diffusion via the longitudinal wood direction. To prevent convective moisture transport, as discussed in

(Vereecken and Roels, 2018), the gap between the wooden beam and the insulation system was sprayed up with flexible PUR-foam and the connection with the interior surface was sealed with an airtight tape. After all, also in hygrothermal studies including a wind-driven rain exposure (Kopecký *et al.*, 2019) an airtight sealing of the beam junction has been put forward.

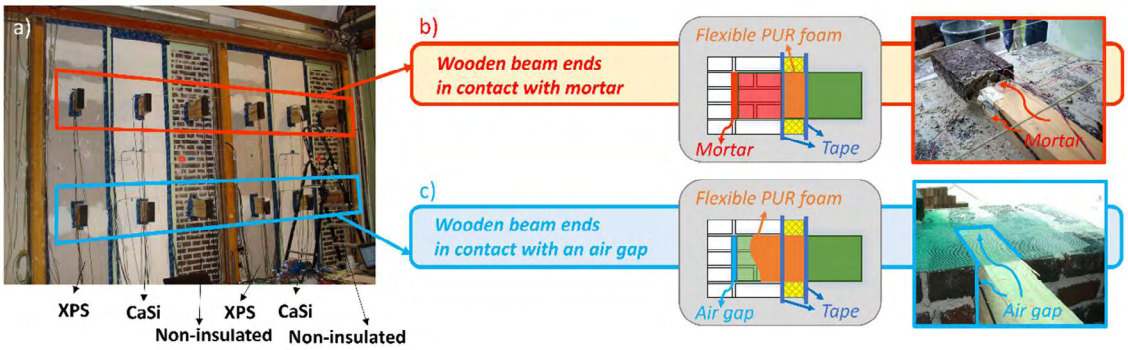

Figure 2. Inside view of the test walls: (a) global overview of the internally insulated and non-insulated test walls with embedded wooden beam ends, (b) wooden beam end in contact with mortar and (c) wooden beam end in contact with an air gap.

Table 1. Overview of the test walls.

Label	Hydrophobisation?	Interior insulation system
NH-XPS	No	XPS
NH-CaSi	No	CaSi
NH-Non	No	Non-insulated
H-XPS	Yes	XPS
H-CaSi	Yes	CaSi
H-Non	Yes	Non-insulated

2.2 Measurement Techniques

The temperature and the relative humidity in the test walls were measured by use of in-house calibrated Thermo Electric Type T (class 1) thermocouples and Honeywell HIH-4021 humidity sensors, with an accuracy of +/- 0.2°C and +/- 2% RH. Furthermore, in-house made moisture pins, measuring the electrical resistance, were used to analyse the moisture conditions at the back of the wooden beam ends, in the mortar in the masonry, in the glue mortar and in the calcium silicate. It is well known that the electrical resistance of a material depends on the material's moisture content, as moisture is a good electrical conductor. The lower the electrical resistance measured in a material, the higher the moisture content of the material. For a more in depth description on the electrical resistance method, the reader is referred to (Otten *et al.*, 2017). At half height of the test walls, additionally a heat flux sensor was glued at the warm side of the masonry. The position of the different sensors is shown in Figure 3. For the moisture pins a preliminary calibration took place, of which an example for the in-situ mortar moisture pins is given in Figure 3c.

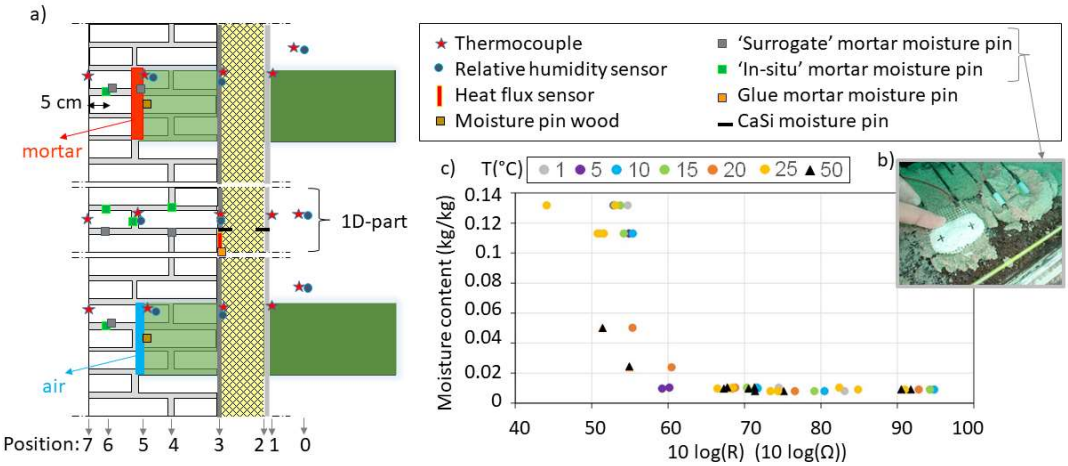

Figure 3. (a) Position of the thermocouples, humidity sensors, moisture pins and heat flow sensor indicated for the wall with CaSi, (b) in-house made surrogate (left) and in-situ (right) mortar moisture pins, (c) preliminary calibration curve for the in-situ mortar moisture pin.

3 Results

Hourly-averaged data are used for the analysis of the hygrothermal performance of the test walls. In what follows, the measurements achieved in the period from June 2018 till the end of October 2019 are shown. Thus, a period in which the walls were all non-hydrophobised and non-insulated is included, showing the similar initial moisture level for the six walls. In the legend of the graphs, from the start however, these walls are indicated by their final state of hydrophobisation and interior insulation system. Focus is put on the moisture conditions in the mortar layer in the 1D-part of the masonry, as measured by the in-situ mortar moisture pins, and on the moisture conditions of the wooden beam ends. To analyse the data measured by the moisture pins, it is important to keep in mind the inverse relation between electrical resistance and moisture content. A lower electrical resistance represents a higher moisture content.

Furthermore, a preliminary calibration of the in-situ mortar moisture pins (Figure 3c) showed an electrical resistance above 60 x 10 log(Ω) to correspond to a similar moisture content. The electrical resistance at which this phenomenon occurs can however slightly vary depending on the material the moisture pins are embedded in (Brischke *et al.*, 2008). Hence, at this point, the moisture pins don't allow an absolute comparison of the measurement data in the lower moisture range (above an electrical resistance in the range of 60 x 10 log(Ω)).

3.1 Moisture Conditions in the 1D-Masonry Part

Figure 4b, c and d show the electrical resistance as measured by the in-situ mortar moisture pins in the middle (1D) part of the test walls. Additionally, the relative humidity at Position 5 is shown (Figure 4e). Both the relative humidity and the electrical resistance show a drying behaviour in the period before the water repellent agent was applied. When applying the hydrophobisation, for the hydrophobised walls an abrupt drop in electrical resistance is shown at Position 6, which is closest to the outer surface. After this, the electrical resistance starts increasing again slowly, which indicates a drying of this outer masonry region. For Position 5,

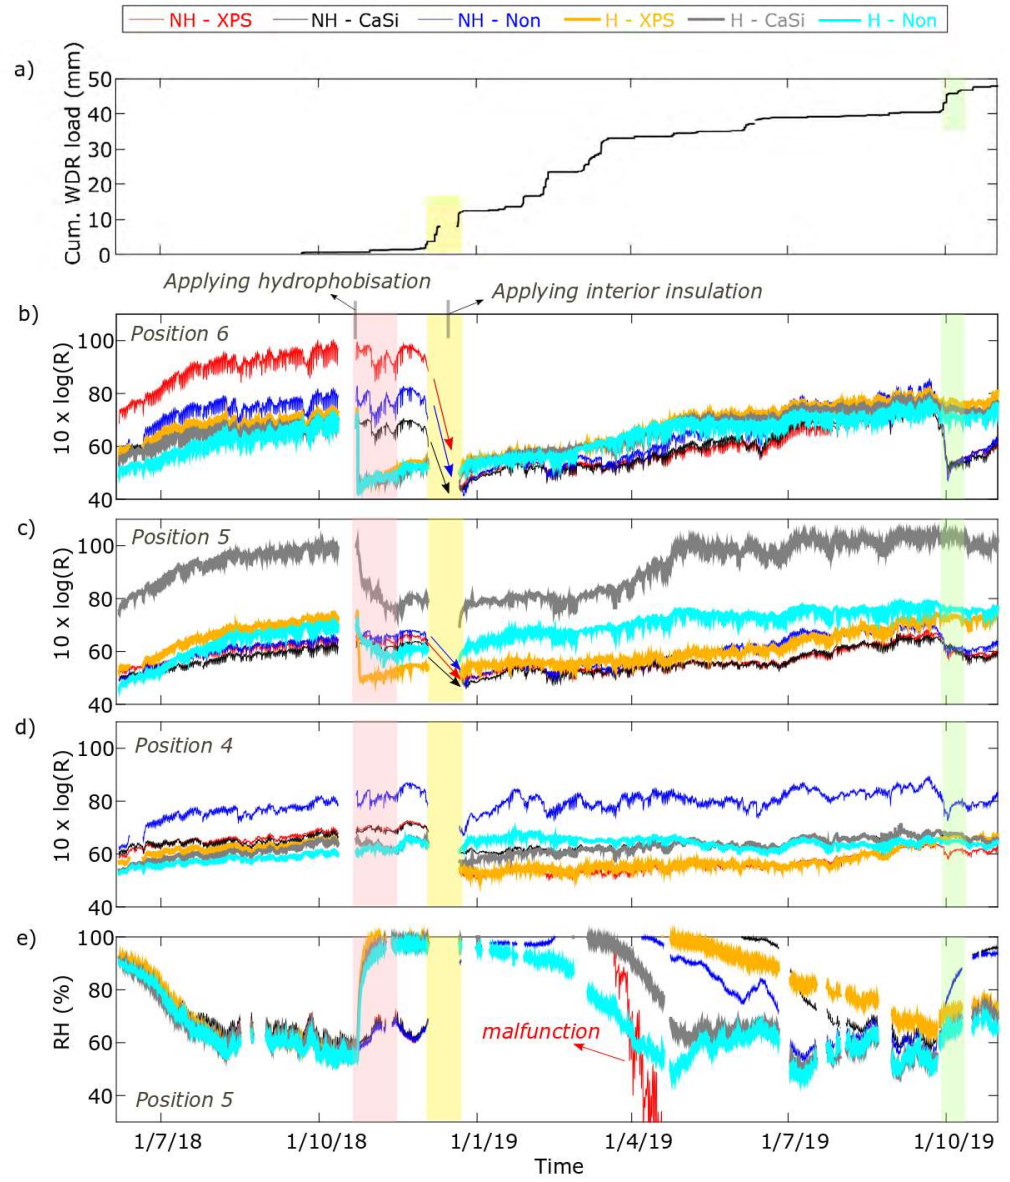

Figure 4. (a) Cumulative wind-driven rain load measured by the top WDR gauge, (b,c,d) electrical resistance measured by the moisture pins in the 1D-part of the walls for (b) Position 6, (c) Position 5 and (d) Position 4, (e) relative humidity measured in the 1D-part at Position 5 (see Figure 3 for an indication of the positions).

a decrease in electrical resistance occurs over a longer time period after the hydrophobisation (pink rectangle), which can be attributed to an inward redistribution of the water used for the water repellent solution. For the hydrophobised wall with a CaSi-interior insulation system, the measurement data seem to be shifted upward compared to the other walls. No explanation is found for this behaviour and a malfunctioning of the moisture pin is assumed; though the decreasing trend is also here visible. For the three hydrophobised walls, the inward redistribution indicated by the moisture pins is confirmed by the relative humidity sensor at

Position 5 (Figure 4e). Deeper in the wall (Position 4), no distinct changes are found during or shortly after the application of the hydrophobisation (Figure 4d).

In December 2018 (yellow rectangle), a reverse behaviour can be observed. In a part of this period the sensors were disconnected to install the interior insulation systems. Though, a comparison of the data before and after this interruption shows, especially for Position 6, a strong decrease in electrical resistance for the three non-hydrophobised walls. This can be attributed to wind-driven rain absorbed by the walls (see Figure 4a). The electrical resistance measured in the hydrophobised walls remains substantially the same. A similar behaviour is found in October 2019. Other WDR loads (*e.g.* in February/March 2019) are less visible, since the moisture level in the wall is already high at that time.

The impact of the interior insulation systems is visible in the relative humidity at Position 5 (Figure 4e). In spring and summer, a decrease in relative humidity is observed, which occurs first for the hydrophobised non-insulated wall, followed by the hydrophobised wall with the CaSi-system and the non-hydrophobised non-insulated wall. Next, the relative humidity in the hydrophobised wall with XPS starts decreasing, but this occurs slower than found for the non-hydrophobised wall with the CaSi-system. The relative humidity sensor in the non-hydrophobised wall with XPS showed some malfunctioning due to the high moisture load.

3.2 Moisture Conditions at the Wooden Beam Ends

Figure 5 shows the relative humidity at Position 5 on the wooden beam ends. For the beam ends in contact with mortar (Figure 5a) the relative humidity at the beginning of June 2018 is found to be above 90%. The test walls are at that moment still non-hydrophobised and non-insulated, and hence show a relative humidity that is in close agreement for the different walls. During the next half year, a drying out takes place until a quasi-equilibrium is found close above 60% RH. For the lower beam ends provided with an air gap between beam and masonry (Figure 5b), the relative humidity level is found to be between 40 and 65% during this entire period.

For the period after January 2019, for both the upper and lower wooden beam end an increase

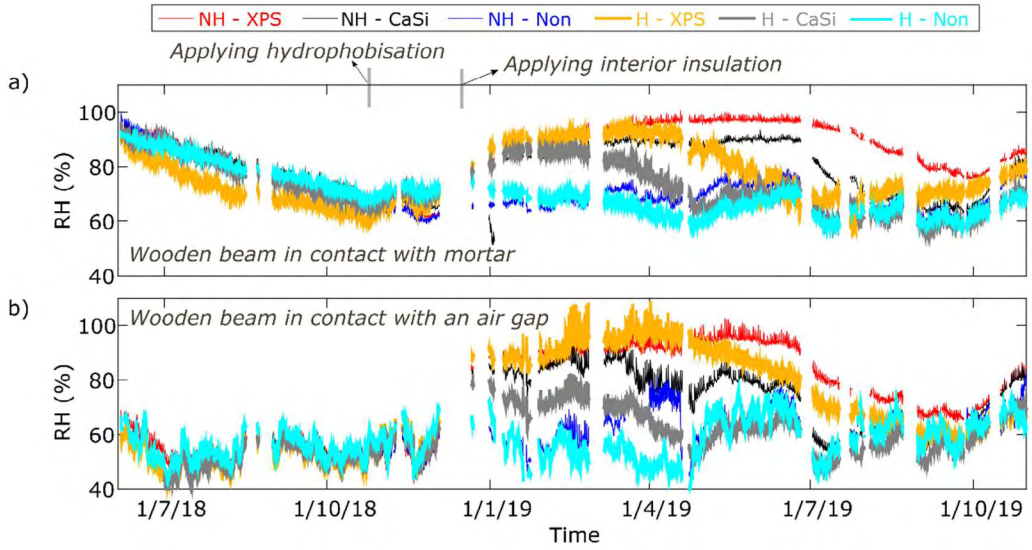

Figure 5. Relative humidity at Position 5 (see Figure 3) at (a) the upper and (b) the lower wooden beam end.

in relative humidity is measured for the walls with interior insulation. This can be partially explained by the lower wall temperature. Apart from this, also a higher moisture content in the wall as indicated by the moisture sensors (Figure 4d) can contribute to this, especially for the upper wooden beam which is in contact with mortar. During spring and summer, the relative humidity starts decreasing again. Also here, the slowest decrease is found for the non-hydrophobised wall with XPS and the fastest for the hydrophobised system with CaSi. The relative humidity level for the non-insulated walls remains rather stable over the entire period.

4 Analysis of the Impregnation Depth

In Section 3, the hydophobisation process was shown to induce a large increase in moisture content in the mortar at 5 cm from the outer surface of the masonry (Position 6). In order to achieve a view on the extent to which also the hydrophobic agent was transported in the wall, the impregnation depth was further analysed via an additional laboratory test setup. Thereto, a small test wall masoned with the same type of bricks and mortar as applied in the VLIET test setup and hydrophobised in a similar way (Figure 6a) was built. This wall was cut in half (Figure 6b) and tilt such that the center plane became a horizontal plane on which the penetration depth of the hydrophic agent could be analysed via the droplet method. Water droplets were dropped on the surface by use of a pipette and the contact angle of the droplet was analysed. For the bricks, three zones were detected (Figure 6c). In the zone closest to the outer (hydrophobised) surface a fully hydrophobised effect was observed. Droplets with a contact angle larger than 90° were clearly noticed (Figure 6e). The impregnation depth in the bricks seemed to be larger than the pursued 3 cm, which might be due to the dynamic way of spraying the hydrophobisation. This zone passed into a second zone where the droplets collapsed and were next absorbed slowly by the brick layer (Figure 6d). Deeper in the wall the bricks seemed not impregnated. After this droplet measurement, a small brick-mortar sample (Figure 6f) was sawn out of the middle surface of the smaller test wall. The non-hydrophobised surface was brought in contact with a water level, while the moisture content in the test sample was analysed by the X-ray projection technique (Roels and Carmeliet, 2006). At the end of this experiment, the moisture front had reached the boundary of the first impregnation zone (figure 6g). In the mortar layer, the impregnation depth was found to be much smaller (1 to 2 cm). Hence, the increase in moisture content observed in Section 3 is expected to be attributed to liquid transport only. The active ingredient is not transported with it to the position of the moisture pins in the mortar.

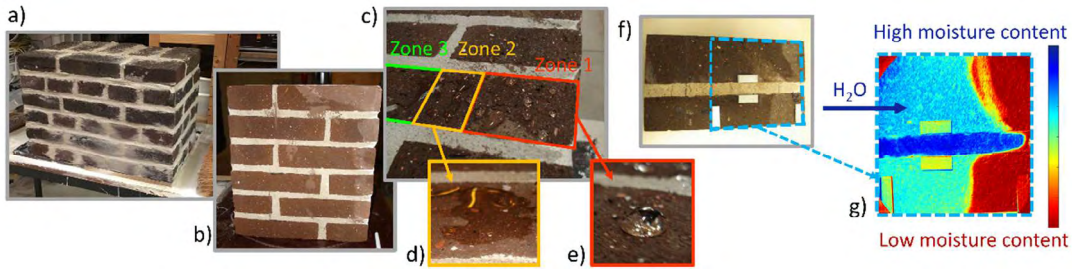

Figure 6. Study on the impregnation depth for a small semi-duplicate test wall: (a) the test wall, (b) test wall vertically cut in half, (c,d,e) droplets and collapsed droplets indicating different hydrophobised zones, (f) test sample sawn out the test wall for the X-ray test with metal dummy's as position references, (g) moisture content measured by the X-ray projection method after bringing the non-hydrophobised surface in contact with water.

5 Discussion and Conclusions

Preliminary results of a field study on the impact of interior insulation and hydrophobisation on the hygrothermal performance of massive masonry walls with embedded wooden beam ends has been presented. In-house made moisture pins yielded valuable information on the moisture transfer in the masonry during and after spraying the water repellent agent. After all, installing RH sensors in the wet mortar entails a risk on malfunction of the sensors and is not obvious in the high moisture range. A further calibration of the moisture pins is however required to make a conversion to the moisture content and a further analysis of the measurements possible.

In the current study, an increased moisture level was induced during the hydrophobisation process. A drying period was needed to again reduce the moisture level near the outer surface.

When disregarding the period shortly after applying the water repellent agent, hydrophobisation showed a positive impact on the wall's hygric performance. Deeper in the wall, near the wooden beams ends, the highest relative humidity was observed for the non-hydrophobised wall with a vapour tight interior insulation system. The non-insulated test walls showed the lowest relative humidity, regardless of the presence of a hydrophobisation. Further research will include an analysis over a longer time period, to exclude the initial influence of the application of the water repellent agent, and this for the total set of sensors and moisture pins embedded in the test walls.

Abstract. *In the framework of Circular Economy policies aimed at reducing the consumption of raw materials, shives, as an agricultural by-product of hemp cultivation, have gained a renovated life in the construction sector. Its excellent thermal insulating properties permitted the development of new building materials to be used in various executive technologies. When shives are mixed with a mineral binder such as lime or cement, the mixture is usually referred to as hempcrete. In Italy, the use of hempcrete and the development of new production chains and implementation techniques dates back only to about the last decade, while other European countries have more long-lasting experiences (90s). In order to assess the potential benefits of hempcrete in the construction sector, its environmental performances were evaluated using the LCA methodology, by comparing four non-loadbearing representative walls, one made with hempcrete blocks and the others with more "traditional" materials. This research constitutes a solid basis for the development of future guidelines and/or regulations at national and international level in order to guarantee the maximum diffusion of this type of product. Then, a study has been carried out regarding the functionality of hempcrete blocks in masonry, layered with finishing plaster made of fine hemp shives, to evaluate the in-situ hygrothermal building performance. In particular, measurement methods were developed and analysis were carried out on two houses, one in northern Italy and one in southern Italy, and precisely in Sicily, focusing the study on the performances of the walls subjected to warm Mediterranean climates. Indeed, the literature on masonry behavior in hot Mediterranean climates is much scarcer than in cold climates.*

Keywords: *Hempcrete, Hygrothermal Behaviour, Sustainable Materials, Mediterranean Climate, Durability.*

1 Introduction

The building sector has a major impact on the natural environment, so sustainable building materials have been developed to reduce the emission into the atmosphere of carbon dioxide and polluting gasses typical of the process of production of traditional building materials. Among sustainable materials, the nature-based solutions are carbon negative and characterized by low-embodied energy (Murphy and Norton, 2008; Ip and Miller, 2012); in addition, they are able to improve the performances of a building envelope because of their remarkable insulating properties.

Many bio-composite materials are produced introducing biomasses, residual of agricultural cultivation (e.g. hemp, straw, rice-husk), into traditional binders (e.g. lime, concrete). In this way, the new building materials exploit natural resources that would otherwise be wasted, being the by-product of agricultural activities (Liu *et al.*, 2017).

This study focusses on hempcrete which is produced introducing hemp shives into an hydraulic binder. The increasing utilization of this material is due to its characteristic hygroscopic properties which determine an improvement of the indoor environmental comfort as reported, for example, by Nordby and Shea (2013). The present research aims to investigate the performances of walls built using hempcrete blocks. The bio-blocks are not- loadbearing and they are used to insulate thermally external or internal walls or to divide internal spaces. The prefabricated blocks production developed in order to solve some issues typical of casting of hempcrete in situ; especially the hardening step which is critical as it significantly influences the homogeneity of the properties in the casted material. Hence, by producing blocks, it is possible to control the hardening phase and to improve the quality of the material (Elfordy *et al*., 2008).

A preliminary evaluation of the environmental performances of a wall made with hempcrete blocks has been performed through LCA (Life Cycle Assessment) methodology according to EN ISO 14040-14044:2006 standards. A comparative assessment with different wall systems was started, preliminarily only at A1-A3 stages, i.e. product stage (EN 15804:2012 +A2:2019).

Then, this research develops experimental methodologies to investigate the hygrothermal behaviour of hempcrete during its service life, so it would be possible to evaluate its durability in situ. The measurements have been performed on walls built using the same type of hempcrete blocks in two residential houses in Sicily (southern Italy) and in Veneto (northern Italy).

2 Durability of Hempcrete

Durability has a crucial importance for building materials, few data exist about the durability of hempcrete in real structures because its utilization is relatively recent, it has been used in France from 1990s and in Italy only from 2000s. The first data collected on buildings have given good results, comparable to the performances of traditional materials (Clarke, 2002). The aim of this project is to perform field test in the two selected buildings, both in Sicily and in Veneto, to obtain information about the behaviour of hempcrete blocks. This would support the users in the utilization of the material. The interesting results on the performances of the material presented in this paper will be implemented with periodical tests to study the evolution of the performances of the material and its durability in residential structures.

The main concern about the durability of hempcrete is determined by the presence of vegetal material because the variation of moisture conditions can cause its degradation. Thus, a decrease of the performances of hempcrete and, possibly, a reduction of the salubrity of the environment could occur.

Data about the durability of hempcrete can be collected carrying out laboratory tests, some studies have simulated possible critical situations, typical of the service life, but field tests are recommended to increase the knowledge about the material. The effects of biological attack by bacteria or fungi have been studied by inoculating microorganisms into the material. Periodic measurements along two years have been carried out by Walker *et al.* (2014) after the abundant introduction of bacteria; the results show that microorganisms, even those able to live in alkaline conditions, did not proliferate and degradation did not occur. Moreover, the alternating high and low values of humidity, typical of Mediterranean climate, further limit their permanence into the material. The alternation of wet and dry periods is fundamental to avoid the biological degradation: high humidity favours the spread of fungi or bacteria on the surface of hempcrete reducing the hygrometric performances of the wall while low humidity allows the penetration of microorganisms inside the material reducing the water vapour permeability (Arizzi *et al.,* 2016). The importance of testing even after several months is underlined by Marceau *et al.* (2017) who have found the conditions necessary for the mould growth: high relative humidity (around 98%) and pH lower than 10. The pH of hempcrete decreases due to the carbonation process, for this reason a long-term monitoring would allow to investigate the behaviour of the material in critical conditions. Some biocide treatments as γ irradiation of hemp shives, addition of anti-microbial or nanoparticles able to increase the resistance to bacteria or fungi have been proposed (Arizzi *et al.*, 2016).

Beside the growth of microorganisms, the moisture content influences also the density and, consequently, the thermal conductivity of the material. Hence, proper ventilation and correct selection of the protective coating, are crucial to preserve the properties of hempcrete besides to counter the biological degradation (Marceau *et al.*, 2017). The resistance to freeze-thaw cycles is good, no cracks or modification of the microstructure have been detected for a year on hempcrete blocks, characterized by different hemp-to-lime ratios, after 10 freeze-thaw cycles in conditions near saturation (RH around 90%). Carbonation reduces the vulnerability to freeze-thaw cycles because the formation of calcium carbonate reduces the porosity of hempcrete and hence the amount of water absorbed (Walker *et al.*, 2014). Furthermore, tests of exposure to salt (NaCl) performed by Walker *et al.* (2014) and Arizzi *et al.* (2016) did not provoke degradation of blocks and no effloresce was detected. If salt precipitates on the surface, it is easily removed by rainfall while, if absorbed, the hygroscopic behaviour helps in weathering through natural wet-dry cycles. Therefore, the weathering of salt is less aggressive in hempcrete than in other inorganic porous materials (*e.g.* stone, mortar).

3 Life Cycle Assessment

In recent years, the interest for hemp-based building materials has increased also due to their expected positive environmental performances (Ingrao *et al.*, 2015). However, few LCA

studies have evaluated different hempcrete wall technologies: spray (Boutin *et al.*, 2006; Pretot *et al.*, 2014) sprayed hempcrete with timber frame support (Ip and Miller, 2012; Pretot *et al.*, 2014) and blocks. A preliminary environmental assessment of the hempcrete technology is given here by evaluating a representative wall made with hempcrete blocks. Recently, the environmental performances of an Italian hempcrete block (Arrigoni *et al.*, 2017) as well as hemp cultivation (Zampori *et al.*, 2013) have been carried out.

In order to assess the environmental sustainability of hempcrete blocks used in non-load bearing walls, three additional alternatives have been selected and compared at the level of materials production (A1-A3, EN 15804:2012+A1:2019): masonry bricks, expanded clay bricks and aerated autoclaved concrete (AAC) blocks with cement-lime mortars. The comparison is based on 1 m^2 of vertical non-load-bearing wall (Functional Unit). Data for alternative bricks are taken from Environmental Product Declarations (EPDs) of selected producers (Aversa *et al.*, 2019; Margutti and Pennati, 2018). The impact categories selected are those reported in the EPDs and the method used to evaluate the environmental burden of the four walls is CML 2001 (Guinée and Lindeijer, 2002).

In Figure 1, the results of the four walls in seven impact categories are compared. The hempcrete wall solution has very positive performances in six out of seven impact categories. This preliminary LCA is highly promising, especially considering that only the first life cycle stages of the building are included in the analysis. Further benefits will certainly come from the use stage and end-of-life. Moreover, a detailed LCA study of hempcrete blocks is being carried out to take into account production improvements occurred in the last year.

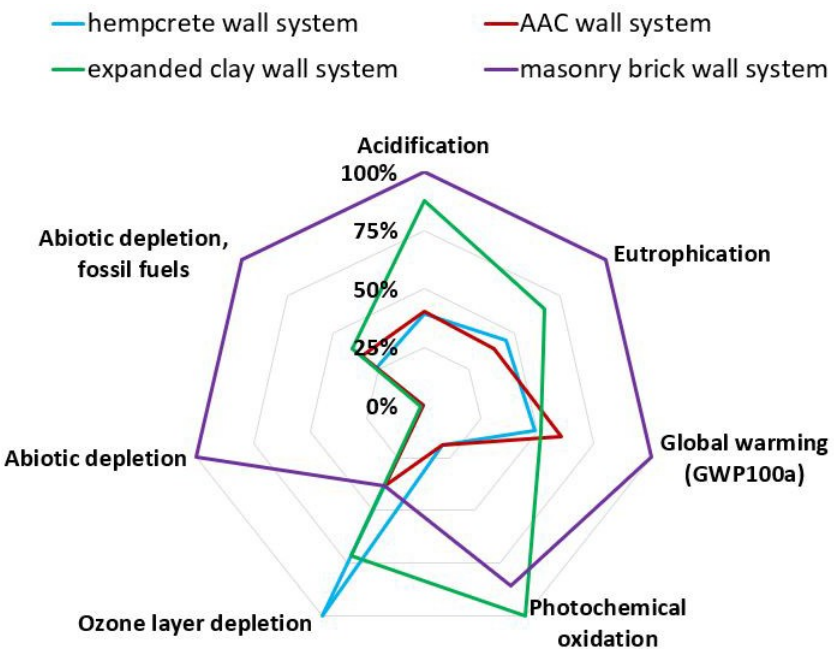

Figure 1. Wall system s comparative LCA assessment at the product stage A1-A3.

4 Case Study

The experimental methodology to perform the field measurements that allow to determine the hygrothermal performances of hempcrete walls has been tested in laboratory on a 1m^2 wall, built in hempcrete blocks, introduced in a climatic chamber. Known temperature cycles have been applied to simulate hot temperate climates (Aversa *et al*., 2019). The test wall had been built employing the same type of blocks used in the perimeter walls of the detached houses in Sicily (Serradifalco, CL).

Currently, the data collected in the Sicilian campaign have been elaborated, the reference standards are UNI EN 15026:2008 and UNI EN ISO 13788:2013. The measurements have been performed on the South-West, South-East and North-West walls for 13 days (in August) during which the inhabitants where not present to exclude the influence of the air conditioning system. The wall system is 400mm thick (Figure 2): the hempcrete blocks have a thickness of 360 mm, the ratio between dolomitic lime and hemp shives is 3:1; the plaster is premixed, constituted by hydraulic lime NHL 5 and it has thickness of 20 mm both on the internal and on the external face of the walls. The bedding mortar is characterized by a dolomitic lime-to- hemp shive ratio of 3:1.

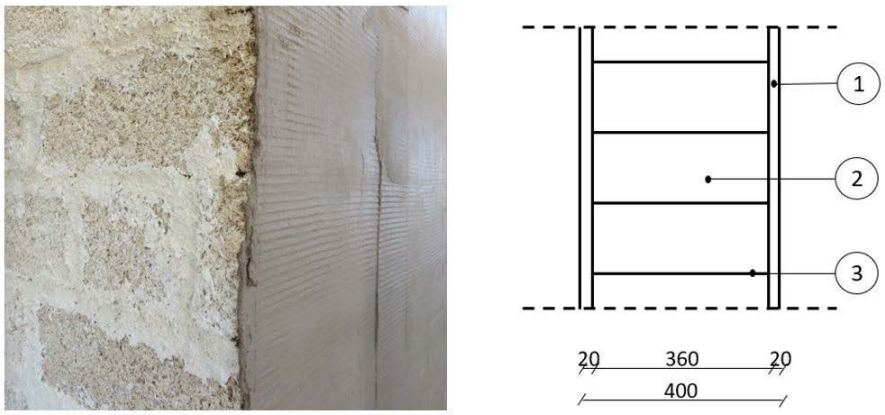

Figure 2. Wall system: 1-plaster (thickness: 20 mm); 2-hempcrete blocks (thickness:360mm); 3-bedding mortar.

Temperature and humidity sensors have been applied on the walls (see Aversa *et al*., 2019) while the outdoor weather conditions have been measured by a weather control unit. The temperature and humidity of internal and external surfaces of the North-West wall, detected during the period of analysis, are plotted in Figure 3.

Regarding the relative humidity, on the internal wall an average value of 67% has been measured while the external value shows variations in between 40% and 100%, due to some rainy days during the monitoring period. Hence, the behaviour of the wall is good, the damping has been higher than 80%. Also, the thermal response has been good, the average temperature measured on the internal wall has been 26°C (with variations of ± 1.5°C) in

response to the variations of external temperature between 15°C and 35°C. Likewise humidity, the damping is higher than 80%. The offset between internal and external humidity is of 6 hours, relatively to the maximum peak of humidity, while the offset was around 8 hours in laboratory tests (Aversa *et al.,* 2019).

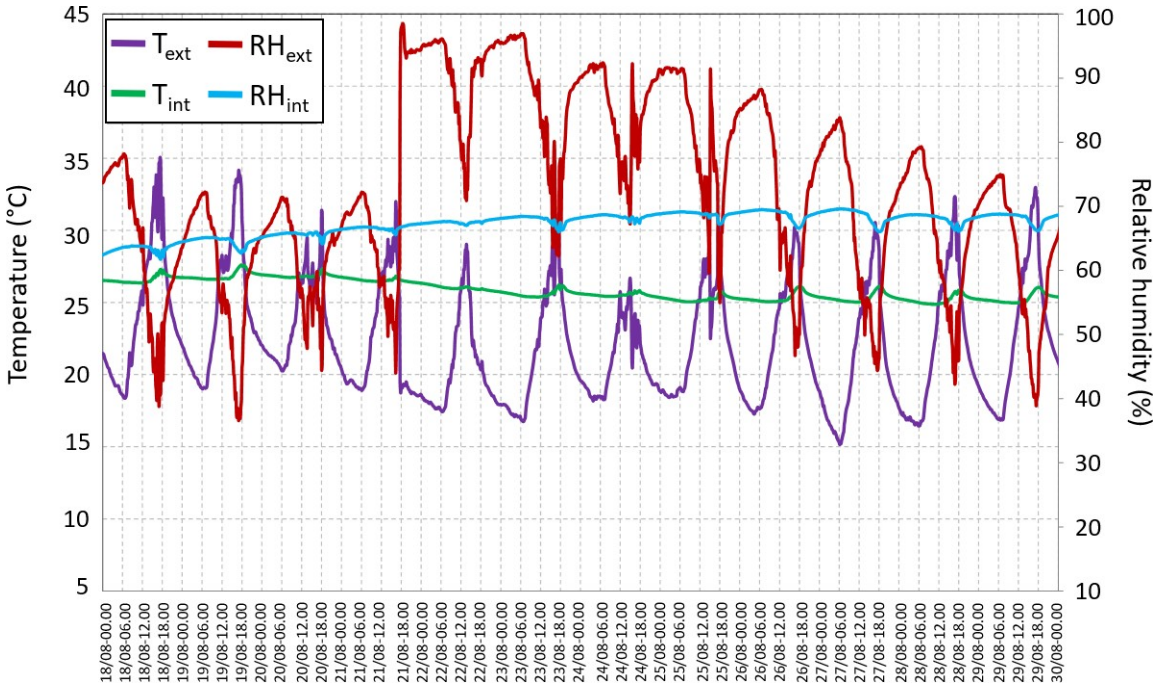

Figure 3. Temperature (T) and relative humidity (RH) measured on the internal (int) and external (ext) faces of the North-West wall of the house in Sicily during the 13 days of analysis.

The implementation of the results with the numerical simulations and the new experimental campaigns will enrich the knowledge about the behaviour of hempcrete in a detached house. This will be implemented by the measurements carried out in Veneto. The case-study in Sona (VR) is different from the Sicilian because hempcrete has been applied only in a room, during the renovation of the building. In this case, the data will provide information both on the performances of hempcrete into a different climate than the Sicilian one and on the behaviour of the material when installed in combination with other materials.

5 Conclusions

This study shows the promising performances of hempcrete blocks both in terms of environmental sustainability and hygrothermal properties. The preliminary environmental assessment through LCA is highly encouraging and seems to confirm what has been already

demonstrated in the recent literature, *i.e.* that the use of hempcrete blocks has a beneficial effect on relevant impact categories. Furthermore, some of the advantages of the hempcrete are not clearly evidenced in the first life cycle stages of a building, in terms of energy saving and recyclability at the end-of-life.

The first evaluation of the hygrothermal performances of hempcrete blocks in the Sicilian climate is positive. The indoor temperature and humidity were almost constant during the analysis period without the utilization of ventilation, air-conditioning systems or air exchange. Further measurement in situ will allow to understand the evolution of the material performances in time. Thus, the durability of hempcrete will be evaluated together with the possibility to install it in place of traditional materials, especially when sudden climatic variations occur, or higher humidity and continuous rain conditions verify.

Moreover, the availability of residential houses for in situ measurements will allow the evaluation of energetic behaviour of the buildings and the evaluation of the environmental performances of the material when applied in construction works. Also, the effects on the indoor comfort will be investigated *i.e.* humidity and temperature of the internal spaces will be measured.

Abstract. *In North America, clay bricks are qualified as durable if they meet either the ASTM C216 or CAN/CSA A82.1 standard. Although these standards are widely used in North America, they have not been linked with pore Structure (PS). Furthermore, moisture content and pore structure (PS) are two significant parameters that influence the performance of clay bricks during the freezing-thawing process. Thus, finding a relationship between them will lead to a quick assessment of water absorption (WA) and knowing their effect on frost resistance (FR). This work aims to investigate the relationship between PS and WA of clay bricks. Five different types of clay bricks were examined. WA of brick samples was determined according to the CAN/CSA A82.1 standard. Mercury Intrusion Porosimetry (MIP) was used to determine the total porosity and pore size distribution (PSD). The variation of 24-h cold water absorption (CWA) among samples of each type of brick was analyzed and each type of brick was divided into three groups according to their 24-h CWA: low – medium – high. The PSD of bricks was also divided into several ranges based on the pore size. The results indicated that some types of brick have a wide variation in 24-h CWA, which could affect the frost resistance evaluation. The strong relationship between WA and PSD was found, which could be used as a base for determining 24-h CWA.*

Keywords: *Clay Brick, Frost Resistance, Water Absorption, Pore Structure.*

1 Introduction

Numerous contributions in the literature have dealt with the frost durability problem regarding its mechanism and theories, influential factors, and evaluation methods (Stupart, 1989). Frost resistance (FR) is defined as the ability of materials to resist frost damage when exposed to climatic conditions (Mallidi and Reddy , 1996). Many researchers also have studied and determined the parameters that influence the FR of clay brick. They concluded that these parameters could be identified through the material characteristics and the physical state of water (ice). These studies indicated that water absorption (WA) and pore structure (PS) affect FR. Essential components of the PS of clay brick, which involve determining the FR, are its porosity and pore size distribution (PSD) (Stupart, 1989). Generally, the pores are the place where ice expansion occurs, resulting in pressure development inside porous materials.

Generated pressure typically depends upon the amount of pores and the degree of saturation of the material during the freezing process. Clay bricks typically are subjected to a wide range of water saturation levels during their service life. Hence, high levels of saturation sometimes cause durability problems, especially when it is accompanied with severe freeze/thaw (F/T)

conditions. Water absorption is defined as the ratio between the mass of absorbed water to the dry mass of the sample (De Rose *et al*., 2014). The relationship between capillary pores, *i.e*., pores are larger than 0.01μm according to (Gao *et al*., 2015) and adsorbed water is a positive relation, whereas increased capillary pores lead to increased WA, which in turn affects frost durability (Davison, 1980). Thus, appropriate evaluation of potential FR of bricks requires a sufficient understanding of the relationship between FR and brick properties (*i.e*., PS and WA).

Predicting the FR of bricks based on a physical property assessment is known as an indirect method. In North America, the clay brick is qualified as durable if it meets the criteria based on a physical property stated in the Canadian standard CAN/CSA A82.1. The CSA A82.1 standard depends on a direct determination of compressive strength and WA. In other words, three conditions should be met which are the minimum compressive strength, maximum water absorption (*i.e*., 24-h CWA), and maximum saturation coefficient (C/B) (CSA-A82.1, 2006). The 24-h CWA is defined as an amount of water that absorbed during a 24-hour divided by the sample's dry mass, while C/B is determined based on the ratio between 24-h CWA and 5-h boiling water absorption (5-h BWA). Besides, several indices have been used to evaluate potential FR such as (Maage, 1984), (Nakamura, 1988), and (Koroth *et al*., 1998). Maage's index (Maage, 1984) is a preferred indirect method (Davison, 1980) that is used for the evaluation of FR. The method depends on measuring the PSD of a brick using mercury intrusion porosimetry (MIP). Ultimately, the durability factor (Df) is calculated using Eq (1) (Maage, 1984).

$$DF = 3.2/PV + 2.4 * P3 \quad (1)$$

Where: DF is a durability factor; PV is maximum intruded pore volume of brick; P3 is the percentage of pores with diameters bigger than 3 μm (% of PV).

Although many previous studies have investigated the FR and material properties, there is no literature reporting the relationship between two essential properties of clay brick (*i.e*., pore system and water absorption). The aim of this paper is to investigate the relationship between pore properties and water absorption to provide the right prediction of the amount of absorbed water thus improving frost durability prediction. To achieve this goal, five different types of clay brick were examined using two approaches and their measurement results were analyzed.

2 Material and Methods

The determination of the relationship between PS and WA properties includes several consecutive procedures. These procedures involve selecting different types of clay bricks, determining their PSD, and measuring WA. Finally, data analysis is carried out to derive the relationship between the PS and WA. To obtain a wide range of properties, five sets of brick specimens from three different types (new exterior brick, reclaimed exterior brick, and reclaimed interior brick) were obtained from local vendors in Montreal, Quebec and examined. Table 1 shows the brick types that used in this research.

2.1 Water Absorption (WA)

Each type of brick was tested in accordance with CSA -A82.1 standard to determine WA. First, the dried weight is determined according to CSA -A82.1 at a temperature of 110 to 115 ºC for at least 24h.

Table 1. Different types of bricks used in this study.

Brick Type	Brick name	Samples number	Nomenclature
Reclaimed exterior brick	LAPRAIRIE	35	PO
	OUTREMONT	35	UO
New exterior brick	BRGG52	35	B52
	OLD ENGLAND	35	OE
Reclaimed interior brick	MOLLE	35	MO

2.1.1 The 24-h cold water absorption (CWA)

The 24-h CWA is determined according to CSA-A 82.1 following the drying and cooling procedure mentioned above. The dried full specimen was immersed completely in clean water at room temperature for 24h. The specimen was removed and wiped of excess water and then mass determined. The 24-h CWA is calculated based on Eq (2).

$$24\text{-}h\ CWA = (W_s - W_d)/ W_d * 100 \quad (2)$$

Where: W_d = dry weight of specimens; W_s = saturated weight of the specimen after 24h submersion in cold water.

2.1.2 The 5-h boiling water absorption (BWA)

The specimen, after being subjected to cold water absorption, was immersed in clean water and the water was heated to boiling for 5 hours. The specimen was cooled by natural loss of heat until reaching room temperature. The specimen was removed from the container and wiped, and then mass determined. The 5-h BWA is calculated based on Eq (3).

$$5\text{-}h\ BWA = (W_b - W_d)/ W_d * 100 \quad (3)$$

Where: W_d = dry weight of specimens; W_b = saturated weight of the specimen after 5h submersion in boiling water.

2.2 Mercury Intrusion Porosimetry (MIP)

MIP has been known as a suitable method to examine the PS of mineral building materials since 1970 (Rubner and Hoffmann, 2006) and used by many researchers to determine open porosity and the PSD (Maage, 1984). A set of pore parameters can be determined and derived by MIP such as pore volume, porosity, pore range, and median pore size. The width of the PSD is expressed using the Scatter coefficient (Cd), which is calculated from Eq (4).

$$Cd = (r20 - r80)/ r50 \quad (4)$$

Porosimetric determinations were performed by means of MIP (PoreSizer 9320). PSD was calculated from the mercury intrusion results by assuming a surface tension of mercury of 0.485 N/m and a contact angle of 124°. The relationship between pressure and size of the pore is given by the Washburn equation (5).

$$D = -4\gamma\cos\theta/\rho \quad (5)$$

Where: D is pore diameter; p = applied pressure; γ= surface tension; and θ = contact angle.

The results showed a wide range of 24-h CWA within the same brick type. To have a range of results, three samples were selected for MIP measurement from the 35 samples tested. Each type of brick was divided into three groups based on the variation in 24h CWA values (low, medium, and high). Eventually, MIP test was performed on small – cored samples taken out from the brick samples to characterize the pore system. Thirty small cores, 15 mm in diameter and 22 to 25 mm length, were derived from all brick types and then examined by the MIP test with two replicates per brick type and absorption value. The small cores were dried in an oven at 105 – 110 ºC for 24-h and stored in a sealed container until testing.

3 Results and Discussion

3.1 Water Absorption Properties

Thirty-five specimens of each brick type were subjected to the WA test to determine 24-h CWA, C/B, bulk density (BD), porosity (P), and apparent density (AD). Table 2 shows all brick properties that were determined based on the WA test. In general, the 24-h CWA values of the bricks as an average ranged from 4.42% (for new exterior brick OE) to about 16.68% (for reclaimed interior brick MO). Brick types PO, B52, and OE on average passed the CSA – A82.1 requirement; these are all bricks intended for exterior use. However, brick types MO and UO failed to meet CSA-A82 requirements of 24-h CWA (8%). This was somewhat surprising as UO was identified for exterior use, which is probably due to the effects of the service life. Table 2 shows the individual results of 24-h CWA test of all brick types. Table 2 also shows that all samples of brick MO did not meet the 24-h CWA criteria requirement, while brick types PO, UO, B52, and OE meet 24-h CWA criteria as percentage 59%, 12%, 86%, 95%, respectively. The results of 24-h CWA also show that there is a variation among 24-h CWA values of the sample from the same type of brick. This variation can be seen through the standard deviation of each brick type, where brick types MO, OE, B52, UO, and PO show standard deviation 1.86, 1.80, 1.65, 1.38, and 0.84, respectively.

Table 2. Brick properties based on water absorption test.

Brick type	24-h CWA %				5-h BWA %	C/B	BD	AD	P
	Ave	SD	Individual			Ave	kg / m^3	kg / m^3	m^3/ m^3
			Pass	Fail					
MO	16.68	1.86	0	35	19.62	0.85	1777	2725	0.35
PO	7.88	0.84	20	15	10.14	0.78	2085	2642	0.21
UO	9.57	1.38	5	30	12.28	0.78	1968	2596	0.24
B52	5.42	1.65	30	5	10.38	0.51	1904	2398	0.20
OE	4.42	1.80	33	2	6.25	0.69	2245	2610	0.14

The C/B values of the bricks as an average ranged from 0.51 (for new exterior brick B52) to about 0.85 (for reclaimed interior brick MO). The results show that on average brick types B52 and OE meet the CSA-A82 requirements for exterior brick. Brick type MO also meets the CSA-

A82 for interior brick. While brick types PO and UO exhibit the C/B at threshold 0.78 of the CSA-A82 standard as shown in Table 2. The porosity (P) of brick types is from 14% (for new exterior brick OE) to 35% (for reclaimed interior brick MO). The bulk density (BD) of brick types is between 1777 kg/m^3 (for reclaimed interior brick MO) to 2245 kg/m^3 (for new exterior brick OE) as shown in Table 2.

3.2 Pore System Properties

From the MIP test, curves of cumulative pore volume and diameter were derived. Based on the calculation from Maage's equation (1) and criteria (*i.e.*, durable DF>70; uncertain durability DF= 55-70; nondurable DF<55), most of brick types have good durability. They show (DF>70) except samples MO12 – H1 and MO9- H2 that show (DF<55) as shown in Table 3. Brick sample OE31-H1 has the lowest pore volume (PV) compared to other samples of brick types while brick sample MO12-H1 has the highest PV. Brick sample B52-27-H2 shows a high percentage, *i.e.* 76%, of pore volume with a diameter bigger than 3μm. In contrast, brick sample MO12-H1 shows a low value, *i.e*. 3%, of pore volume with a diameter bigger than 3μm.

According to Maage's principle, sample B52-27-H2 with a DF of 226 has low water absorption and better frost resistance. In contrast, the sample MO12-H1 with a DF of 20 has high water absorption and poor frost resistance. The scattering coefficient (Cd) of all brick types ranges between 0.52 and 36. If Cd is less than 1, it means the PSD is narrow. The samples MO9-H2 and MO12-H1 have narrow PSD thus most ice will form within a small temperature interval.

The rest of the samples PO, MO15, B52, UO, and OE have Cd bigger than 1, thus they have a wide PSD and ice formation will occur in wide temperature interval. It can be drawn from the data analysis that samples MO15 and MO12-2 of type MO (that exhibits a high WA) have a predominant pore size ranges between 0.1and 0.3 μm. While sample MO9 has a predominant pore size range between 0.3 and 1.0 μm. The Sample B52-27 of type B52 (that exhibits a low WA) has a dominant range of pore size, which is 10-20 μm. Sample OE31 of type OE with the lowest value of WA has a predominant pore size ranges between 7 and 20 μm.

3.3 Relationship Between 24-h CWA and PSD

As shown in Figure 1, a linear correlation between 24-h CWA and its PV (porosity) exists with a high correlation coefficient ($R^2 = 0.93$). With the increase of porosity, i.e., pore volume, the 24-h CWA increases. To obtain a better analysis of the effect of PSD on WA, some further analysis was undertaken. Three features were investigated: PSD of the samples that had the highest and lowest values of 24-h CWA among all brick types, PSD of three samples from the same type, and PSD of the sample have the same PV. The samples MO12-H1 and MO9-H2 have the highest 24-h CWA 19.81 and 15.36, respectively. It can be seen from PSD of these samples, as shown in Figure 2, that their PSD range between 0.03 and 2μm. The samples OE31-H1 and B52-27-H2 have the lowest 24-h CWA 1.57 and 3.24, respectively with pores larger than 2 μm. The samples with higher porosity had smaller pores.

The PSD of three samples of brick type B52 shows that they have a bimodal pore structure (*i.e*., two different ranges of median and large pores). Comparing their PSD with the change in 24-h CWA, it can be observed that increasing a percentage of pores with diameters bigger than 5 μm results in decreasing 24-h CWA and vice versa. The samples UO30-H2 and UO13-H1

have approximately constant PV, 0.0906 ml/g and 0.0909 ml/g, respectively. The samples PO14-H1 and OE2-H2 also have nearly the same PV, 0.1045 ml/g and 0.1039 ml/g, respectively. It can be seen from Figure 3 that 24-h CWA of these samples increases with pores having diameters smaller than 2 μm and vice versa. The empirical analysis of the relationship between 24-h CWA and PSD showed that 24-h CWA has a good correlation with the range of pores between 0.03 and 2 μm.

Table 3. Durability factor with 24-h CWA and C/B for all selected samples.

Brick Sample	MIP Method				WA Method	
	PV (ml/g)	P3 (%)	DF	Cd	24-h CWA %	C/B
PO-08-H1(low)	0.0893	72	209	2.74	6.03	0.74
PO-14-H1 (med)	0.1045	58	170	2.51	8.04	0.76
PO-09-H2 (high)	0.1186	48	141	12.38	9.19	0.77

According to findings in previous studies, which indicated that larger pores are filled with water first, then water is delivered to smaller pores (Fagerlund, 1973). Furthermore, small pores have a greater suction stress due to their diameters, but a lower rate of uptake compared with large pores. The variation between the different pore sizes will result in sucking water from the large pores and delivery to small pores. When equilibrium is reached, the movement of water will be stopped. Hence, it can be observed that water absorption is also influenced by the relationship between the amount of pores volume in the range of 0.03 μm to 2 μm and the amount of pores volume bigger than 2 μm. Thus, the parameter (A) can be derived from the empirical analysis of the relationship between these pores, as shown in Eq (6).

$$A = (MP - LP)/LP \tag{6}$$

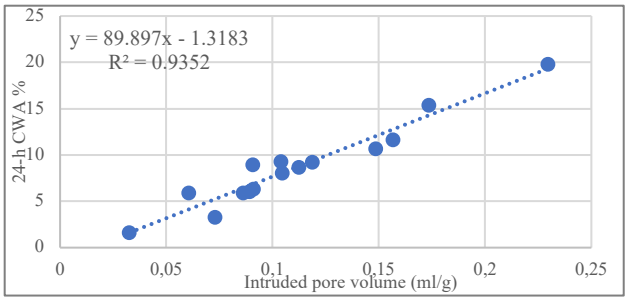

Figure 1. The correlation between 24-h CWA and intruded pore volume.

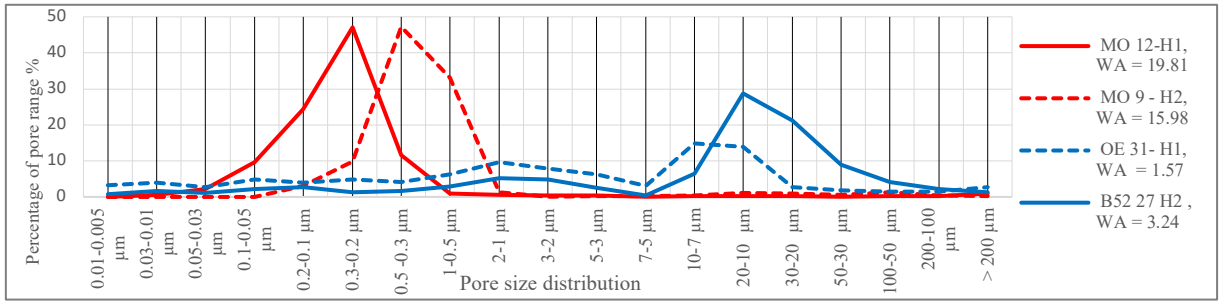

Figure 2. Pore size distribution of brick sample having maximum and minimum WA.

The ration between subtracting the percentage of pores bigger than 2µm (LP) of the percentage of pores in the range of 0.03 µm to 2 µm (MP) divided by (LP) shows a good correlation with WA. Eventually, the correlation between 24-h CWA, PV, the percentage of pores (0.03-2 µm), percentage of pores bigger than 2 µm, and the parameter (A) were input into regression analysis and the Eq (6) for determining 24-h CWA based on pore size was derived.

$$CWA_{24\text{-}h} = 59.68\,PV + 0.023MP - 1441.78/LP + 14.58A + 29.65 \quad (R^2=0.97) \tag{7}$$

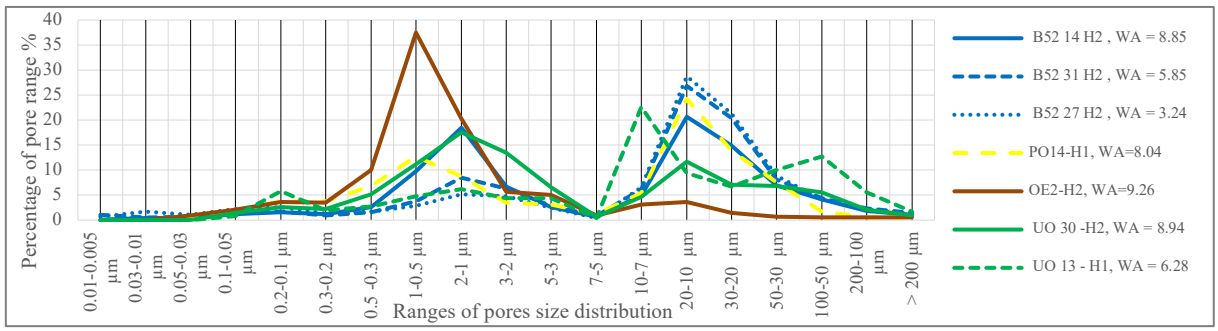

Figure 3. Pore size distribution of brick samples type B52 and other samples of different types having the same PV but with different levels of WA

4 Conclusions

The study investigates the relationship between WA and PS, as well as their effect on the prediction of FR. Main findings from this study are summarized as follows:

- All brick types show a variation in water absorption properties, which are essential

elements for the evaluation of frost durability using CSA and ASTM standards. The variation may attribute to manufacturing process control and conditions exposed through their service life for reclaimed bricks. Therefore, relying on 24-h CWA and C/B for predicting frost resistance could result in a misleading assessment.

- The WA of clay brick is considerably increased with the increase of pore volume having pore size ranging between 0.03- 2μm. Thus, decreasing the percentage of these pores will enhance the frost resistance of clay brick.
- Despite PSD is an important factor when evaluating the FR, it is not involved in the WA method. Hence, combining PSD with WA can give a good estimation of FR.

Maage's index deals with pores bigger than 3 μm as if they have uniform size and the same effect. But in fact, this contradicts several facts, namely, that pores have a different impact in terms of the size of their diameters when absorbing water. Consequently, further investigation of this issue will be required. Furthermore, a study about the relationship between the critical degree of saturation and PSD will be worthwhile to add a good contribution to the evaluation of frost resistance of clay brick.

Abstract. *Multi-scale analysis of photodegradation are conducted for pigmented coating containing acrylic urethane + TiO_2 pigment and for non-pigmented coating containing only acrylic urethane. We discuss the intrinsic differences in the photodegradation mechanism between the pigmented and non-pigmented coatings and the effect of the interface between the pigment and the binder. Photo-aging tests are conducted using artificial ultraviolet (UV) irradiation under conditions of 60 °C and dry atmosphere. The results of Fourier transform infrared spectroscopy (FTIR), solvent swelling experiments, ultrasonic measurements of elastic moduli, and colourimetry used for material characterisation before and after photo-aging. Although the behaviour of E and the carbonyl index (CI) show common trends for both samples, the overall trends of yellowness index (YI) and swelling degree (Q) differ significantly between the pigmented and non-pigmented samples. The results reveal that changes in macroscopic properties may not necessarily correspond with the CI behaviour and that characteristic interfacial effects exist between the pigment and the binder. The onsets of coating erosion and chalking are observed in the pigmented coating as surface topological changes. The different behaviour of YI and Q between the sample types can be attributed to the interfacial effect at pigment/binder interface based on the photo-catalytic effect from TiO_2 pigment.*

1 Introduction

The durability of protective surface coatings is a critical factor for long-term quality with respect to buildings and infrastructures because these coatings act as gas barrier material and enhance the aesthetic qualities. Thus, improvement is needed in the long-term performance of these coatings, and an appropriate evaluation procedure should be established.

For assessing the degree of degradation in polymer-based materials, the carbonyl index (CI) is commonly applied because it reflects the macroscopic degradation occurring in barrier properties, elasticity, and surface colour and gloss in these materials. Although it is well accepted as a relevant criterion, CI may be not appropriate for evaluating the degradation level in all physical properties (Rouillon *et al*., 2016). CI could be applied to analyse the chemical oxidation level microscopically; however, it is not appropriate for evaluating some macroscopic

properties related to the material's internal morphology such as macromolecular architecture, pore structure, and configuration of fillers. Hence, recent multi-scale degradation research has been conducted to analyse microscale phenomena and macroscale properties with a focus on mesoscale alteration of materials (Courvoisier *et al.*, 2018; Richaud *et al*., 2010).

Two types of coatings are used for buildings and construction: pigmented and non-pigmented in coloured and clear coatings, respectively. Unfortunately, it can be difficult to evaluate the degradation level by applying only a single index to the durability of both coating types because they exhibit intrinsic differences in the photodegradation mechanisms such as the interfacial effect between the pigment and the binder, as evidenced by the differences in internal structures.

In this work, multi-scale analysis of photodegradation is conducted for both pigmented and non-pigmented coatings, as shown in Figure 1. We analyse the intrinsic differences noted in photodegradation between the two coatings and the effect of the interface between the pigment and the binder. Titanium dioxide (TiO_2) is most commonly used as white pigment for coatings of buildings owing to its good brightness and photo-catalytic effect. However, the photo-catalytic effect might be responsible for these differences because it produces hydroxyl radicals (·OH) under ultraviolet (UV) irradiation as part of the decomposition of surface contaminants (Pang *et al*. 2014).

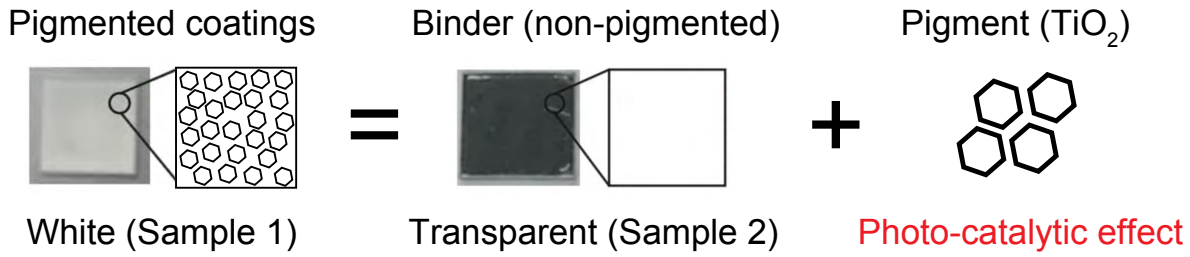

Figure 1. Composition of sample coatings.

2 Materials and Experimental Methods

2.1 Coating Sample Preparation

The coating was applied on Si substrates using the spin-coating technique at a speed of 2000 rpm for both the pigmented and non-pigmented coatings. The pigmented coating, which was purchased from Japanese industry, is a two-part-type urethane-based white paint (Sample 1). The main chemical component of the pigmented paint was analysed by pyrolysis gas chromatography mass spectroscopy, which detected acrylic polyol and hexamethylene diisocyanate (HDI) trimer. The elemental analysis revealed that the pigment particles are composed of TiO_2. The non-pigmented paint (Sample 2) was provided by Japanese industry. This paint had the similar chemical structure as that detected in the binder component of Sample 1—acrylic urethane—with no additives.

The curing process was the same as that discussed in our previous study (Ishida *et al*., 2019). The thickness of the coating film sample was approximately 30 um and 10 um for the pigmented and non-pigmented samples, respectively. The reason for using such thin film samples was to obtain homogeneously degraded samples with no obvious heterogeneous oxidation.

2.2 Artificial Photo-Aging

Ultraviolet irradiation was performed by simulating the aging conditions by UV irradiation in our lab (Ishida *et al*., 2019). This apparatus effectively controls the sample surface temperature under UV irradiation by blown air to eliminate radiation heat emitted by a metal halide lamp. The lamp was set with wavelengths below 295 nm and was filtered by using borosilicate glass; the light intensity was set at 180 W/m^2 (calculated λ = 300–400 nm). Photo-aging tests were conducted under a surface temperature of 60 °C and low relative humidity (RH) at <10%.

2.3 Characterisation Methods

We performed multi-scale analysis of photodegradation according to the combined results of Fourier transform infrared spectroscopy (FTIR), solvent swelling experiments, ultrasonic measurements of elastic moduli, and colourimetry. The FTIR and solvent swelling experiments were conducted to detect changes in the chemical structure and in the pore structure, respectively, by using the same method as that reported in an earlier study (Ishida *et al*., 2019). Ultrasonic measurements were conducted by using an ultrasonic device (38DL, Olympus, Japan, and the elastic moduli (E) were calculated on the basis of the ultrasonic speed in the materials (Göbel *et al.* 2018) as

$$E = 2\rho v_T^2 + \frac{v_L^2 - 2v_T^2}{v_L^2 - v_T^2}\rho v_T^2 \quad (1)$$

where ρ is the sample density, v_L is the longitudinal wave speed in the samples, and v_T is the transverse wave speed in the samples. Colour measurements were performed by using a spectrophotometer (CM-600d, Konica-Minolta, Japan) with the illuminant set to D65 and the observer set to 10°; the scale selected was L*a*b*. Colour data were illustrated as changes in the yellowness index (YI) according to the ASTM D1925 standard. For evaluating the changes in surface topology, tapping atomic force microscopy (AFM) and scanning electron microscopy (SEM) were applied to the pigmented coatings.

3 Results and Discussions

Firstly, we evaluated the CI change behaviour in the aging process, which is a widely accepted degradation indicator. The CI is calculated as the ratio of the peak areas (C=O vibration and C–H vibration) and is expressed as

$$CI = \frac{A_{C=O}}{A_{C-H}} = \frac{\text{Peak area } (1600\ cm^{-1} - 1850\ cm^{-1})}{\text{Peak area } (2800\ cm^{-1} - 3000\ cm^{-1})} \quad (2)$$

Figure 2 illustrates the CI behaviour for both pigmented and non-pigmented coating samples. Similar behaviours were shown, which indicates little difference in the chemical degradation (oxidation) rates between the two types. This result was expected because the chemical structures of their organic components are essentially the same. We then compared the CI and the macroscopic properties, E and YI. Figure 3 (a) illustrates the changes in E and YI values as a function of photo-aging time. For the pigmented sample, the E values roughly

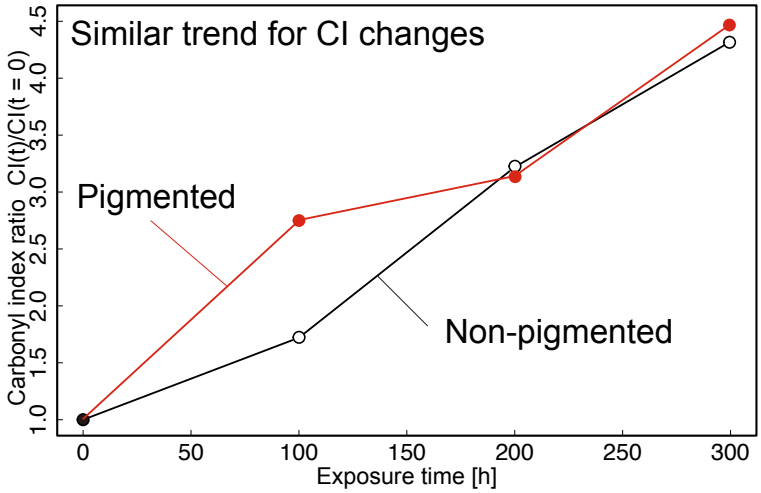

Figure 2. Carbonyl index (CI) as a function of exposure time for pigmented and non-pigmented coatings.

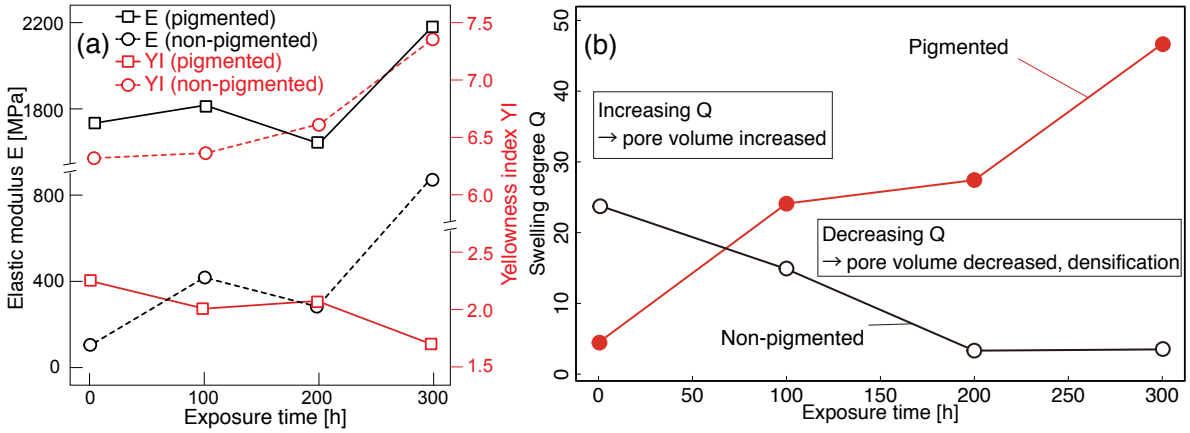

Figure 3. (a) Elastic modulus (E) and yellowness index (YI) as functions of exposure time for pigmented (solid lines) and non-pigmented coatings (dashed lines). (b) Swelling degree (Q) as a function of exposure time for pigmented and non-pigmented coatings.

increased and the YI values decreased with an increase in aging time. For the non-pigmented samples, the E value trend was similar to that in the pigmented samples; however, the YI values were decreased. Although the changes in E value behaviour corresponded with the CI behaviour for both coating types, those in the YI behaviour did not conform with the CI in the pigmented sample. In addition, a decrease in the b* value was observed in degraded pigmented samples, which implies a blue shift (Rosu *et al.*, 2009). Although carbonyl species are well known as typical coloured chemical products, carbonyl growth may not necessarily contribute to yellowing in all pigmented coatings. Figure 4 illustrates the relationship of colour with the absorption wavelength and number of conjugated double bonds for coloured chemical products (Bacaloglu and Stewen, 2001). The results imply differences in the chain length of degraded (oxidised) chemical products between pigmented and non-pigmented coatings, i.e. yellow chemical products from non-pigmented samples had longer conjugated

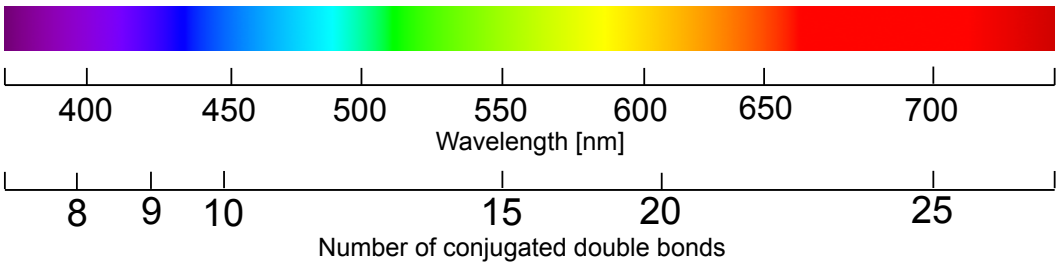

Figure 4. Continuous colour chart and its relationship with wavelength and number of conjugated double bonds.

double bonds than those from pigmented coatings. The photo-catalytic reaction of TiO_2 on pigmented coatings may have increased the efficiency of chain scission compared with that in the non-pigmented coatings. In addition, this effect appears to have influenced even the internal morphological changes in photo-aging. The behaviour of swelling degree showed differences between both coating types, as shown in Figure 3 (b). The swelling degree is derived as the sample volume change ratio before and after immersion in a solvent, which in this case was toluene (Ishida *et al*., 2019), and may be related to the internal total pore volume. The pigmented samples might have become porous because the total pore volume increased for the pigmented coating; however, the pore volume for the non-pigmented coating decreased. This occurred because the organic component (binder) hardened and shrank as a result of extensive cross-linking formation in the photo-aging process, which corresponds with our previous results using positron annihilation spectroscopy and FTIR (Ishida *et al*., 2019). In the pigmented coating, pore generation at the interfacial region between the pigment and the binder might be implied by considering the swelling behaviour combined with the changes in E value behaviour. As shown in Figure 5, surface topology alteration for the pigmented samples further substantiates this inference. We observed pigment particles exposed at the surface and an apparent increase in surface roughness, which correspond to the 'chalking' and 'coating erosion' described by Skaja *et al*. (2006) and Pang *et al*. (2014). Figure 6 summarises these intrinsic differences in the photodegradation mechanisms between the pigmented- and non-pigmented coatings, particularly the internal morphological changes. These apparent differences might be attributed to the two following mechanisms.

- Binder selective decomposition around pigments induced by photo-catalytic reaction, i.e. attacking of ·OH radicals generated from TiO_2 pigment (Pang *et al*., 2014).
- Binder shrinkage accompanied by the release of volatile degradation products (Skaja *et al*., 2006); approximately 10% shrinkage and 15 wt% mass loss were observed in the non-pigmented coating in this study after 300 h of photo-aging.

Neither chalking nor coating erosion occurred on the non-pigmented coatings because these are characteristics of pigmented coatings. Obviously, the interfacial effects occurring at pigment/binder under UV irradiation requires further investigation for better understanding of the photodegradation mechanisms.

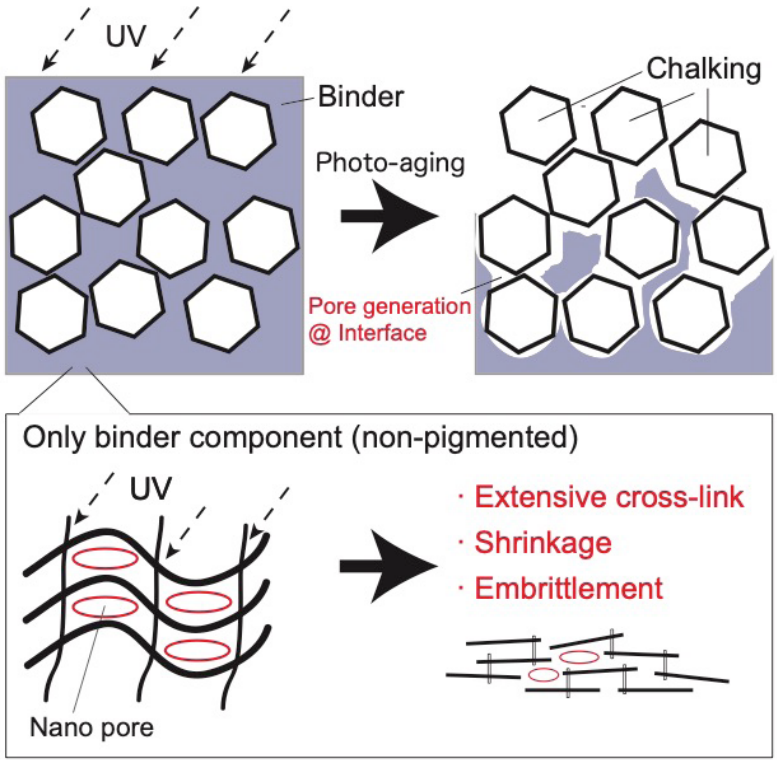

Figure 6. Schematic diagram of the intrinsic differences in the photodegradation mechanisms between pigmented- and non-pigmented coatings in terms of internal morphological changes.

4 Conclusions

Multi-scale analysis of photodegradation was conducted for both pigmented and non-pigmented coatings containing acrylic urethane + TiO_2 pigment and only acrylic-urethane, respectively. We discussed the differences in photodegradation between pigmented and non-pigmented coatings and the effect of the interface between the pigment and the binder.

The CI was increased for both coating types in photo-aging, which implies the progression of chemical degradation (oxidation). However, the changes in macroscopic properties did not necessarily correspond with the CI behaviour. Although the E value increased in accordance with the change in the CI, the YI increased for non-pigmented samples and decreased for pigmented samples, showing showed blue shift. It should be noted that although carbonyl species were produced, they were created by differences in the conjugated double bond length. This implies that the photo-catalytic effect of TiO_2 pigment might have an influence on the photo-oxidative degradation.

Internal morphological alterations were also studied by analysing the swelling behaviour of samples immersed in toluene. The pore volume of the organic component (binder) was decreased, which might be associated with hardening and shrinkage as the result of extensive cross-linking formation in the aging behaviour of the non-pigmented sample. On the contrary, pore generation at the interfacial region at pigment/binder interface was implied in the pigmented coating. In addition, we observed pigment particles exposed at the surface and an apparent increase in surface roughness. These two features, which are referred to as chalking and coating erosion, respectively, are characteristics of pigmented coating. The interfacial effects at the pigment/binder under UV irradiation involves complicated physicochemical processes. Therefore, further investigation and diversified experimental observation are needed for better understanding of the photodegradation mechanisms.

Ionic Diffusivity and Pore Structure of Hardened Cement Paste Exposed to High Temperature Environment for Long Period

Isao Kurashige

Nuclear Fuel Cycle Backend Research Center, Civil Engineering Research Laboratory,
Central Research Institute of Electric Power Industry, 1646 Abiko, Abiko-shi, Chiba, 270-1194, Japan,
kurasige@criepi.denken.or.jp

Abstract. *Ion diffusion through cement-based barrier is key to safe radionuclide transfer in intermediate radioactive waste disposal facilities. The purpose of this research is to elicit the behavior of ionic diffusivity and pore structure of hardened cement paste specimens for the barrier system when exposed to high temperatures (up to 80°C) for long periods (up to one year). The cement paste is made of an ordinary Portland cement base- and a low-heat Portland cement / fly ash / limestone filler (LF) system. The results of the adsorption isotherms of N_2 and water vapor of the specimens exposed to lime-saturated water of different temperatures, 20, 40, 50, 60, and 80°C, are presented, and their pore size distributions are analyzed by the Barrett-Joyner-Halenda method. The change of specific surface areas is measured and the influence of high temperature on the pore structure is discussed. Additionally, results of chloride ionic diffusivity test for the specimens after the high-temperature exposure are contrasted with the tendency of pore structure change. It is found that the LF system has much higher resistance to high-temperature exposure than ordinary Portland cement; however, temperatures greater than or equal to 60°C deteriorate the ionic diffusivity. These experimental results may indicate the ionic diffusivity of hardened cement paste can be influenced by the spatial electrical charge in micropores depending on the electrical charge of pore wall and the ion composition of pore solution.*

Keywords: *Radioactive Waste Disposal, Cement-Based Barrier, High Temperature, Ionic Diffusivity, Hardened Cement, Microstructure.*

1 Introduction

The microstructure of hardened cement with micro- and nano-sized hierarchical pore structure is not fully understood. The amorphous structure of calcium silicate hydrate (C-S-H), which is the main product of the hydration of cement, is considered one of the reasons for that.

The structure of C-S-H can change due to the hydration and polymerization reactions under the influence of temperature (Scrivener, *et al*., 2019). Consequently, changes in the microstructure influences the ionic diffusivity in the hardened cement. Evaluation of ionic diffusivity is also a key issue for the design and assessment of a radioactive waste disposal system with a cement-based barrier. Especially, for disposal of heat exothermic radioactive waste, the influence of high temperature on the performance of a cement-based barrier should be thoroughly examined to build a disposal system with high reliability and safety. The temperature of the action depends on the actual concentration of exothermic radionuclides such as cobalt-60 in nuclear waste, assumed to be around 60°C below the design temperature, to prevent excessive influence of temperature on the disposal system. The duration of the exposure to the high temperature can extend over several decades or hundred years. However, until now, few studies have reported on the influence of long-term high temperature on the ionic diffusivity of hardened cement.

doi:10.23967/dbmc.2020.088

Therefore, it is necessary to gain deeper understanding on the behavior of the hardened cement under the high temperature.

The purpose of this study is to investigate the ionic diffusivity of hardened cement exposed to high temperatures over a long period. From the results of the investigation, we discuss the effectiveness of a prime candidate material for the disposal system. The rest of the manuscript is structured as follows: Section 2 discusses the composition of the hardened cementitious specimens and the experimental methodology (adsorption tests and ion-diffusion test). Section 3 produces experimental results and discusses about the pore structure of the specimens exposed to various temperature levels for one year. It also compares the effect of temperature on Cl^- ion diffusivity with that of the pore structure of hardened cement paste.

2 Materials and Methods

2.1 Materials

The cement-based barrier for the nuclear waste disposal system should be durable and denser, experience little shrinkage, and have low hydration heat among others, for enhancing the barrier performance. In this context, two specimens of cement paste were prepared with a water-binder mass ratio (W/B) of 0.45, as shown in Table 1. The first specimen was made of ordinary Portland cement. The second specimen was made of low-heat Portland cement, which is a mix of siliceous fly ash and lime stone filler (fly ash binder mass ratio (FA/B) = 0.30: lime stone filler powder mass ratio (LS/P) = 0.38). LF30 is a prime candidate mix for the nuclear waste disposal system.

The specimens were cast in molds of 2 × 2 × 8 cm^3 volume. They were then demolded and subsequently stored in a saturated atmosphere at 20°C for one year, for an adequately mature hydration reaction. This is because the high temperature condition in a nuclear disposal facility occurs after the backfill closure of the disposal tunnel. After curing, the specimens were immersed in lime-saturated water at 20, 40, 50, 60, and 80°C for one year.

Table 1. Mix proportions of cement paste.

Mix code	W/B	W/P	FA/B	LS/P
OPC	0.45	0.45	-	-
LF30		0.28	0.30	0.38

2.2 Methods

2.2.1. Nitrogen gas and water vapor adsorption tests

For the adsorption test, the specimens were ground into particles of size 106-500 μm and degassed at 105°C in vacuum for 24 h. Adsorption tests with N_2 gas and water vapor were carried out using Quantachrome instruments autosorb iQ and VSTAR, respectively. The measurement temperatures were 77 K for N_2 adsorption and 293 K for H_2O vapor adsorption.

The pore size distribution (2 nm to 500 μm) was determined by the Barrett-Joyner-Halenda (BJH) method using the N_2 desorption isotherm data. In addition, from adsorption isotherms of N_2 and H_2O, based on the Brunauer-Emmett-Teller theory, under a relative pressure (P/P_0) of 0.05-0.30, the specific surface areas of the specimens were calculated.

2.2.2. Measurement of effective diffusion coefficient of Cl^- ions

The effective diffusion coefficient of Cl^- ions of the specimens after exposure was measured by the steady-state penetration-type diffusion test, with a concentration difference of 1,700 ppm of Cl in lime-saturated NaCl solution at 20°C. Samples for the diffusion test were cut to 2 × 2 × 0.5 cm^3 and saturated in lime water under vacuum for one day. The effective diffusion coefficient was determined when the diffusion was in steady sate. The test time to reach equilibrium was less than six months for OPC and more than one year for LF30.

3 Results and Discussion

3.1 Adsorption Isotherms and Microstructure of Cement Paste

3.1.1. Nitrogen adsorption isotherms

The measured N_2 adsorption isotherms of the OPC and LF30 specimens are shown in Figures 1 and 2, respectively. According to the classification of adsorption isotherms by IUPAC, these isotherms correspond to type IV(a), the type of hysteresis loop in their isotherms have characteristics of both H2(a) and H2(b) as pore blocking/percolation effects and evaporation via cavitation in a relative pressure range of 0.42 to 0.50 are indicated (Cychosz, *et al.*, 2017).

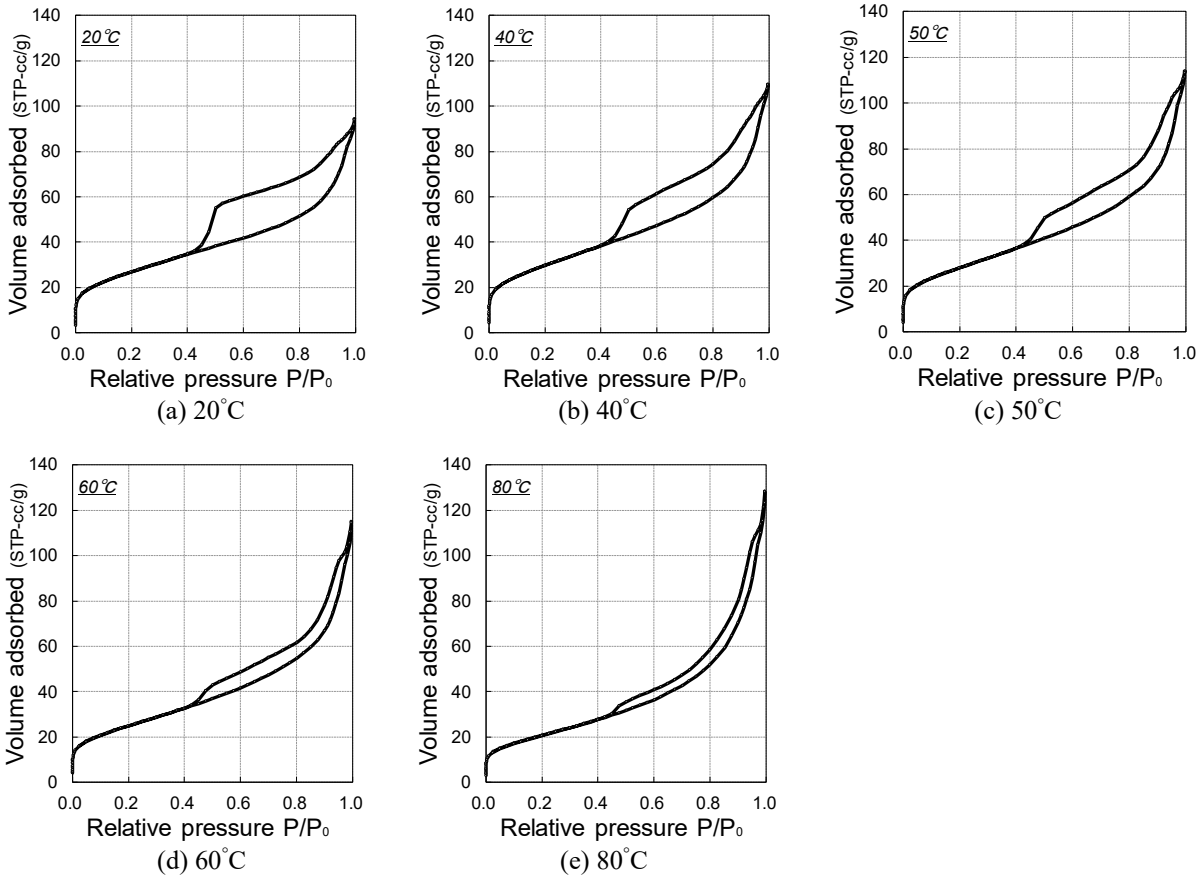

Figure 1. N_2 gas adsorption isotherms of OPC specimens exposed to various temperature conditions.

On the one hand, as shown in Figure 1, it is evident that the level of exposure temperature has a significant impact on the N_2 adsorption isotherms of OPC where higher temperature makes the hysteresis weak and remarkably reduces the desorption volume via cavitation. These changes are presumably due to the coarsening of the pore structure with expanded neck pores as well as a simplified pore network with ink-bottle-shaped pores (Gallucci, *et al.*, 2013). On the other hand, the isotherms of LF30 in Figure 2 are not influenced by the temperature so much as OPC, indicating the superiority of mix proportion of LF30 on resistance to high temperatures. Since solid-state ^{29}Si NMR detected the reaction progress of unreacted fly ash in LF30 during the high temperature exposure, the change for the worse in pore structure of LF30 could be reduced by the healing effect of fly ash.

Figure 3 illustrates pore size distributions determined for the different specimens and temperatures by the BJH method. A clear difference in the pore size distributions of OPC due to the exposure to high temperature can be seen Figure 3 (a), where higher temperature leads to an increase of gel pores around 10 to 50 nm. It should be noted that the sharp peaks at approximately 4 nm do not correspond to the actual pore in the specimens, which is an apparent peak calculated from the drastic evaporation via cavitation. The total pore volumes as well as the change in pore size distribution in LF30 are smaller than those in OPC.

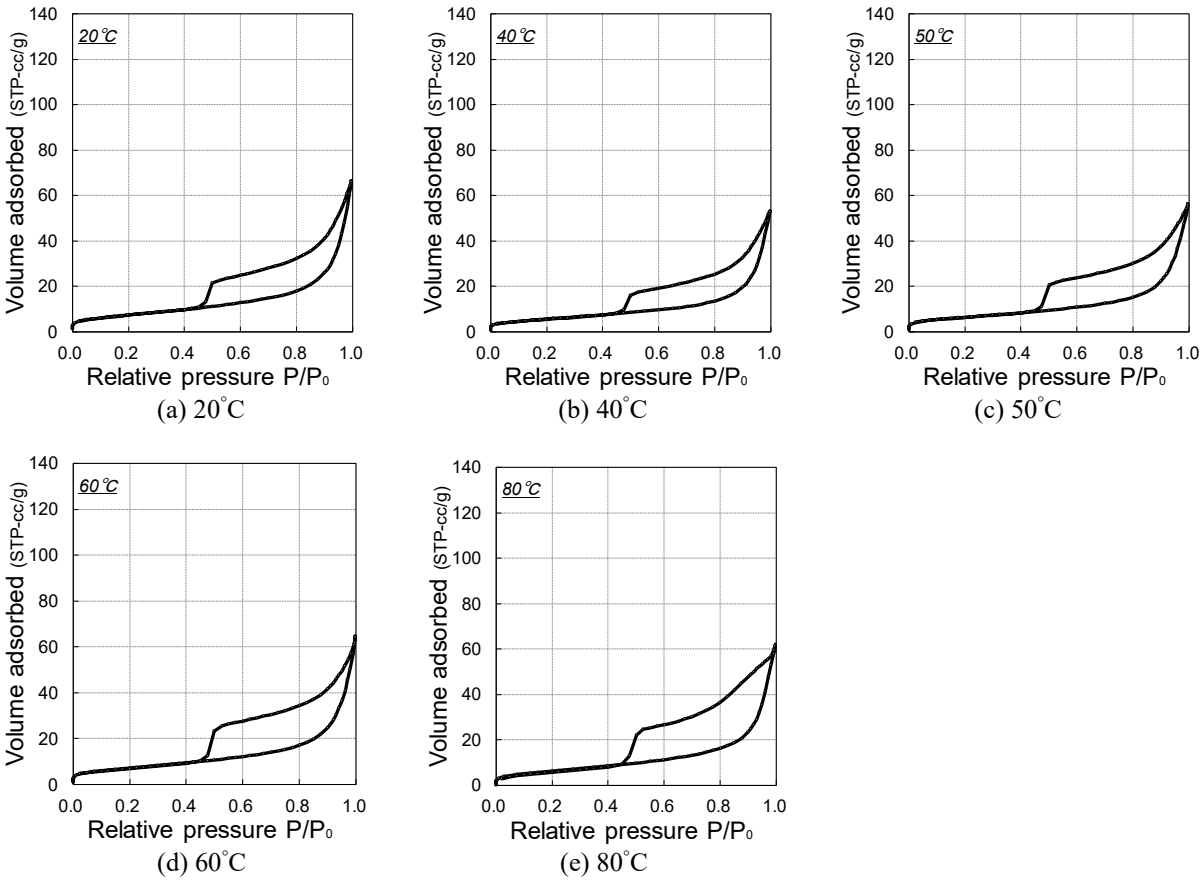

Figure 2. N_2 gas adsorption isotherms of LF30 specimens exposed to various temperature conditions.

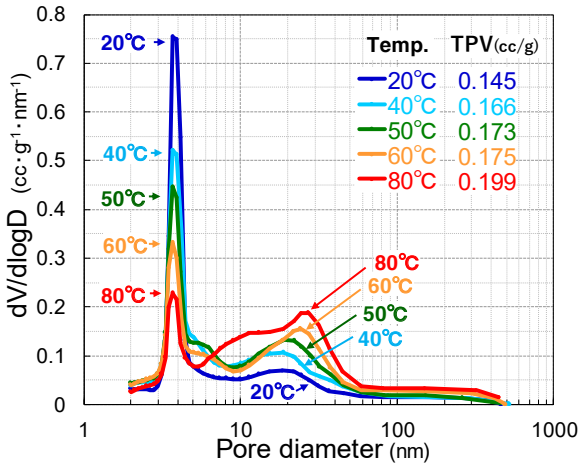
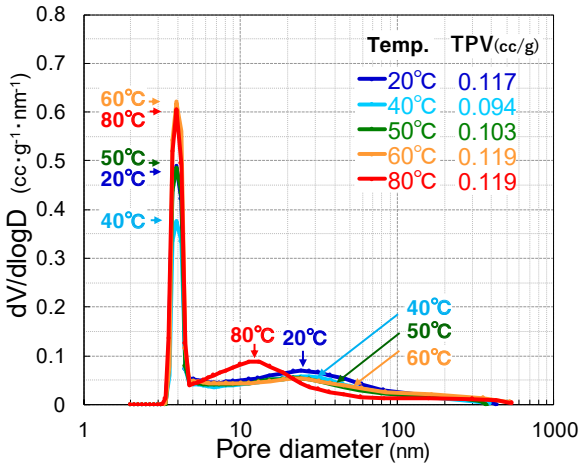


(a) OPC

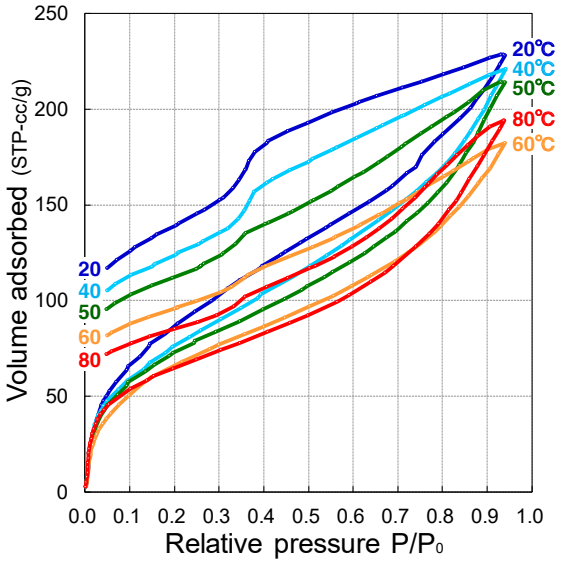


(b) LF30

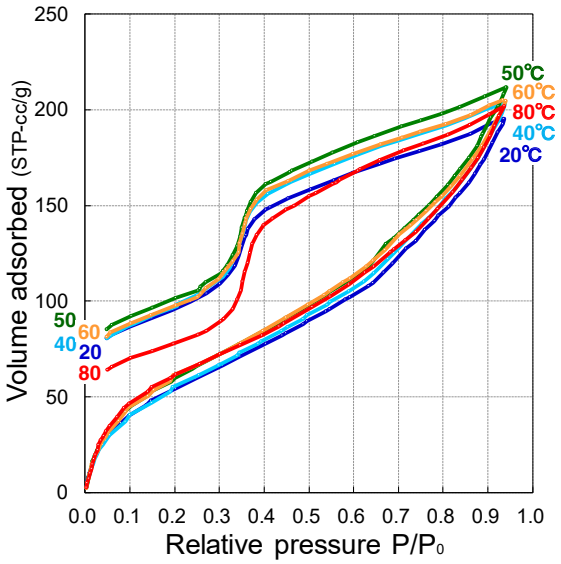
Figure 3. Pore size distributions calculated from N_2 gas desorption isotherms.

3.1.2. Water vapor adsorption isotherms

Adsorption isotherms of water vapor in Figure 4 show a similar trend with those of the N_2 gas. In the case of OPC, volume of drastic desorption shown at P/P_0 = approximately 0.35 is found to be smaller at the higher temperature, which can be due to the cavitation of water (Maruyama, *et al.*, 2018). The difference in the isotherms of LF30 is found to be smaller than those of OPC. This trend is similar to that of the N_2 gas adsorption isotherms. The adsorption volume remained uniform at $P/P_0 = 0.05$ in the desorption branch of OPC is decreased with higher temperature level. This result indicates that the water retention capacity of the OPC specimens can be degraded by high temperature. By contrast, in the case of LF30, this trend is not clear except at 80°C.



(a) OPC



(b) LF30

Figure 4. Water vapor adsorption isotherms of specimens exposed to various temperature conditions.

3.1.3. Specific surface area

BET surface areas of N_2 and H_2O for all specimens can be compared in Figure 5. Water molecules smaller than N_2 molecules can access narrower pores than the accessible size (approximately 0.45 nm diameter calculated from the cross-section area of N_2 molecule). Therefore, from Figure 5, BET surface areas of H_2O for any specimens is larger than that of N_2. The decrease in the BET areas of N_2 and H_2O for OPC when exposed to high temperature was caused by polymerization of the silicate chains in C-S-H (Gallucci, *et al.*, 2013), which was

detected by the NMR measurement. In contrast, in the case of LF30, there were no significant changes in the BET surface areas. However, as with OPC, the NMR detected the polymerization of C-A-S-H under higer temperature.

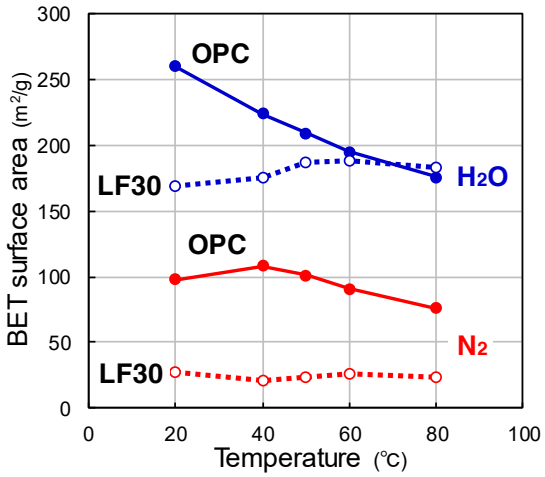


Figure 5. BET surface areas obtained from N_2 gas and water vapor adsorption isotherms.

3.2 Chloride Ionic Diffusivity

The effective diffusion coefficient of Cl^- ions, D_{cl} in the specimens are shown in Figure 6. The results revealed that D_{cl} of LF30 is nearly four orders of magnitude lower than that of OPC, when exposed to temperatures below 50°C. On the other hand, the influence of temperature varied with the specimen; higher the temperature, larger the D_{cl} of OPC. On the other hand, D_{cl} of LF30 slightly increased at 60°C and significantly at 80°C. This increase of does not agree with the trend of change in pore structure shown in subsection 3.1. Hence, a clear understanding about the mechanism of this phenomenon is needed. It is recognized that the incorporation of aluminum in fly ash modifies the structure of C-S-H (C-A-S-H) and also the surface charge (L'Hopital, *et al.*, 2015). Moreover, the surface charge and ionic composition in pore solution have a strong influence on the ionic diffusion through hardened cement, especially when the microstructure is very dense (Yang, *et al.*, 2019). Furthermore, the decomosition of AFt and AFm phases and its influence on the ionic compositon in pore solution and ionic diffusivity should be discussed for this mix proportion and materials.

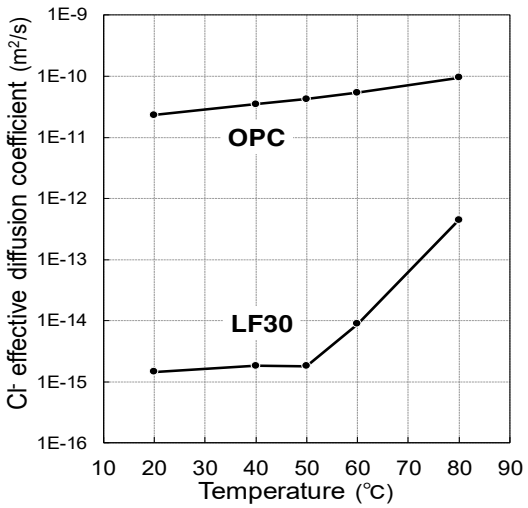

Figure 6. Effective diffusion coefficients of Cl^- ions.

4 Conclusions

- In the case of OPC, the pore size distribution determined from N_2 gas desorption isotherms using the BJH method shows obvious temperature-dependent coarsening of the microstructure of hardened cement. In the case of LF30, temperature had a negligible influence on the microstructure, except at 80°C.
- BET surface area of OPC calculated from N_2 gas and water vapor adsorption isotherms decreased with temperature. In contrast, the BET surface area of LF30 had low sensitivity to temperature.
- The Cl^- ionic diffusion coefficient of OPC increased with temperature. The coefficient of LF30 is nearly four orders of magnitude lower than that of OPC below 50°C. However, the value slightly increased at 60°C and significantly at 80°C.

Abstract. *The durability of Portland-limestone cement with high limestone content was monitored at conditions promoting thaumasite formation. Pore structure and deterioration characteristics were assessed with X-ray micro-computed tomography and correlated with material's strength. Changes in crystalline and amorphous phases of the cement paste were investigated with X-ray powder diffraction and solid state nuclear magnetic resonance spectroscopy. Rapid deterioration was observed, evolving as a front causing concentric crack patterns followed by detachment of the part of specimen in contact with the corrosive solution. This ultimately led to loss of structural integrity after 4 months of exposure. During sulfate attack, thaumasite, ettringite and gypsum formed at the expense of portlandite, calcite and monocarboaluminate hydrate. Furthermore, polymerization of silicate chains in C-S-H and deterioration of C-S-H also occurred.*

Keywords: *Limestone Cement, Thaumasite Sulfate Attack, Microstructure, Solid State NMR Spectroscopy, X-Ray Micro-Computed Tomography.*

1 Introduction

Portland-limestone cements (EN 197-1:2011), developed as alternative to ordinary Portland cement, are characterized by competitive properties and lower environmental impact (Tsivilis *et al.*, 2000; Worrell *et al.*, 2013). These features are in line with the global trend towards the reduction of CO_2 emissions and energy needs of the cement production process, and with the rationalization of raw materials usage as well. However, the high limestone content increases the risk for a specific type of sulfate attack, occurring at low temperature and excess humidity. Under such conditions, sulfate and carbonate ions react with calcium silicate hydrates (C─S─H), leading to the formation of thaumasite ($CaSiO_3 \cdot CaCO_3 \cdot CaSO_4 \cdot 15H_2O$) and, subsequently, to the deterioration of the hardened material (Irassar, 2009).

Long-term mechanical performance of limestone cement concrete exposed to conditions promoting this type of chemical attack is, thus, a crucial issue in real structures. A model able to predict the mechanical properties of cementitious materials in sulfate-bearing environments would allow for optimizing concrete composition both in terms of durability and environmental impact. Aiming at the development of a predictive mathematical model, this study is focused on obtaining necessary data concerning the microstructure and strength of the material.

Insights into the pore structure of Portland-limestone cement paste specimens were obtained with X-ray micro-computed tomography (XmCT), following an approach similar to previous studies (Yang *et al.*, 2018; Ma *et al.*, 2018). Paste compressive strength was correlated with the

damage observed in the specimens. Changes in phase composition were monitored with X-ray powder diffraction (XRPD) with the Rietveld method and solid state nuclear magnetic resonance spectroscopy (ssNMR); the usage of these techniques allowed for assessing both crystalline and amorphous fraction of the hardened cement paste (Álvarez-Pinazo *et al.*, 2012; Richardson *et al.*, 2010).

2 Experimental

2.1 Materials

Portland-limestone cement paste was produced (water-to-cement ratio of 0.45) employing a commercial CEM II/B-LL cement (Cement Hranice, a.s.), and casted in the form of cylinders (d=20 mm; h=50 mm). The paste remained in the molds for 24h. After demolding, the specimens were water-cured for 27 days, and then exposed to magnesium sulfate solution (S) of 20 g/L SO_4^{2-} content until loss of structural integrity, and in water (W) as reference, both at 5 °C.

2.2 Tests

Tests were performed after initial curing (at 28 days) and then regularly on specimens stored in magnesium sulfate solution and water.

Cylinders were scanned with the custom developed patented Twinned Orthogonal Adjustable Tomograph (TORATOM), made up of two imaging axes, each bearing an X-ray tube and a detector, with a shared rotational stage. In this study, the configuration involved a reflection-type cone-beam XWT-240-SE tube (X-ray WorX, Germany) (190 kV and 132 μA; power output of 25.1 W at the target), and a Dexela 1512 NDT detector (Perkin Elmer, USA) (active area of 1944 × 1536 pixels; 74.8 μm pixel size). Scans were performed on one specimen for each exposure environment and storage period. Aiming at sufficient magnification for providing pixel size between 12 and 17 μm, the source-to-sample distance and sample-to-detector distance were properly adjusted. A total number of 3200 projections were collected for each tomographic scan, which were flat-field corrected. VG Studio Max software was employed to obtain 3D models, using filtered back projection algorithm. Visualization of the data acquired was accomplished with ImageJ software. Quantitative image analysis of the cement matrix was carried out on volumes of interest, cut from the original volume and excluding large defects (pores, cracks), using Pore3D software which allowed for deriving porosity, specific surface area of pores (S_v), and integral of mean curvature of pores (M_v).

Compressive strength tests were performed on five specimens for each exposure environment and storage period. The results are the average values from five measurements.

Fractions from cylinders stored in water, and material obtained from the deteriorated surface of the specimens exposed to magnesium sulfate solution, were powdered (particle size below 63 μm) and employed for XRPD and ssNMR spectroscopy measurements. One specimen stored in water and eight specimens stored in sulfate solution, were used for each storage period.

XRPD data were collected with a Bruker D8 Advance diffractometer [CuKα radiation (λ = 1.5418 Å)] in the angular range 5–80° 2θ, at 40 kV and 40 mA. Rietveld refinements of the XRPD patterns were performed with the TOPAS 4.2 software (Bruker AXS), allowing for quantitative phase analysis (QPA). The internal standard method was applied for determining

the amorphous fraction.

One-pulse ^{29}Si MAS NMR spectra were collected at 25 °C with a Bruker Avance-Neo 500 spectrometer (magnetic field of 11.75 T), using a 4-mm CP/MAS probe at the Larmor frequency of 99.4 MHz. Samples were loaded into a zirconium oxide rotor (4 mm in diameter) spinning at 12.5 kHz. As external reference, 4,4-dimethyl-4-silapentane-1-sulfonic acid (DSS) (0.0 ppm) was used. 10000 scans were recorded during each measurement with 4.0 μs pulse length, and 20 s relaxation delay. Components of ^{29}Si MAS NMR spectra were deconvoluted with PeakFit 4.12 software (Systat Software).

3 Results and Discussion

Sulfate attack resulted in rapid disintegration of the specimens; structural integrity was lost already after 3.5─4 months, not allowing for performing further compressive strength tests. XRPD and ssNMR measurements on samples obtained from the deteriorated part of the specimens continued up to 5 months.

In Figure 1, cross sectional XmCT slices of specimens exposed for 3 (left) and 4 (right) months to magnesium sulfate solution, are illustrated. The deterioration proceeded through the formation of concentric cracks, as indicated by the white arrows, resulting in expansion of the specimen and, eventually, detachment of the damaged part. As the process evolved, concentric cracks formed closer to the center of the cylinder, pointing to a layer-type deterioration.

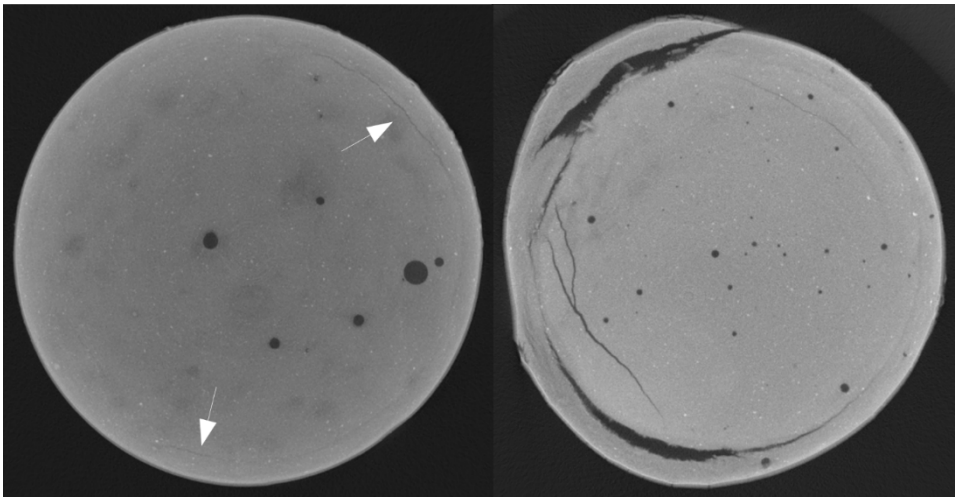

Figure 1. Cross sectional XmCT images of specimens exposed to magnesium sulfate solution for 3 months (left) and 4 months (right); white arrows indicate cracks formed due to sulfate attack.

Quantitative image analysis of the reconstructed volumes allowed for obtaining detailed information about the microstructure of the specimens. The values determined for porosity, S_v and M_v are summarized in Table 1. They indicate that the microstructure of the sound part of specimens exposed to S solution resembles to that of the specimens stored in W, supporting the assumption that sulfate attack proceeded as a deterioration front moving from the surface to the center of the specimen. Although attention was paid for excluding large defects during analysis, slightly higher average values were calculated for the specimens stored in S solution. Considering that entrapped air should be on average the same in all samples, random

irregularities in the matrix of the deteriorated specimens were most likely included in the reconstructed volumes processed, affecting the results.

Table 1. Numerical results derived from quantitative analysis of XmCT images relative to the sound part of the specimens (S_v: specific surface area of pores; M_v: integral of mean curvative of pores).

	Specimens exposed to W			Specimens exposed to S		
Exposure period (months)	Porosity (%)	S_v (mm^{-1})	M_v (mm^{-2})	Porosity (%)	S_v (mm^{-1})	M_v (mm^{-2})
REF	0.26	0.34	36.28	—	—	—
1	0.34	0.85	529.71	0.78	1.50	215.11
2	0.39	0.86	536.45	0.70	1.48	457.38
3	0.65	0.95	66.25	0.64	2.82	606.24
4	1.02	1.55	193.24	0.49	1.20	214.76
Average	0.53	0.91	272.39	0.65	1.75	373.37

In Figure 2, the compressive strength of the specimens exposed to sulfate solution relative to that measured for the specimens stored in water, is presented. Although the damage is not extensive at 3 months (Figure 1), the specimens had lost already 55% of their strength by this time, pointing to a rapid decline of compressive strength due to deterioration.

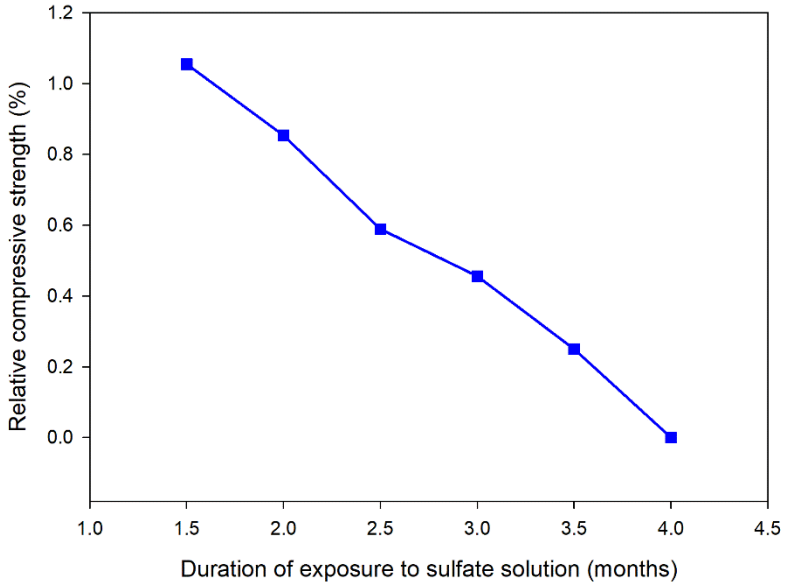

Figure 2. Relative compressive strength of specimens exposed to sulfate solution and water.

QPA results are summarized in Table 2. Decreasing amounts of belite were detected in the specimens stored in water, contrary to the other clinker phases which are absent already at 3 months. Large quantities of portlandite and traces of hydrogarnet were detected in these specimens. Gypsum was consumed towards ettringite formation. Reduction in calcite content and formation of carboaluminate hydrates indicated the participation of calcite in the hydration process of cement. During sulfate attack, ettringite content increased, whilst gypsum and thaumasite formed. The formation of these minerals is directly linked to the consumption of

portlandite and carboaluminates, and to the decrease in calcite content. Sulfate attack led to significant reduction of the amorphous fraction, pointing to severe degradation of calcium silicate hydrate phase, which is the main amorphous component of the hardened cement paste. The presence of brucite was inherited from the magnesium content of the corrosive solution.

Table 2. Quantitative phase analysis (wt.%) of the cement used, of the samples obtained from specimens exposed to W, and from the deterioated part of spesimens exposed to S.

Phase	Cement	Exposure period to W (months)			Exposure period to S (months)

One-pulse ^{29}Si MAS NMR spectra are illustrated in Figure 3.

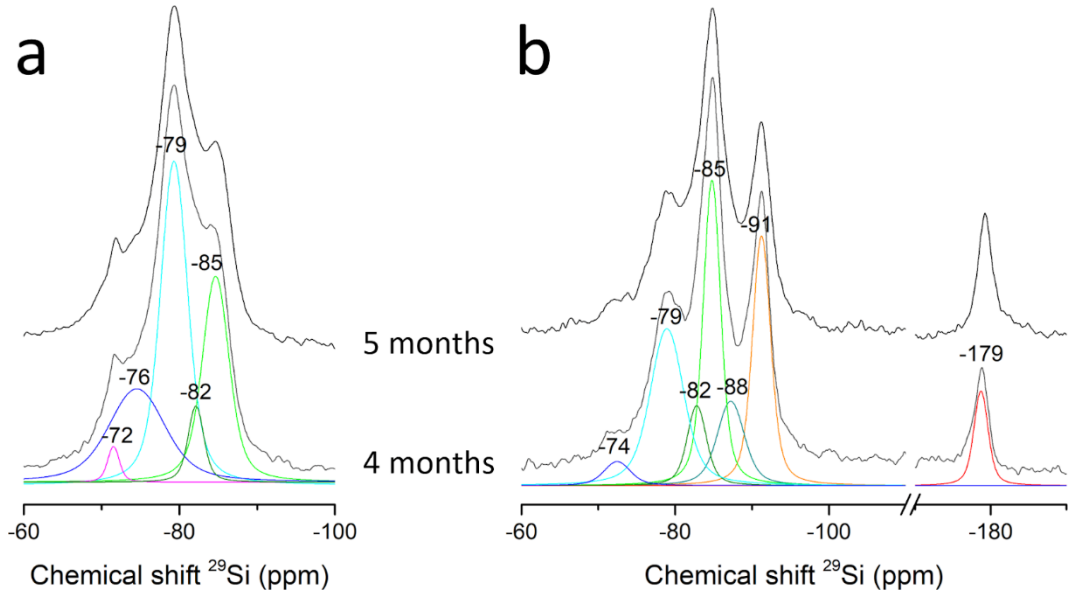

Figure 3. ^{29}Si MAS NMR spectra collected at 4 and 5 months for specimens stored in water (a) and for samples obtained from the deteriorated surface of specimens exposed to magnesium sulfate solution (b). Black curves: experimental spectra; Colored curves: deconvoluted spectra.

Five components were detected in the water-cured specimens with isotropic chemical shifts at around ─85 ppm, ─82 ppm, ─79 ppm, ─76 ppm and ─72 ppm. The first three values correspond to Q^2, Q^2(1Al) and Q^1 species, respectively, which are characteristic for the C─S─H phase (Walkley and Provis, 2019; Richardson *et al.*, 1993; Kunther *et al.*, 2015). The quite broad component at ─76 ppm is in close proximity to the isotropic chemical shift values assigned to anhydrated alite grains (Rawal *et al.*, 2010), indicating an amorphous environment which is related to hydrated clinker grains. The isotropic chemical shift at ─72 ppm is characteristic of unreacted belite (Andersen *et al.*, 2003), in agreement with XRPD results.

Q^2, Q^2(1Al) and Q^1 species were also identified in the samples obtained from the deteriorated surface of specimens exposed to S solution. Another component at around ─88 ppm, attributed to bridging SiO_4 tetrahedra in C─S─H connected to each other through hydrogen bonding (Q^2_u species) (L' Hôpital *et al.*, 2015), was identified in these samples. In addition, two more components were detected; one at ─179 ppm assigned to SiO_6 group, which is characteristic of the thaumasite structure (Grimmer *et al.*, 1986), and another at ─91 ppm which is attributed to Q^3(1Al) species in cross-linked aluminosilicate chains (Richardson *et al.*, 2010). The presence of both components points to deterioration of C─S─H phase during sulfate attack. The broad shape of the component at around ─73 ppm, most likely, corresponds to partially hydrated clinker phases, since there is no indication of anhydrated grains in the XRPD patterns. Quantitative results derived from the deconvolution of spectra are reported in Table 3.

Table 3. Intergrated area (%) derived from component deconvolution of ^{29}Si MAS NMR spectra.

		Exposure period to W		Exposure period to S	
Isotropic chemical shift (ppm)	Component	4 months	5 months	4 months	5 months
─179	SiO_6	─	─	6.6	10.0
─91	Q^3(1Al)	─	─	21.8	19.2
─88	Q^2_u	─	─	10.9	12.9
─85	Q^2	26.1	25.2	25.5	23.4
─82	Q^2(1Al)	5.7	5.1	7.4	7.9
─79	Q^1	41.4	39.4	24.9	22.8
─76	Q^1	24.9	28.6	─	─
─74	Q^1	─	─	3.0	3.7
─72	Q^0 (belite)	2.0	1.7	─	─

Minor differences were observed between samples obtained from specimens exposed for 4 and 5 months to the same environment. The main observation, regarding the water-cured specimens, is the increase of the component at ─76 ppm and the decrease of the one at ─72, indicating the ongoing hydration of clinker. In samples obtained from deteriorated specimens, the increase in the content of SiO_6 component with time is related to the increase of thaumasite content, as confirmed by XRPD (Table 2). Comparison of the sulfate-affected specimens with those stored in water reveals that, besides thaumasite formation, sulfate attack led to consumption of Q^0 phases and polymerization of silicate chains (formation Q^2, Q^2_u and Q^3(1Al) species at the expense of Q^1).

4 Conclusions

- The aggressive chemical environment employed in the study produced intense deterioration of the limestone cement paste specimens, which resulted in the rapid decline of compressive strength.
- Deterioration proceeded as a front that initiated through the formation of concentric crack patterns, followed by detachment of the sulfate-affected external part from the sound core.
- Thaumasite, ettringite and gypsum formed during sulfate attack at the expense of portlandite, calcite, monocarboaluminate hydrate and C─S─H; gypsum was the most abundant deterioration product, whose quantity increased with time.
- Sulfate attack promoted polymerization of silicate chains in C─S─H (increase of Q^2 and increase of Q^1 species), and extensive deterioration of C─S─H phase as indicated from the presence of Q^3(1Al) component.
- The collected quantitative data will be employed in the development of a micromechanical model for predicting mechanical properties of cementitious materials exposed to thaumasite sulfate attack.

Acknowledgements

The study was performed within the project "Experimental quantification and modelling of deterioration in Portland-limestone cement pastes affected by thaumasite sulfate attack" (grant number 18-26056Y), supported by the Czech Science Foundation (GAČR). CIISB research infrastructure project LM2015043 funded by Ministry of Education, Youth and Sports of the Czech Republic is gratefully acknowledged for the financial support of the measurements at the CF Josef Dadok National NMR Centre.

Abstract. *Self-Compacting Concrete (SCC) is an effective, reliable and safer technology to cast-in-place concrete structures. However, the large amount of paste required to achieve its high flowability may increase drying shrinkage at early age, due to the undesirable effects of curing conditions, producing micro-cracking and damaging concrete members. When this happens, an evaluation of the hardened SCC is necessary and Non-destructive testing techniques (NDT) can be suitable. Among NDT, Ultrasonic pulses (US) have showed to be very useful due to its portability, easiness of application and sensitivity to changes in material microstructure, porosity and presence of defects. In order to evaluate the applicability of ultrasonic (US) waves to better understand the relations among composition, microstructure, properties, curing conditions and micro-cracking, an experimental program using transmission P- and S- waves was carried out on SCC with limestone filler (LF), microsilica (MS) and nanosilica (NS), set and hardened under different curing conditions: 10, 20 and 30 °C and 40 and 80 % relative humidity. Free shrinkage and double displacement restrained slabs were tested and cracking potential due to Early Age Shrinkage was assessed. Ultrasonic transmission time and wave amplitude of the raw US signal were measured and Ultrasonic pulse velocity (UPV) and attenuation coefficient were calculated. In addition, some physical and mechanical properties of cracked and un-cracked samples were measured. The aim of this study was to compare US parameters to hardened properties of cracked and un-cracked SCC. Correlations for SCC micro-cracking based on US parameters were identified, demonstrating the potential of using transmission US P- and S- waves as an evaluation technique for micro-damaged SCC.*

Keywords: *Ultrasonic, P and S Waves, Micro-Cracking, SCC, Hardened Properties.*

1 Introduction

Self-Compacting Concrete (SCC) is designed to improve cast-in-place structures by increasing paste phase and enhancing fresh rheology. However, larger paste volume makes SCC more sensitive to curing conditions, increasing early age (EA) drying shrinkage and micro-cracking potential (Puentes *et al.*, 2014). SCC usually incorporates supplementary cementitious materials (SCM) in its composition. The type and amount of SCM used has been identified to also affect cracking potential damage jointly with curing conditions on SCC with limestone filler, microsilica and nanosilica (Barluenga *et al.*, 2018). When EA cracking occurs, an evaluation of the hardened properties of SCC is necessary. Among the Non-destructive testing techniques (NDT) available, radar, electrical resistivity, capacitance measurements and ultrasound have been described to be suitable for estimating material properties (Garnier *et al.*, 2013). Ultrasonic

pulses (US) is often preferred due to its portability, easiness of application and sensitivity to changes in material microstructure, porosity and defect detection (Selleck *et al.*, 1998; Aggelis, 2013; Barluenga *et al.*, 2015; Palomar *et al.*, 2017). US parameters such as ultrasonic transmission times and wave amplitude of the raw US signal propagated through the material can be used to evaluate the relations among composition, microstructure, properties, curing conditions and micro-cracking (Yim *et al.*, 2012; Shiotani *et al.*, 2009). The most commonly used US wave type is compressive or P-wave, although there are transducers commercially available that combine P- and S-waves (shear pulses). Thus, the wave velocity propagation (UPV), the wave attenuation coefficient (AT) and Young modulus, Shear modulus and Poisson's coefficient ratio can be calculated (Palomar *et al.*, 2017). The combination of US parameters considering both UPV and AT can be used for concrete micro-cracking assessment (Shiotani *et al.*, 2009).

The aim of this study was to compare US parameters to hardened properties of cracked and un-cracked SCC with limestone filler (LF), microsilica (MS) and nanosilica (NS). An experimental program using transmission P- and S- waves was carried out on SCC set and hardened under different curing conditions. The applicability of ultrasonic (US) waves to better understand the relations among composition, microstructure, properties, curing conditions and micro-cracking was evaluated.

2 Experimental Program

2.1 Materials and Mixtures

SCC mixtures are summarized in Table 1. A reference SCC containing a CEM I 42.5 R cement, limestone filler; fine and coarse aggregates, water and 1% by weight of cement (bwoc) of a high range water reducing admixture (HRWRA) was designed (HCA). Afterwards, limestone filler was replaced by densified microsilica (HCAMS) and colloidal nanosilica (HCANS), 10 and 5% bwoc respectively (see Barluenga *et al.*, 2018 for further descriptions).

2.2 Experimental Methods and Preliminary Results

2.2.1 Early age cracking potential in different curing conditions

Early age (EA) cracking potential was measured using a double restrained slab test subjected to 10, 20 and 30 °C curing temperatures and 40 and 80 % relative humidity (RH) during the first 24 h. The test setup consisted of 400 x 300 x 45 mm slabs, with double displacement restricted by internal plugs attached to the mold, in order to maximize EA cracking potential (Barluenga *et al.*, 2018). The slabs were demolded at 24 h and stored in laboratory conditions until crack measurement at 7 days. The cracked area (A_c) summarized in Table 2 was calculated measuring cracks length (L) and width (W) (Puentes *et al.*, 2014). The results of the SCC mixes with filler (HCA) showed high A_c. It can also be observed that the L and W for HCA were higher, especially at 20°C and 40% RH. SCC with Microsilica (HCAMS) reduced significantly EA cracking, except for hot-dry conditions. In the case of SCC with nanosilica (HCANS) A_c was slightly lower, although the cracks were narrower than HCA and HCAMS. In general, silica based additions at hot-dry conditions showed a high EA cracking risk, whereas it was minimized

in hot-wet conditions. The increase of hydration speed and microstructure formation in hot-dry curing conditions may explain this effect on EA cracking (Barluenga *et al.*, 2018).

2.2.2 NDT assessment by ultrasonic pulse propagation

Ultrasonic pulses (US) were applied on hardened samples of cracked and un-cracked SCC samples with dimensions of 400 x 300 x 45 mm and 60 x 50 x 100 mm, respectively. P- and S-

waves 250 kHz transducers were used. The amplitude (V) in time domain (μs) of the P- and S-wave raw signal through SCC samples were obtained. P-wave (Pw) and S-wave (Sw) pulse velocity were identified using the Hilbert transform algorithm (Birgül, 2009). In addition, attenuation coefficient (AT_{250}) was calculated (Palomar *et al.*, 2017), where the higher AT_{250}, the lower the US energy absorbed by the SCC sample.

2.2.3 SCC hardened properties

Table 2 also summarizes several hardened physical and mechanical properties measured on 400 x 300 x 45 mm cracked slabs or 100 x 100 x 100 mm un-cracked samples. Air and water permeability were measured on cracked SCC slabs with a Figg's method based apparatus (Porosiscope™). The measured time for air or water to permeate through the concrete was used to estimate Air Exclusion Rating (AER) and Water Absorption Rate (WAR), respectively (Barluenga *et al.*, 2017). Open porosity accessible to water (P_O) and compressive strength (CS) were measured on cubic un-cracked samples at 28 days. HCA showed higher air permeability than SCC with silica based additions, while water permeability values were similar for all SCC compositions. Regarding curing conditions, HCA and HCANS samples showed large AER values even when cracks were not observed on the slabs. In contrast, the most damaged HCAMS slab presented the highest AER value. WAR was larger for HCA and HCAMS slabs without visible damage. SCC with nanosilica (HCANS) produced large values of WAR at cold-dry conditions despite its higher CS. Some correlations among the composition parameters, hardened properties and curing conditions have been described in a previous work (Barluenga *et al.*, 2018). Regarding SCC compositions, HCAMS reduced open porosity and HCANS increased compressive strength. In general, hot-wet curing conditions produced lower P_O, independently to the SCC composition, and increased CS on HCA samples. Cold-dry environment on HCMS and HCANS produced higher CS.

Table 3. P- and S-wave velocity and attenuation coefficient of US signal for SCC un-cracked samples.

	Pw m/s	**Sw** m/s	**AT_{250}** dB/mm
HCA	3938	2472	0.36
HCAMS	3926	2342	0.53
HCANS	3684	2201	0.52

3 Experimental Results and Discussion

3.1 Ultrasonic Characterization of Un-Cracked SCC Samples

Table 3 summarizes the experimental results of P- and S-wave propagation velocities (Pw and Sw) and attenuation coefficient (AT_{250}) of un-cracked SCC samples. Pw and AT_{250} presented lower variability related to SCC compositions. In contrast, Sw was sensitive to SCC composition: the smaller the particle size, the slower S-wave propagation velocity. Figure 1 plots the experimental results of Pw and Sw and AT_{250} of un-cracked SCC samples in different curing conditions. Pw and AT250 presented a high variability, although they showed different trends, while Sw did not depend on curing conditions.

3.2 Ultrasonic Evaluation of Cracked SCC Samples

Figure 2 and 3 plot the experimental results of Pw and Sw and AT_{250} of cracked SCC samples.

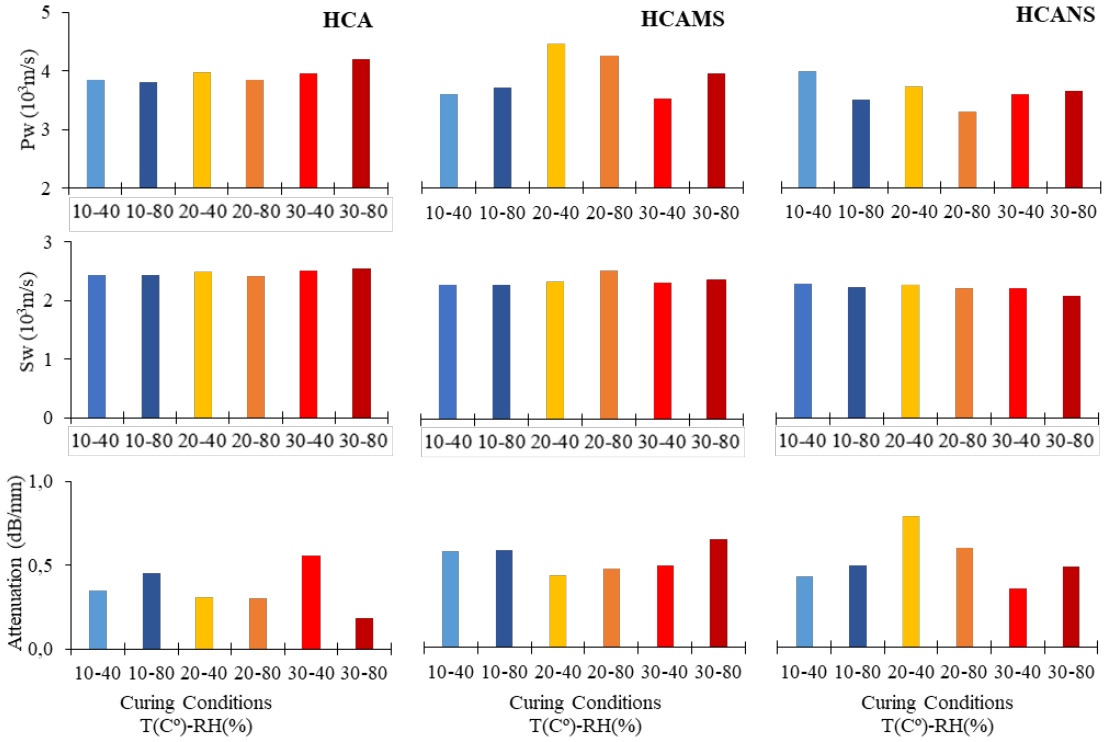

Figure 1. P- and S-wave velocity and attenuation coefficient of US signal for SCC un-cracked samples at different curing conditions.

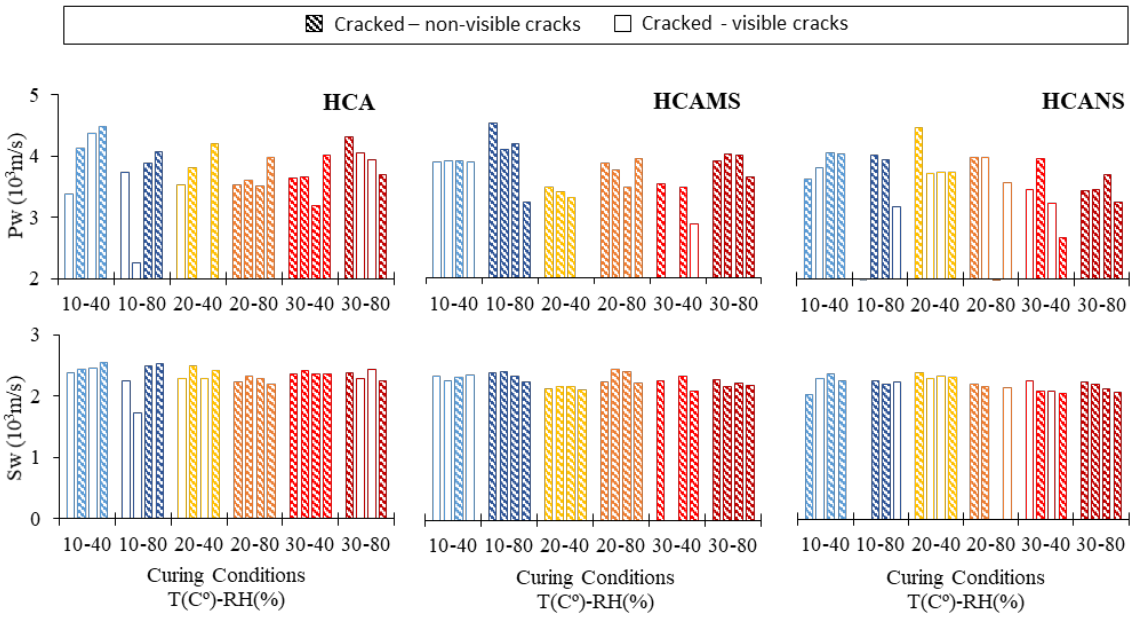

Figure 2. P- and S-wave velocity of US signal for SCC cracked samples at different curing conditions.

US propagation was measured on damaged slabs with visible (VC) and non-visible cracks (NVC). Regarding US velocities, Pw scatter was slightly higher in cracked samples than in un-cracked samples, although cracked values were lower than un-cracked. Pw on NVC was around 230 m/s faster than VC. Sw showed very low variability on cracked samples despite the effect of composition, curing conditions and NVC or VC. In addition, some damaged samples showed similar Pw and Sw values, with differences smaller than 1000 m/s. These values do not correspond to undamaged SCC and cannot be used to calculate mechanical properties of damaged slabs, as elastic modulus or Poisson Coefficient (Barluenga *et al.*, 2018).

A large dispersion of attenuation was recorded for cracked samples (Figure 3) and AT_{250} was higher for VC than NVC. The highest AT_{250} values (closely 1.00 dB/mm) corresponded to the widest cracks measured (HCA-1080 and 2040 and HCAMS-3040). Thus, cracks decreased the amplitude of the wave in damaged areas due to scattering and diffraction effects (Yim *et al.*, 2012). These results points out the sensitivity of AT_{250} to concentrated damage as visible cracks. However, some cracks produced by EA shrinkage of displacement restrained SCC members can progress from inside of the sample (Serpukhov *et al.*, 2010), producing AT_{250} values with little differences between VC and NVC areas. Accordingly, AT_{250} can detect both VC and NVC.

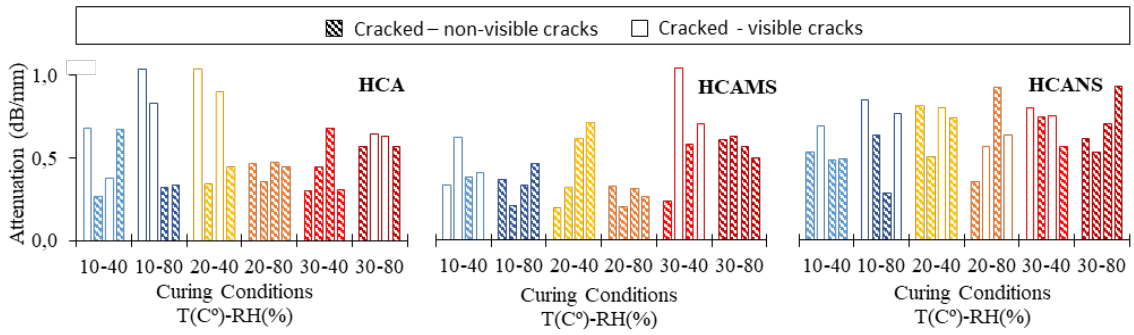

Figure 3. Attenuation coefficient of US signal for SCC cracked samples at different curing conditions.

3.3 Damage Evaluation of SCC Using NDT

An evaluation of damage and cracking potential by US analysis was carried out and is plotted in Figures 4 and 5, respectively. Regarding damage and US parameters, in general velocities of cracked samples were slower than on un-cracked samples (Selleck *et al.*, 1998), except HCA and HCAMS cured at 10º C. On the other hand, two behaviors were identified in AT_{250}: 1) HCA and HCANS; values of un-cracked samples were lower than cracked ones; 2) HCAMS AT_{250} values were higher for un-cracked than for cracked samples. These differences can be explained considering the effect of SCC composition on cracking potential. HCA and HCANS showed larger cracking potential, whereas HCAMS cracking potential was remarkably lower. There were two exceptions to this trends: HCAMS 3040 (visible damage) and HCANS-2040 (red labeled in the graph). This last case showed long and wide cracks and low AER and WAR, meaning concentrated damages that can explain its exceptionality.

As a predictive tool for EA cracking potential of SCC, cracked area (A_c) can be compared to the ratio between Pw and Sw (Pw/Sw) of un-cracked samples (Figure 5). The results showed an inverse relationship between Pw/Sw and A_c until a constant value of 1.60 or 1.80, which

depended on sample composition. A ratio of 1.80 means a Poisson's ratio (υ) around 0.28: the larger the ratio the lower the compressibility. Therefore, if the un-cracked sample reaches a certain Pw/Sw or compressibility, EA cracking potential will be minimized (HCAMS and HCANS). In the case of HCA, Pw/Sw showed littele cracking potential variability.

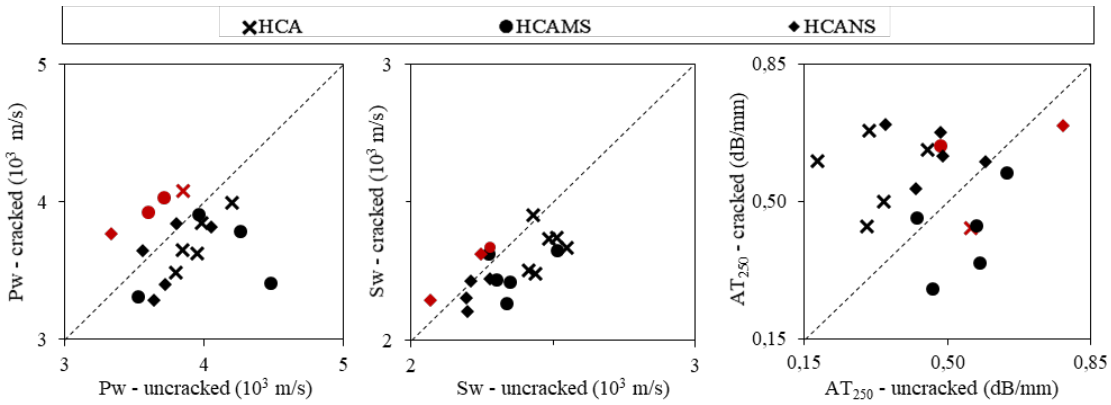

Figure 4. Ultrasonic pulse velocity and attenuation coefficient: un-cracked vs cracked values.

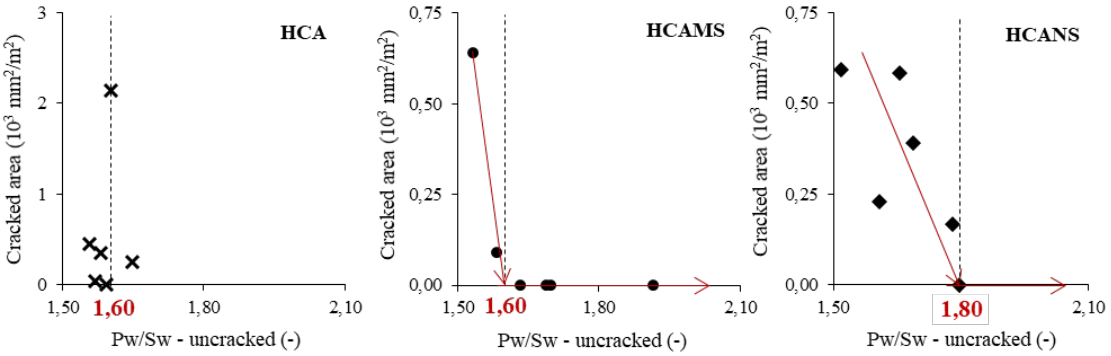

Figure 5. P- and S-wave velocity ratio (Pw/Sw) for un-cracked samples vs EA cracking parameters (A_c).

4 Conclusions

The applicability of ultrasonic (US) waves to better understand the relations among composition, microstructure, properties, curing conditions and early age cracking potential of SCC with limestone filler (LF), microsilica (MS) and nanosilica (NS) was assessed. The influence of composition, curing conditions and micro-damage on US parameters (P- and S-wave velocities and signal attenuation) were analyzed. The main conclusions were:

- Changes in SCC compositions and curing conditions modified early age (EA) cracking potential and hardened properties.
- SCC compositions and curing conditions had a significant effect on US velocity propagation and attenuation coefficient in un-cracked and cracked samples, although the effect on US parameters it is not linear.
- US parameters were identified as key parameters to assess the micro-damage or the EA cracking potential of SCC.
- US velocities of un-cracked samples were higher than those of cracked samples. The

attenuation coefficient of un-cracked SCC was lower than the damaged samples, either when the cracks were externally visible and when they were internal and non-visible.
- EA cracking potential was estimated for samples set and hardened under same curing conditions, using P- and S-wave velocity ratio (Pw/Sw) of un-cracked samples.

On Bio-Deterioration of Solar Reflective Materials: An Innovative Experimental Procedure to Accelerate the Ageing Process of Surfaces

Giulia Santunione[1], Chiara Ferrari[1], Alberto Muscio[1] and Elisabetta Sgarbi[2]

[1] Department of Engineering "Enzo Ferrari", University of Modena and Reggio Emilia, Italy, giulia.santunione@unimore.it

[2] Department of Life Science, University of Modena and Reggio Emilia, Italy, elisabetta.sgarbi@unimore.it

Abstract. *Solar reflective materials are one of the most efficient solution to the urban heat island effect, according to which temperatures, in urban areas are significantly higher than those in the surrounding rural areas. Solar reflective materials (SRM) are characterized by the ability to reflect solar radiation in the whole wavelength spectrum remaining cooler under the sun. The importance of radiative properties focused the attention more on SRM subjected to aging processes instead of the new products. According to this, several standards are, nowadays, available to investigate natural (ASTM G7, ANSI CRRC/S100) and accelerated (ASTM D7897) aging. Unfortunately, these standards do not take into account the presence and the growth of microorganisms such as algae and cyanobacteria, which can be responsible not only for the decrease of radiative properties against time, but also for the decay of physical and chemical properties of SRM themselves. This study outlines an experimental procedure to accelerate natural bio-deterioration of building materials through a laboratory test. Two types of SRM have been involved, studying their thermal properties before and after the bio-deterioration accelerated treatment. The methodology involves the use of a Temporary Immersion System (TIS bioreactor), which is based on the temporized soaking of materials samples with a liquid growth medium inoculated by selected species of algae or cyanobacteria. The system promotes a homogeneous contact between the materials surfaces and these microorganisms blowing sterilized air into the medium inside the bioreactor chamber. Within three weeks into TIS bioreactor, materials samples have shown large areas of biofilm deposition on themselves. The experimental procedure, hence, confirms the capability of the system to optimize environment conditions where the growth of microorganism and their interactions with materials results accelerated. Very high attention is given to the aim to make the procedure repeatable. For this proposal, all the variable factors are minimized, maintaining constant the environmental condition and working on sterility in order to do not contaminate or alter the growth inside the bioreactor.*

1 Introduction

Building materials are affected by several aesthetical and functional issues due to ageing processes which can be related to physical, chemical or biological factors (Sleiman *et al*. 2014). Among these factors, the biological growth represents a phenomenon in addition to physical and chemical problems due to weathering and soiling, which accelerates the fouling process of outdoor materials (Ferrari *et al*. 2015). The biofilm changes the aesthetical appearance of materials and can even compromise the durability of structures by corrosion and biodeterioration induced by the microorganisms (Maury-Ramirez *et al*., 2013).

Several studies on natural conditions suggests that bio colonization is primarily related to the physical characteristics of the stone surface (porosity, roughness, and permeability) and secondarily to the nature of substratum (Gaylarde *et al*., 2011). Microorganisms produce variously coloured patinas on the materials inducing aesthetical damage (Ortega-Calvo *et al.*, 1995). Biological growth also exerts a pressure inside the pores on the surface, resulting in biogeophysical deterioration, i.e. the surface detachment and superficial losses. Definitively, microorganisms play an important role in the deterioration of building materials, being responsible for aesthetic, biogeophysical and biogeochemical damage.

Considering Solar Reflective Materials (SRM), bio-deterioration process takes part to important performances losses in terms of surface thermal properties, such as solar reflectance and thermal emittance. Since studying microbial growth under natural conditions is too slow as an investigation approach to develop and to improve industrial products, several studies have been carried out on surface bio-ageing with the aim of analyse and to assess the energy impact on the buildings (Cheng *et al*., 2011; Cheng *et al*.,2012; Gaylarde and Gaylarde, 2005; Mastrapostoli *et al*., 2016). However, due to its the wide variability depending on environmental conditions and mainly by geographical position of the building, bio-deterioration is not yet being completely understood and quantify by the scientific community.

Thus, this study is aimed to study biological colonization on building materials in a repeatable and reproducible way, in order to quantify the changes on the surfaces properties due to biological growth. An innovative and laboratory protocol to accelerate biological colonization effects on building surfaces by different pioneering organisms (algae and cyanobacteria) is here presented. The goal was to provide a faster, reproducible and reliable test method to assess the long term behaviour of building surfaces relevant to, among the other, energy performance for cooling.

2 Material and Methods

A laboratory protocol to expose building material samples to biological colonization is here presented. The setup consists in a growth chamber (Figure 1), where all the environmental factors have been maintained constantly monitored and stable. The device chosen as growth chamber is a TIS (Temporary Immersion System) bioreactor (Welander *et al.*, 2014).

a.  b. 

Figure 1. (a) TIS bioreactor equipped with the samples; (b) couple of TIS bioreactors for different environmental microorganisms (*Chlorella mirabilis* and *Nostoc commune*), start time of the test (t0).

It is a sealing growth camera where the samples are placed on a tray and temporarily flooded by 500 ml of culture medium, inoculated by selected microorganisms according to 1:50 concentration rate. The submersion is induced by a pump (10 W), which inputs sterilized air inside the liquid medium in order to raise the level of that and submerge the samples on the tray. The level of the medium is subsequently lowered by stopping the air supply into the

medium and raising the air pressure inside the camera, through a second pump (5 W). These working conditions were turned on and off trough a complete automated system. A complete bio-ageing cycle lasts 3 weeks and two types of building material were involved in this preliminary work: single ply cool white membrane (WM) and asphalt shingle (AS). Two samples for each type of material were included for each bioreactor, and each bio-ageing cycle was performed in triplicate in order to get statistically significant results.

Two specie of different microorganisms were used separately to study biofilm formation on sample surfaces: the green microalga *Chlorella mirabilis* and the cyanobacteria *Nostoc commune*. They were chosen among the huge variability of environmental ubiquitous organisms (Ferrari *et al*. 2015) and different culture medium were used for each microorganism: Bold Basal Medium (BBM) (ref) was applied for *Chlorella m.* and Blue Green medium (BG-11) for *Nostoc c.* TIS bioreactors were put into the incubator (Biolog, AG-System) where the temperature and relative humidity level was stable (23°C and 50% respectively), and 14h light/10h dark periods are contemporarily alternated by a fluorescent lamp system.

Since the study is finalized to develop a repeatable and reproducible protocol for bio-ageing trial, TIS bioreactors and culture medium are therefore completely sterilized before use to minimize the variability of environmental factors and avoid contamination of the biological cultures on growth. Two different sample submersion times were investigated: 10 minutes/6 times a day every 4 hours (setup #1) and 30 minute /6 times a day every 4 hours (setup #2): each time condition has been tested three repeated times as abovementioned. The complete overview on experimental setup studied in this work are shown in Figure 2.

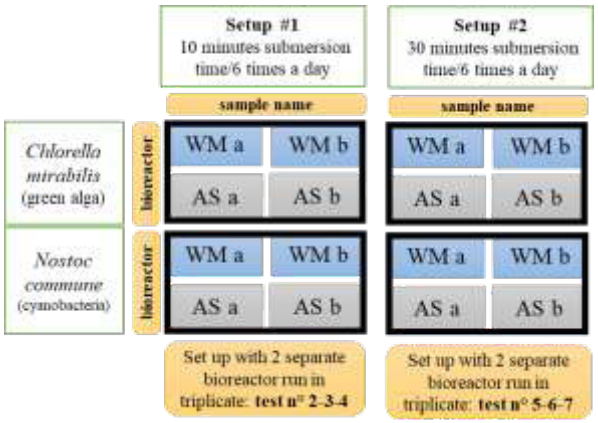

Figure 2. Bio-ageing experimental design: 2 bioreactors types were prepared for each trial; 4 samples were included into each bioreactor (double samples for each material); two setups were studied; the trials have been run in triplicate.

Such "*flood and dry*" approach tries to replicate the natural wetting and dry cycles that typically occur outdoor on the building surfaces. Reproducing a bio-deterioration phenomenon in laboratory allows to choose and set up stable environmental conditions, which are the optimum for biological growth, and to compress colonization time.

2.1 Material Characterization

Material characterization was performed on sample surface before and after the bio-ageing test through several analyses. Firstly, surface microstructure were investigated by Environmental Scanning Electron Microscope (ESEM, Quanta200) operating in low vacuum conditions; Solar Reflectance (ρ_{sol}) was analyzed by UV-Vis-Nir Spectrophotometer (Jasco V-670), according with ASTM Standard E903 (ASTM E903, 1996). To evaluate how the surface color was modified during the whole campaign L*a*b* values were calculated both on new and aged samples starting from solar reflectance values in visible region (λ range: 300-800 nm). ΔE values were calculated by means of $\Delta E = \sqrt{(L_1^* - L_2^*)^2 + (a_1^* - a_2^*)^2 + (b_1^* - b_2^*)^2}$ to quantify the difference in color between the two stages of aging. Statistical analysis by ANOVA (Past3 Software) has been run in order to evaluate the repeatability of the preliminary protocol.

3 Results and Discussion

The differences collected between setup#1 and setup #2 trials are visibly high as the example reported in Figure 3. The first set up trial, reported in triplicate, shows a weaker but more homogeneous growth on materials samples then the second set up trials, where the submersion time has been 30 minutes for 6 times a day.

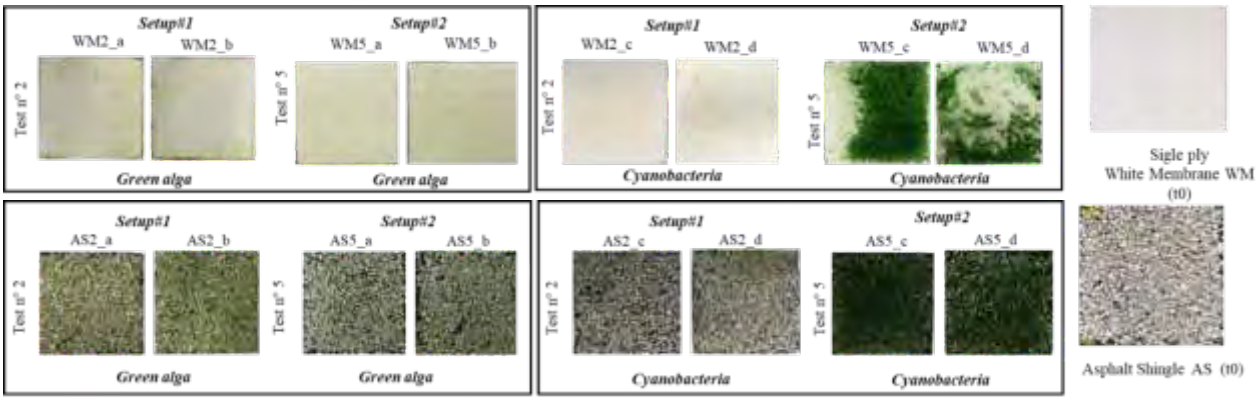

Figure 3. WM and AS aged samples are shown: *a* and *b* samples come from bioreactor run with green alga inoculum; *c* and *d* ones come from bioreactor run with cyanobacteria inoculum; the results from 1 (test n° 2 and test n° 5) of 3 repeated tests by both setups types are shown; on the right, new (t0) sample are shown.

3.1 Electron Microscopy

Micromorphology and chemical composition analysis through Electron Microscopy carried out on samples before colonization, additional analysis were performed on aged samples immediately after the end of the bio-ageing trials. This allow to check microorganisms while they were still alive. Figure 4 shows the two different colonies of organisms in separate TIS bioreactor on AS sample: green alga (*Chlorella m.*) build spherical shape colonies (Fig. 4a) and cyanobacteria (*Nostoc c.*) are set in filamentous colonies (Fig. 4b).

Roughness on AS samples is high due to the presence of grains: this create the presence of several niches on surfaces, which represents a suitable place for biological growth thanks the

longer staying of humidity. C is the most aboundant element in both AS (65.0% ± 22.7%) and WM (96.6% ± 4.4%) materials, but AS samples are richer in elemental diversity: traces of Mg, Al, Si, S, K, Ca, Ti, Fe compounds have been detected by ESEM.

a.  b. 
Figure 4. ESEM images from ESEM analysis: (a) *Chlorella m.* spherical cells colonies on AS sample; (b) *Nostoc c.* filamentous structure on AS sample. Mag. 1000X.

3.2 Solar Reflectance

Solar reflectance (ρ_{sol}) values and standard deviation calculated on average values between samples exposed to the same microorganism (*a* and *b* to *Chlorella m.* and *c* and *d* to *Nostoc c.*) have been reported in Table 1. New and aged values are shown. Results have been elaborated comparing the same material ρ_{sol} values between two different setup trials (#1 and #2) and within the same set up trial. The evaluation on sample surface colonized by two different microorganisms (green alga and cyanobacteria) have been kept separated.

Solar reflectance values got on aged surfaces through two different TIS bioreactor submersion time (setup #1 and #2) highlight significant differences on both types of material, rising the strong variability among setups. Moreover, the colonization level due to green alga (*Chlorella m.*) compared with the one due to cyanobacteria (*Nostoc c.*) are significantly distant: they have been evaluated separately.

Table 1 shows ρ_{sol} decrease considering only *a* and *b* samples, before and after bio-ageing process. Samples *a* and *b*, exposed to green alga, underline a lower ρ_{sol} decrease through setup #2 compared with setup #1. This is true for both WM and AS samples. A reverse situation was achieved on samples *c* and *d* for both material types, exposed to cyanobacteria: the ρ_{sol} decrease is higher through setup #2, where the submersion time is tripled compared with setup #1.

Statistical analysis among solar reflectance results obtained through repeated trials within the same setup type was performed. TIS bioreactor system, in particularly the case with green alga and setup#1 shows a good repeatability: the differences among ρ_{sol} on the same material type (AS or WM) from different trials are not significant (p-value >0.05). However, this not occurs on ρ_{sol} measured on aged samples *c* and *d* exposed to cyanobacteria colonization, neither for setup#1 and setup #2: in these cases, the statistical analysis highlight high significant differences among repeated trials (p-value<<0.05).

Table 1. Solar reflectance values by ASTM E903 are shown: AS and WM samples from both bioreactors with green alga (*a-b*) and cyanobacteria (*c-d*) inoculum; mean values on *a-b* and *c-d* samples are reported; $\Delta\ \rho_{sol}$ between new and aged samples are reported; SD among repeated ρ_{sol} measurements are considered.

	Sample name	ρ_{sol} (new)	Mean ρ_{sol} (aged)	$\Delta\ \rho_{sol}$	SD

set up #2	WM5_*c-d*	0.832	0.600	-0.232	0.037
	WM6_*c-d*	0.828	0.705	-0.123	0.024
	WM7_*c-d*	0.819	0.574	-0.244	0.034

Since ASTM E903 spectral chart analysis (Figure 4) underlines how the main difference occurred within the Visible range of the complete solar reflectance spectrum, as showed in Figure 5, colorimetry analysis was deemed important to better evaluate the results of bio-ageing protocol.

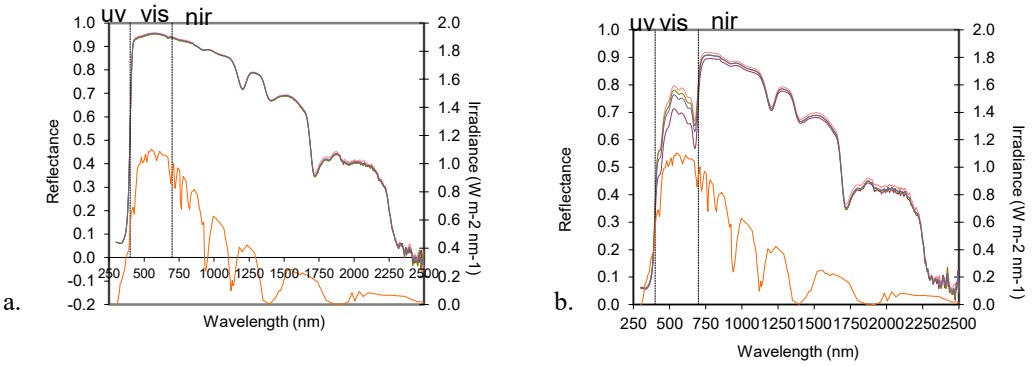

Figure 5. ASTM Solar Reflectance spectral chart on WM sample: (a) results on new sample; (b) results on bio-aged sample. 3 repeated measurements on the same sample have been performed.

3.2 Colorimetry

Figure 5 reports the colorimetric differences between new (L* values) and aged (ΔL* and ΔE) material types. Colorimetric differences have been calculated using the difference ρ_{sol} within 300-800-nm λ range (visible region). ΔL* and ΔE have been assessed comparing all the samples (*a,b,c,d*) coming from two different setup: again, the repeatability was described within the three trials with the same setup. These results confirm what noticed through solar reflectance:

while the colonization level and solar reflectance decrease showed a good repeatability within the trials of setup#1, this was not happened to setup #2, where sample submersion time was tripled compared with #1.

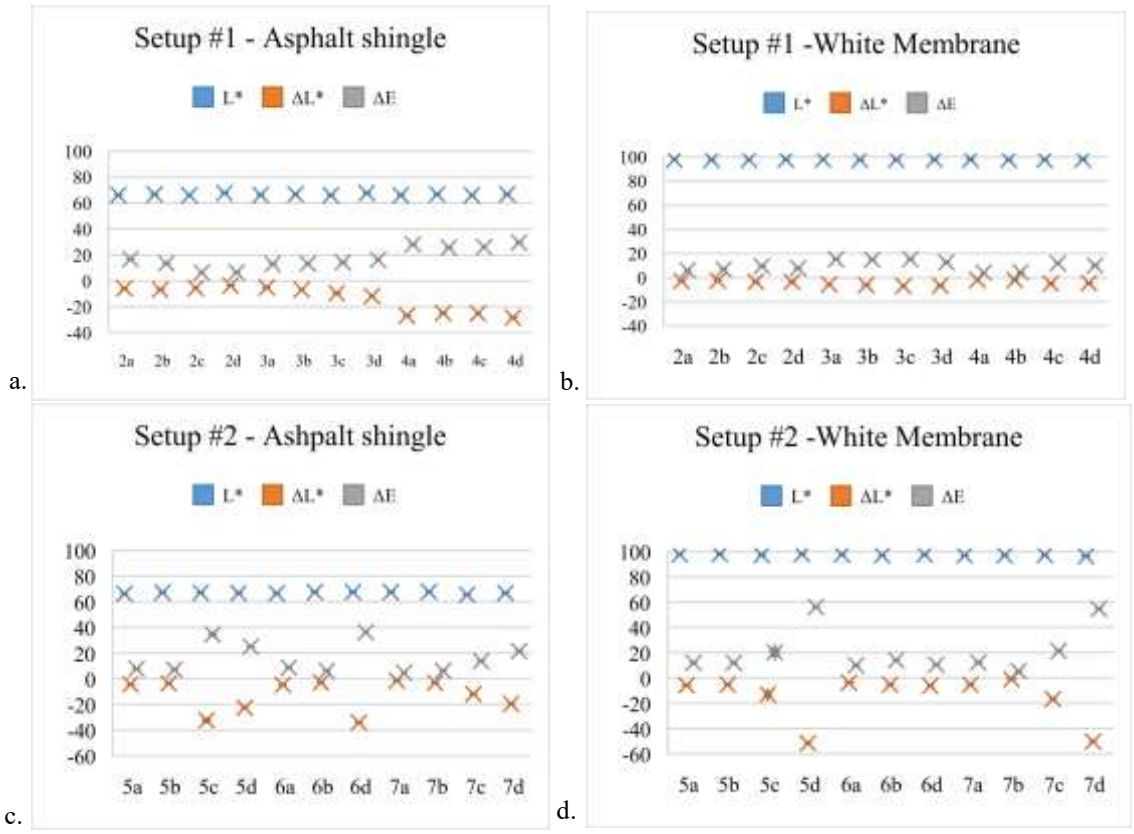

Figure 6. Colorimetry values among bio-ageing trials 2-3-4 run through setup#1 (*a, b*) and among bio-ageing trials 5-6-7 run through setup#2 (*c, d*). All sample values are shown.

Microorganisms pigments are the main responsible of aesthetical damage on surfaces and they sharply contribute to losses in solar reflectance, as observed in this study. As shown in Figure 5, ΔL* and ΔE are averagely higher on AS samples (mean ΔL* -13.4±1.3; mean ΔE 17.5±1.1) than in WM ones (mean ΔL* -4.3±0.5; mean ΔE 9.9±0.9) for setup #1. ΔL* and ΔE from setup #2 are similar to #1 for AS samples (mean ΔL* -14.4±1.5; mean ΔE 17.2±1.3), but the colorimetric distances from new and aged surfaces are deeper.

4 Conclusions

This work provides a preliminary laboratory bio-ageing protocol suitable to study the bio-deterioration dynamics on building materials surfaces, in particular solar reflective materials. Since biological growth variability that occurs on surfaces in natural environment is really high, the bio-ageing protocol here proposed has been thought in order to keep stable and monitored all the laboratory environmental factors. Two specie of microorganisms, *Chlorella m*. and *Nostoc c*., and two different laboratory setup have been investigated (setup#1 and setup#2) in

order to study the more repeatable experimental conditions. Solar reflectance and colorimetry analysis on repeated trials shows setup#1 (where 10 minutes of sample submersion time are repeated 6 times a day every 4 hours) as the most repeatable, and specifically when run with the green alga (*Chlorella m.*). All the other experimental conditions achieved differences among the same sample type statistically significant. Even though the challenge to make repeatable something that it is not for its meaning definition, the preliminary bio-ageing setup#1 confirms the capability of the system to optimize environment conditions where the growth of microorganisms and their interactions with materials results faster, providing a way to investigate bio-deterioration processes on materials.

Abstract. *This paper is a report on the investigation results of the Former Shime Mining Office Vertical Derrick, which was built in 1943 and was 75 years old at the time of the investigation. The building suffered from serious deterioration including rebar corrosion, which led to large area of concrete spalling. In this report, aggregation data of concrete spalling has been presented along with the investigation results of cover thickness. According to the investigation results, concrete spalling occurred in places where cover thickness was less than 25 mm. And According to the aggregation data, concrete spalling flakes increased by approximately 200 pieces per year, with the average size of 10 cm in diameter. Also, a possible relation between concrete spalling and rainfall was observed during the investigation. Equations using the proportion of wet area affected by rainfall to estimate the area of spalling are proposed, although the value of empirical coefficient α needs further discussion, including collecting data from other buildings where spalling occurs.*

Keywords: *Durability, Historical Buildings, Concrete Spalling, Concrete Moisture, Rebar Corrosion.*

1 Introduction

Concrete moisture is known to be a key parameter of rebar corrosion which leads to spalling and deterioration of the concrete structure. While reports on evolution of water content in real structures are still scarce, This paper is a report on the investigation results of the Former Shime Mining Office Vertical Derrick, which was 75 years old at the time of the investigation and had suffered from severe deterioration including rebar corrosion, which led to large area of concrete spalling. In addition, a possible relation between concrete spalling and rainfall was observed.

The introduction and the photo of the Former Shime Mining Office Vertical Derrick are shown in Table 1 and Figure 1.

2 Approach

To monitor the inner relative humidity evolution where the concrete cover was thin, from June 1st to July 25th, 2018, several thermo-hygrometers were implanted inside the concrete with cover thickness of 10mm and 40 mm. Concrete spalling had been observed and calculated every 3 months since February 2011. Cover thickness was measured with an electromagnetic radar method or a scale according to the condition of the cover.

Table 1. Introduction of the Former Shime Mining Office Vertical Derrick.

Location	Shime town, Fukuoka	Structure	RC
Owner	Shime town	Completion	May, 1943
Size (m)	height	47.6	
	length	15.3	
	width	12.3	

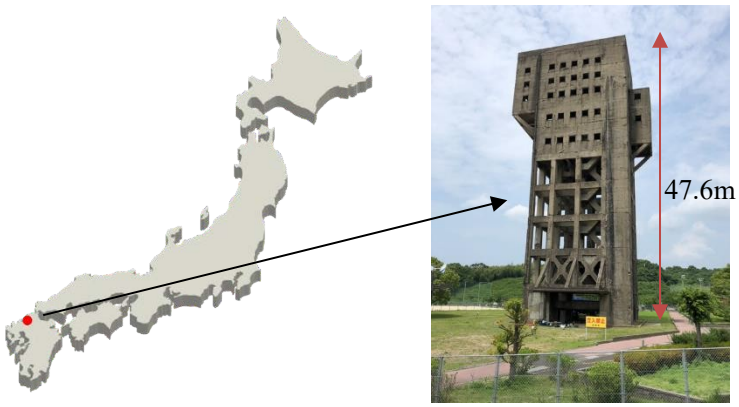

Figure 1. Photo of the Former Shime Mining Office Vertical Derrick.

3 Results

3.1 Results of Relative Humidity Monitoring

The results of relative humidity and temperature monitored during June 1st to July 25th, 2018, along with precipitation observed by Japan Meteorological Agency are shown in Figure 2. These results indicate that places with thinner cover thickness tend to be influenced by weather events such as rain.

3.2 Results of Concrete Spalling and Cover Thickness

Concrete spalling had been observed every 3 months since February 2011. The Figures used below are based on the observation record. Figure 3 shows the accumulated number of concrete flakes, which increased by the rate of approximately 200 pieces per year. However, the influence of weather events or earthquake was still unclear. Figure 5 shows the size and numbers of the flakes, which are around 5~10 cm in diameter. In addition, cover thickness

and level of rebar corrosion in relation to concrete spalling were also investigated. The subjects investigated included pillars and beams of 4 directions from 1st floor to 3rd floor. The aggregated results of cover thickness by are shown in Figure 6. According to the results, rebar exposure induced by concrete spalling occurred when cover thickness was less than 25 mm.

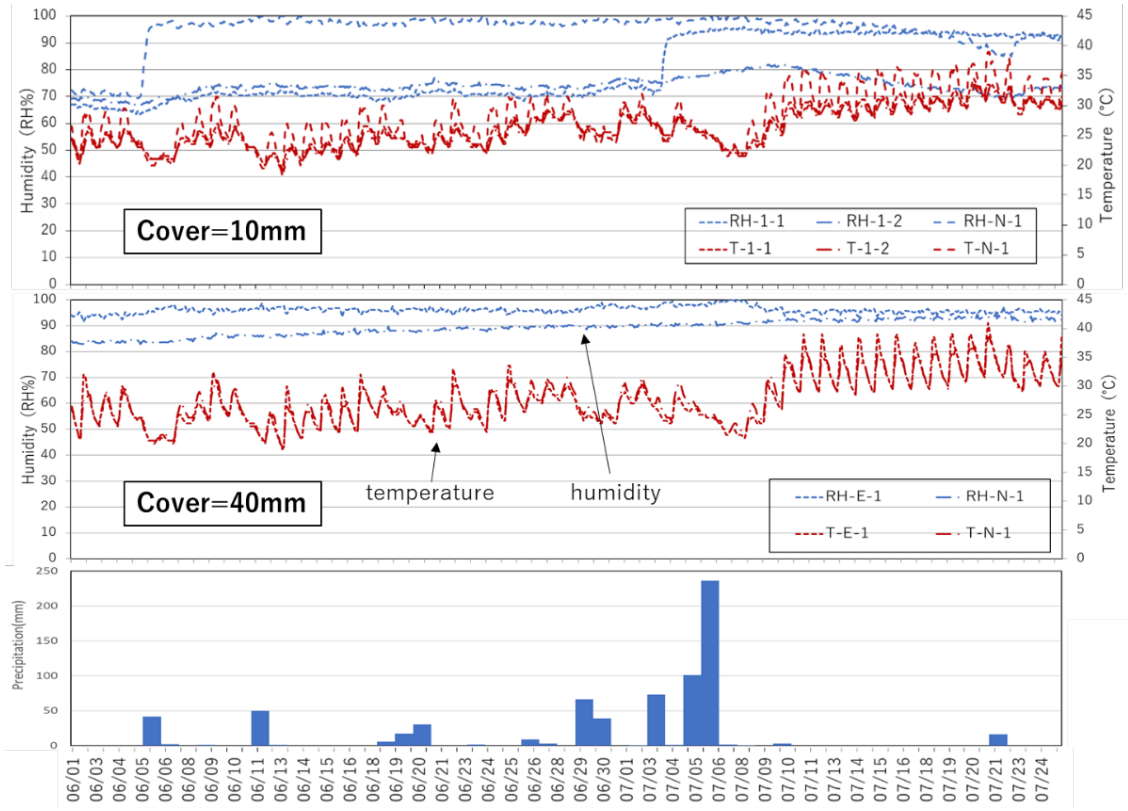

Figure 2. Evolution of Relative Humidity and Temperature (Upper: Cover=10mm, Middle: Cover=40mm) and Precipitation.

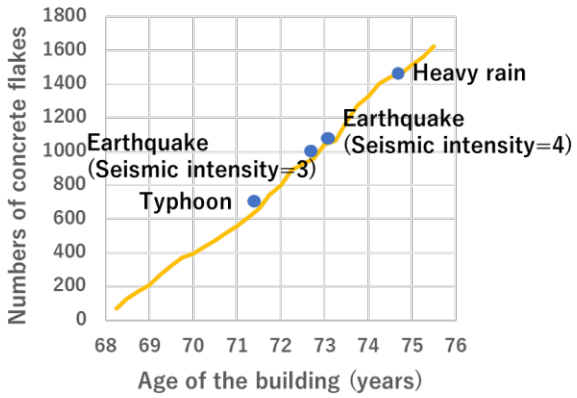

Figure 3. Accumulated number of concrete flakes.

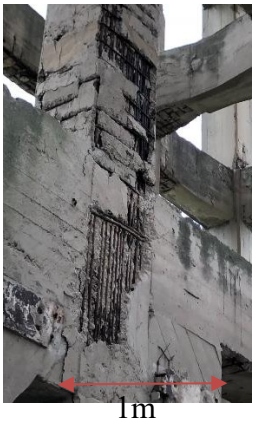

Figure 4. Rebar exposure due to spalling.

3.3 Results of Air Permeability Test and Carbonation

The results of the relation between the coefficient of carbonation and the coefficient of air permeability are shown in figure 7, along with previous investigation results of other buildings. The coefficient of carbonation is calculated by C/√t, where C stands for the depth of carbonation and t stands for years of use. The depth of carbonation is measured by applying phenolphthalein solution to concrete cores following the instructions in JIS A 1152. The coefficient of air permeability is calculated by the Torrent method (double chamber method). According to previous investigations, the coefficient of air permeability increases when the coefficient of carbonation increases. According to Figure 5, the results Vertical Derrick are within the range of previous results.

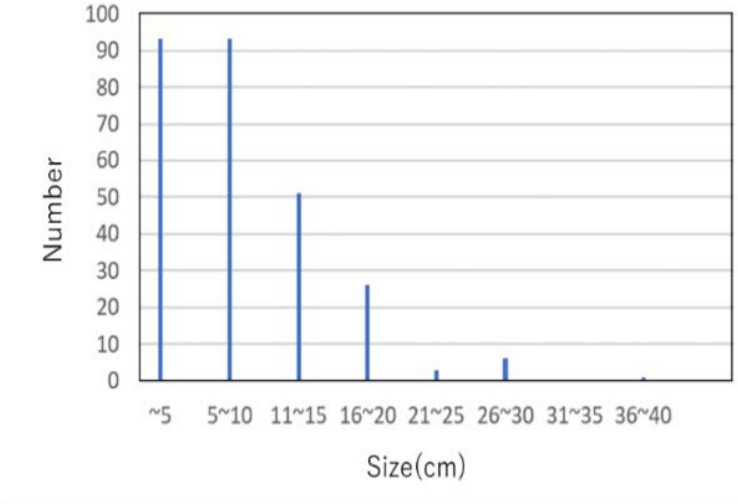

Figure 5. Size of concrete flakes.

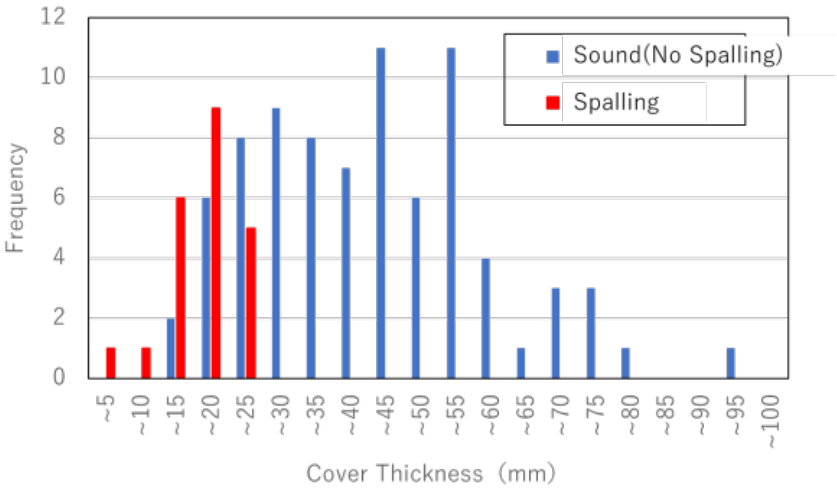

Figure 6. Cover thickness and rebar expose. (Tomotaka Ide, 2019)

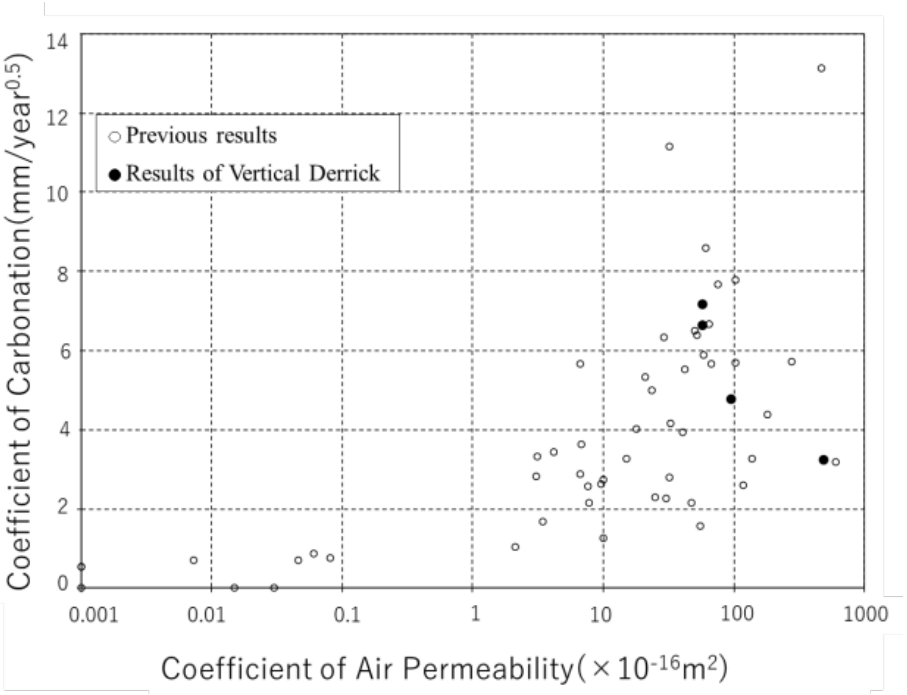

Figure 7. Relation between coefficient of air permeability and coefficient of carbonation. (Akio Tanaka; Kei-ichi Imomoto, 2013).

4 Discussion

4.1 Flying Distance of Flakes

Figure 8 shows the number and horizontal flying distance of flakes of each direction. According to Figure 8, concrete flakes mostly fell within the 7 meters range from the building. The height of the building was 47 meters. For the flying distance of 7 meters, the falling degree was 21.7° and the horizontal flying distance was 0.15 times the height of the building. Concrete flakes that fell out of this range needs further discussion concerning the windswept condition of this location. Table 2 shows the percentage of the spalling area of each direction. According to Table 2, the percentages of spalling area are between 5~10%.

Table 2. Spalling percentage of each direction. (spalling/total area of each side of the wall).

West	South	North	East
9.91%	5.20%	9.35%	3.71%

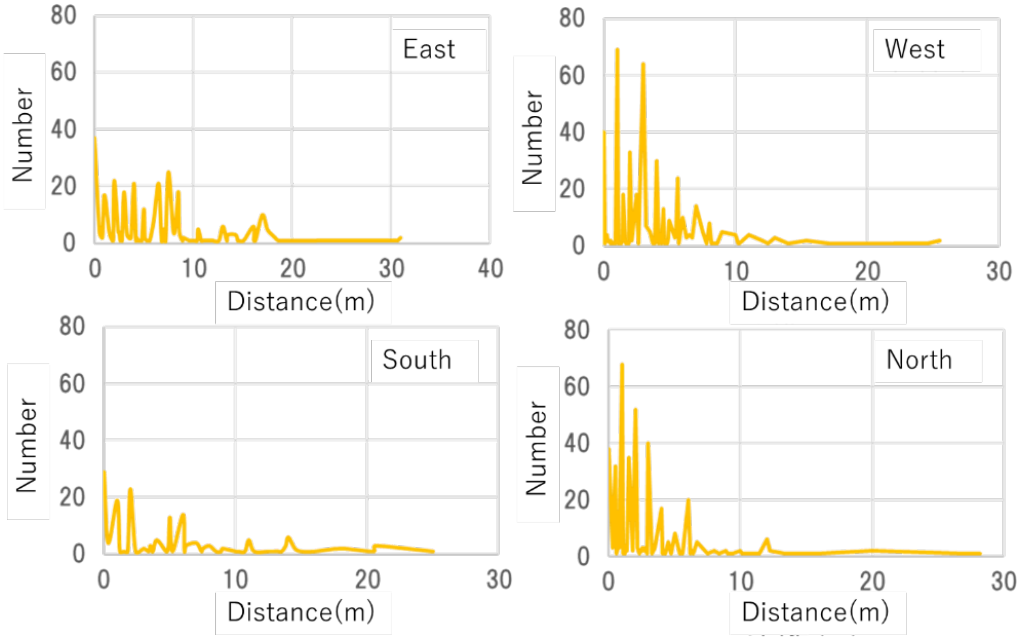

Figure 8. Number and horizontal flying distance of concrete flakes.

4.2 The Relation between Rainfall and Spalling

Figure 9 shows the percentage of wet area after rainfall. The percentages were calculated by wet /total area of each side of the wall. The calculation of wet areas from photos involved the image processing software, ImageJ. By circling the target areas, ImageJ automatically calculated the pixels of the selected areas. The manual selection of the wet areas brought an uncertainty to the results. To increase accuracy, image processing method should be further discussed in future researches. According to the results, the north and the west side with higher number of concrete flakes also showed higher percentage of the wet area. At this location, due to northwest wind blew throughout the year, the north and the west side of the building were more possible to be affected by rainfall than the south and the east side. This observation indicates that there might be a relation between spalling and rainfall. The following equations are proposed considering the relation between the two.

$$\textit{Coefficient of Rainfall} = \textit{Percentage of Wet Area} \times \textit{Number of Days with Precipitation over 10mm} \quad (1)$$

$$\textit{Percentage of Spalling Area} = \textit{Years after Carbonation reaches 25mm} \times \textit{Coefficient of Rainfall} \times \textit{Percentage of Cover Thickness Less than 25mm} \times \alpha \quad (2)$$

Table 3 shows the results of the *Coefficient of Rainfall* and the empirical coefficient α by applying equation (1) and (2) to the north and the south side. When the value of α is 0.006, according to the *Coefficient of Rainfall* in Table 3, the estimated values of spalling area along with measured spalling area are shown in Table 4.

Table 3. Results of the coefficient of rainfall and the empirical coefficient α of the south and the north side.

	South	North
Coefficient of Rainfall	1.231	4.537
α	0.0062	0.0012

West, 78% wet South, 19% wet North, 70% wet East, 36% wet

Figure 9. Percentage of wet area (wet/total area of each side) after rainfall.

Table 4. The estimated value and measured value of spalling area of the east and the west side.

Percentage of Spalling Area	East	West
Estimated Value	3.63%	5.45%
Measured Value	3.71%	9.91%

5 Conclusions

Post peak behaviors of carbonated concrete structures are as follows.

- Concrete spalling flakes increased by the rate of 200 pieces per year while the influence of climate events was still unclear. The sizes of the flakes were around 10 cm in diameter.
- The horizontal flying distance of concrete flakes were approximately 0.15 times the height of the building.
- The sides of the walls with higher proportion of concrete spalling also present higher proportion of wet area during rainfall.

Abstract. *New thermoplastic polyolefin (TPO) roof membranes have been extensively analyzed in laboratories, roof exposure farm fields, and under accelerated weathering conditions. The ASTM International material standard specification for TPO membranes has been regularly improved since its inception to incorporate more demanding tested-product performance, including requirements for accelerated weathering and aging. Industry data on the aged performance of TPO roof membranes to date has largely been based on laboratory work, regional studies, and anecdotal case studies of TPO roofs, predominantly those that have been improperly designed and/or installed, and membranes with retired formulations that resulted in premature failure. Today, there are TPO roofs in the United States that have been in service for nearly 20 years. This paper will review the long-term performance of a large sampling of TPO roof membranes installed throughout the United States by evaluating thickness, flexibility, inspection under 7X magnification, aged seam strength, and repair weld adhesion. The intent of this study was to evaluate 1) field-aged TPO roof membrane performance and 2) the ability to repair field-aged TPO roof membranes.*

Keywords: *TPO, FPO, Aged Performance, Field-Study, Long-Term Performance, Repairability.*

1 Introduction

Flexible Polyolefin (FPO) roof membranes have been part of the European roofing market since the late 1980's. In the early 1990's, this technology migrated to the United States as Thermoplastic Polyolefin (TPO). FPO and TPO are the same polymer that use different terminology in the European and United States markets, respectively, and will be referred to as TPO throughout this paper.

TPO roof membranes are the fastest growing commercial roof membrane on the market, and has grown significantly over the past 20 years. According to the European Single Ply Waterproofing Association (ESWA), TPO is growing in market share, and according to the Single Ply Roofing Institute, TPO represents almost half of the installed low-slope roofing in the United States. The global TPO roof membrane market is expected to reach $2.2 billion by 2024, with a compound annual growth rate (CAGR) of 3.7-percent from 2019 to 2024 (ResearchAndMarkets, 2019).

These membranes are now regarded as a mature technology with properties defined by the ASTM International material standard for TPO membranes, ASTM D6878. These standards have been improved since their inception to incorporate more demanding tested-product performance, including stronger requirements for accelerated weathering and aging.

Today, there are TPO roofs that have been in service for over 20 years (ASTM D573; Taylor and Xing, 2015). This paper reviews the long term performance of field-aged TPO roof membranes to assess performance and the ability to repair aged TPO roof membranes. Specifically addressed are known failure modes of some manufactured TPO membranes which include erosion of the cap (thickness over scrim) down to the scrim and surface cracking, as well as concerns surrounding the ability to repair aging TPO membranes.

2 Program

The intent of this study was to evaluate field-aged TPO roof membrane performance and the ability to repair membranes as they age. Membrane samples were collected from roofs around the United States that were at least 12 years in service. Roofs were selected to gain a general sense of typical performance in various locations across the country. Most of the roofs evaluated to date in this study were installed between 2005 and 2006; the oldest sample reviewed to date was installed 18 years ago. All samples were from the same manufacturer and were predominantly 45 and 60-mil (equivalent of 1.2 and 1.5 mm) smooth-back membranes. Samples were taken from mechanically attached, induction welded, and adhered roofs. Self-adhered membranes were excluded from this study.

2.1 Sample Selection

Each Samples approximately 60 cm by 90 cm (2-foot by 3-foot) and captured a field-welded seam, were taken from the field of the roof and in a location that resulted in increased heat exposure.

The large samples were cut into smaller pieces to evaluate membrane thickness, thickness over scrim, brittleness, heat aging and weather resistance, ply adhesion of existing welds, and ply adhesion of repair welds. Each test was conducted on five unique specimens from each location on the roof.

2.2 Test Program

The testing program was built around ASTM D6878-19, with modifications as needed for aged samples. The artificial aging tests were replaced with field aging for a minimum of 12 years. All tests were conducted in a commercial test laboratory. All data gathered was used in the analysis.

2.2.1 Membrane Thickness and Thickness of Coating Over Scrim

TPO membranes consist of two polymer layers of TPO, the cap and the core, which are laminated together with a polyester reinforcing scrim in-between. Following ASTM D751 and ASTMD7635/D7635M respectively, the overall membrane thickness and the thickness of the coating over the scrim (or cap layer) was measured. This measurement was compared to the current ASTM TPO standard requirements for new membranes to evaluate how they are weathering.

2.2.2 Heat Aging and Weather Resistance

ASTM D6878-19 requires 56 days of heat aging or a radiant exposure of 10,080 kJ/(m^2.nm) prior to the mandrel bend and inspection. As the membrane samples were already aged, the artificial UV and heat aging exposures were eliminated from the test protocol and the pass/fail requirements were applied to the field aged materials.

Heat aging and weather resistance are evaluated per ASTM D573 and ASTM G151/G155 respectively, which includes an inspection at 7X magnification when bent over a 3-inch diameter mandrel for surface cracking.

2.2.3 Low Temperature Flexibility

Low temperature flexibility or the brittleness point was evaluated per ASTM D2137, method B. The specimens were examined at 5X magnification for any visible fracture or crack in the cap layer after having bent the specimens to an angle of 180° in the same direction caused by the test impact.

2.2.4 Aged Ply Adhesion

ASTM D1876, also referred to as the T-Peel Test, was used to evaluate the welded seam ply adhesion. The ply adhesion values reported are the average of the maximum load values at the initial break.

Ply adhesion testing of a proper weld will fail cohesively within one of the plies, exposing the underlying scrim. This is called a “film tearing bond” and is also used to evaluate the integrity of the weld. For the purposes of this evaluation, anything over 70-percent film tearing bond was considered a proper weld.

2.2.5 Repair Ply Adhesion

New TPO membrane that was commensurate in type and thickness of the existing membrane, was welded to the aged membrane to evaluate the ability to repair aged materials. Repairs with new membrane welded to the cap of the aged membrane were evaluated, as well as new material welded to the core (the underside) of the aged membrane. Ply adhesion to the core was not evaluated for adhered membrane samples due to remnants of adhesive and/or facer

from the insulation or cover board. Given the remnants attached to the underside of adhered membranes, repairs to the core would not be reliable.

3 Data Analysis

Samples were taken from 20 different roofs across the United States (See Figure 1). Climatic conditions of the United States cities were matched up with their European counterparts, and are shown in Figure 2 to illustrate the approximate European climate equivalents captured in this study. These roofs were installed over office buildings, manufacturing facilities, retail outlets, libraries, automotive repair shops, warehouses, and a grocery store. All data gathered was used in the analysis.

Figure 1. To date, samples have been collected from 20 roofs across the United States.

Figure 2. European climatic equivalent locations to the samples collected across the United States.

On average, a typical roof membrane in this study was installed between 2005 and 2006 has been exposed to 20 hail storms, over 50 feet of rain, over 500 days of 32°C+ (90°F+) and wind gusts of up to 148 kph (92 mph). Specifically, the roof membrane from Orlando, Florida has been exposed to the elements for over 17 years. This roof has weathered 9 hurricanes, 13 hail storms, 56 feet of rain, 1,660 days of 32°C+ (90°F+) and wind gusts of up to 169 kph (105 mph). While the United States and European climates are somewhat comparable, the wind gusts are more aggressive than what is typical in Europe.

3.1 Membrane Thickness and Thickness of Coating over Scrim

Retention of the cap material, *i.e.* the thickness over scrim, is critical to the membrane's long-term performance as it provides the UV and heat stabilization properties of the membrane. As the cap erodes, the scrim can become exposed and the weather tightness of the membrane is then compromised.

The analysis of aged roof samples began with overall membrane thickness. ASTM standard D6878-19 requires the as-produced membrane to be within +15%, -10% of stated thickness, and not less than 39-mils. Even after 12 or more years of aging, all of the 45 and 60-mil (1.2mm and 1.5 mm equivalent) membrane samples complied with the current ASTM requirements for newly manufactured TPO membranes.

ASTM standard D6878-03, the active specification at the time the sampled roofs were installed, required 12-mil (0.30mm) thickness over scrim. The current version of this standard requires the thickness over scrim to be at least 30-percent of the overall membrane thickness and not less than 18-mils (0.45mm). Both the 45 and 60-mil (1.2mm and 1.5 mm equivalent) membranes analyzed in this study are still in compliance with the newly manufactured membrane requirements and are even in compliance with the current standard ASTM D6878-19, with the thickness over scrim exceeding ASTM minimums and averaging 37- to 40-percent of the nominal membrane thickness. The 45-mil (1.2mm) samples averaged 18-mils (0.45mm) over scrim and the 60-mils (1.5mm) samples averaged 22-mils (0.56mm) over scrim. It should be noted that the EN 13956-12 does not include thickness over scrim measurements.

3.2 Heat Aging and Weather Resistance

Surface cracking was evaluated by visual inspection of the roof membranes at the time the samples were collected, and through modified versions of heat aging and weather resistance testing. Both ASTM tests require inspection at 7X magnification when bent over a 7.6mm (3-inch) diameter mandrel. As the samples were field aged for a minimum of 12 years artificial heat aging and weathering were eliminated, and a focus placed on visual assessment. This evaluation is an important indicator of long term performance (Taylor and Xing, 2015). Surface cracking can lead to quick deterioration of the membrane and is a good indicator of long term performance concerns. All of the samples, both the 45 and 60-mil (1.2mm and 1.5mm equivalent) membranes, exhibited no signs of cracking when bent over the mandrel and viewed at 7X magnification.

3.3 Low Temperature Flexibility

The aged roof samples were evaluated for low temperature flexibility to determine if the membrane became more brittle and prone to cracking as it aged. ASTM standard D6878-19 requires new membranes to have a brittleness point of -40°C (-40°F) or lower. All of the 60-mil (1.5mm) samples tested to date still met this requirement after 12 or more years of field aging. The 45-mil (1.2mm) samples showed signs of cracking at -37°C (-35°F). While this is still good performance and aged membranes cannot be expected to perform at the same level as new membranes, the data does support the use of thicker membranes for longer term performance.

3.4 Aged Ply Adhesion and Repair Ply Adhesion

The ply adhesion of the aged samples averaged approximately 8.76 N/mm (50 lbf/in.) for both the 45 and 60-mil (1.2mm and 1.5mm equivalent) membranes, with a minimum of 70-percent film tearing bond. Representative data are shown in Figure 14. Ply adhesion of TPO membranes should be evaluated throughout the day during installation. The film tearing bond sample is evaluated to confirm the membrane is properly welded together. If the sample fails

and the scrim is not exposed, or the film tearing bond is not greater than 70-percent, the contractor must adjust the heat and/or speed at which the welding equipment is being used. While failures associated with welded seam delamination are not common, and poor welds are generally identified during routine inspections during installation, ply adhesion is used as a quality control tool in the field. However, there is not a clear industry consensus on the minimum strength requirement to evaluate ply adhesion.

New TPO membrane samples included in a broad TPO sampling study of all industry manufacturers conducted by Structural Research, Inc. (SRI) (Dupuis, 2019) averaged a ply adhesion (T-Peel) value of 7.01 N/mm (40 lbf/in.), with a minimum value of 5.13 N/mm (29.3 lbf/in.) However previously, (Simmons *et al*., 1999) found that the ply adhesion tests typically failed adhesively, meaning there was not a strong bond between the TPO layers, when the ply adhesion was 4.55 N/mm (26 lbf/in.) or less. Simmons findings supports SRI's minimum value threshold for ply adhesion. The ply adhesion values of the aged TPO membranes were 15-percent above the average ply adhesion value from the SRI study on new TPO membranes. Therefore, as expected, the aged welds appear to be performing well and are of adequate strength. To address questions around the ability to repair aged TPO membranes, this study examined the adhesion of new membrane to aged membrane. Two approaches were examined; welding the new membrane to the cap of the aged membrane, and new membrane welded to the core of the aged membrane.

The ply adhesion of the new membrane to the aged cap averaged 7.5 N/mm (43 lbf/in.) for 45-mil (1.2mm) membranes and 8.23 N/mm (47 lbf/in.) for 60-mil (1.5mm) membranes. For the new membrane welded to the aged core, the ply adhesion averaged 9.28 N/mm (53 lbf/in.) and 9.98 N/mm (57 lbf/in.) for the 45-mil and 60-mil (1.2mm and 1.5mm equivalent) membranes, respectively.

The ply adhesion values of new repair membrane to the aged TPO membrane are above the average ply adhesion value of 7.01 N/mm (40 lbf/in.) from the SRI study on new TPO membranes. This provides validity to the integrity of repairs to aged TPO membranes and the ongoing maintainability of these roofs.

4 Next Steps and Interim Conclusions

While this paper summarizes data from 20 different roofs from around the country, samples will continue to be collected and analyzed. It is noted that all data received to date has been included in this analysis. No data detrimental or otherwise has been excluded from the analysis or findings.

The findings to date, as summarized in Figure 3, illustrate the robust performance of TPO membranes as they age. Given the inherent flexibility and fungal resistance of TPO, and the UV and heat stabilizers, this comes as no surprise. However, the ability to repair aged TPO membranes has been undefined and anecdotal to date. The interim findings of this study clearly demonstrate the weld integrity of properly executed repairs.

While this study is focused on TPO membranes the United States, this evaluation only strengthens the findings of previous studies on the durability and repairability of TPO roof membranes in Europe.

60 mil (1.5mm) white TPO	Average	Performance	45 mil (1.2mm) white TPO	Average	Performance

Figure 3. Average findings from study to date for 45 and 60-mil (1.2mm and 1.5mm equivalent) membranes as compared to ASTM D6878-19.

5 Conclusion

In summary, the aged TPO membrane roofs in this study are performing well and in most instances, meeting the current ASTM D6878-19 requirements for newly manufactured membranes.

- Even after 12 or more years of aging, both the 45 and 60-mil (1.2mm and 1.5mm equivalent) membranes analyzed in this study are still in compliance with these newly-manufactured membrane requirements, with the thickness over scrim averaging over 40-percent of the actual aged membrane thickness.
- All of the samples, both the 45 and 60-mil (1.2mm and 1.5mm equivalent) membranes, exhibited no signs of cracking when bent over the mandrel and viewed at 7X magnification.
- All of the 60-mil (1.5mm) samples tested to date still meet cold temperature flexibility requirements of -40°C (-40°F) after 12 or more years of aging. The 45-mil (1.2mm) samples showed signs of cracking at -37°C (-35°F).
- Ply adhesion values of new repair membrane to the aged TPO membrane are above the average for new TPO membranes. This provides some validity to the integrity of properly executed repairs to aged TPO membranes.

Rainwater Management of Ventilated Facades: Impact of Joint Width and Cavity Size

Stéphanie Van Linden and Nathan Van Den Bossche

Ghent University, Faculty of Engineering and Architecture, Building Physics Group, Sint-Pietersnieuwstraat 41 B4, Ghent, Belgium, stephanie.vanlinden@ugent.be

Abstract. *During a rain event, most of the raindrops reaching the facade either splash back or run off the exterior surface of the facade. However, it is evident that also a portion of the water infiltrates through the open joints of a ventilated facade. The infiltrated water may either be drained in the cavity to the bottom of the wall or reach the insulation layer. If there are any deficiencies present in the insulation layer or at the connection of the brackets, the infiltrated water might introduce problems. Additionally, if the cavity is not able to drain all the infiltrated water or adhered droplets to one of the cavity surfaces do not dry out, moisture problems might occur. Experiments were conducted to determine the infiltration rate through ventilated facades with open joint widths of 5 mm, 10 mm and 15 mm and cavity widths ranging from 190 mm to 40 mm. It was observed that the amount of infiltrating water was larger for larger joints widths. Due to the larger kinetic energy of the drops flowing through the larger joint widths, the drops were able to reach the exterior surface of the insulation layer, even for large cavity widths. The results from the experimental assessment were used as input parameters for hygrothermal simulations to determine the risk of moisture problems.*

Keywords: *Water Infiltration, Drainage, Ventilated Facades, Moisture Loads.*

1 Introduction

Ventilated facades are usually designed according to the open rainscreen principle to control rainwater penetration (Garden, 1963). The external cladding, which usually consists of independent facade panels, is supposed to keep out most of the rain. Evidently, also a portion of the driving rain infiltrates through the open joints between the facade panels and reaches the air cavity behind the external cladding. This cavity acts as a capillary break and drains the infiltrated water to the bottom of the wall where it may flow back to the exterior through drainage holes. The air barrier at the interior side of the facade restricts the airflow through the wall. Combined with the open joints between the facade panels, the pressure difference over the cladding is minimized. This reduces the pressure difference acting as one of the main driving forces for water to infiltrate (Suresh Kumar, 2000). Other forces that may affect water infiltration through joints are surface tension, capillarity, kinetic energy and gravity. Experiments conducted by Mas *et al.,* (Mas, Gutiérrez, Gil, Gil, and Galvan, 2011) revealed that for joint widths larger than 8 mm, gravity and kinetic energy are the main forces driving rain through the joints, capillarity and surface tension having less importance.

For the same weather conditions, the amount of infiltrating water depends on the geometry of the joints and the material characteristics. When raindrops infiltrate, they are either drained to the bottom of the wall or they may reach the drainage layer at the back of the cavity dependent

on the cavity size and the geometry of the joints. If there are any deficiencies present at the drainage layer or at the connection of the brackets, the infiltrated water might introduce problems. Additionally, if the cavity is not able to drain all the infiltrated water or if adhered water drops to one of the cavity surfaces do not dry out, moisture problems might occur. However, the amount of experimental work that quantifies the portion of infiltrating water through ventilated facades and the portion of water reaching the drainage layer at the back of the cavity, is very limited.

Recatala *et al.,* (2017) assessed the watertightness performance of a full-scale ventilated facade specimen with joint widths of 10 mm. Laboratory experiments showed that the airtightness level of the wall did not have an impact on the infiltration rates as pressure moderation over the external cladding was achieved for both leaky and sealed constructions. The applied spray rate, however, did have a significant impact on the infiltration rate. A parabolic correlation was obtained between both parameters. It was observed that when a lot of water was running down the external cladding, the water runoff film prevented driving rain drops from infiltrating through the open joints and bounced and splashed off the surface instead. The results also showed that the infiltration rate of water through the horizontal joints was significantly larger than the infiltration rate through the vertical joints. Also the impact of the horizontal joints on the amount of water reaching the drainage layer at the back of the cavity was larger compared to the impact of vertical joints. The splattering effect of raindrops in the joints and onto the brackets caused additional raindrops to reach the drainage layer. However, most of the infiltrated water was drained to the bottom of the cavity. Only 0,54% of the impinging water on the external cladding averagely reached the drainage layer which was situated 10 cm behind the cladding panels. The ASHRAE standard 160 (2016), however, proposes a default penetration rate of 1% deposited on the water-resistive-barrier. It is clear that more research on the amount of rain that penetrates through various types of claddings and different wall configurations is necessary.

The objective of this study is to assess the impact of the joint width and cavity size of a ventilated facade specimen on the amount of water infiltrating through the joints and the amount of water reaching the drainage layer at the back of the cavity. Additionally, the impact of a panel installed out of plane of the exterior surface on the infiltration rate was assessed. The results from the experimental assessment were used as input parameters for hygrothermal simulations to determine the risk of moisture problems.

2 Test Setup and Methodology

2.1 Test Setup

The impact of joint width, cavity size and construction errors on the infiltration rates through ventilated facades was evaluated by means of five test specimens. Each test specimen was mounted in a steel frame with dimensions 2390 x 1070 mm and incorporated 24 fibre cement boards. These boards were screwed onto vertical timber studs with a cross-section of 38 x 90 mm. The vertical studs were positioned at the vertical joints between the facade panels. Flashing was applied between the studs and the facade panels as recommended by the manufacturer to avoid water being absorbed by the wood studs. The vertical studs were affixed to a wood frame, simulating the structural wall, by means of threaded rods. In between the vertical studs and the

wood frame a PMMA panel was installed, simulating the drainage layer which in case of ventilated facades usually is the insulation layer. The PMMA panel could be moved further away or closer to the facade panels in order to vary the cavity width. The fibre cement boards had a thickness of 8 mm and a width and length of 300 mm. The width of the boards at the sides of the specimens was dependent on the applied joint width.

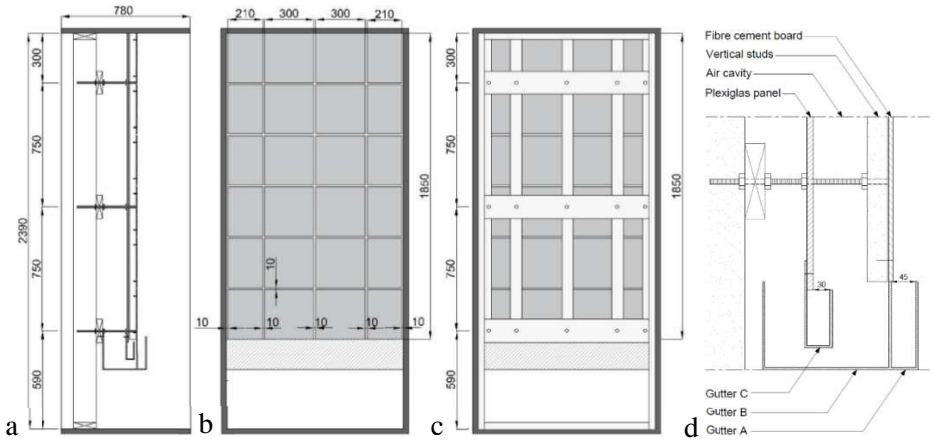

Figure 1. a) Cross section, b) Front view, c) Rear view of test setup 2, d) Detailed cross section gutter system.

The specimens evaluated by Recatala *et al.,* (2017) had a joint width of 10 mm. The same width was chosen as the standard joint width in this study. Additionally, a joint width of 5 mm was evaluated, as Mas *et al.,* (2011) stated that the impact of surface tension and capillarity increased for joint widths smaller than 8 mm. The largest evaluated joint width was 15 mm.

The smallest evaluated cavity width was 40 mm as this was the combined thickness of the vertical studs and the flashing. The largest evaluated cavity width was 190 mm as it was observed that no significant differences were measured for a cavity width of 160 mm and 190 mm.

Three gutters were installed at the bottom of each specimen: gutter A collected the water which flowed downward at the exterior side of the facade panels during the test or splashed back up to 45 mm in front of the panels, gutter B collected the water which flowed downward at the back of the facade panels, the vertical studs and in the drainage cavity, and gutter C collected the water which flowed downward at the PMMA panel and up to 30 mm in front of the panel. In case a cavity width of 40 mm was applied, gutter B only collected the water that ran off the interior side of the facade panels and gutter C collected the remaining portion of water that reached the cavity.

2.2 Test Procedure

Water was sprayed onto the test specimens by means of a spraying rack with full cone nozzles which were installed at the top of the specimens and at a horizontal distance of 250 mm. A constant spray rate of 120 l/h was applied. No pressure difference was applied to the external cladding as Recatala (2017) already observed that pressure equalization was achieved for both leaky and sealed specimens. The water collected by the gutters was weighed both during and after the test by means of weighing scales with an accuracy of ± 0,1 g. Water was sprayed for 400 seconds or until the infiltration rate for all gutters was constant for a significant amount of

time. The pattern of water droplets which adhered to the PMMA panel after the test was visually evaluated. The repeatability of the test procedure was evaluated by conducting the same experiment at least two times.

3 Experimental Results and Discussion

3.1 Impact of Joint and Cavity Width

Figure 2 shows the percentage of water collected by gutter A, B and C relative to the total amount of collected water. The tests were conducted for different cavity widths ranging from 4 cm to 19 cm and joint widths of 5 mm, 10 mm and 15 mm for respectively specimen 1, 2 and 3. As the timber studs were situated at the vertical joints, the collected water only infiltrated through the open horizontal joints.

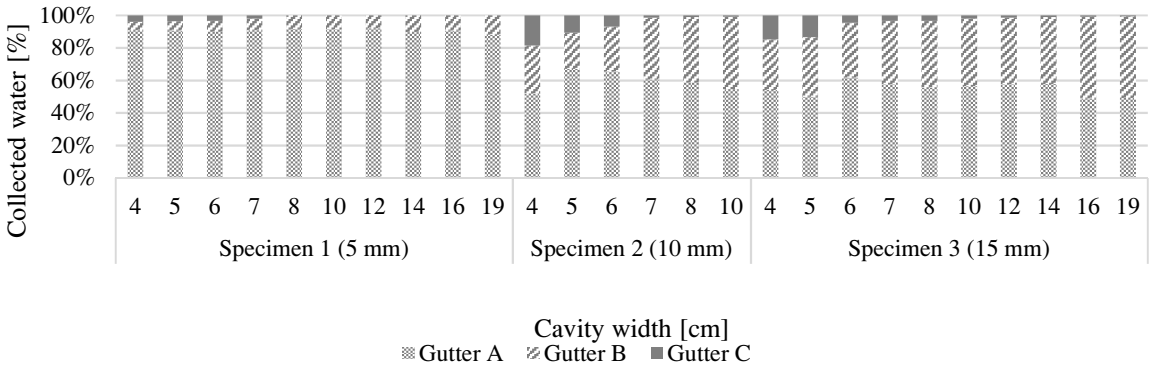

Figure 2. Percentage of water collected by gutter A, B and C for all specimens and different cavity widths.

The total amount of infiltrated water through the open joints is collected by gutter B and C at the bottom of each specimen for different cavity widths. Figure 2 shows that the percentage of infiltrated water through specimen 1 with a joint width of 5 mm (9,48% ± 1,13%) is significantly smaller than the percentage of infiltrated water through both specimen 2 (40,30% ± 5,89%) and 3 (45,15% ± 4,29%) with respective joint widths of 10 and 15 mm. Raindrops may either infiltrate due to kinetic energy, gravity, surface tension or capillarity. Also some drops might stagnate on top of the facade panels. In case other drops impinge on these stagnating drops, water may infiltrate due to splattering. Raindrops may also bounce on top of the facade panels or splash open. The larger percentage of infiltrated water through larger joint widths implies that more raindrops are able to flow freely through the larger joints and therefore the kinetic energy of the water drops has a larger impact on the infiltration rates. In case of smaller joint widths (5 mm) the effect of capillarity and surface tension becomes more important and water bridging of the joint is observed at some locations. Water drops are no longer able to flow freely through the joints and splatter onto the occluded joints, significantly reducing the infiltration rate. The increase in infiltration percentage from 10 mm joint widths to 15 mm joint widths, however, is not significant.

The reduced impact of kinetic energy on the infiltration rate for smaller joint widths is also apparent when the amount of water reaching the back of the cavity and collected by gutter C is compared for the different specimens. For specimen 1 with a joint width of 5 mm, water reaches the back of the drainage cavity for cavity widths of 7 cm and smaller (2,05% of collected

water). In contrast, water was already collected in gutter C for specimen 2 with a cavity width of 10 cm (0,88% of collected water) and for specimen 3 even for cavity widths of 19 cm (0,82% of total collected water). For a cavity width of 5 cm and 4 cm, a constant water runoff was visible at the PMMA panel for both specimen 2 and 3. In case of a cavity width of 4 cm, 18,71% and 14,80% of the total amount of collected water was collected by gutter C for respectively specimen 2 and 3. For specimen 1, no runoff was present for these cavity widths at the PMMA panel, only some drops reached the panel, in particular at the height of the spraying rack. The collected water in gutter C of specimen 1 was mainly attributed to water running off the vertical studs instead of water reaching the PMMA panel.

The results obtained by Recatala et al. (2017) are within the same order of magnitude as the results obtained in this study. For a cavity width of 10 cm and a joint width of 10 mm Recatala measured an infiltration rate at the drainage layer of 0,0029 l/min.m, compared to an infiltration rate of 0,0024 l/min.m in this study.

3.2 Impact of Construction Errors

Figure 3 shows the percentage of water collected by gutter A, B and C for specimens 2, 4 and 5. Specimen 4 and 5 incorporated one facade panel installed respectively 5 mm and 10 mm out of the exterior plane. The joint width applied to all specimens was 10 mm. The tests were conducted for cavity widths of 4, 8 and 12 cm.

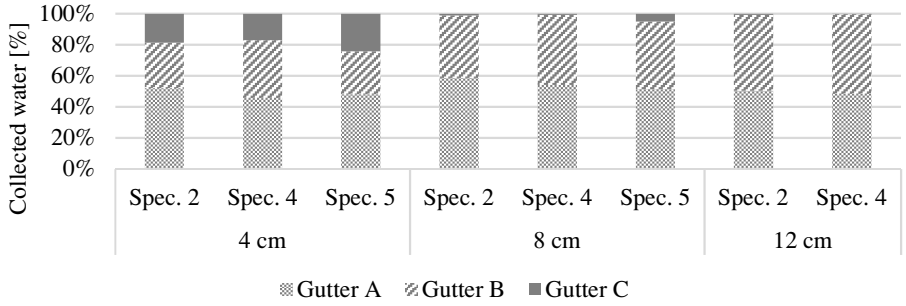

Figure 3. Percentage of water collected for specimen 2 (no error), specimen 4 (5 mm error) and specimen 5 (10 mm error) at different cavity widths.

Although a larger opening was present through which water could infiltrate freely due to the out of plane installed panels, only a small increase in the percentage of infiltrated water was measured. As the panel of specimen 4 was only installed 5 mm out of plane and the total thickness of the facade panels was 8 mm, there was still an overlap between the other panels and the panel out of plane. This prevented downward flowing drops from infiltrating due to gravity. Water drops instead bounced, splashed or stagnated on the top of the out of plane installed panel, with only a small increase of the infiltrated water as a result. When the panel was installed 10 mm out of plane (specimen 5), downward flowing water drops were able to infiltrate due to gravity. As the panels were installed vertically out of plane, however, these infiltrated drops were able to flow further down along the exterior surface of the underlying panel. Due to the larger horizontally oriented open joint, water drops could flow more freely through the opening and due to kinetic energy they were able to reach further into the cavity resulting in larger percentages of water collected in gutter C of specimen 5.

4 Hygrothermal Evaluation

As observed in the laboratory experiments, water drops are able to infiltrate through the open joints of ventilated facades and reach the insulation layer. In case a small cavity width is applied and deficiencies are present at the insulation layer, *e.g.* an open joint between two insulation panels, raindrops are able to flow through this open joint. These raindrops can either stagnate on top of the insulation panel and dry out again or flow further inward and reach the brick layer of the wall. This might cause mould growth or a reduced thermal performance of the insulation. The risk of both phenomena was assessed by means of the hygrothermal simulations. A common used ventilated facade construction in Belgium was modelled in WUFI PRO 5.3. A worst-case scenario was simulated, i.e. a small cavity width of 40 mm was applied and it was assumed that all infiltrating water reached the brick layer behind the insulation. The construction had a south-west orientation and a height up to 10 m. The material properties used in the simulations can be found in Table 1. The simulations start at October 1st and run for a period of 3 years. A time step of 1 hour was applied.

Table 1. Material properties (based on WUFI material database).

Material	t (mm)	ρ (kg/m^3)	C_p (J/kgK)	λ_{dry} (W/mK)	W_{sat} (kg/m^3)	w_{80} (kg/m^3)	Porosity
Eternit Duripanel A2	8	1326	1500	0,4	345	119,5	0,345
Air layer	40	1,3	1000	0,23	-	-	0,999
Isover GW Integra ZFK - 032	100	32,5	840	0,032	473	0,82	0,950
Solid Brick, extruded	140	1650	850	0,6	370	9,2	0,410
Interior Plaster (Gypsum Plaster)	10	850	850	0,2	400	6,3	0,650

4.1 Risk of Mould Growth

In case raindrops are able to reach the brick layer of the wall assembly, the raindrops will be absorbed by the brick. High infiltration rates combined with drying out to the inside of the wall can possibly cause mould growth at the interior surface of the wall assembly.
The risk of mould growth is assessed by means of the isopleth model by Sedlbauer which is implemented in WUFI. The isopleth curves separate favourable from unfavourable temperature and relative humidity conditions for mould growth for different substrate groups (Sedlbauer, 2001). A moisture source was implemented in the brick layer of the modelled wall assembly.

In case 15% of the driving rain reaches the brick layer and the air change rate in the air cavity is 10 h^{-1}, some data points are situated above the LIM I curve of Sedlbauer, meaning that there is a risk of mould growth for biologically recyclable materials. If the infiltration percentage is increased to 20% of the driving rain, the limiting isopleth for biologically adverse recyclable building materials (LIM II) is exceeded for a longer period and the risk of mould growth at the interior surface is significant. The results from the experimental study showed the highest infiltration percentages (collected by gutter C) for a ventilated facade with a joint width of 10 mm and a cavity width of 4 cm, i.e. 18,71%. However, in reality only a portion of the infiltrated water will reach the insulation layer and a small percentage will infiltrate toward the brick layer. It can therefore be stated that the risk of mould growth is limited for the assessed ventilated facade.

If the air change rate is increased from 10 h^{-1} to 1000 h-1, the limiting isopleth for biologically adverse recyclable building materials is still exceeded for an infiltration percentage of 20%. This implies that in case raindrops are able to reach the brick layer behind the insulation, increasing the air change rate only has a limited impact on the mould growth.

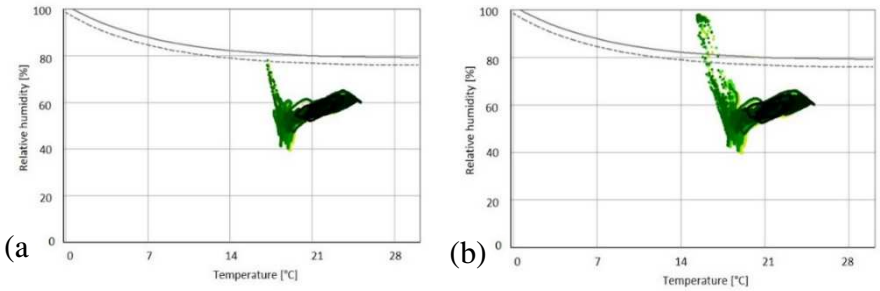

Figure 4. Isopleths on the interior surface, (a) infiltration percentage of 15% and (b) infiltration percentage of 20%.

4.2 Impact on Heat Flux

As the thermal conductivity of the insulation is moisture-dependent, infiltrating water in the wall assembly will have an impact on the heat losses through the wall assembly. As insulation is a non-hygroscopic material, raindrops infiltrating through deficiencies in the insulation layer, will either dry out or flow further inward. In case of a worst-case scenario, infiltrating raindrops might reach the brick layer behind the insulation. The drops will then be absorbed by the brick and accumulation of moisture can occur, increasing the relative humidity over the wall assembly. This may cause moisture to condensate at the cold side of the insulation which will reduce the thermal performance of the insulation.

Table 2. Impact of infiltration percentage in brick layer on air change rate on heat flux at interior surface.

Infiltration percentage [%]	**Heat flux [MJ/m²] per year**			**Increase relative to no moisture**		
ACH	10 h^{-1}	100 h^{-1}	500 h^{-1}	10 h^{-1}	100 h^{-1}	500 h^{-1}
No moisture source	96,56	97,68	99,23	0%	0%	0%
1	99,74	100,93	102,55	3,29%	4,00%	3,35%
5	112,30	114,22	116,14	16,66%	20,38%	17,04%
10	129,30	129,97	132,36	33,91%	39,79%	33,38%
15	149,60	144,00	147,05	54,93%	57,07%	48,19%
20	172,92	154,46	158,22	79,08%	69,97%	59,45%

In case a moisture source of 1% of the driving rain is implemented in the middle of the brick layer, an increase of 3,29% of the heat flux at the interior surface is measured compared to the case with no moisture source. This increase in total heat flux is primarily attributed to the increase of the latent heat flow associated with vapour diffusion at the surface. In case the latent heat flow is excluded, the increase in heat flux is 0,04% for a moisture source of 1% of the driving rain. In case a moisture source of 10% of the driving rain is applied, an increase of the total heat flux at the interior surface of 34,62% is measured. Excluding the latent heat flow, the moisture source causes an increase of the total heat flux of 3,41%. In case of a moisture source of 10% of the driving rain, the insulation layer still dries out over a period of one year. In case however, a moisture source of 15% of the driving rain is applied, i.e. all the infiltrating water

reaches the brick layer behind the insulation, the water in the insulation layer does not evaporate over a period of 1 year and instead accumulates. Increasing the air change rate in the air cavity in front of the insulation, increases the air velocity at the insulation layer, resulting in an improved drying of the wet insulation and therefore a reduction of the heat flux.

5 Conclusions

An experimental study was conducted to assess the impact of the joint width and the cavity size of a ventilated facade specimen on the amount of water infiltrating through the open joints and the amount of water reaching the drainage layer at the back of the cavity. Additionally, the impact of a panel installed out of plane of the exterior surface on the infiltration rate was assessed. The results from the experimental assessment were used as input parameters for hygrothermal simulations to determine the risk of moisture problems.

The experimental study showed that the infiltration percentage of raindrops through open joints of 5 mm (9,48% ± 1,13%) was significantly smaller compared to the infiltration percentage through joints of 10 mm (40,30% ± 5,89%). Raindrops infiltrating through the 5 mm joints of the ventilated facade reached the drainage layer and up to 3 cm in front of the drainage layer for cavity widths of 7 cm and smaller. For joint widths of 10 mm and 15 mm however, water was already collected 3 cm in front of the drainage layer for cavity widths of respectively 10 cm and 19 cm and a runoff film was present at the drainage layer for cavity widths of 4 and 5 cm. Hygrothermal simulations showed that the risk of mould growth at the interior surface of a ventilated wall assembly is limited for the measured infiltration percentages. The impact on the heat flux at the interior surface is however, significant, in case a cavity of 40 mm is assumed and all infiltrating water reaches the brick layer at the interior side of the wall through deficiencies in the insulation layer. An infiltration percentage of 1% of the driving rain in the brick layer and an air change rate of 10 h^{-1}, causes an increase of the heat flux of 3,29%. This increase in heat flux is primarily attributed to the latent heat flow associated with vapour diffusion at the surface. In case of an infiltration percentage of 10%, the increase in heat flux measures 34,62% and 3,41% excluding the latent heat flow.

Salt and Ice Crystallization Resistance of Lime Mortars with Natural Lightweight Aggregate

Martin Vyšvařil and Patrik Bayer

Brno University of Technology, Faculty of Civil Engineering, Veveří 331/95, 602 00 Brno, Czech Republic, vysvaril.m@fce.vutbr.cz

Abstract. *In this study, the comparison of lava sand, pumice, and natural zeolite as lightweight aggregate in air lime mortars, natural hydraulic lime mortars, and cement-lime mortars has been investigated with emphasis on the resistance of salt and ice crystallization. The lava sand and pumice improved frost resistance of the mortars while natural zeolite mortars remained without this effect due to their high water absorption. Salt crystallization resistance of the mortars was improved by using lava sand and natural pumice, while the mortars with natural zeolite were not resistant to crystallization of sodium chloride. The mortars have relatively little resistance to the reacting of Na_2SO_4, where gypsum and calcium sulfoaluminates were formed breaking the structure of the mortars. The best results were obtained using natural pumice.*

1 Introduction

The protection of historic buildings requires the use of traditional building materials compatible with the historical ones or as close to them as possible. Air lime mortars are not suitable for use in the moist environment because of their non-hydraulic properties and low frost resistance. The use of renders made of natural hydraulic lime (NHL) is therefore often preferred for renovation purposes, although lime–cement mortars are also accepted (Pacheco-Torgal *et al.*, 2012). Significant change of air lime mortars properties can be achieved by addition of pozzolanic admixtures or aggregates with pozzolanic properties. In the past, the most used ones were natural pozzolanic materials such as crushed bricks, ceramic, volcanic ash, scoria, pumice, which are still many times mentioned in conservation mortar works (Henry *et al.*, 2012; Matias *et al*., 2014; Moropoulou *et al.*, 2005; Sánchez-Moral *et al*., 2005; Silva *et al*., 2010). Porous aggregate with pozzolanic properties can improve not only the mechanical properties of mortars, but also their ability to salt accumulation from masonry, frost resistance, and liquid water transport to the mortar surface. The use of natural lightweight aggregates such as lava sand, pumice, or natural zeolite is quite common in concrete, however their utilization in lime mortars is still scarce (Barnat-Hunek *et al*., 2017; Ferraz *et al*., 2014; Lemougna *et al*., 2018).

In this study, the comparison of lava sand, pumice, and natural zeolite as lightweight aggregate in air lime mortars, natural hydraulic lime mortars, and cement-lime mortars has been investigated with emphasis on the resistance of salt and ice crystallization. The strength characteristics, pore structure and capillary water action of natural zeolite mortars and lava sand mortars, respectively, have already been investigated (Vyšvařil *et al*., 2019, Vyšvařil *et al*., 2019) with the conclusion that both natural aggregates positively affect the mortar strength, increase their porosity by forming coarse pores and facilitate water capillarity.

2 Materials and Methodology

A commercial hydrated lime CL90-S (Čertovy Schody, Inc., Lhoist group, Tmaň, Czech Republic), a natural hydraulic lime NHL 3.5 (Zement- und Kalkwerke Otterbein GmbH & Co. KG, Großenlüder, Germany), and a laboratory prepared blend of CL90-S and Portland cement CEM I 42.5 R (Českomoravský cement Inc., Mokrá, Czech Republic) were used as binders in prepared 3 groups of mortar mixes. Each mortars group consisted of reference samples made of quartz sand (Filtrační písky, Ltd., Chlum u Doks, CZ), and 3 types of samples with different natural lightweight aggregate (0/2 mm), fully replacing quartz sand, namely, natural zeolite (ACRE, Ltd., CZ), lava sand (Der Naturstein Garten, Hillscheid, DE), and natural pumice (Der Naturstein Garten, Hillscheid, DE). The chemical composition of all raw materials is given in Table 1. The phase compositions obtained by the X-ray diffraction analysis are presented in Table 2. Particle size distribution and loose bulk density of the aggregates are shown in author`s previous publication (Vyšvařil *et al*., 2019).

Mortar mixtures were made using the correct amount of water required to obtain a normal consistency and a good workability of the mortars (160 ± 5 mm; measured by the flow table test). This consistency of lime mortars enables their easy application and good adhesion to the substrate. The proportioning of the mortar mixtures is given in Table 3. The composition of mortar mixtures considers constant binder:aggregate volume ratio of 1:1.15 based on a practical point of view supported by the results obtained by Lanas *et al*. (2003). Fresh mixtures were cast into prismatic moulds of size 40 × 40 × 160 mm. Standard conditions of sample storage were 22 ± 2 °C and relative humidity of 50 ± 5%.

The water absorption of mortars was measured according to EN 13755:2008 after curing times of 28 d. Three mortar specimens were used to conduct the test. The total porosity of the specimens was assessed using a mercury intrusion porosimetry (MIP). Frost resistance tests were carried out according to modified Czech standard ČSN 722452. The samples were tested after 28 curing days. The total test required 15 freeze-thaw cycles. One cycle consisted of 6 h freezing at −20 °C and 12 h thawing in a desiccator at constant relative humidity of 98 % and temperature of 20 °C. The frost resistance coefficient D_f was determined as the ratio of

flexural strength of specimens subjected to 15 freeze-thaw cycles to the flexural strength of reference specimens that did not undergo the frost resistance test. The salt crystallization resistance of mortars was determined using following solutions: 10% Na_2SO_4, 3% NaCl, and 3% NH_4NO_3. The dried samples were immersed into the solutions for 7 h and then dried for 16.5 h at 60 °C. The process was performed in the number of 10 cycles or till the partial disintegration of the samples. The procedure was performed according to the relevant European standard (EN 12370:1999). The state of the test specimens was monitored photographically, and detailed microstructure images were taken via a scanning electron microscope (SEM) equipped with EDX probe. The content of anions in aqueous leaches of the samples was determined by routine chemical analyses (10 g of mortar sample, 500 ml of deionized H_2O). Sulfates were set gravimetrically according to ISO 9280:1990, chlorides by mercurimetric method (ISO 5790:1979), and nitrates using Nitratax sc optical probe allowing the determination of nitrates directly in the medium.

3 Results and Discussion

3.1 Total Porosity and Water Absorption

Since the resistance and durability of lime mortars is very dependent on their pore structure, the total porosity of the mortars (obtained by MIP) and the water absorption has been determined before the resistance tests (Figure 1). The increasing total porosity of the mortars corresponds to the decreasing loose bulk density of the lightweight aggregate (Vyšvařil *et al*., 2019), therefore the mortars with the lightest pumice aggregate (-Pu) showed the highest total porosity, which can be potentially beneficial for salt and ice crystallization resistance of these mortars.

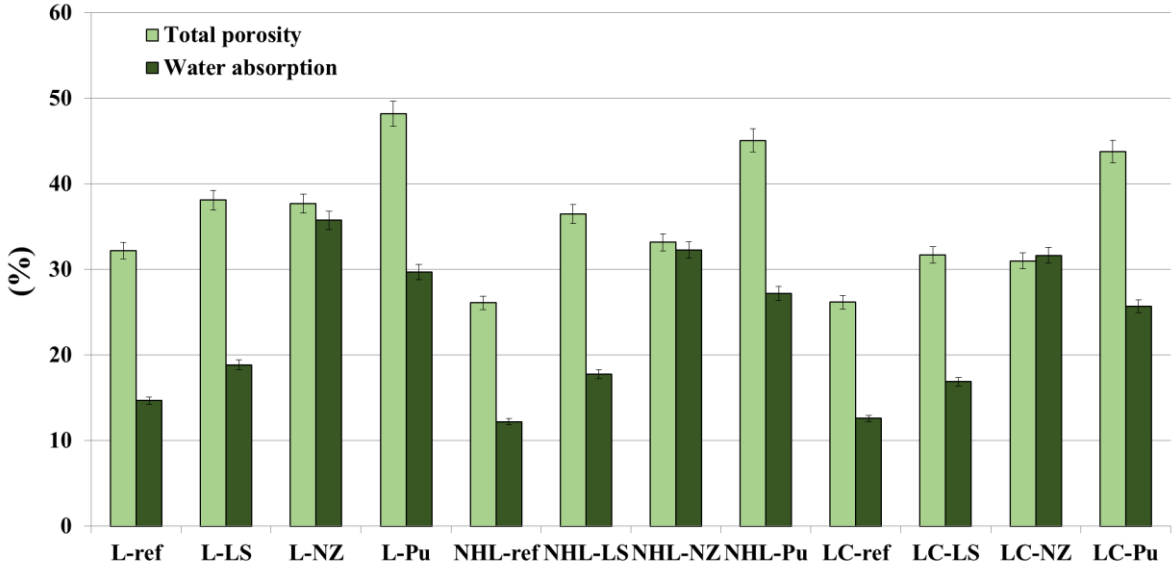

Figure 1. Total porosity and water absorption of mortar samples.

The type of lightweight aggregate had a great influence on the water absorption of mortars. Above all, the open porous structure of the aggregate and its water-binding capacity plays an important role in water absorption, which is especially evident when using natural zeolite. This is also obvious from the high dosages of mixing water required to achieve the desired consistency of these mortars (Table 3).

3.2 Frost Resistance

Determination of frost resistance of mortars according to ČSN 72 2452 is a test of alternating freezing and thawing of water-saturated mortar beams in the number of 15 cycles. Due to the saturation of the samples with water, air lime mortars usually break up in this test before the completed 15 cycles. In this study, all tested mixtures withstood 15 freeze-thaw cycles and it was possible to determine their flexural tensile strengths and subsequently evaluate the frost resistance coefficients, D_f (Figure 2). The frost resistance of mortars increased with increasing porosity of the samples, except for natural zeolite mortars, where the huge water-binding capacity led to a decrease in the frost resistance. Only NHL-Pu, LC-ref, LC-LS, and LC-Pu mortars exceeded the frost resistance coefficient of 0.75 and thus met the frost resistance criterion. In general, replacement of quartz sand with natural lightweight aggregate has led to a substantial improvement in the frost resistance of mortars (except natural zeolite); the best results were obtained using natural pumice.

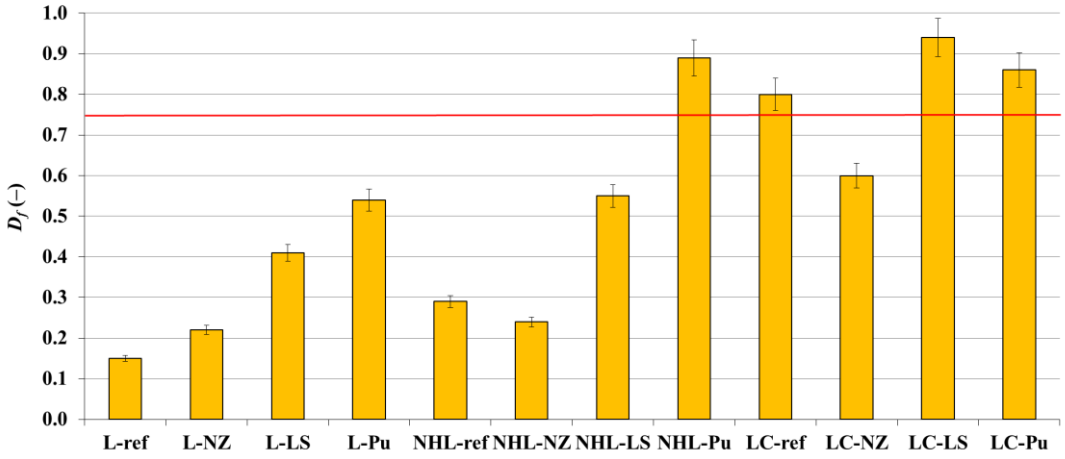

Figure 2. Frost resistance coefficient of mortar samples (red line – standard frost resistance criterion).

3.3 Salt Crystallization Resistance

The content of anions in aqueous leaches of the samples before and after salt crystallization resistance test is presented in Table 4 together with the sequence of the decay cycle. The results show that the concentration of the monitored anions in the samples after treatment with saline solutions increased more than 100 times; mostly in pumice samples, which also best resisted crystallization of the salts used. Thus, it has been confirmed that increased porosity is a good prerequisite for higher ability to salt accumulation and mortar resistance to salt crystallization. Table 4 shows that the mortars with NZ are not resistant to crystallization of sodium chloride. All mortar samples were also broken down after several crystallization

cycles of sodium sulfate, where gypsum with high molar volume are formed. The NHL and LC mortars break down in the sodium sulphate solution earlier due to the presence of the aluminate phase and the formation of bulkily calcium sulfoaluminates (monosulfate and ettringite) breaking the structure of the mortar.

The microstructure of mortar samples was determined before and after the salt crystallization resistance test. Microstructure images of NZ mortar samples were selected for presentation due to the largest differences between them (Figure 3). The images show that the structure of the L-NZ sample prior to the salt crystallization resistance test was relatively compact. After Na_2SO_4 treatment, the formation of crystalline neoplasms, namely plate-shaped hexagonal crystals of monosulfate and needle-like ettringite, was enormous, while the structure became more porous. Natural zeolite acted as an aluminum source for the formation of sulfoaluminate phases. Despite the higher aluminum content in the mortars with NZ aggregates compared to the reference samples and thus easier formation of the aluminate phases, the samples disintegrated later, probably due to higher porosity of these samples. In the case of NH_4NO_3, no products of relevant degradation reactions were observed in the microstructure of mortars, only calcite recrystallization occurred during each cycles of treatment, which is represented in the SEM image in the form of a large number of sharp-edged calcite crystals. The structure remained relatively close. Treatment with NaCl solution resulted in a very porous mortar structure for both the L-NZ sample (Figure 3, d) and the NHL-NZ sample (Figure 3, e). The poor resistance of lime mortars with natural zeolite to NaCl crystallization is likely due to leaching of the binder from the mortar structure, since no degradation reaction products have been observed in these mortars. For comparison, the microstructure of the LC-NZ sample, which is much more compact and characterized by the presence of amorphous CSH gel and ettringite needles, is also shown in Figure 3. This sample remained intact after NaCl treatment.

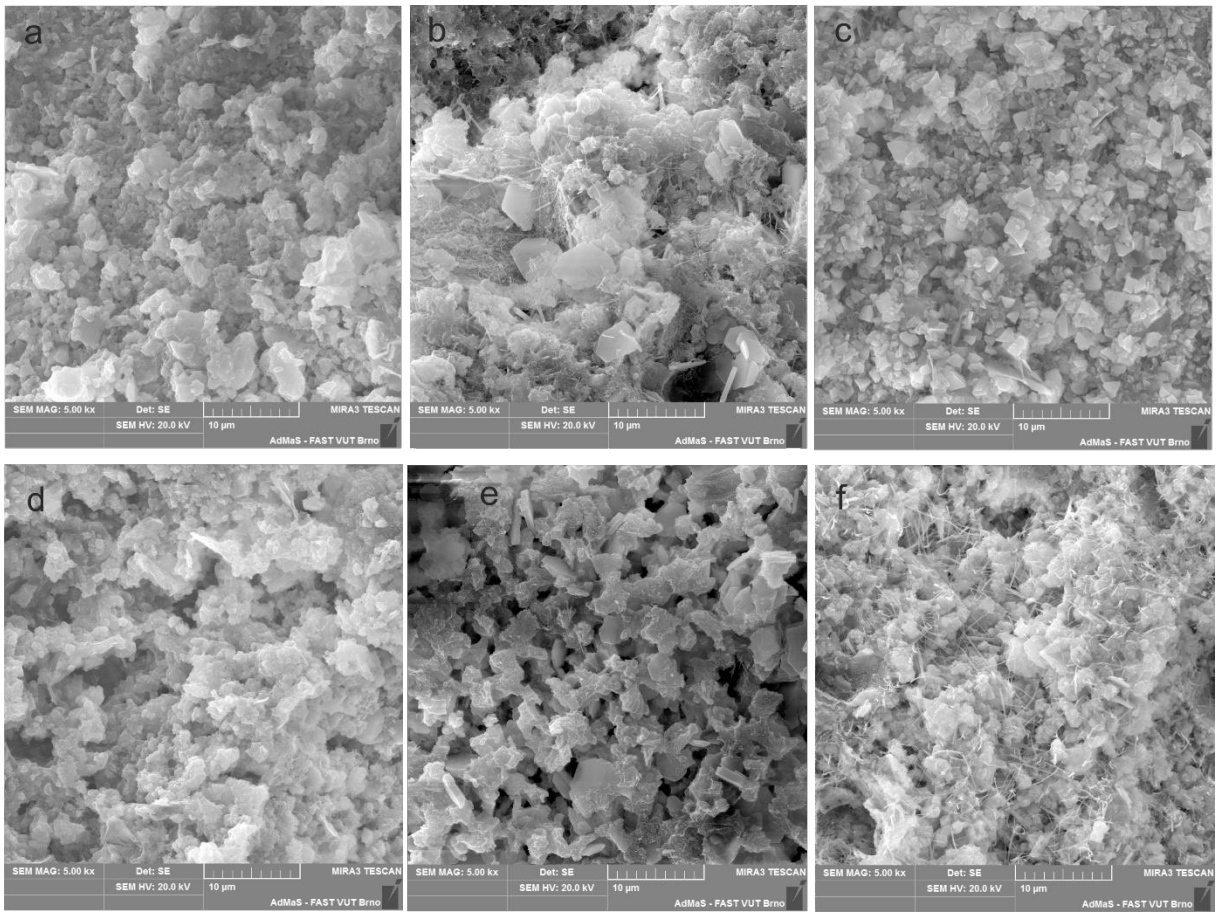

Figure 3. SEM images of L-NZ sample before salt crystallization resistance test (a), after 8 cycles in Na_2SO_4 (b), after 10 cycles in NH_4NO_3 (c), after 6 cycles in NaCl (d), NHL-NZ sample after 7 cycles in NaCl (e), LC-NZ sample after 10 cycles in NaCl (f).

4 Conclusions

- All lightweight aggregates increased the total porosity of mortars in accordance with their decreasing loose bulk density. Enhanced total porosity appears to be beneficial for salt and ice crystallization resistance of the mortars.
- Full replacement of quartz sand with natural lightweight aggregate has led to a considerable improvement in the frost resistance of mortars (except natural zeolite); the best results were obtained using natural pumice.
- Salt crystallization resistance of the mortars was improved by using lava sand and natural pumice, while the mortars with natural zeolite were not resistant to crystallization of sodium chloride. The mortars have relatively little resistance to the reacting of Na_2SO_4, where gypsum and calcium sulfoaluminates were formed breaking the structure of the mortars.
- In terms of salt and ice crystallization resistance, natural pumice seems to be the most suitable natural lightweight aggregate for lime mortars.

Abstract. *The use of waste in civil-engineering products, such as concrete and asphalt mixes, is a very effective strategy for reducing high consumption levels of Natural Aggregates (NA) in the construction sector. In this research, rejected precast concrete elements of high compressive strength are studied, following their crushing for use as a high quality Recycled Concrete Aggregate (RCA) in the manufacture of Self-Compacting Concrete (SCC). High volumes of this waste stream are employed in the mixture, completely replacing the coarse fraction of the natural aggregate (100% replacement rate) and half of the fine fraction (50% replacement rate). Once hardened, samples of the recycled SCC are exposed to several aggressive external agents, in order to evaluate their performance and durability in aggressive environments. Behavioral tests on the concrete in the presence of the most frequent aggressive agents in the surrounding environment demonstrated that the SCC containing RCA was resistant to freeze/thaw and moist/dry cycles, and sulphate attack, according to the results obtained in 4, 3 and 2 samples respectively, and of sufficient durability for use in structural concrete components.*

Keywords: *Self-Compacting Concrete, Recycled Concrete Aggregate, Freeze/Thaw Test, Moist/Dry Test, Sulphate Attack Test.*

1 Introduction

Modern-day society currently faces two immense environmental problems: climate change and the lack of natural resources (IPCC, 2014). Climate change is mainly due to the emission of greenhouse gases, resulting from a wide range of collective human actions related to manufacturing, transport, and energy production. High consumption in some areas of natural resources has led to shortages over recent years, as expanding populations need continual development of technology and infrastructure.

The construction sector is a major contributor to these problems (Sandanayake *et al.*, 2019): the cement industry emits high volumes of CO_2 (Maddalena *et al.*, 2018) and many other construction activities have a high carbon footprint (Noh *et al.*, 2018). Aggregate consumption in asphalt mixes, and concretes is also very high, in the order of 80% and 95% by volume. (CESCE, 2018). According to the Asociación Nacional de Empresarios Fabricantes de Áridos (ANEFA) [National Association of Aggregate Manufacturers of Spain], in 2017, 112 million tons of aggregates were consumed in Spain (ANEFA, 2018). The sector therefore has some responsibility to contribute to the reduction of these problems.

Aggregate substitution in several materials, including concrete, by different types of waste, such as rubber, slag, and even Recycled Concrete Aggregate (RCA), is an area of study that has opened several research lines (Busic *et al.*, 2018; Safiuddin *et al.*, 2013; Verian *et al.*, 2018). Hence, the use of RCA in this study is evaluated for the manufacture of concrete.

The mechanical performance of vibrated concrete with RCA is well-known: RCA, especially the fine fraction, decreases compressive strength (Evangelista *et al.*, 2014; Silva *et al.*, 2015). Durability is also affected, because of the high porosity of the attached mortar, which raises permeability levels and the entry of external agents (Guo *et al.*, 2018).

Self-Compacting Concrete (SCC) is of greater fluidity, so its porosity is lower. RCA can even improve its durability and enhance some other properties (Boudali *et al.*, 2016; Pereira-De-Oliveira *et al.*, 2014). The RCA effect on mechanical properties will not change due to self-compactability (Fiol *et al.*, 2018; Grdic *et al.*, 2010). Nevertheless, there is a scarcity of studies on precise definitions of the RCA effect.

In line with the above, the durability of an SCC design consisting of 100% coarse RCA and 50% by volume of fine RCA will be evaluated in this research. This concrete underwent three tests: behavior during freeze/thaw and moist/dry cycles, and resistance to sulphate attack, demonstrating its performance when exposed to highly aggressive environmental agents.

2 Materials

Three types of materials were employed: RCA, natural aggregates (NA), and non-aggregate.

CEM I 52.5 R with a density of 3.1 kg/dm^3 was employed as a non-aggregate material. Water was obtained from the mains water supply system of Burgos. Two admixtures were also used: a viscosity adjuster (called admixture 1) and a superplasticizer (called admixture 2). Previous studies showed that, if the amount of water is optimal, the quantity of these admixtures will range between 0.5-1.5% of the cement weight (Fiol *et al.*, 2018).

Only the fine NA fractions were used. Siliceous sand with a density of 2.58 kg/dm^3 and a 24h water absorption of 0.25% was used. In addition, SCC requires a large fines content for acceptable flowability, so limestone sand 0/1.2mm (density of 2.62 kg/dm^3 and a 24h water absorption of 2.08%) and limestone filler <0.063 mm (density of 2.77 kg/dm^3) were used.

The RCA consisted of rejected precast elements with a characteristic compressive strength of 40-45 MPa prior to crushing. The crushed RCA was sized between 0 and 30 mm, for which reason it was screened to obtain the desired fractions: the fine fraction 0/4 mm (density of 2.37 kg/dm^3 and 24h water absorption of 7.36%) and the coarse fraction 4/12.5 mm (density of 2.42 kg/dm^3 and 24h water absorption of 6.25%). Particles larger than 12.5 mm were discarded, because they were considered too large to make an SCC.

The appearance of the aggregate and their granulometry are shown in Figure 1 and Figure 2.

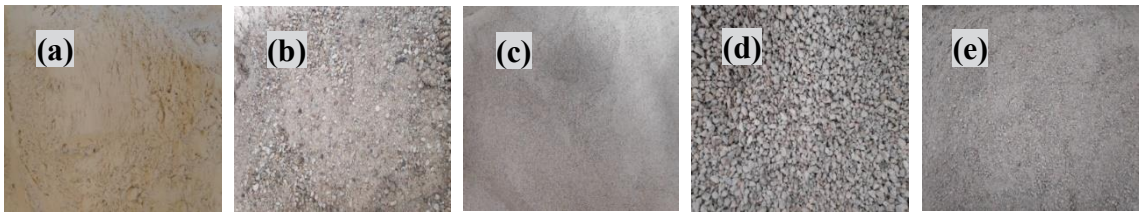

Figure 1. Appearance of the aggregates used for the manufacture of the SCC: a) Limestone filler <0.063 mm; b) Siliceous sand 0/4 mm; c) Limestone sand 0/1.2 mm; d) Coarse RCA 4/12.5 mm; e) Fine RCA 0/4 mm.

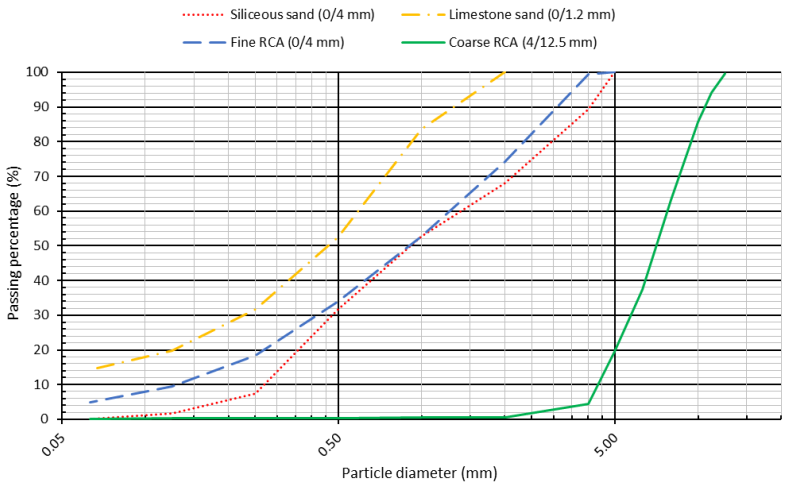

Figure 2. Aggregate granulometry.

3 Mix-Design

The SCC under evaluation was designed with the materials detailed in the preceding section and labelled SCC-I-50/100-D.

The dosage of the SCC was designed, so that neither segregation nor exudation would affect the final SCC and so that it would have an SF2 slump-flow class (maximum diameter between 650 and 750 mm). Design by trial and error began with a very common dosage in the precast cement component industry as the initial dosage. The results of a slump-flow test, norm EN 12350-8 (EN-Euronorm.), suggested adjustments to the proportions of the materials in a second stage. The process of trial and error was repeated several times (third dosage, forth one…) until the definitive optimal dosage was obtained: 296 kg/m^3 of cement, 122 kg/m^3 of filler, 183 kg/m^3 of water, 522 kg/m^3 of coarse RCA, 570 kg/m^3 of fine RCA, 343 kg/m^3 of siliceous sand 0/4 mm, 215 kg/m^3 of limestone sand 0/1.2 mm, 2.20 kg/m^3 of admixture 1, and 4.35 kg/m^3 of admixture 2. In Figure 3, some slump-flow trials during the design process can be observed.

Figure 3. Dosages by trial and error during the development of the SCC: a) Initial dosage; b) Dosage with high segregation in the central area: c) Dosage with minimal segregation in the central area; d) Optimal dosage.

4 In-Fresh State Behavior

The slump flow test is insufficient in itself to ensure optimal SCC flowability and further characterization of the in-fresh state behavior is necessary (EFNARC, 2002).

- The slump flow test was performed first (EN 12350-8). A diameter of 500 mm was

achieved in 4 s, being the maximum diameter 720 mm (SF2 slump-flow class).

- Viscosity was measured by the time it took the SCC mix to pass through a V-funnel (EN 12350-9), which took 7s (viscosity class VF1, time under 8s).
- The 2-bar L-box test (EN 12350-10) measured the passing ability of the SCC. The quotient between the maximum and the minimum height was 0.97 (passing-ability class PA1, quotient greater than 0.80 and 2-bar L-box).
- The sieve segregation test (EN 12350-11) assessed the segregation resistance. The result obtained was 0.41% (SR2 class, segregation lower than 15%).

5 Compressive Strength

Compressive strength at different ages was measured, to guarantee its structural suitability. Two specimens were tested at each age (1, 7 and 28 days),

At 1 day, the normalized sample already had a high compressive strength (28 MPa, 61.4% of 28-days strength). Increased strength over the first seven days was very fast (84.0% of the final strength was reached at 28 days, 38.3 MPa). After three weeks, the compressive strength increase slowed down, reaching 45.6 MPa at 28 days. The SCC could therefore be suitable for precast elements (compressive strength greater than 45MPa).

6 Durability

Three durability tests were performed as part of the analysis of the effects of aggressive external agents: freeze/thaw and moist/dry test cycles, and sulphate attack. All the tests began on the same day. 10 cm-side cubic samples cured over 30 days were used. On first day of the tests, the compressive strength, measured on two cubic samples, was 47.61 MPa on average, which subsequently became the reference for any quantifiable decrease in compressive strength.

6.1 Freeze/Thaw Test

Freeze/thaw tests were performed according to UNE-CEN/TS-12390-9-EX (2008) (CEN). Four 10 cm-side cubic samples were introduced into a container full of water with 3% by mass of NaCl and subjected to 56 freeze/thaw cycles. In each 24h cycle, the container was exposed to 16h of freezing at a temperature of -15ºC and to 8h of thawing in water at 20ºC. Any loose materials were removed every 10 cycles and the specimens were then dried and weighed. Figure 4 shows the loss of mass and, Figure 5, the initial and final state of the test specimens.

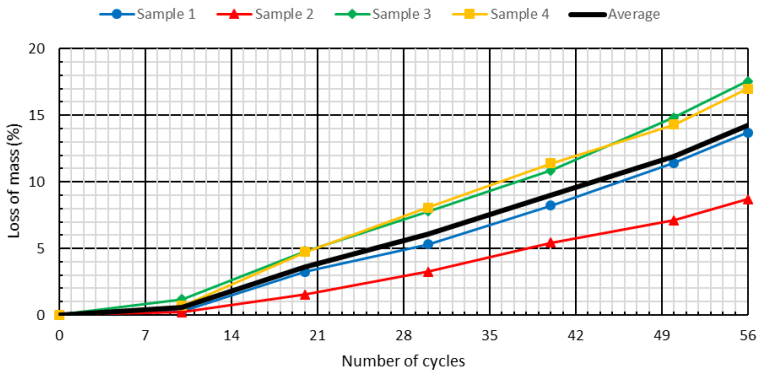

Figure 4. Loss of mass over freeze/thaw test. Average loss of mass at the end of the test: 14.23%.

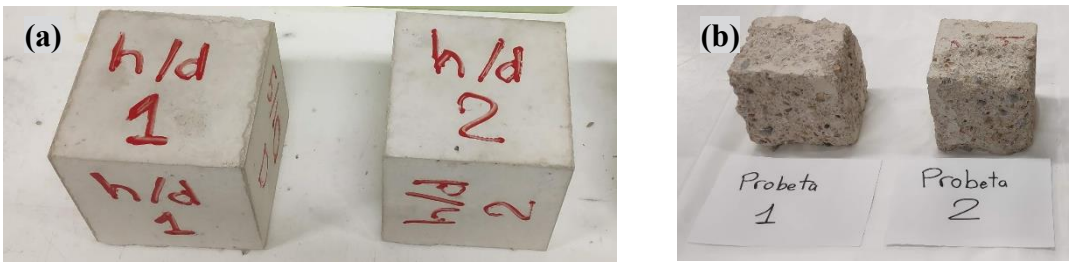

Figure 5. Freeze/thaw test: A) Initial state; B) Final state.

In addition to loss of mass, Ultrasonic Pulse Velocity (UPV), an indirect measure of compressive strength, was evaluated both before and after the test. The strength was also measured after the test. All the results are shown in Table 1.

Table 1. Freeze/thaw test. Results related to UPV and compressive strength.

Test/Sample	Sample 1	Sample 2	Sample 3	Sample 4	Average	Standard deviation
UPV before the test (km/s)	3.95	3.57	3.72	3.51	3.69	0.20
UPV after the test (km/s)	3.13	3.11	3.28	3.07	3.15	0.09
Comp. strength after the test (MPa)	37.06	20.94	32.62	34.46	31.27	7.12
UPV average variation (%): -14.67%		Comp. strength average variation (%): -34.32%				

The decrease in compressive strength was high, unlike the loss of mass. A decrease that could be due to the increased volume of water that expanded when frozen, opening internal micro-voids in the mortar that had adhered to the aggregate (a process that the mortar assists, because of its high porosity). It all caused a sharp decrease in compressive strength.

6.2 Moist/Dry Test

This test was performed by adapting the test in the ASTM D 559 standard (ASTM-International, 2008) that simulates the effects of rain and subsequent drying by solar radiation on concrete. Fundamentally, the thermal shock inflicted during the changeover from a wet to a dry situation. To do so, three 10 cm-side cubic specimens were subjected to 30 24-hour cycles, which consisted of full immersion in water at a temperature between 18ºC and 22ºC, over 16h, followed by oven drying for 8h at 60ºC.

The external appearance of each sample after the test is shown in Figure 6. Every 10 cycles, each specimen was weighed and its UPV was measured, a parameter that had also been measured before the beginning of the test. When the trial ended, the samples were tested to compressive strength. The results obtained can be seen in Table 2.

Figure 6. Moist/dry test. Final state of the samples.

Table 2. Results of moist/dry test.

Test/Sample	Sample 1	Sample 2	Sample 3	Average	Standard deviation
Initial mass (g)	2,068.8	2,189.1	2,094.1	2,117.33	63.42
Mass after 10 cycles (g)	2,043.5	2,152.0	2,047.1	2,080.87	61.63
Mass after 20 cycles (g)	2,022.2	2,146.3	2,044.8	2,071.10	66.10
Mass after the test, 30 cycles (g)	2015.8	2,140.0	2,043.9	2,066.57	65.13
UPV before the test (km/s)	3.72	3.79	3.64	3.71	0.08
UPV after the test (km/s)	2.60	2.65	2.56	2.60	0.04
Comp. strength after the test (MPa)	35.00	32.92	32.17	33.36	1.47
Mass average variation (%): -2.40%		UPV average variation (%): -29.87%			
Compressive strength average variation (%): -29.93%					

The external appearance (without appreciable changes except the increased number of external voids on sample Nª3) and the loss of mass showed no visible change in the concrete. However, the compressive strength and the UPV showed significant changes at a microscopic level. Both changes could be explained by the appearance of larger internal micro voids than in the freeze/thaw test. Nevertheless, the decrease in compressive strength was very similar in both the moist/dry test and the freeze/thaw test. It appears that the large number of micro voids in the moist/dry test was compensated by the negligible loss of mass.

6.3 Sulphate Attack Test

This test was performed according to the ASTM C 1012 standard (ASTM-International, 2008), in which the concrete is exposed to sodium sulphate decahydrate that crystallizes within the sample, thereby increasing its volume. Each of the 15 24-hours cycles consisted of a 5-hour immersion in water with 14% by mass of $Na_2SO_4 \cdot 10H_2O$, oven drying for 17h at 60ºC and cooling at room temperature (23ºC) for 2h.

The final appearance of the two specimens tested is shown in Figure 7. No visible change was detected, except discoloration in the form of darkening, due to sodium sulphate precipitation. Before and after the trial the samples were weighed, the length of their sides was measured (in order to determine the expansion of concrete by the absorption and crystallization of the salt) and the UPV was determined. In addition, both specimens were tested to compressive strength. All the results are indicated in Table 3.

Table 3. Sulphate attack test. Individual and average results.

Test/Sample	Sample 1	Sample 2	Average	Standard deviation
Initial mass (g)	2,098.8	2,199.2	2,149.0	70.99
Final mass (g)	2,083.9	2,193.3	2,138.6	77.36
Initial average side length (mm.)	100.11	100.33	100.22	0.16
Final average side length (mm.)	100.13	100.34	100.24	0.15
UPV before the test (km/s)	3.69	3.58	3.64	0.08
UPV after the test (km/s)	3.38	2.63	3.01	0.53
Compressive strength after the test (MPa)	41.44	35.68	38.56	4.07
Mass average variation (%): -0.48%	Side expansion (%): +0.02%			
UPV average variation (%): -16.62%	Comp. strength average variation (%): -19.01%			

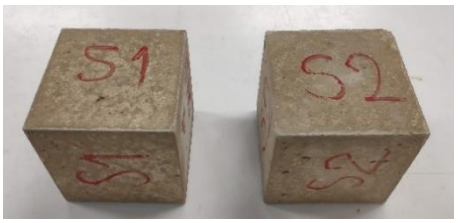

Figure 7. Sulphate attack test. Final state of the samples.

Neither the variation in either mass or length nor in the external appearance of the concrete samples showed relevant changes. The only noticeable effect was the reduction in compressive strength and the logical decrease in UPV. Nevertheless, compressive strength was less effected by the sulphates than by consequences of exposure to water in the moist/dry test. This difference can be explained by the high flowability of SCC, which implies that the concrete had a very low number of small-sized surface pores in the hardened state. Hence, the penetration of higher density solutions within the concrete was less likely, because water with no salt solutions penetrates with greater ease through surface pores than a sulphate solution, meaning that the sulphate effect would be lower towards the interior of the sample.

7 Conclusions

The following conclusions can be drawn from the study reported in this paper:

- Correct dosage design of an SCC with large amounts of both coarse and fine RCA will result in high flowability in the fresh state and a high compressive strength.
- A good design will mean that the SCC with RCA can be used in environments with aggressive external agents, with high precipitation and frequent frosts. These agents adversely affect the properties of the concrete, although the affections are not critical.
- The durability of the SCC exposed to aggressive external agents is linked to their external porosity. In other words, the greater the ease with which the external agent penetrates within the concrete, the worse the effect of those agents on the concrete.
- The concrete samples showed uniform behavior in all the tests, with similar results for all specimens, although those test results can vary depending on the surface finish. The homogeneity and workability of the mix was optimal when the specimens were manufactured, clearly demonstrating the uniform behavior and the durability of this SCC concrete for use in structural elements. This conclusion is based on the results obtained on four specimens in the freeze/thaw test, on three samples in the moist/dry test and two specimens in the sulphate attack test.

Abstract. *This paper is the study of sulfate attack resistance of reactive powder concrete (RPC). RPC that is also known as ultra-high performance concrete is a special type of concrete material obtained when fine powders like silica fume (SF) are added into the concrete mortar along with very low water-to-binder ratio (w/b). SF is a pozzolanic material obtained as a by-product of silicon metal or ferrosilicon alloys production. In this study, total 6 different RPC mixtures with various w/b (0.18, 0.22 and 0.26) and various SF content were studied. SF was added into the concrete mixtures in the amount of 15%, 20% and 25% of cement by weight. The other testing parameter includes 3 different concentrations of sodium sulfate (Na_2SO_4) solutions (0.35 M, 0.7 M and 1.4 M concentrations). Broad laboratory investigations of behavior of the RPC mixtures were conducted in terms of compressive strength and mass gain of cubes (50×50×50 mm^3) and expansion and mass change as in accordance with ASTM C1012. Test results had been analyzed and assessed by Taguchi method. The significance level of experimental parameters was determined by using Analysis of variance (ANOVA) method. According to statistical and analytical results it was observed that RPC has high sulfate attack resistance. Moreover, addition of optimal amount of SF into the RPC mixtures as well as decreasing w/b can significantly improve Na_2SO_4 resistance of RPC.*

Keywords: *Reactive Powder Concrete, Taguchi Method, Silica Fume, Sulfate Attack Resistance.*

1 Introduction

Sustainable development concept has recently become one of the most important topics in the construction industry. Moreover, development of alternative sources of energy in the face of energy crisis due to limited natural resources is foremost issue of the industry. Compressed air energy storage system incorporated into pile foundation system of the apartment building is proposed as a viable alternative to accumulating excess energy from solar panels installed on the building during the off-peak hours to be able to use it during the increased demand periods (Tulebekova *et al.*, 2017, Zhang *et al.*, 2018). Hence, complex structural and internal loading conditions require the piles to be made of superior performance material such as ultra-high performance concrete (Tulebekova *et al.*, 2019). Reactive Powder Concrete (RPC) is a type of

ultra-high performance concrete that is obtained by removing coarse aggregates from and addition of pozzolanic materials like silica fume (SF) to the concrete along with very low water-to-binder ratio (w/b) (Sun *et al.,* 2015). RPC has a densified microstructure that is attributed to the removal of coarse aggregates and the pozzolanic reaction that lead to the formation of strong bonds in interfacial transition zone due to the increased formation of strong calcium silicate hydrate lattices (Beglarigale and Yazıcı, 2015). It was investigated that the optimization of SF content and w/b results in the RPC with very high compressive and tensile strength (Ahmad *et al.,* 2015; Bektimirova *et al.,* 2018). Moreover, compressive strength of RPC could be increased further by optimization of packing degree of small aggregate (Ji *et al.,* 2011, Bektimirova *et al.*, 2020). Nevertheless, RPC is a relatively new type of concrete material, and its durability properties is still an ongoing topic of research.

External sulfate attack (ESA) is a concrete durability issue arising from the migration of sulfate ions from surrounding soils into the concrete structure, resulting in the series of chemical reactions and physical processes that cause irrecoverable damage to material (Marchand *et al.,* 2003). Even though the exact mechanism of sulfate attack is still questionable, it is agreed that the physical damage in the material occurs through the formation of expansive products such as gypsum and ettringite (Tixier and Mobasher, 2003) that leads to dimensional expansion and mass gain of the specimen. Expansive products form in the cracks in the microstructure of concrete and exert pressures that could be sustained by the pore spaces in the material (Ikumi *et al.,* 2019). However, the extensive or prolonged formation of expansive products might lead to the irreclaimable damage to concrete microstructure causing material degradation, loss of cohesiveness and strength (Gu *et al.,* 2019). Although Haufe and Vollpracht (2019) reported that RPC has moderate to high resistance to ESA due to its improved microstructure and reduced porosity, little data are available on the ESA resistance of RPC.

In this study, the ESA resistance of different RPC mixtures was investigated. SF content w/b, and concentration of sodium sulfate (Na_2SO_4) solution were selected as primary factors to influence on the compressive strength and expansion of the RPC mixtures exposed to the ESA environment by Taguchi method. Analysis of variance (ANOVA) was used to assess the significance level of experimental parameters.

2 Experimental Program

2.1 Materials

Ordinary Portland cement (ASTM type I) and SF with specific gravities 3.15 and 2.22 correspondingly were used as binder materials in this study. The chemical composition of cement and SF is provided in Table 1. Locally available quartz sand with specific gravity 2.4, absorption capacity of 6.2% was used as a fine aggregate for the RPC mixtures.

Liquid superplasticizer (SP) Master Glenium ACE 430 with specific gravity 1.02, and ordinary tap water were used in RPC mixing.

Table 1. Chemical composition of binders.

Components	Cement	SF
CaO [%]	65.91	0.22
SiO_2 [%]	21.55	97.54
Al_2O_3 [%]	5.55	0.2
Fe_2O_3 [%]	4.7	0.06
SO_3 [%]	1.9	-
MgO [%]	1.46	-
K_2O [%]	0.35	-
Loss on Ignition [%]	0.49	2.08

2.2 Mixture Proportion and Levels of Evaluation Variables

The experiments were designed to analyze the influence of various w/b, SF content, and sulfate concentration on the compressive strength and expansion of RPC. Mixture proportioning of RPC mixtures was completed using the absolute volume method. The details of mixture proportion are provided in Table 2.

Table 2. Mixture proportion of RPC (kg/m^3).

No.	Mixture ID	WB	SF	Cement	SF	Sand	Water	SP [% of binder]
1	0.18WB-20SF	0.18	20	1000	200	903	216	2
2	0.22WB-20SF	0.22	20	1000	200	788	264	1.5
3	0.26WB-20SF	0.26	20	1000	200	673	312	1.5
4	0.22WB-15SF	0.22	15	1043	157	802	264	1.5
5	0.22WB-25SF	0.22	25	960	240	776	264	1.5

The Taguchi statistical analysis method was used to determine the optimal mixture that will have the maximum compressive strength and the highest ESA resistance which is determined by the lowest expansion and mass gain during the exposure. Taguchi analysis was performed for 3 factors at a time with 3 levels each. Thus, 2 sets of analyses were performed: first one for w/b, second one for SF content, while sulfate concentration and exposure time were factors of analysis for both sets. Factors and levels of Taguchi analysis are shown in Table 3.

Table 3. Levels of the variables in the experimental program.

Factors	Level 1	Level 2	Level 3
w/b	0.18	0.22	0.26
SF content	15	20	25
Na_2SO_4 concentration	0.35	0.7	1.4
Time of exposure	1 week	4 weeks	13 weeks

2.3 Casting, Curing and Maintaining the Samples

Mixing RPC was completed in pan type mixer with total mixing time of 9±1 min. Immediately after mixing was complete, RPC was placed into the molds: 50 x 50 x 50 mm cube mold as required in ASTM C109 for compressive strength test; and, 25 x 25 x 250 mm prism molds as required by ASTM C1012 for length and mass change test. RPC specimens were cured for 24 hours in molds covered by plastic sheets to avoid water evaporation, after which they were placed into the Na_2SO_4 solution where they were stored until the test date.

2.4 Test Methods

The length and mass change tests of RPC were performed in accordance with ASTM C 1012 and ASTM C490 on the same samples. Accuracy of digital length comparator and digital scales used for measurements of length and mass change are ±0.0001 mm and ±0.001 g correspondingly. The compressive strength test of RPC was conducted in accordance with ASTM C109.

A number of samples are varied from mixture to mixture: 4-8 samples. To achieve better statistical reliability, outliers had been removed from calculated data as in accordance with ASTM E178. The test set up is provided in Figures 1 (a) and 1 (b).

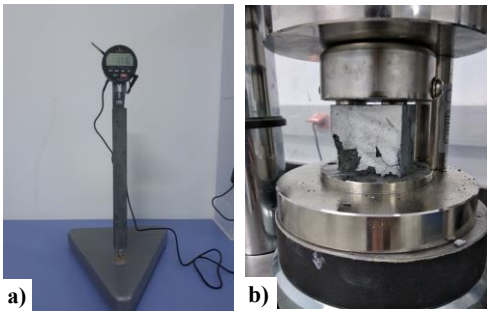

Figure 1. Test setup: (a) length change test; (b) compressive strength test.

3 Results and Discussion

3.1 Statistical Analysis

General Linear Model of analysis of variance (ANOVA) was used to observe statistically important parameters of experiments. Furthermore, to assess the contribution percentage of each parameter to the compressive strength, length and mass change, P-value was used: smaller P-value indicates more affective parameter in the concrete performance characteristics (Lin *et al., 2000*). The results of ANOVA for both sets of w/b-concentration-time and SF content-concentration-time are shown in Table 5.

Table 5. Results of ANOVA for w/b-concentration-time set and SF content-concentration-time set.

Source	SS	MS	F	P-Value	Source	SS	MS	F	P-Value
ANOVA for Compressive Strength of RPC									
w/b	48	24	0.31	0.735	SF	472.6	236.29	2.16	0.142
conc	329.4	164.7	2.15	0.143	conc	143.4	71.72	0.65	0.53
time	4731.02	2365.51	30.86	0	time	4090.2	2045.12	18.67	0
ANOVA for Length Change of RPC									
w/b	0.002954	0.001477	41.65	0	SF	0.001211	0.000605	19.76	0
conc	0.000478	0.000239	6.74	0.006	conc	0.000404	0.000202	6.59	0.006
time	0.000484	0.000242	6.82	0.006	time	0.000353	0.000177	5.77	0.011
ANOVA for Mass Change of RPC									
w/b	6.1525	3.07624	41.31	0	SF	0.3926	0.1963	7.22	0.004
conc	1.1562	0.57808	7.76	0.003	conc	2.604	1.302	47.89	0
time	0.8825	0.44127	5.93	0.01	time	1.0554	0.52768	19.41	0

According to Table 5, time is the most important parameter for compressive strength in both sets of experiments while length change is controlled by w/b and SF factors in w/b-concentration-time and SF content-concentration-time sets respectively. Mass change is also influenced mostly by w/b in w/b-concentration-time set; nevertheless, in SF content-concentration-time set it is affected by time and concentration factors. Hence, it is possible to suggest that time of exposure and RPC mixture content play more important role in ESA resistance of RPC.

3.2 Taguchi Analysis

The "smaller is better" Taguchi's quality loss function for compressive strength, length, and mass change of RPC was used to determine the optimal conditions for both w/b-concentration-time and SF content-concentration-time sets. The loss function is transferred further into utility function called Signal-to-Noise ratio (S/N) developed by Taguchi. S/N allows to identify performance characteristic deviating from desired value (Rahimi et al., 2016). Noise factor is any factor that causes deviation from targeted value for measurable product or process characteristics. Minitab statistical software was used for the statistical analysis of the results which are discussed in following sections.

3.2.1 Compressive strength

The main goal of every experiment is to determine the highest possible S/N value that will indicate that random effects of the noise factors are negligible compared to that of the signal. Fig. 2 shows the S/N ratio of compressive strength for w/b-concentration-time and SF-concentration-time sets.

As presented in Fig. 2, the minimum variation in compressive strength was obtained for the RPC containing w/b=0.26 and SF=25 %. Fig. 2 also shows that optimal values of concentration and curing time are 0.35M and 1-week in both w/b-concentration-time and SF content-concentration-time sets. In fact, compressive strength of RPC generally tends to decrease with

increasing the concentration of Na_2SO_4 solution: The higher concentration of Na_2SO_4 solution, the more deterioration of in RPC performance. It is possible to observe from Fig. 2 that 1.4M Na_2SO_4 solution not only has lower S/N ratio, but also has more damaging effect on compressive strength than 0.7M solution. This result may be attributed to stoichiometry of chemical reaction occurring during the sulfate attack exposure of concrete: As the concentration of Na_2SO_4 solution increases, more sulfate ions penetrate in to the specimen, consequently leading to more deteriorative cracks inside specimen and the reduction of the strength.

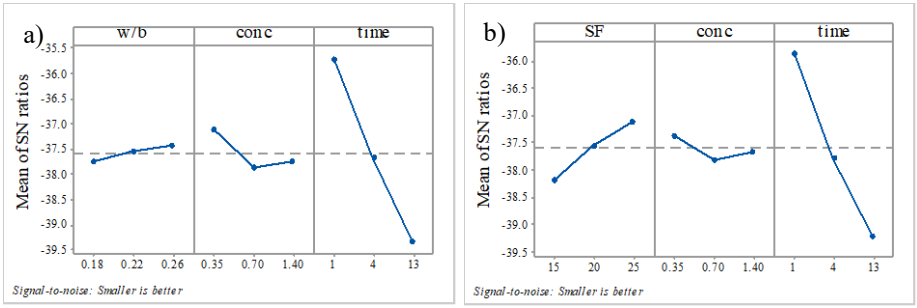

Figure 2. Main effects plots for SN ratios (Compressive strength): (a) w/b-concentration-time set; (b) SF content-concentration-time set.

3.2.2 Length and Mass change

Fig. 3 shows the S/N ratio of length change for two sets of experiments. According to Fig. 3 (a), the minimum variation of length change is created by w/b=0.18 at 0.35M Na_2SO_4 concentration at 1-week exposure. According to Fig. 2 (b) SF content=25 has the most stable reading.

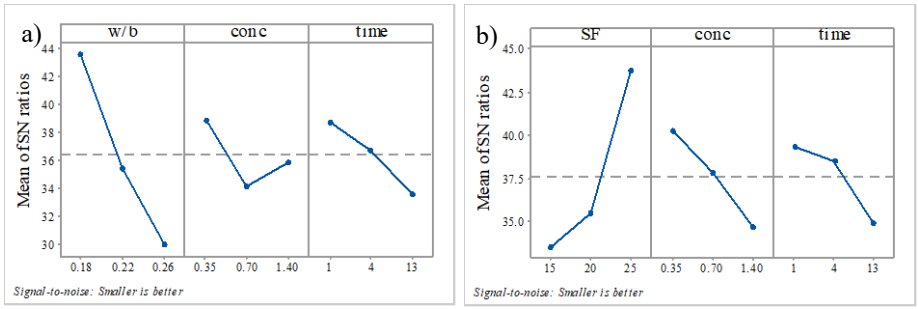

Figure 3. Main effects plots for SN ratios (Length change): (a) w/b-concentration-time set; (b) SF content-concentration-time set.

Fig. 4 shows the S/N ratio of mass change for two sets of experiments. Accordingly S/N ratios of mass change show the same trends as for length change for both sets of experiments. The reason is possibly that the same samples were used for both measurements. Furthermore, expansion of RPC exposed to sulfate attack result in both mass gain and elongation of the sample. Thus, formation and accommodation of expansive products in the RPC internal structure is indicated by the mass gain of the samples. Moreover, the process of accommodation of expansive products (ettringite formation) leads to internal cracking resulting in the expansion

of concrete. Hence, it appears to be logical that both length and mass change measurements show similar statistical behavior as it is observed by Taguchi analysis in this study.

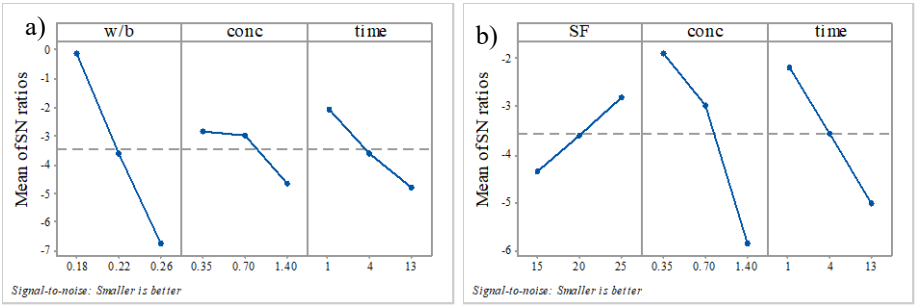

Figure 4. Main effects plots for SN ratios (Mass change): (a) w/b-concentration-time set; (b) SF content-concentration-time set.

4 Conclusion

Sulfate attack is an important durability problem of concrete structures exposed to groundwaters containing sulfate ions as in case of pile foundations. RPC is a relatively new type of material that has superior durability and mechanical characteristics. This study statistically analyzed sulfate attack resistance of RPC in two sets of influence factors. Accordingly, the following conclusions can be made:

- The ANOVA analysis showed that compressive strength of RPC exposed to Na_2SO_4 environment is influenced by time factor for both sets of experiment; while length and mass change are mostly affected by the RPC mixture content (w/b and SF content) and time of exposure.
- Based on Taguchi analysis, it is possible to suggest that optimal w/b=0.18 and optimal SF content=25 % for all three performance characteristics, namely compressive strength, length and mass change.

In conclusion, RPC appears to have high resistance to sulfate attack; however, this study is limited by the statistical analysis of standard test methods. Thus, more comprehensive study of sulfate attack resistance of RPC considering temperature effect and other types of sulfate solution may be needed to assess the resistance of RPC to sulfate attack incorporated with statistical analysis.

Abstract. *Concrete cracking caused by drying shrinkage adversely affects the durability of a structure. The results of past research has shown that drying shrinkage can be reduced by adding urea as an admixture to the concrete. However, mixing various admixtures at the factory increases the costs for equipment and labor. To reduce drying shrinkage more easily and inexpensively, the urea solution can be applied to the concrete surface by soaking or brushing. However, urea solutions are not suitable for use in cold weather because urea in solution crystallizes at low temperatures. This study attempted to solve this problem by mixing antifreeze, which resists freezing, with a urea solution. It was found that the crystallization temperature of urea can be lowered by mixing the urea solution the antifreeze. Furthermore, it was confirmed that the antifreeze/urea solution reduced drying shrinkage for both mortar and concrete.*

Keywords: *Urea Solution, Drying Shrinkage, Soaking, Antifreeze, Cold Weather.*

1 Introduction

Concrete cracking caused by drying shrinkage adversely affects the durability of a structure. Adding urea to concrete is an effective method for reducing drying shrinkage[1)]. However, in ready-mixed concrete factories in Japan, adding various admixture materials to concrete will increase equipment and labor costs. Moreover, drying shrinkage occurs mainly on the surface of concrete, so applying an agent to the surface is more efficient and economical. This paper describes a method of applying urea solution to the surface of concrete after demolding that efficiently and economically reduces drying shrinkage.

2 Past Achievements

In previous studies, specimens soaked in a urea solution had less drying shrinkage than untreated specimens (Figure 1). Moreover, the amount of drying shrinkage continue to fall as the soaking time increased[2)]. However, soaking concrete in a urea solution of site is not practical, so an experiment was conducted in which urea solution was brushed onto the surface of the concrete. It was found that the brushing method provide an equal or greater effect on drying shrinkage as soaking[3)].

On the other hand, the specimens had higher compressive strength after soaking in a urea solution, as shown in Figure 2. Moreover, the strength increased as the soaking time increased. These results were likely due to the urea solution entering the concrete and the urea recrystallizing in the voids. The expansion pressure from the urea crystals helped to reduce the drying shrinkage and increase the compressive strength. The water retention effect of the urea crystals may also prevent the dissipation of moisture inside the concrete, which also helped to suppressing drying.

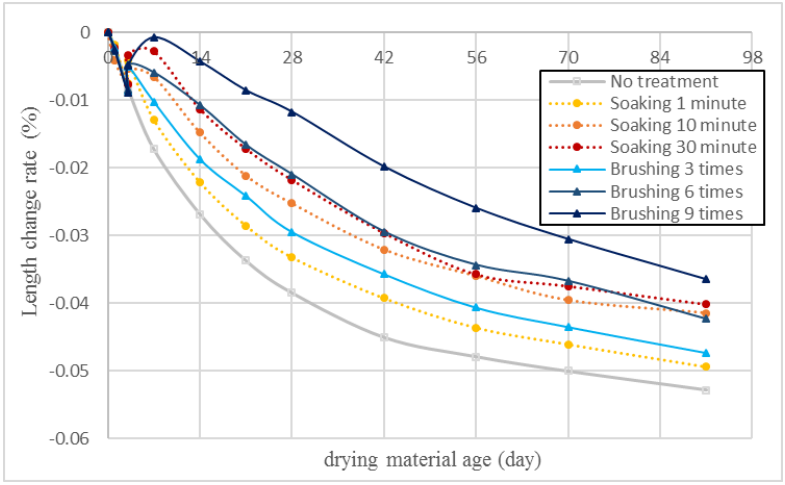

Figure 1. Drying shrinkage reduction.

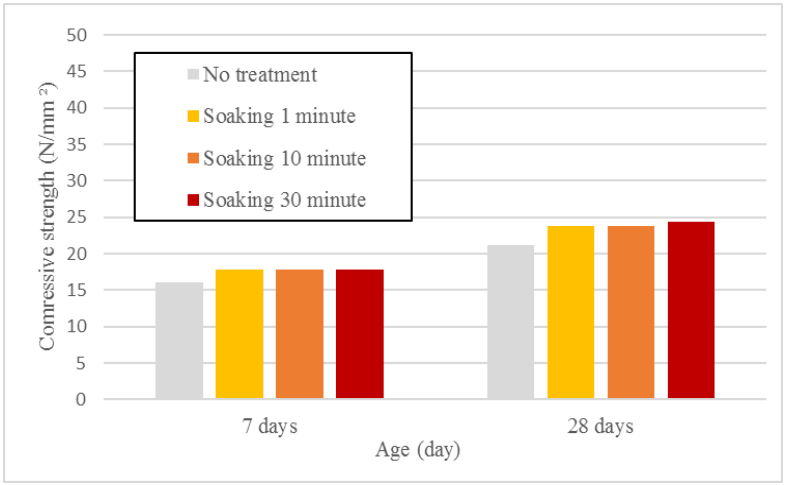

Figure 2. Result of compressive strength test.

3 Applying Antifreeze in Cold Weather

3.1 Outline

Previous studies have shown that applying a urea solution to concrete helps to reduce drying shrinkage. However, the solubility of urea decreases at lower temperatures, causing the urea in the water to crystallize and separate out. In cold weather, the urea crystallizes before the solution can be applied to the concrete, thereby reducing the solution's effect on drying shrinkage. To prevent the crystallization of the urea in the solution at low temperatures, antifreeze with freezing resistance was added to the solution. This lowered the crystallization temperature, allowing the urea solution to be used in cold weather.

3.2 Crystallization Temperature of Urea When Antifreeze is Mixed at Different Rates

The freezing resistance property of the antifreeze can be varied by adjusting its concentration

in the urea solution. Therefore, this study investigated the effect of different concentrations of antifreeze on the crystallization temperature of urea in a solution.

3.2.1 Antifreeze mix solution

In this test, a commercially available antifreeze used for air conditioner or refrigeration facility was used. The main component of this antifreeze is ethylene glycol. In order to produce different freezing temperatures, the ratio of antifreeze to water were set to 3:7, 4:6 and 5:5 (Figure 3). Moreover, in order to make comparisons with a urea solution containing the maximum amount of urea that can dissolve in water at 20 (°C), the maximum amount of urea that can dissolve at 20 (°C) was added to the antifreeze solution.

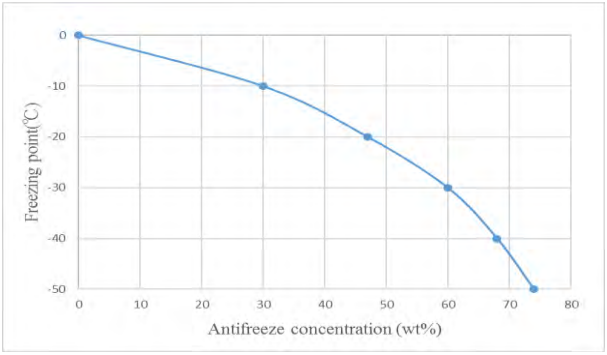

Figure 3. Freezing point of antifreeze.

Photo 1. Antifreeze concentrations in a solution.

3.2.2 Test method

Photograph 1 shows the different antifreeze concentrations in a urea solution. First, solutions with different antifreeze concentrations were placed in transparent containers. Next, the temperature of the solutions was lowered by immersing the containers in ice water. Using a thermometer, the crystallization temperature (the temperature at which urea crystals formed) was measured.

3.2.3 Test result

As shown in Table 1, the crystallization temperature decreased as the concentration of antifreeze increased. Therefore, it was considered that antifreeze solutions can be applied to concrete in cold weather to reduce drying shrinkage.

Table 1. Crystallization temperature of urea.

Name	Component (mass ratio) Antifreeze : Water : Urea	Crystallization temperature (°C)
Antifreeze 30%	3 : 7 : 8	5
Antifreeze 40%	4 : 6 : 7	4
Antifreeze 50%	5 : 5 : 6.5	1
Urea solution	0 : 1 : 1	8

3.3 Effect of a 30 % Antifreeze Solution on Shrinkage Reduction in Mortar

3.3.1 Materials

Table 2 shows the materials used in this test.

3.3.2 Mix condition

Table 3 shows the mixing conditions and the properties of the fresh mortar. The target values were 200 ± 20 mm for 15 strokes flow, 2.0 ± 1.5 % for the air volume.

3.3.3 Mixing method

For mixing, an omni type mixer with a nominal capacity of 10 liters was used. First, cement and sand were mixed for 15 seconds. Next, water was added and mixed for 60 seconds. Finally, the mortar was discharged.

Table 2. Materials.

Type	Name	Symbol	Density g/cm^3

The 15 stroke flow test was carried out in accordance with ISO 679 2009.
(2) Air volume test
The air volume test was carried out in accordance with ISO 1920-2 2016.
(3) Drying shrinkage test
The drying shrinkage test was carried out in accordance with ISO 1920-8. Figure 4 shows the method used for this test. Prismatic specimens (40 × 40 × 160 mm) were made for this test. The specimens were demolded one day after mixing, and this day was taken as day 0 for the start of air curing. The specimens were cured in a room at a constant temperature of 20 ± 3 (°C) and 60

± 5 % relative humidity and changes in length and mass were measured. Next, some specimens were soaked in a 30% antifreeze solution for 1 minute, 10 minutes, and 30 minutes (Table 1). Other specimens were not soaked. Changes in the length and mass of all of the specimens were measured for 91 days.

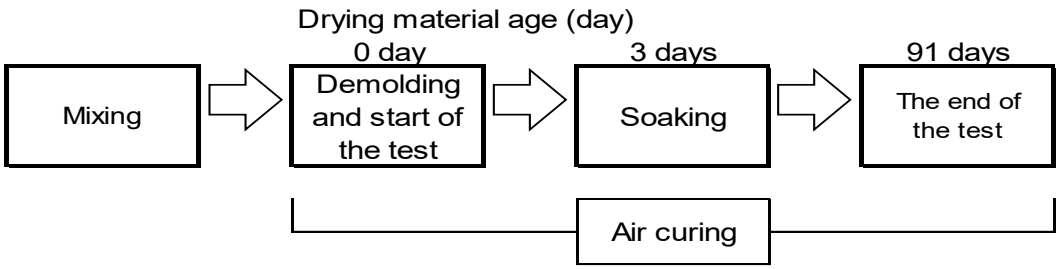

Figure 4. Method used for drying shrinkage test.

3.3.5 Test results

The results of the drying shrinkage test of mortar show that the specimens soaked in a 30% antifreeze solution exhibited a greater drying shrinkage effect than the specimens that were not soaked (Fig. 5). Moreover, the effect became larger as the soaking time increased.

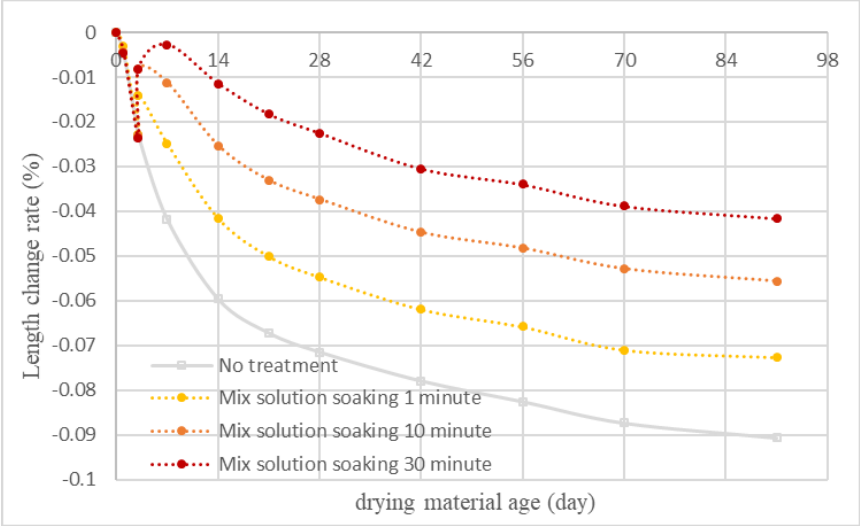

Figure 5. Drying shrinkage test of mortar.

3.4 Concrete Soaked in 30 % Antifreeze Solution

Since the 30% antifreeze solution clearly reduced drying shrinkage in mortar, the same experiment was conducted using concrete.

3.4.1 Materials

The materials used were the same as those described in section 3.3.1 above.

3.4.2 Mixing conditions

Table 4 shows the mixing conditions and properties of fresh concrete. The target values of the

freshness properties were 8.0 ± 1.5 cm for slump, 4.5 ± 1.5% for air volume.

Table 4. Mixing conditions and properties of fresh concrete.

W/C (%)	Unit quantity (kg/m³)				Addition rate (C×%)	Air volume (%)	Slump (cm)
	W	C	S	G	SP		
50	170	340	798	969	0.10	4.0	8.5

3.4.3 Mixing method

A pan type mixer with a nominal capacity of 55 (L) was used for mixing. First, cement, sand, and gravel were mixed for 15 seconds. Next, water mixed with SP was added and mixed for 60 seconds. Finally, the concrete was discharged.

3.4.4 Test items

(1) Concrete slump test
The concrete slump test was carried out in accordance with ISO 1920-2 2005.
(2) Air volume test
The air volume test was carried out in accordance with ISO 1920-2 2016.
(3) Drying shrinkage test
The drying shrinkage test was carried out using the same method and room conditions used for the mortar experiment, but with 100 × 100 × 400 mm prismatic specimens.
(4) Compressive strength test
The compressive strength test was carried out in accordance with ISO 1920-8. After demolding on day 1, the specimens were cured in a room at a constant temperature of 20 ± 3°C and 60 ± 5 % relative humidity. but soaked in antifreeze mix solution at 3rd day. Then the compressive strength tests were conducted at age of 7 and 28 days.

3.4.5 Test result

The test results confirmed that soaking concrete in a 30% antifreeze solution reduces drying shrinkage (Fig. 6). Previous studies have shown a drying shrinkage reduction effect when specimens are soaked in a urea solution. This study showed that antifreeze solutions also reduce drying shrinkage. Urea recrystallizes in the voids of concrete after soaking in an antifreeze solution also reduce drying shrinkage due to the recrystallization of urea in the voids of the concrete.

Figure 7 shows the results of the compressive strength test. As shown in previous studies, this study confirmed that soaking concrete in an antifreeze solution increased the compressive strength. Moreover, the strength increased as the soaking time increased. The urea crystals help improve compressive strength.

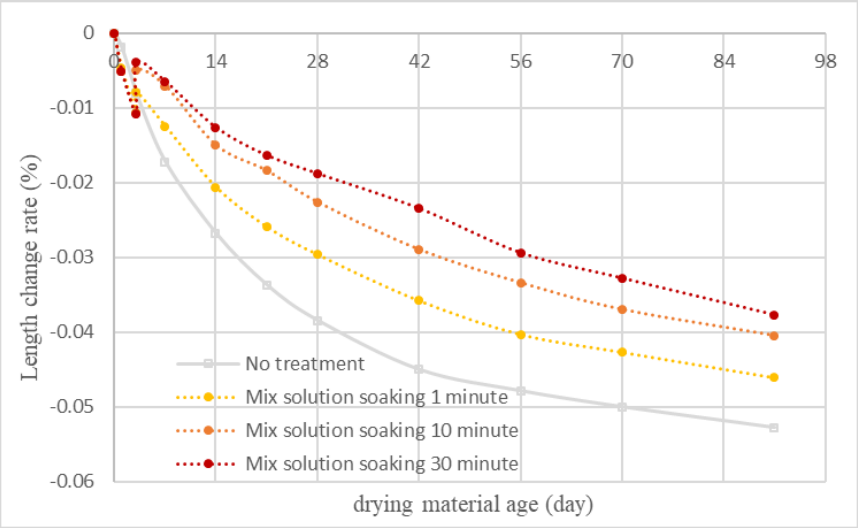

Figure 6. Drying shrinkage test of concrete.

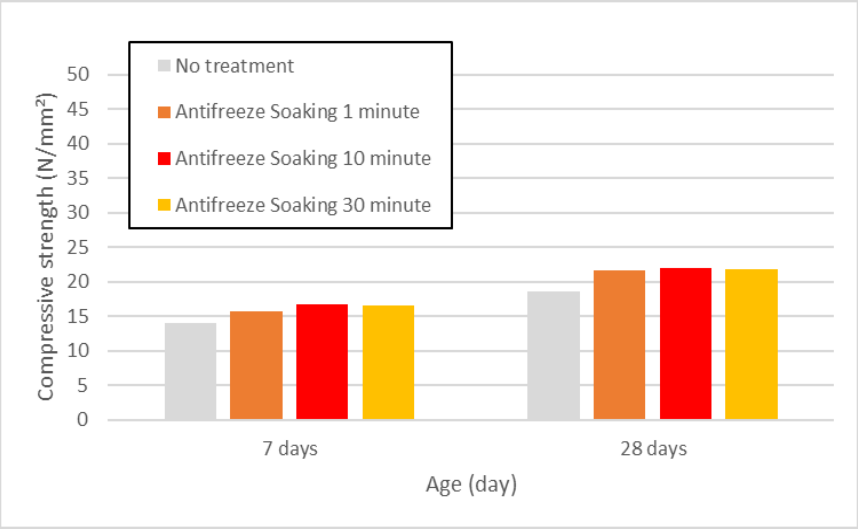

Figure 7. Compressive strength.

3.5 Conclusion

This study showed that the crystallization temperature of urea can be lowered by mixing it with antifreeze. Furthermore, soaking the concrete in an antifreeze solution reduces drying shrinkage, as indicated by the lower length change rate in the drying shrinkage test. These results confirm that an antifreeze solution can be used as a drying shrinkage reduction agent in cold weather. The practical application of this method in the field, however, requires further study.

The Durability of Plant-Based Air Filtering Systems in Buildings: From an Air Quality and Energy Reduction Perspective

Ahu Aydogan

Bernard and Anne Spitzer School of Architecture, City College of New York, NY 10031, USA,
aaydogan@ccny.cuny.edu

Abstract. *After the oil crisis, all the commercial and residential buildings were designed with tightly sealed envelopes to minimize the air leakage through the building to save energy. Since buildings were no longer able to breathe naturally, indoor air quality problems started to occur. Currently, there is still a dilemma between these two parameters inside the buildings. To address IAQ issues and reduce the energy loads in mechanical conditioning systems, the plant-based air filtering system is designed. The proposed system is a hydroponic system (plants growing without soil) that is composed of a mixed bed of activated carbon adsorbents and porous glass stones that capture and filter the toxins in the air. HVAC-integrated plant walls that include growth media are designed to support the plants and capturing toxins. These toxins are then metabolized by the plants which can create a self-regenerating filtration system that requires less outdoor air being fed into the building, thereby reducing the conditioning costs associated with HVAC. This paper is focused on the durability of the design and fabrication of a plant-based air filtering system from an air quality and energy reduction perspective.*

Keywords: *Filter, Indoor Air Quality, Mechanical Conditioning Systems, HVAC, Hydroponics.*

1 Introduction

Buildings and construction operations are responsible for about 40% of the final energy consumption and generation of energy-related carbon dioxide (UN, 2017) In mechanically ventilated buildings, most of the energy consumption is related to the heating and cooling outdoor air and distributing it internally (Chan, 2010; Hughesa, 2011). The American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) has designated of the health of the occupants and energy consumption profiles of the buildings (Roth, 2002) as the two key contributing factors in assessing the indoor air quality (IAQ) in ASHRAE standards. However, after 40 years of research and practical experiments in the field, finding a satisfactory solution to reduce building energy consumption while mainlining high indoor air quality remains a challenge. Even though HVAC filtration systems seem to be among the best solution for IAQ, they are mostly ineffective for volatile organic compounds (VOCs) and mostly contaminate the air instead of filtering it by infrequently changed filters (Bluyssen, 2003; Schleibinger, 1999).

Indoor air can be more contaminated than outdoor air and may lead to serious health problems related to the length of exposure (Liu, 2007). People, particularly living in urban areas, spend up to 90% of their time in indoor environments (Klepeis N.E., 2001; Robinson, 1995; USEPA, 2002). In the US alone, the annual economic losses related to IAQ is between $40 billion and $160 billion (Fisk, 1997; Lomborj, 2002), the cost which is associated with the loss of productivity and medical costs for the individuals who suffer from asthma, sick building syndrome and allergies caused due to poor IAQ (Guo, 2009). Passive techniques like increasing ventilation in buildings can improve IAQ. However; they are not suitable for many climate

doi:10.23967/dbmc.2020.165

conditions due to the increasing energy expenditures of HVAC systems related to the heating and cooling loads (Kibert, 2008). Since filters are also not efficient to remove most of the cancerogenic pollutants like formaldehyde and benzene, efficient filters need to be designed to protect building occupants from indoor air pollutants. There is a clear need for the design of a system that can address the IAQ concerns in the buildings and reduce the energy load from the HVAC systems at the same time. The successful design of such a system would have significant impacts on the urban environment and sustainability.

Plants can improve IAQ by metabolizing airborne pollutants such as formaldehyde, benzene, and xylene (Wolverton, 1993; Yoo, 2006; Aydogan, 2011). The utilization of the root zone (rhizosphere) of the plant is paramount to achieving high purification ability. There have been numerous applications of plants in buildings and the most relevant to our work is the integration of the plants into buildings to improve the quality of life in the indoor environment (Blanc, 2012). However; this system does not take advantage of the full cleaning capacity of plants, especially the root zone. Therefore, they do not sufficiently remediate pollutants within an indoor environment, nor do they incorporate their performance with the commercial buildings HVAC systems. For that reason, air remediation capacity, maintenance, energy savings and the cost of the system is lower than building-integrated systems. Building-integrated botanical air filtration systems are integrated into the building's conventional air handling units to save energy and provide a filtration system for the entire building. These systems take advantage of root zone of the plants which were the direct agents of toxin removal (Wolverton, 1993; Wang, 2014; Wolverton, 1993; Wood, 2002; Orwell, 2006). Building-integrated botanical air filtration systems have been recommended by the U.S. Department of Energy's Building Technologies Program for industrial-scale research, development and demonstration to improve air quality, energy efficiency and public health (USDOE, 2010).

The proposed botanically-based air purifying system constitutes plant-based air remediation strategies. It is a hydroponic system (plants growing without soil) that is composed of adsorbents and porous glass stones to capture and filter the toxins in the air. Plant-associated microbes in the rootzone convert these toxins to nutrients, which are then consumed by the plants. Through this, a self-regenerating filtration system is created. Significant work in plant-based filtering systems has been completed (Aydogan et al., 2016; Aydogan and Tardos, 2017) In continuation of earlier works of the author, this paper is focusing on the durability of the prototype design, fabrication, and assembly of an alternative filtration system by utilizing plants to clean indoor air and reduce energy consumption.

The paper is outlined as follows. In section 2, a discussion on the methods and the material used for the design is presented. Section 3 presents the results of the analysis, and section 4, concludes the paper by discussing the potential future developments of the system.

2 Materials and Methods

2.1 Materials

The prototype of the plant-based air filtering system is composed of three main parts: *(1)* a cassette holding the mesh, *(2)* a mesh holding the plants and growing media, and *(3)* a structure holding the cassettes together. The system components are shown in the exploded diagram in Figure 1. The heaviest elements of the prototype are the base and water basins (for watering the plants), which provide structural stability when located on the bottom.

The design of the modular system utilizes a series of cassettes that are repetitive and arranged to form a wall system. Through this design, natural channels are created on the back of the cassettes

to allow the air pass through and circulate back to the environment by the fans on each side of the panel prototype (Figure 2a). Each cassette holds the mesh containing lightweight growing media and the plants, LED lighting and drip irrigation tools (hose and drippers) (Figure 2b). The LED lighting system, which aids photosynthesis, is designed to be hidden within the three sides of the cassettes' lids. The irrigation is a closed-loop system, where the water flow is controlled using a timer. This allows the exact amount of water to drip and reach to the plants' roots without excess water overflowing in the prototype system. Five 0.25 gallons per hour drip emitters are aligned to be used in each of the cassettes. The pumps are located at the bottom of the prototype inside the water basins and the hoses of the drippers are hidden (on the back) between the cassettes (Figure 3a).

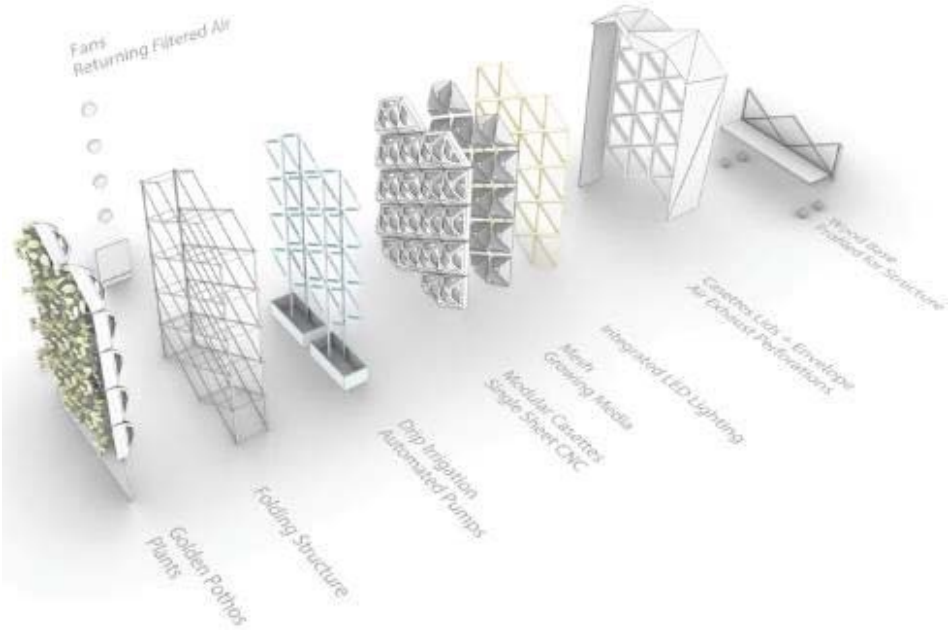

Figure 1. Exploded diagram of plant-based air filtering system.

In the design of the structure, steel bars with the dimension of 1/2" (width) x 1/8" (depth) are used. Since the prototype is double-sided (plant cassettes on both sides), the structure is designed to be versatile with easy and fast assembly by creating pockets that cassettes settle in. The bottom of the bars is embedded in the groves created in the wooden base that are profiled for the flat steel bars.

A mesh that holds the plants and growing media is designed by using a three-dimensional reinforcement mat (Enkamat7020), commonly used for erosion control on the slopes in the urban scale applications. This material is selected due to its performative features. It allows airflow to pass through the growing media and plants without creating additional pressure on the surface, it doesn't absorb moisture, it is UV resistant and holds the growing media with plants in place even it is installed vertically (Figure 3b).

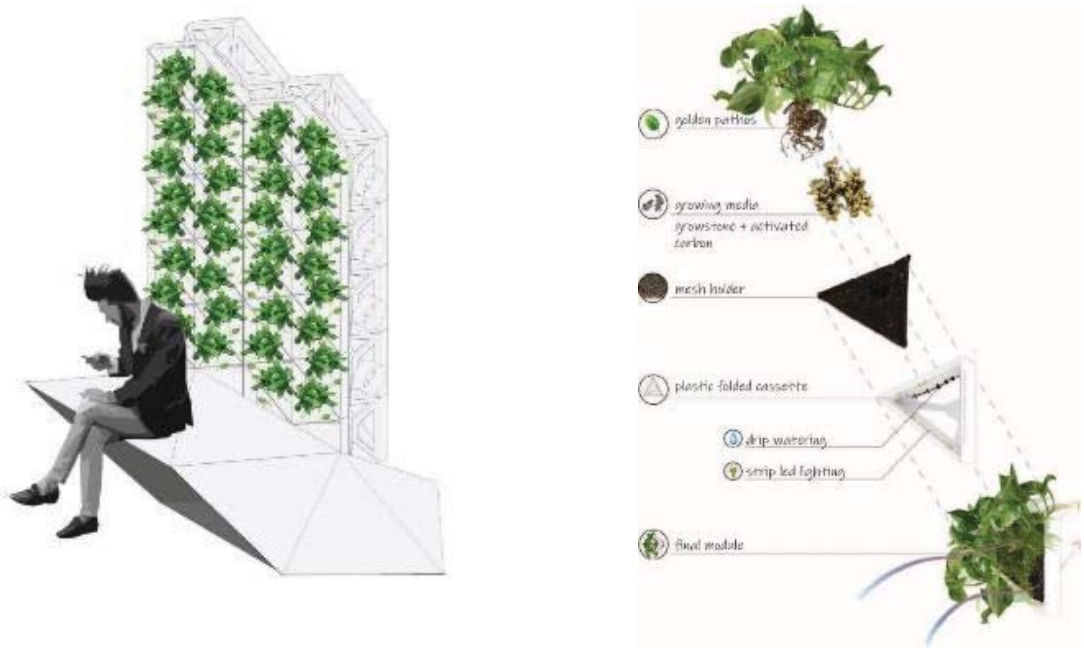

Figure 2. a. The double-sided prototype of plant-base air filtering system; b. Components of plant-based air filtering system.

Figure 3. a. Folded cassettes and dripper attachments**;** b. 3d mesh holding growing media and plants.

Growing media used in this system is composed of a mixed bed of activated carbon (4 × 8 Coconut Shell Granular) adsorbents and porous glass stones (GS2 Soil Aerator) that capture and filter the toxins in the air. The role of activated carbon in this mix is to capture toxins whereas porous glass stones are used for creating an environment for roots to grow. The porous surface on the glass stones makes it ideal for the roots to get water and climb.

Different kinds of plant species can be used in indoor environments and, essentially, depending on the specific functions that they can serve. Additional knowledge of the conditions that are required for their growth such as lighting requirements, watering, and maintenance are also vital factors. However, the most important principle for this project is their toxin degradation capacity through their rhizosphere. Golden Pothos (*Epipremnum aureum)* and English Ivy (*Hedera Helix*) are the two plants that are used in this prototype, based on the results of the toxin removal capacity that was discovered through our previous studies (Aydogan, 2011).

2.2 Methods

In this prototype, different materials and techniques of fabrication are investigated. Emphasis is placed on designing a lightweight and collapsible scissor structure, which allows the project to be easily transported and assembled. Subtractive manufacturing methods are selected to be used to conduct the base and the cassettes of the prototype. Computed-numerically-controlled (CNC) machine is used to cut the 1” wood base and sides. Precise 3/4” deep grooves are routered on the interior faces of the base so that the steel structure would snap into its designated shape. The structure’s geometry is designed to hold two abutting cassettes per one parallelogram (Figure 4a and Figure 4b). While the base’s hidden grooves and inserted cassettes hold the metal scissor structure’s geometry in place, it is the 1” plywood walls on both sides that provide support against shear stresses. These sidewalls are holding the fans that are used to distribute the air, which was cleaned by the plant cassettes.

Figure 4. a. Assembly of the prototype; b. Plant assembly of the prototype.

17 sheets of HDPE are used to CNC cut the cassettes of this prototype. A total of four cassettes are cut from a 49” × 96” sized sheet. The cassettes are designed and assembled by folding technique (Figure 5).

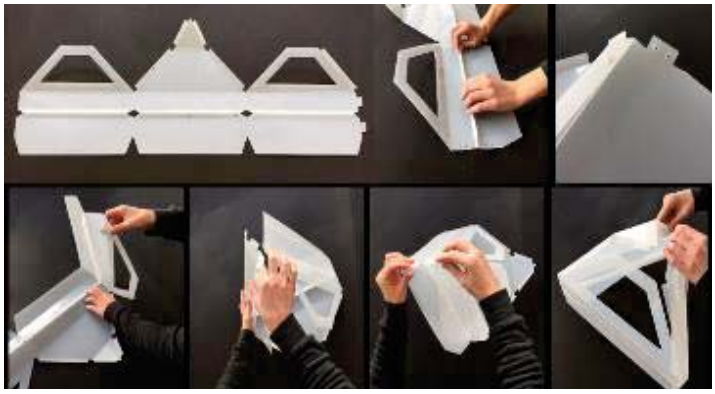

Figure 5. Cassette assembly by folding.

Cutout sheets are used to cut the mesh and create individual mesh holders. It is designed to fold and sewed a zipper in the seams, which makes planting easier. Three zippers are used in the mesh, two of them on the sides and one in the middle, which are preventing the growing media to fall and holding plants in place. In plant-based filtering systems, porous glass stones and activated carbon have different particle sizes and creates opportunities for settling in the planters. This creates a loss of active adsorption area in the cassettes. To prevent this problem two growth media are granulated (bonded together).

3 Results

In this project, a prototype containing 68 modules was designed and fabricated (Figure 6a and Figure 6b). Folding technique for the structure and cassettes seemed to be a practical solution, however; due to connection problems on the corners, the fabrication technique needs to be revisited for the cassettes. Using CNC for cutting the material was not the ideal solution due to time-inefficient and waste of material concerns. Two different solutions were generated to solve this problem.

Figure 6 a and b. The plant-based air filtering system prototype.

Those solutions are either using different fabrication techniques as traditional die cutting to cut the HDPE sheets for the cassettes or changing the folding technique to a different design so that more cassettes can be generated through one sheet of HDPE. 1/8" thick HDPE is also found not to be practical for reusing after disassembly of the cassettes and it can easily crack. Instead of HDPE, more flexible materials are recommended as Styrene, Vinyl or Polypyrene.

The structural scissor system is a practical technique to allow the ability to open and fold easily with lighter elements that carry the cassettes and growing media. The prototype generated valuable feedbacks on the structure by showing arising potential problems.

The mesh holding the plants worked very well with the media. Zippers around the perimeter of the mesh and sleeve create easiness for the assembly of the growing media and planting. Since the system is designed on the premise of flexibility and modularity, the mesh can be easily replaced for the maintenance without shutting the whole system, which allows the durability of the system in the long run.

4 Conclusion and Future Potentials

The durability of the plant-based filtration system is investigated by exploring the design, fabrication and installation properties of the materials. Most of the plant-based integrations in the field do not take advantage of the root zone (rhizosphere) cleaning capacity and have limited applicability in terms of modularity, scalability, flexibility, disassembly /reassembly and life cycle factors. In this paper, the project focused on the design and prototyping of the system to analyze the ways to minimize the maintenance cost and maximize the durability of the system by demonstrating the constructive feasibility of the modular, durable, easily transportable, flexible, adaptable approaches that can be efficiently mounted in indoor spaces. The conclusion of these investigations is showing that especially the structural scissors system and mesh holding (the growth media and plants) has a high potential to be applied to the plant-based filtration system.

Full-scale implementation of plant-based air filtering system is an alternative filtration solution that provides fresh air through the purification of recirculated air. In addition, by this system, end-use energy efficiency will be obtained due to the reduced outdoor air intake and recirculated indoor air. The proposed plant-based air filtering system would provide crucial support for building air handling systems.

Acknowledgments

I would like to thank all the research assistants at Spitzer School of Architecture, who participated on the design and fabrication of this system and Mahdieh Allahviranloo, Grove School of Engineering, City College of New York for her invaluable comments on this article.

Thermodynamic Processes in Nanostructured Thermocoatings

David Bozsaky

Department of Architecture and Building Construction, Faculty of Architecture, Civil Engineering and Transport Sciences, Széchenyi István University, H-9024 Győr, Hungary, Egyetem tér 1, bozsaky@gmail.com

Abstract. *In the 21st century, global climate change and the high level of fossil energy consumption have introduced changes affecting all sectors of the economy, including the building industry. This process has prompted EU members to create strict regulations in building energetics. It has become a serious task for architects to find more effective ways for thermal insulation. One of these options is the application of nanostructured materials. Among them nano-ceramic thermocoatings open a wide range of research fields, because complete agreement had not been already found about their insulating effect. In order to explore and describe the thermodynamic process inside nano-ceramic thermocoatings 6 series of heat transfer resistance experiments were performed in 2014-2018. Several building structure configurations with 12 different orders of layers were tested with a standard heat flow meter. On basis of these results it could be concluded that in case of nano-structured thermocoatings convective heat transfer coefficient might be taken account in different way than in case of traditional macro-structured thermal insulation materials. Based on research results, the limits of its applicability can also be concluded. It has also been found that the insulating effect of nanostructured thermocoatings depends on the material characteristics of the insulated surface.*

Keywords: *Thermal Insulation, Nanotechnology, Thermocoating, Thermodynamics, Building Physics.*

1 Introduction

In the 21st century, humanity has faced serious problems of energy and environmental aspects. Reducing energy consumption and preferring renewable materials with low environmental impact are fundamental tools in order to slow the degradation of our environment as well as early exhaustion of non-renewable fossil energy resources. Building sector represents over 40% of global energy consumption and 56.7% in carbon dioxide emissions, which is considerable (Shea *et al.*, 2012; Anestopoulou *et al.*, 2017). Because of these reasons regulations relating to thermal insulation performance of buildings are getting more and more rigorous nowadays. It has become a serious task for architects and civil engineers to find more and more effective ways for thermal insulation of buildings.

The appearance of nanotechnology-based thermal insulation materials in building industry opened several possibilities in the 1990s for designers because of their high-performance thermal insulating quality (Leydecker, 2008). A variety of nanotechnology-based thermal insulation materials could be found in building industry (*e.g.*, aerogel, VIPs), from which nano-ceramic thermocoatings are generally considered to be the most critical because of the contradictory technical data about their thermal insulating mechanism that could be founded in producers' handouts and also in special literature. Therefore, this material has become the focus of this paper.

2 Nano-Ceramic Thermocoatings

Synthetizing of nano-ceramic microspheres was developed in 1981 by S. Komarneni and R. Roy. This so-called 'sol-gel' process enabled researchers to test the properties of nano-ceramics (Hoffman *et al.*, 1984). To produce nano-ceramics at a more efficient way this process was later replaced by microwave sintering.

The most paint-on insulation products contain microscopic vacuum-hollow ceramic microspheres with a diameter of 20-120 μm and with a cellular wall thickness of 50-200 nm. Nano-ceramic thermocoatings are made of melted glass or ceramics on high gas-pressure and high temperature (1500 °C). After cooling down, the pressure ends, leaving vacuum inside the microspheres. A mixture of synthetic rubber and other polymers is used as binding materials. Its main components are styrene (20%) and acryl latex (80%). Styrene enhances mechanical strength and acryl latex makes nano-ceramic coating resistant against weather conditions and provides flexibility. Other additives (*e.g.,* biocides, anti-fouling and antifungal materials) make the final product durable and mold-proofed (Thermo-Shield Inc., 2017; Lan *et al.*, 2014).

Nano-ceramic coatings are typically used for exterior and interior wall insulation, but they are also suitable for pipe insulation and protection against fire and corrosion. They can be easily transmitted to hard-to-reach places. After mixing the ceramic microspheres with binding material, additives and water, a brush, roller or spray can be used to apply on the surface to be insulated. All surfaces must be clean and free from any contamination before painting. Generally two insulating layers are required, the first of which acts as a primer layer. The drying time of a layer depends on the temperature (at 20 °C, it takes 4-5 hours). The complete solidification takes 72 hours (Thermo-Shield Inc., 2017; Lan *et al.*, 2014).

3 Literature Summary

Special literature provides different data about thermal insulation quality and thermodynamic details about nano-ceramic thermocoatings (Paul *et al.*, 2010; Koniorczyk *et al.*, 2004). Some sources state that their thermal conductivity is around 0.001-0.003 W/mK based on measurements of university laboratories in Latvia, Russia (Volgograd) and Hungary (Debrecen) (Orbán, 2012; Thermo-Shield Inc., 2017). Other sources publish much higher values (from 0.014 W/mK to 0.140 W/mK) and talk about their effective thermal conductivity which contains the internal and external convective heat transfer coefficients (h_i and h_e) of the enclosed nanoscale pores inside the nanostructure. These details are often not confirmed by documented laboratory tests or refer to insufficiently introduced experiments (Orbán, 2015; Lakatos, 2016; Chukhlanov *et al.*, 2017). Others calculate thermal conductivity of nano-ceramic coatings from heat transfer coefficient (U-value) of a global building structure (Lakatos, 2016). Each method has the same problem that it tries to determine thermal conductivity by an indirect way using conventional data and calculation and it does not take in account that physical and chemical processes inside structures in range from 1 to 100 nanometers can occur differently than in traditional macro sizes.

In order to test thermal performance of nano-ceramic thermocoatings energy balance was investigated in periods of heating and also in the summer at external building surfaces using dynamic outdoor testing. Measurements demonstrated that coating consisting of hollow ceramic microspheres has the same thermodynamic properties as a standard facing coating

(Čekon, 2013; Čekon *et al.*, 2014). Spectral emissivity properties and reflective ability of nano-ceramic thermal insulation coatings were also tested and measured data demonstrated that coatings have the same radiant properties as standard building coatings (Čekon, 2012; Ádám *et al.*, 2016). Based on GOST 23630.2-79 (Russian standard) using an IT-λ-400 instrument thermal conductivity of nano-ceramic coatings consisted of hollow inorganic microspheres measured to be 0.10-0.18 W/mK and the effective thickness of the thin-film insulation coating was determined at least 5 mm (that requires application of 4 layers of material at each layer thickness of 1-1.5 mm) (Chukhlanov *et al.*, 2017).

Nano-ceramic thermocoating was applied on façade walls of an experimental building and the total energy consumption of the building was examined. It has been shown that there is an effective thermal insulating effect of the coating both in winter and summer. However, exact value of conductivity was not determined (Oda *et al.*, 2015). Similar conclusion was made after examining a 10 cm thick masonry wall with heat chamber method under summer climatic conditions (outside wall surface was covered with nano-ceramic thermocoating). It was found that thermal insulating ability is up to 25% more effective when the coating was applied in 2 or 3 layers (Esfandyari *et al.*, 2018).

Other researchers claim that thermal insulation coatings can highly increase heat transfer resistance of the insulated surface by reducing convective heat transfer coefficient (Orbán, 2015). Experiments have shown that they are able to improve the heat transfer coefficient of solid brick masonry (Lakatos, 2016). It has also been found that thermal insulation capacity of nano-ceramic thermocoatings is affected by its thermal inertia (thermal lag). During the review of heat transfer processes, a further discovery has been made that the physical equations used for atomic diffusion can be applied to heat diffusion (Lakatos, 2017).

4 Laboratory Experiments

The main research task was to clear and describe the thermphysical processes inside nano-ceramic thermocoatings. Based on the literature review, it was intended to perform series of laboratory tests that can provide clear information about the heat reflectivity, thermal conductivity and heat transfer resistance of nano-ceramic thermocoatings. After studying the special literature six experiments were made in the Laboratory of Building Materials and Building Physics at Széchenyi István University (Győr, Hungary) in 2014-2018.

4.1 Experiment 1 and Experiment 2

Experiment 1 and Experiment 2 were conducted to find out that the material really has heat reflective ability (heat mirror effect) and to check whether it has an extremely low thermal conductivity claimed by some special literature references and the manufacturer's handouts. Results of these experiments were published in 2015-2017 but in order for better understanding a brief summary is important (Bozsaky, 2015; Bozsaky, 2017).

In Experiment 1 five types (Type 1-5) of samples were made from different kind of traditional thermal insulation materials: expanded polystyrene (EPS), extruded polystyrene (XPS) and oriented strand board (OSB). Sample Type 1 was uncoated and homogeneous, other samples were sprayed with nano-ceramic thermocoating. According to EN 12667:2001 standard Taurus TCA 300 heat flow meter was used for measurements. Thermal conductivity of homogeneous samples and the effective thermal conductivity (λ_{eff}) of inhomogeneous

samples (Type 2-5) were compared and results seemed to show a minor negative effect of nano-ceramic coating to thermal insulation quality. Only XPS samples showed a small positive effect with an insignificant decreasing value (Bozsaky, 2015; Bozsaky, 2017).

During Experiment 2 thermal conductivity of the pure nano-ceramic coating was measured directly with a standard heat flow meter on samples with thicknesses of 25, 30 and 35 mm (However, this material is practically not used with such thickness, because they are applied as a 0.5-2.0 mm thin membrane). The average thermal conductivity in air-dry condition was 0.0690 W/mK. In addition each sample was measured 3 times in order to increase measuring accuracy (standard requires only one measurement). Analyzing the results the average thermal conductivity in air-dry condition was 0.0690 W/mK regardless of thickness. Due to the significantly increased measurement accuracy and the fact that there was no difference in thermal conductivity of samples with different thicknesses, it could be concluded that thickness has no significant effect on thermal conductivity. Therefore it could not be clearly declared that thermal conductivity of this material has the same thermal conductivity if it is used as a very thin membrane (Bozsaky, 2015; Bozsaky, 2017).

4.2 Experiments 3-6

Based on former experiments it was concluded that insulating effect of nano-ceramic thermocoatings is probably not caused by their extremely low thermal conductivity. As it was formerly mentioned, some sources claim that insulating effect of these materials is generated by not their extremely low thermal conductivity but their high surface heat transfer resistance. Considering it as a basic concept four more heat transfer resistance experiments were conducted in 2016-2018 (Experiments 3, 4, 5 and 6). For these experiments 6 different order of layers were constructed from 30x30 cm samples of thermal insulation materials. Moreover, an additional Air Gap (AG) was included into the construction with different sizes (Table 1). There were configurations (Figure 1), which contained nano-ceramic coated and uncoated samples as well (Type 1-6).

Table 1. Size of air gap in Experiments 3-6.

Experiment	Size of AG (cm)
3	10 x 10 x 2
	10 x 10 x 3
4	20 x 20 x 2
	20 x 20 x 3
5	20 x 20 x 5
6	20 x 20 x 8

Measurements were carried out by the same heat flow meter used in Experiments 1 and 2. Effective thermal conductivity of 3-3 pieces from each type of configurations was measured using 3 different kinds of thermal insulation materials (EPS, XPS, and OSB plates). Each sample was measured 3 times. Moreover, sample Types 1-4 were measured in two ways; firstly coating was on the warm side; secondly it was on the cold side. Consequently, a total number of 883 thermal conductivity measurements were conducted. Unfortunately, because of the measuring limits (120 mm maximum sample thickness) it was possible to test only 4 Types (Types 1-4) of configurations in Experiment 6. Sample Types 5-6 were too thick (16-

18 cm); therefore, they could not fit to the measurement chamber of the heat flow meter.

Because of the inhomogeneous, multi-layer structure heat flow meter was able to determine effective thermal conductivity (λ_{eff}). The main focus of experiments was the difference in effective thermal conductivity between coated and uncoated samples.

All of the samples contained air gap, the effect of convection and conduction inside it was included by the λ_{eff} value. Air gap has the same position and the same size in each sample so the conduction and convection inside air gap should be also the same in each case. This is why difference between effective thermal conductivity of coated and uncoated samples could be attributed only to the coating.

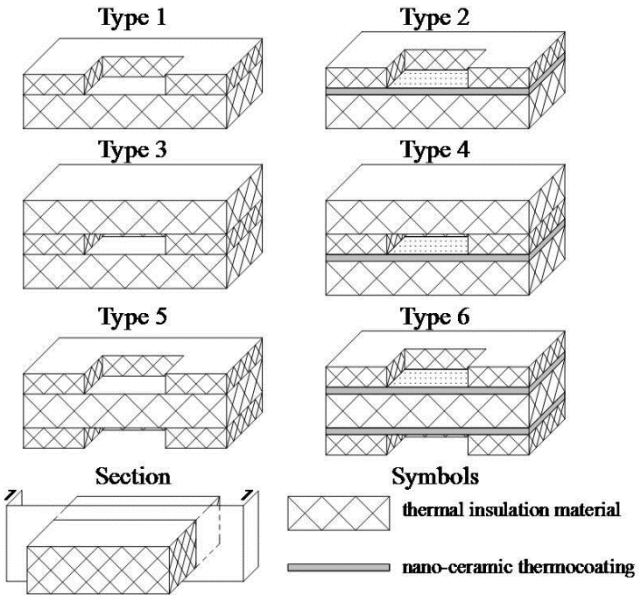

Figure 1. Sample types for Experiments 3-6.

From these tests is was expected that there will be significant differences in effective thermal conductivity between coated and uncoated samples and the increasing size of air gap should cause higher changes. It was supposed that in larger air gaps air particles should have more possibility for bulk movements; thereby surface heat transfer resistance can prevail much better and higher differences may arise between coated and uncoated samples. Results were correspondent for expectations.

Unfortunately, most of the test results showed lower differences than the measurement accuracy of Taurus TCA heat flow meter (5%). Due to the fact that measurement accuracy was increased by testing the samples in 3 times this problem was eliminated (Standard prescribes only one measurement). However; in 89% of the measurements there were no deviation between 3 test results of an individual sample and in 11% the difference was only ± 0.0002 W/mK which means also 0.1-0.4% accuracy instead of the theoretically 5% accuracy of the heat flow instrument. Therefore, the resulted changes in effective thermal conductivity could be considered to be relevant.

Table 2. Changes of effective thermal conductivity in Experiments 3-6.

Experiment	AG size (cm)		Change of λ_{eff} (%)								
			EPS			XPS			OSB		
			1/2	3/4	5/6	1/2	3/4	5/6	1/2	3/4	5/6
3	10x10x2	$\Delta\lambda_{eff, cold}$	-6,16	-4,69	-	-3,57	-3,64	-	+3,74	+2,57	-

		$\Delta_{\lambda eff}$	-12,74	-7,37	-	-8,91	-4,26	-	+2,25	+1,05	-

Table 2 summarizes the analysis of measurement results. Looking at the data it could be stated that changes in EPS samples were the most apparent. The most significant differences (8.66% and 8.19% in Experiment 3, 9.96% and 12.04% in Experiment 4 and 12.84% in Experiment 5) were found in configuration Types 5-6. In case of configuration Types 1-2 change level was also high even if the coating was on the cold or warm side. The lowest changes were measured in case of Types 3-4. This phenomenon can be explained that if an air gap is closed inside two layers of thermal insulation air particles are less able to move and the effect of surface heat transfer resistance becomes smaller.

In case of XPS samples smaller changes can be observed (Table 2). Change of thermal conductivity was the most significant in configuration Types 1-2. Just like EPS samples, using the coating on the warm side the changes were lower, and the difference from samples with cold-side painting became more and more significant. In case of Types 5-6 lower changes were measured, and the lowest changes were measured in case of Types 3-4 (excepting Experiment 3). In case of XPS samples smaller changes can be observed than in case of EPS. This could be explained by the results of Experiment 1 where nano-ceramic coating itself had resulted reduction of thermal conductivity. This is why surface heat transfer resistance seems to have minor effect on thermal insulation quality

It was also a novelty that in Experiment 3 and Experiment 4 there were detectable but not enough significant differences between measurement results depending on the location of the coating (warm or cold side) in case of EPS and XPS samples. These differences became more and more significant by increasing the size of the air gap (see the results of Experiment 5 and Experiment 6 in Table 2) which showed that nano-ceramic coating has stronger effect on the

cold side.

In case of OSB boards insulating effect of nano-ceramic coating was undetectable in Experiment 3 and 4. All measurements showed that coating has a negative effect on thermal insulation quality. Except sample Types 5-6 in Experiment 5, all measurements showed that coating has a negative effect on thermal insulation quality. It can be observed that this negative effect is decreasing by increasing the size of the air gap. In Experiment 4 nearly zero (0.02%) change was measured and in in Experiment 5 a very small decreasing of effective thermal conductivity was detected (-1.04%).

However, it should be noted that the negative effect of nano-ceramic thermocoating was reducing by increasing the size of the air gap. Probably, not the same material quality and composition is suitable for all building structures and materials. Every time we need to find correct solution and the same material is not suitable for all surfaces. Presumably, insulating OSB plates needs different material quality, composition or application technology than EPS and XPS plates to achieve significant insulating effect.

5 Conclusions

Former laboratory tests showed that nano-ceramic thermocoatings do not have an extremely low thermal conductivity that was described by the available documents of producers and distributors. Moreover, thermal conductivity of nanostructured thermocoatings is independent from materials thickness.

Due to the fact that test results of EPS and XPS samples were consistent with preliminary expectations, Experiments 3-6 confirmed the previously raised theory that because of their special nanostructure, insulating effect of nano-ceramic thermocoatings lies in their significantly higher surface heat transfer resistance than traditional, macro-structured thermal insulation materials.

It can be declared that in case of using nano-structured thermocoatings on the surfaces of building structures convective heat transfer coefficient (h_i or h_e, according to the location of the coating) might be taken account in different way than in case of traditional macro-structured thermal insulation materials. New results also showed that the effectiveness of nano-ceramic thermocoatings is more intensive using them on the cold side of the structure (contrary to producers' claim that the effect is the same on warm and on cold side).

It can also be stated that the application of nano-ceramic thermocoatings between two structural layers is the least effective method from thermal insulating point of view.

Test results of OSB samples showed that the same material quality, composition and application technology may not be suitable for insulating different kind of surfaces.

Furthermore; it would be important to make in-situ heat transfer experiments with nano-ceramic thermocoatings in order to understand better the thermal insulation behavior of the material. In order to achieve this goal heat transfer coefficient of several sample buildings should be measured without any thermal insulation. These basic data should be compared with the heat transfer coefficient of structures with nanostructured thermocoating.

Abstract. *Reinforced concrete (RC) structures, such wharfs or floating structures, are submitted to chloride ingress which can lead to rebar corrosion. Before the corrosion initiation, in a preventive point of view, engineers can be interested in non-destructive evaluation and inspection methods. In that way, electrical resistivity tomography is a promising tool to access to resistivity profiles then to chloride profiles in real RC structures in the future. We would like to present herein the advances in the necessary research developments to reach this goal, i.e. the resistivity profiles obtained in reinforced concrete slabs submitted to chloride ingress. The 4 slab dimensions are 90x70x13 cm. The specimens are cured, dried during 9 months then submitted to salted water imbibition during 4 months. Electrical resistivity tomography measurements are performed at short terms during 1 week of imbibition. The monitoring show that several phenomena influence the resistivity profiles such as the penetration of water and chloride ions. Meanwhile, steel rebar effect can be considered thus eliminated from electrical resistivity profiles following the method developed by (Alhajj et al. 2019).*

Keywords: *Electrical Resistivity Tomography, NDT, Inversion, Durability, Reinforcement.*

1 Introduction

The preservation of our civil engineering infrastructure heritage is part of sustainable development initiatives and programs. Reinforced concrete (RC) structures exposed to de-icing salts and the marine environment may corrode through the action of chloride ions, water and oxygen. It has been shown that the methods for measuring the electrical resistivity of concrete are effective in alerting the potential corrosion risk (Gowers *et al.* 1999, Andrade *et al.* 2009). They are particularly sensitive to the moisture and chloride contents in concrete (Saleem *et al.* 1996). Finally, electrical resistivity tomography methods also have the great advantage of investigating the concrete from the surface to the core in a non-destructive manner and of drawing as information the apparent resistivity. However, such data need to be inverted to obtain a resistivity profile with depth (Loke *et al.* 1996, Chouteau *et al.* 2002, Fares *et al.* 2018). The calibration determines the conversion function to obtain the desired indicator: either the water content or the chloride content (Villain *et al.*, Fares *et al.* 2018). But the presence of metal reinforcements disturbs the electric field and the measurement of apparent resistivities (Sengul

et al. 2009, Presuel-Moreno *et al.* 2013, Garzon *et al.* 2014) and can prevent the inversion process, which is why the RILEM recommends to place itself at a distance from the reinforcements (Polder, 2001). The work of Alhajj *et al.* (2019) showed that it was possible to reproduce by finite elements modelling the effect of the reinforcements on the measurement of apparent resistivities.

The objective of this paper is to present the first results of the inversion programmed by Alhajj *et al.* (2020) for reinforced and unreinforced slabs subjected to an imbibition of a saline solution in the laboratory. The first part presents the measurement method and summarizes the inversion procedure. The second part details the experimental program. The third one shows the measurement results and the monitoring of resistivity profiles over time in both reinforced and unreinforced slabs.

2 Method used for Non-Destructive Evaluation

The selected non-destructive evaluation (NDE) method is electrical resistivity tomography (ERT) because it is very sensitive to the water content and chloride content of concrete.

2.1 Electrical Resistivity Measurement Principle and Method

The electrical resistivity method used is based on the Wenner principle for 4 electrodes regularly spaced (spacing a). The current is injected by the 2 external electrodes and the potential difference measured between the 2 inner electrodes. The apparent resistivity is calculated from current and potential measurements and a geometric coefficient G (Marescot *et al.* 2006). G is calculated by finite element modelling taking into account the geometry of the test body and the position of the electrodes. If the medium is homogeneous the apparent resistivity is equal to the «true» resistivity of the medium.

The device used was developed by (Du Plooy *et al.* 2013). It consists of 14 inline electrodes, 2cm-spaced. This allows the implementation of 26 Wenner configurations with 4 different spacings a=2 cm, a=4 cm, a=6 cm and a=8 cm. The larger is the spacing, the larger the volume examined from the surface. The raw results correspond to apparent resistivities at each level of spacing. They give information about the presence of a gradient in concrete.

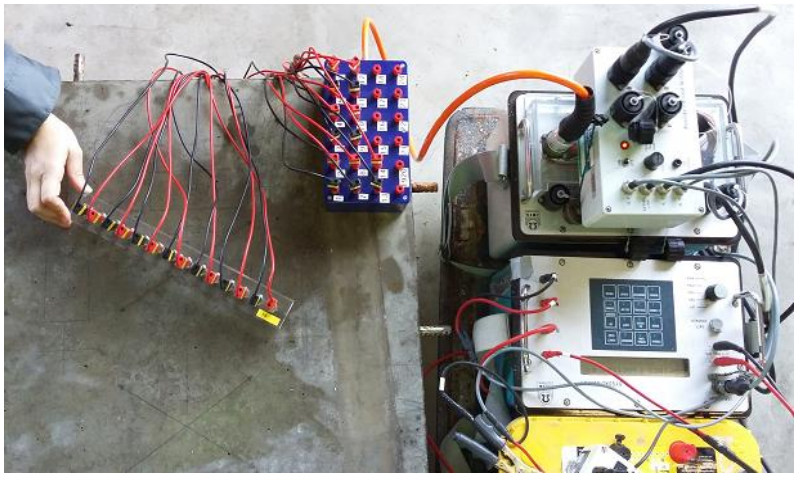

Figure 1. Picture of the ERT testing device.

2.2 Inversion Process

The inversion of these raw results allows to obtain a resistivity profile according to the depth. Loke *et al.* (1996) notably developed an inversion algorithm for a discrete, multi-layer material model. The resulting RES1D software is free of access and gives good results for unreinforced concrete slabs. However, the presence of metal reinforcements alters the current lines in the reinforced concrete slabs, thus influencing apparent resistivity measurements. This influence can be quantified by finite element modelling (Alhajj *et al.* 2019). It must be taken into account in the inversion process.

An inversion process has been developed and is presented at the DBMC 2020 Congress by Alhajj *et al.* (2020). In summary, the imposed initial true resistivity profile is continuous and follows a Weibull law with 4 parameters. The direct finite element model (Comsol Multiphysics®) calculates the modelled apparent resistivities. The least squares cost function between the modelled and the measured apparent resistivities is computed. A Levenberg-Marquardt algorithm minimizes this cost function in order to fit an estimated resistivity profile of the concrete. The iterative optimization algorithm is written in Matlab® linked with Comsol and is called "IFSTTAR inversion program" in the following. The finite element model may or may not take into account steel reinforcements present or not in concrete slabs. The resistivity profile obtained corresponds to the resistivity of the concrete material with a gradient of saline solution, independently of the conductive steel influence.

3 Experimental Program

A research project called APOS (Villain *et al.* 2015) aimed to compare embedded sensor results and non-destructive evaluations of reinforced concrete slabs submitted to chloride ingress in the initiation phase then in the corrosion phase (Bouteiller *et al.* 2018). The present study is limited to ERT in the initiation phase to evaluate chloride ingress in the cover concrete. The purpose of this section is to present the concrete formulation, the geometry of the slabs, their preconditioning and the chronology of the experimental program of this study.

Porosity (water saturation under vacuum)	ϕ (%)	15.9 ± 0.7

Concrete is of type C30 containing ordinary Portland cement (Table 1). Its 28-day compressive strength equals 36.3±0.9 MPa and its porosity equals 15.9±0.7%. For this concrete, 10 slabs

were casted to study the penetration of a saline solution of concentration [NaCl] = 35 g/L, close to that of the Atlantic Ocean. Among these slabs, we will study here 1 non-reinforced slab placed in salt solution (noted 13-NS), 2 slabs reinforced with carbon steel placed in salt solution (noted 14-CS and 15-CS), and 1 reinforced slab with stainless steels (noted 18-SS).

The dimensions of all the slabs are 90x75x13 cm. The reinforced slabs contain 1 single bed of rebars placed at 3 cm of depth, forming 4 meshes of 20x30 cm (Figure 2).

After casting, the moulds were removed at the age of 3 days. Then, the slabs were placed in a room first not ventilated for 3 months and then ventilated with fans for 6 months to accelerate drying. The side faces are protected by 2 layers of epoxy resin to keep transfers along the depth.

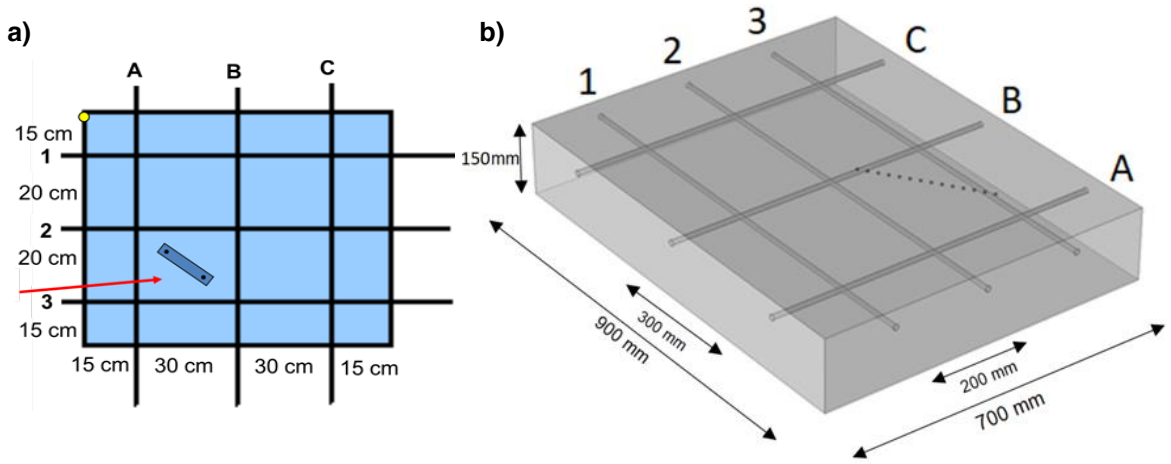

Figure 2. Scheme of the reinforced concrete slab -a- Position of the ERT testing device -b- FE model.

3.2 Imbibition Program

At the age of 9 months (T0 test time for imbibition process), the slabs were tested by non-destructive evaluation methods (NDT) and then placed in 1 to 2 cm of salt solution in pools, so that it can penetrate by imbibition on the reinforced side (Figure 3). At each test time, the slabs are removed from the salt solutions and subjected to NDT testing; then, they are put back in the pools. The chosen test times are about 1h, 4h, 1day, 2days, 7 days, 1 month, 4 months. Note that there can be differences between the slab for the out-of-water duration due to the numerous slabs and NDT methods. Here, we present the results of the first 4 test times (T1 to T4) which correspond to the imbibition of salt solution under temperature conditions of about 18-20°C. Moreover, at these early test times, the resistivity contrasts are higher and the ERT method gives thus the best results.

For each test time, the resistivity measurements were performed on the mesh AB23 along both diagonals (Figure 2), minimum twice, usually 3 or 4 times. The mean values are used for inversion.

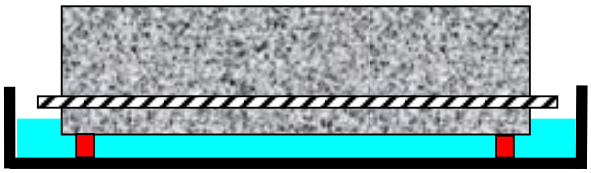

Figure 3. Scheme of the slab during the imbibition process in a pool filled with saline solution and showing the steel reinforcement.

4 Raw Results and Profiles of Resistivity versus Depth

The influence of the steel reinforcement on the apparent resistivity measurements is presented, first. Then, the inverted resistivity profiles are show in the 2nd and 3rd sub-sections.

4.1 Raw Results and Influence of Steel Rebars

Figure 4 shows the apparent resistivity measurements determined for 4 spacings of the Wenner configuration, for test times T1 to T4. The resistivity measurement was impossible at T0 because the slab surface was too dry. In Figure 4-a, corresponding to the non-reinforced slab 13-NS, at T1, the apparent resistivity is lower near the face in contact with the salt solution (a = 2 cm) than for larger spacings corresponding to higher volumes of investigation. Moreover, for later test times, the apparent resistivity decreases due to salt solution ingress into the concrete.

In Figure 4-b, corresponding to the reinforced slab 14-CS, for small spacing a = 2 cm, the apparent resistivity values are similar for both slabs, they decrease when the salt solution penetrates along time. But, for the other spacings, the larger are the spacings, the lower are the apparent resistivities. This is due to the steel rebar influence in accordance with literature results (Polder, 2001). This influence was quantified by a direct model using finite elements by Alhajj *et al.* (2019).

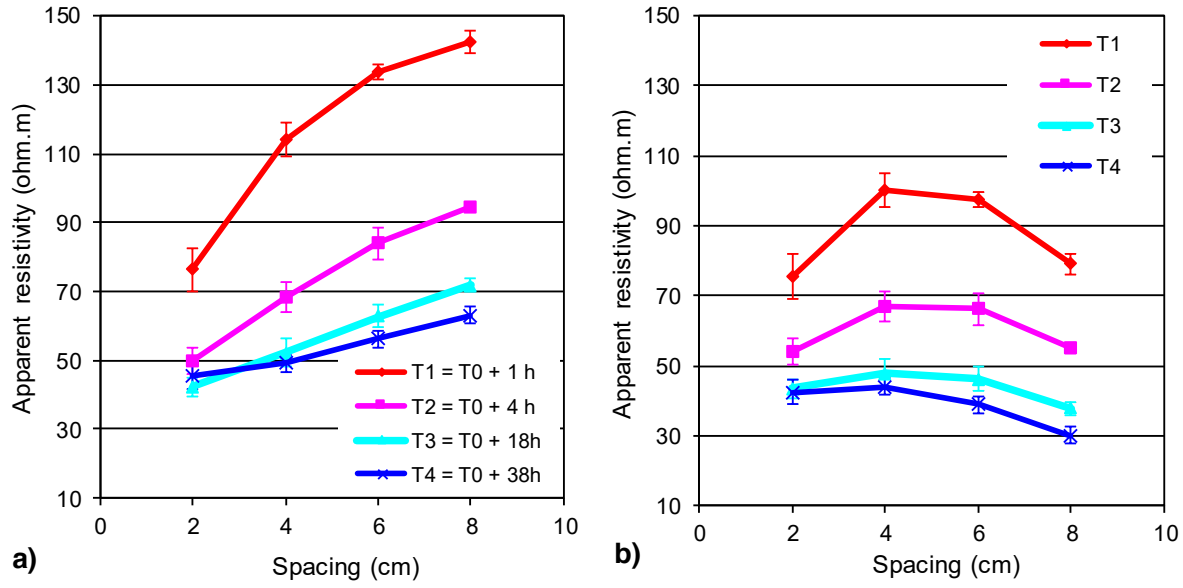

Figure 4. Apparent resistivity measurements for 4 Wenner configuration spacings -a- Unreinforced slab 13-NS - b- Reinforced slab 14-CS.

4.2 Resistivity Profiles versus Depth in the Unreinforced Concrete Slab

For each test time, the apparent resistivities obtained for the unreinforced slab (13-NS) are inverted:

- Firstly, by using the free-access software RES1D from Loke (2001); the resulting resistivity profiles are shown in Figure 5-a;
- Secondly, by using the ISTTAR Program; the resulting resistivity profiles are shown in

Figure 5-b and compared to the RES1D resistivity profiles.

In Figure 5, the resistivity profiles show the salt solution ingress. Concerning RES1D (Fig. 5-a), the inversion process is very fast. Figure 5-b presents the results of both inversion programs which are in a good agreement especially at the 2 first test times. This can be explained by the ERT method, more informative about shallower volumes, thus less accurate for deeper volumes.

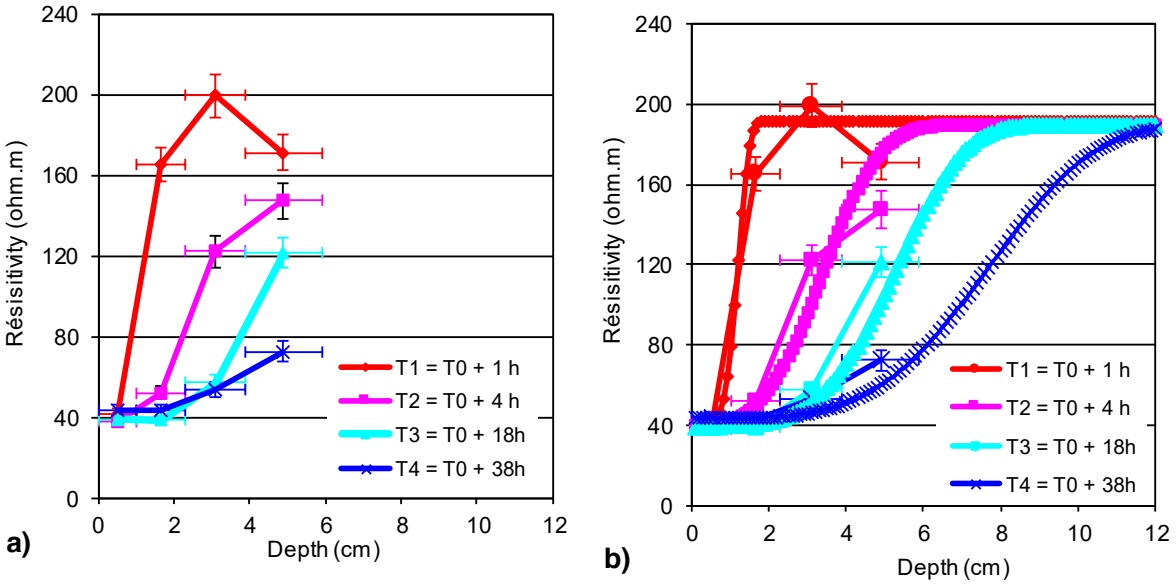

Figure 5. Inverted Resistivity profiles at test times T1 to T4, for the slab 13-NS -a- Inversion with RES1D -b- Inversion with "IFSTTAR program" (superimposed on the RES1D results).

4.3 Resistivity Profiles versus Depth in Reinforced Concrete Slab with HA Carbon Steel and Stainless Steel

Then, for each test time, the apparent resistivities obtained for the reinforced slabs (14-CS, 15-CS and 18-SS) are inverted by using the same initial parameters as those used for the slab 13-NS. The inversion is performed with IFSTTAR program because it is not possible with RES1D.

Figure 6-a makes it possible to compare the resistivity profile obtained for unreinforced slab (13-NS) and reinforced slab (14-CS). Figure 6-b presents the resistivity profiles obtained for the 3 reinforced slabs.

The profiles in non-reinforced and reinforced slabs are very similar for T1, T2 and T3 (Fig. 6-a). The discrepancies between the profiles are of the same order of magnitude as the ones between the profiles of the 3 reinforced slabs (Fig. 6-b). This uncertainty can be due to the concrete material variations which influence the kinetics of the penetration of the salt solution. For the later test times, the discrepancies between all the curves increase. The uncertainty of the measurement method for a higher spacing is higher.

Moreover, the resistivity profile of the slab reinforced with stainless steel rebars (18-SS) is similar to the profiles of the 2 other slabs reinforced with carbon steel rebars (14 and 15-CS). The reinforcement is indeed in passive conditions in this study.

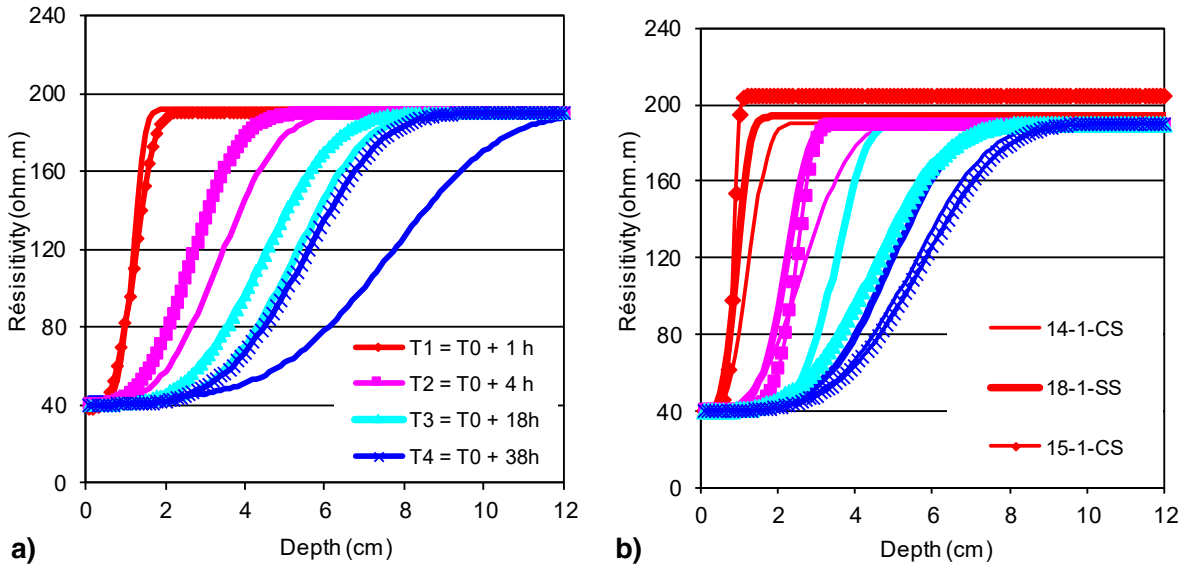

Figure 6. Comparison of resistivity profiles corresponding to salt solution ingress in non-reinforced and reinforced concrete slabs -a- Slabs 13-NS and 14-CS (line with marks) -b- Slabs 14-CS, 15-CS and 18-SS.

5 Conclusions and Further Developments

This paper presents the first results of an ERT inversion code tested on both reinforced and unreinforced slabs subjected to an imbibition of a saline solution in the laboratory. This study shows that it is possible to take into account the influence of steel reinforcement on the apparent resistivity measurements, to proceed to their inversion and obtain the "true" resistivity profiles. These profiles make it possible to monitor and evaluate the penetration of a salt solution (35 g/L) in the cover concrete.

Four slabs, either non-reinforced or reinforced with carbon or stainless steel rebars were submitted to the same imbibition process. The similar resistivity profiles obtained enable us to assess the uncertainty range due to both the concrete material variability and the ERT method itself. Indeed, the ERT uncertainty increases with high value of resistivity (it is higher for the dry core of slabs) and ERT give less information for larger volumes of investigation.

Note that carbon and stainless steel give similar resistivity results in passive conditions.

However, to convert resistivity profiles into free chloride content profiles, calibration curves are needed, but they are not available at various water contents. Imbibition is a rapid process but more complex than diffusion in saturated conditions. This point has to be developed.

In further developments, non-destructive evaluations by ERT will be compared to embedded sensors in the concrete slab in view of structural health monitoring.

Acknowledgements

The authors would like to thank all the team from the Regional Laboratory of de Saint-Brieuc (Cerema) in particular B. Thauvin, R. Queguiner, S. Pasquiet, P. Boulaire for the slab instrumentation and casting, as well as the slab survey during the experimental campaign. The authors are also grateful to the Ministry of Ecology MTES, IFSTTAR and Cerema for their financial support of the research project APOS.

Abstract. *Ordinary Portland Cement (OPC) is a mixture consisting of various phases. Because of mineralogical complexity, the relationship between chemical reactivity of the mixture and each individual phase is still unanswered question. In this study, computational method based on Density Functional Theory (DFT) was applied to investigate the chemical reactivity of different polymorphs of dicalcium silicate crystals. At first, computationally generated dicalcium silicate crystals were geometrically optimized to achieve targeted convergence criteria for computing the total internal energy, lattice parameters, and atomic arrangement at 0K. The simulations performed explain well the thermodynamic stability as well as the synthesis temperatures of the different polymorphs of dicalcium silicate.*

Keywords: *Ordinary Portland Cement, Dicalcium Silicate, Reactivity, Density Functional Theory.*

1 Introduction

Ordinary Portland Cement (OPC) is one of the most manufactured materials in the world. Cement presents a mixture of various minerals as the elevated temperature decreases during the cement manufacturing process (Taylor, 1997). Because of the mineralogical complexity of clinker materials and complicated chemistry at high temperature, the origin of different reactivity of various minerals or different polymorphs in cement is still an open question. For instance, the reactivity of dicalcium silicate, which accounts for the second largest portion in typical OPC can be a key issue to produce high performance cement or reduce carbon dioxide emissions in cement manufacturing. However, the origin of the different reactivity of the polymorphs of dicalcium silicate has not been studied yet. Dicalcium silicate forms five different polymorphs (α-C_2S, α'_H-C_2S, α'_L-C_2S, β-C_2S, γ-C_2S) depending on sintering temperatures (Balonis and Glasser, 2009; Cuberos *et al*., 2009; Taylor, 1997). It is well known that these polymorphs have identical chemical formula and mineral composition, albeit with slightly different ion substitution rates. They exhibit different crystal structures and reactivity characteristics which determine the entire chemical reaction kinetics of cement particles containing dicalcium silicate.

Several experimental methods have been conducted to study the reactivity of dicalcium silicate. Bensted (1978) found that γ-C_2S has significantly lower reactivity than β-C_2S by studying X-Ray Diffraction and Differential Thermal Analysis. The results of Cuberos et al.

(2009) and Fukuda and Taguchi (1999) suggest that the order of reactivity between the polymorphs of dicalcium silicate is α-C_2S > α'$_H$-C_2S > β-C_2S > α'$_L$-C_2S > γ-C_2S. These experimental methods, however, have limitations in terms of the difficulty of synthesizing pure polymorphs with and without ion substitution and the quantitative interpretation of the order of reactivity.

To accurately and quantitatively determine the reactivity among the different polymorphs of dicalcium silicate, the effect of foreign ion substitution should be eliminated. Recently, the reactivity of pure polymorph states has been studied through simulations. Among the simulation methods, DFT calculation has an advantage of high accuracy in simulating the crystal structures. Recent works on the reactivity of dicalcium silicate using the DFT calculation have been mainly conducted through identifying the Density of States (DOS). Wang et al. (2014) proposed the reactivity of α'$_H$-C_2S, β-C_2S and γ-C_2S in terms of Partial DOS (PDOS) and Local DOS (LDOS) based on data obtained using DFT calculation. Other results (Rejmak, Dolado, Aranda, and Ayuela, 2019; Tao, Zhang, Li, Wang, and Hu, 2019; Wang, Manzano, López-Arbeloa, and Shen, 2018) also show efforts to use DFT calculations in the reactivity studies of dicalcium silicate. However, as a result of the combined peak data from the PDOS, it is difficult to grasp the behavior of individual atoms, thus it is still difficult to find the origin of the difference in reactivity.

In this study, the relationship between the order of reactivity of different polymoprhs of dicalcium silicate and its total energy was investigated by DFT calculation. In addition, the effects of sintering temperature and the total energy of each polymorph are discussed.

2 Computational Methods

Quantum Espresso DFT package was used to perform the basic modeling and analysis of crystals of dicalcium silicates (Giannozzi *et al*., 2009). The initial model of dicalcium silicate was taken from the lattice parameters and crystal structures published for all cement phases by Balonis and Glasser (2009). In the two crystal structures of α-C_2S and α'$_H$-C_2S, the atoms with occupancies were removed due to the duplicate positions with other atoms. Figure 1 shows α-C_2S which has duplicate atoms in a unit cell. All of the crystal structures were relaxed by Quantum Espresso pw.x executable to obtain a basically stable crystal structure at 0K. The DFT calculations were performed by Perdew-Burke-Ernzerhof (PBE) Generalized-Gradient-Approximation (GGA) functionals. The pseudopotentials made out of ultrasoft-postprecessing (USPP) were used to obtain the electronical information of each atom. The force convergence threshold and energy convergent threshold were 10^{-4} Ry/au and 10^{-3} Ry, respectively. The plane-wave biases set was converged by the energy cutoff of 800 Ry. The crystal structures of all polymorphs were relaxed with Broyden-Fletcher-Goldfarb-Shannno (BFGS) algorithm. Due to the large scale of unit cell, gamma-point sampling was used.

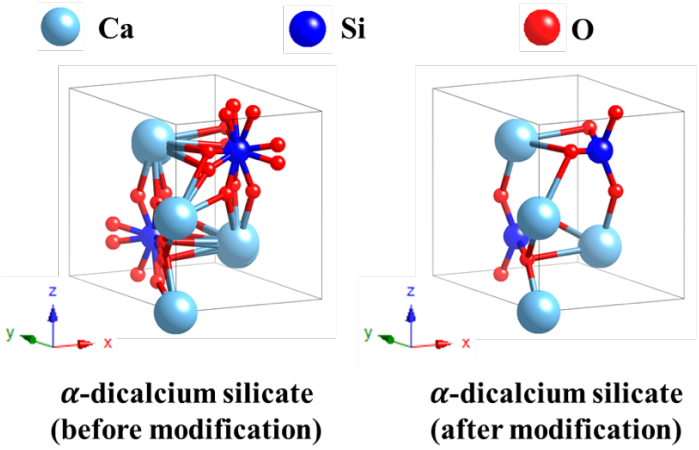

Figure 1. The crystal structure of α-C_2S before and after modification.

3 Results and Discussion

3.1 Relaxation of Polymorphs

The crystal structures of all polymorphs of dicalcium silicate were relaxed from the original crystal structure starting from the lattice parameters and positions taken from the data of cement phases as shown in Table 1 (Balonis and Glasser, 2009). Figure 2 shows the crystal structure viewed from (100), (010) and (001) planes and the standard orientation for the five relaxed dicalcium silicate crystal structures. Since the relaxation method was used which did not change the lattice parameter itself, the basic crystal shape did not change significantly.

Table 1. Cell parameters of dicalcium silicate unit cells.

Polymorphs	Crystal Structure	*a* (Å)	*b* (Å)	*c* (Å)	*α* (°)	*β* (°)	*γ* (°)	Z
α-C_2S	Hexagonal	5.579	5.579	7.15	90	90	120	2
α'$_H$-C_2S	Orthorhombic	6.85	5.49	9.49	90	90	90	4
α'$_L$-C_2S	Orthorhombic	20.871	9.496	5.6	90	90	90	12
β-C_2S	Monoclinic	5.502	6.745	9.297	90	85.45	90	4
γ-C_2S	Orthorhombic	5.081	11.224	6.778	90	90	90	4

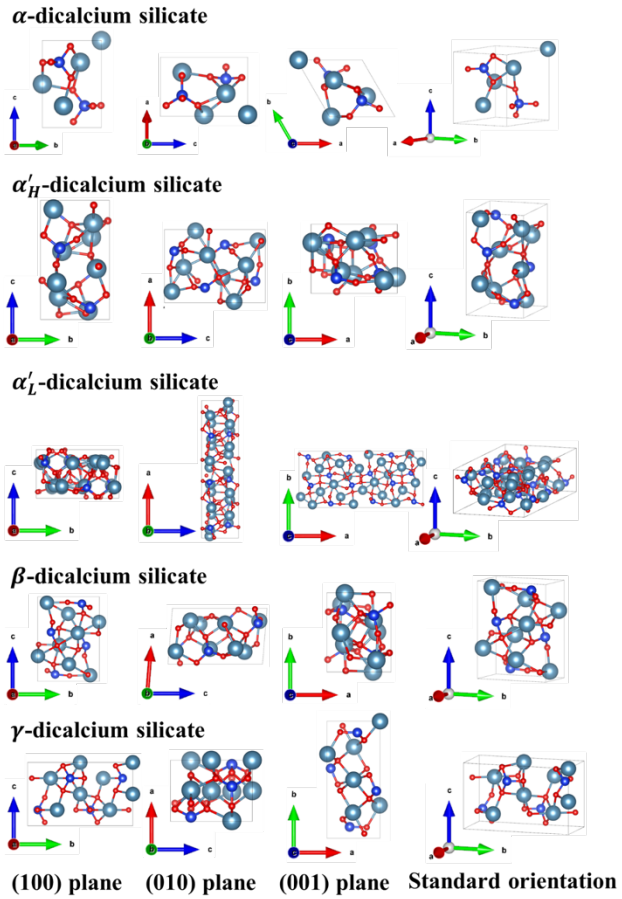

Figure 2. Relaxed crystal structures of the polymorphs of dicalcium silicate.

3.2 Total Energy

The total energy value from the DFT calculation was used to explain the origin of different reactivity among the five polymorphs of dicalcium silicate. A significant difference was found in the total energy values of the five polymorphs of dicalcium silicate. The total energy values of each crystal structure are shown in Table 2. The total energy values were divided by the Z values for comparison between each formula. Figure 3 shows that the higher the total energy value of the crystal structure, the higher the reactivity. This phenomenon can be explained by the high total energy possessed by the crystal structure which causes the instability of the structure, leading to higher reactivity.

Table 2. The total energy values of the polymorphs of dicalcium silicate.

Polymorphs	Crystal Structure	Total Energy/Z (Ry)	Reactivity Order
α-C_2S	Hexagonal	-288.31	1st
α'$_H$-C_2S	Orthorhombic	-288.33	2nd
α'$_L$-C_2S	Orthorhombic	-288.37	4th
β-C_2S	Monoclinic	-288.36	3rd
γ-C_2S	Orthorhombic	-288.41	5th

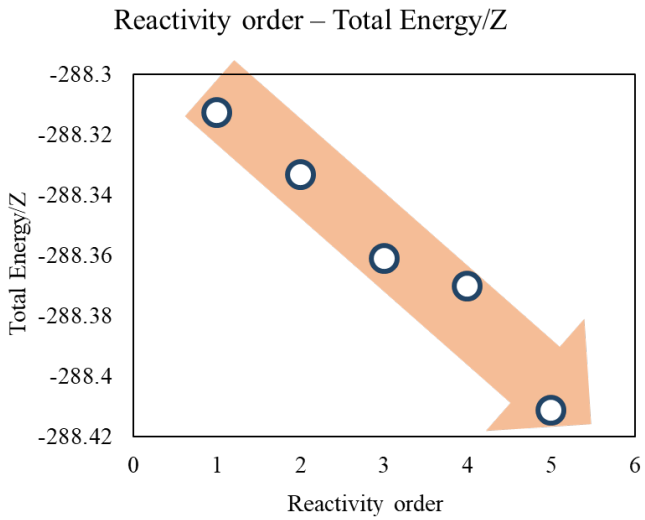

Figure 3. The relationship between the total energy and the order of reactivity.

3.3 Sintering Temperature

This can be also linked to the order of sintering temperature. It is well known that the polymorphs of dicalcium silicate forms at different sintering temperatures. Table 3 shows the relationship between the sintering temperature and the order of reactivity. As the sintering temperature required for the formation of each crystal structure increases, more unstable polymorphs are produced. This is observed for α'_H-C_2S, α'_L-C_2S and γ-C_2S. For these three polymorphs having the same orthorhombic structure, it can be inferred that the orders of sintering temperature, total energy, and reactivity match well. The reversed reactivity order of α'_L-C_2S and β-C_2S can be explained due to the different crystal structures.

Table 3. The sintering temperature and the order of reactivity of polymorphs of dicalcium silicate.

Polymorphs	Crystal Structure	Sintering Temperature (°C)	Reactivity Order
α-C_2S	Hexagonal	>1425	1st
α'_H-C_2S	Orthorhombic	1160-1425	2nd
α'_L-C_2S	Orthorhombic	680-1160	4th
β-C_2S	Monoclinic	500-680	3rd
γ-C_2S	Orthorhombic	<500	5th

4 Conclusion

- This study presents a new perspective to quantitatively explain the order of total energy, instability, and the reactivity of dicalcium silicate crystals in cement.
- In summary, the relationship between the total energy and the reactivity order of the five dicalcium silicate polymorphs was revealed by DFT calculation. The order of α-C_2S > α'_H-C_2S > β-C_2S > α'_L-C_2S > γ-C_2S, which is the well-known order of reactivity for dicalcium silicate, matches well with the order of the total internal energy calculated from the DFT. This indicates a C_2S polymorph with a higher total energy is more

unstable and thus shows higher reactivity.

- In addition, the order of sintering temperature which plays an important role in cement production was shown to be almost identical with the order of reactivity or the order of total internal energy. In particular, the sintering temperatures of α'_H-C_2S, α'_L-C_2S and γ-C_2S correspond exactly to the order of reactivity. Possible explanation is that materials which are stable at higher temperatures present a more unstable structure at lower temperature, thus resulting in higher reactivity.

Abstract. *Today, it is globally known that climate change needs to be addressed to mitigate its harmful effects on our environment. It is also common knowledge that the contribution of historical buildings to the energy consumption of the existing Canadian building stock is severe. Buildings of historical identity are often poorly thermally insulated. Thus, to increase energy efficiency and occupant comfort in cold climates, the application of thermal insulation on the interior side of solid masonry walls offers a possibility to improve the historic buildings' energy performance, without compromising their identity and cultural heritage values. As a result, the historical masonry will be subjected to lower temperature during the heating season, which can increase the potential for condensation and frost within the wall. A balance must therefore be reached between durability measures and thermal performance objectives. This paper intends to achieve this balance through determining the impact of the interior insulation thickness on the durability of a typical historical masonry wall under the effect of climate change. A stochastic approach is used in hygrothermal simulations to account for the uncertainty in material properties. Results in Ottawa indicate a higher risk to frost damage after interior insulation is added to a brick wall having a moisture critical degree of saturation (Scrit) of 0.25 and 0.35. Moreover, both deterministic and the stochastic results were in good agreement. Also, both methods showed an increase risk to frost damage under a changing climate.*

Keywords: *Historical Buildings, Solid Masonry, Stochastic Approach, Future Climates, Durability.*

1 Introduction

One typical way to reduce a building's heating energy consumption is insulating its envelope. Generally, exterior insulation systems are considered the best alternative to retrofit existing buildings due to their ability to prevent thermal bridges (Straube *et al.,* 2012). However, in the case of historical buildings, exterior insulation is not possible due to architectural and aesthetical reasons. Thus, the only way to retrofit these buildings is through adding interior insulation. Straube *et al.* (2012) suggested spraying an airtight insulating foam directly to the interior side of the existing masonry. However, normally after insulation is installed, the moisture content of the masonry wall increases, which may lead to a higher potential for hygrothermal problems, such as frost damage.

Frost damage is one of the main reasons threatening durability of masonry structures in cold climates. Previous research has shown that under a changing climate, higher rainfall intensity, strong winds, and more frequent storms are expected, which may increase WDR loads on the façade and subsequently, risks for rain penetration (IPCC, 2001). On the other hand, increased solar radiation and air temperature may increase the drying potentials. It is therefore important to assess the effect of climate change on the potential risk to freeze-thaw (FT) damage.

The hygrothermal performance of masonry walls are usually assessed by means of deterministic approach. Though, the hygrothermal responses are influenced by stochastic factors, such as the variability of material properties, boundary conditions and environmental loads. The uncertainties of the input parameters may lead to a deviation between simulation results and the actual performance of the wall assemblies, consequently, leading to faulty designs.

The objective of this paper is to investigate the impact of the interior insulation thickness on the freeze-thaw damage risk of the existing masonry wall assemblies. A masonary basewall and three retrofit options having three different insulation thicknesses were tested. First, a deterministic approach was used to evaluate the hygrothermal performance of wall assemblies using Delphin. Second, a stochastic approach was used to take into account the uncertainties in brick masonry properties under different climate conditions and design configurations.

2 Methods

The methodology includes a deterministic and a stochastic modelling approaches. The latter was developed by Wang and Ge (2018) and applied to investigate the impact of insulation thickness on the FT risk of masonry walls.

2.1 Weather Data

Weather data for Ottawa were provided by the National Research Council of Canada (NRC). A continuous time-series[1] of hourly climate data was prepared for a baseline time-period spanning from 1986-2016 and 31-year long future time-period when global warming of 3.5°C is expected to be reached in the future (Gaur et al., 2019). Future data of 3.5ºC increase, will be reached between 2062-2092 (Environment and Climate Change Canada, 2018). Each data set includes 15 realizations; however, only the median realization based on MI was used.

2.1.1 Selection of reference years

The selection of reference years was made with the intention to test wall assemblies under more representative design weather years in the selected timelines. Annual average of the Moisture Index (MI) (Cornick *et al.,* 2003) and Severity Index (Isev) (ASHRAE, 2010) were computed for the chosen time-periods, and the years were ranked in ascending order. The year corresponding to the 97th percentile (ranked second out of the 31 years) in each time-period was chosen as the MRY. Table 1 summarizes the selection of MRYs under historical and future time-periods.

[1] The full dataset can be accessed from: 10.17605/OSF.IO/UPFXJ.

Table 1. Summary of selected moisture reference year and their values.

City	Data	MI – MRY	Isev_MRY
Ottawa	Historical	2010	2009
	Future	2085	2066

A comparison was then made between the selected MRYs weather data, as shown in Figure 1 for historical and future data. The temperature difference between the MI and Isev MRYs was not as significant as the difference of their rain amount. Monthly rain variation looked relatively uniform throughout the year for MRYs selected by the MI method (2010 and 2085) and considerably less than that found for the years selected using the Isev method (2009 and 2066). MRYs selected using Isev seem to be more severe than years selected by MI; therefore, 2009 and 2066 were selected as the MRYs for this study.

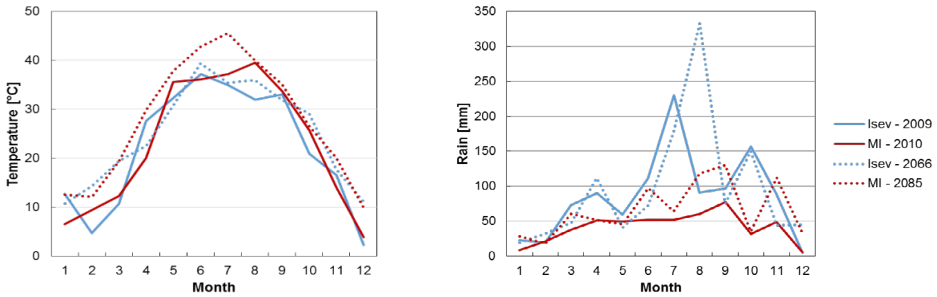

Figure 1. Comparison of monthly temperatures (a) and rain (b) for the years selected in historical data using MI (2010) and Isev (2009) and future data using MI (2085) and Isev (2066) for Ottawa.

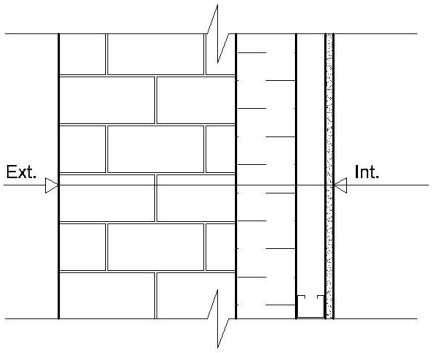
2.2 Wall Assemblies

Four wall assemblies were evaluated in this study: a solid masonry wall assembly and three internally retrofitted solid masonry wall assemblies. The first configuration consists of 300mm historical brick (Old Building Brick Rote Kaserne Potsdam – outer brick 1) and 15mm of gypsum plaster. Retrofitted wall assemblies differ only by their insulation thickness: 50 mm (2 inches) and 100mm (4 inches) of polyurethane foam were added as recommended by Straube *et al.* (2012); the insulation thickness was increased to 200mm (8 inches) to satisfy the Passive House requirement (Straube, 2009). Figure 1 shows the configuration of the retrofitted wall assemblies. Material properties are from the Delphin Material Library.



- Existing old brick (300mm)
- Added polyurethane foam
- Added (38mm x 50mm) steel stud
- Added gypsum board (12.7mm)

Figure 2. Solid masonry Wall retrofit solution.

2.3 Stochastic Model's Setup

The stochastic models were generated according to the stochastic hygric material properties of brick. The Latin Hypercube Sampling method was applied to generate the stochastic models (Wang and Ge, 2018). The basic material parameters such as effective saturation (θ_{eff}), water vapor diffusion resistance factor at dry state (μ) and liquid water conductivity at effective saturation (k_l) are considered as stochastic variables. Their mean values were based on DELPHIN material properties. Whereas, the standard deviation was calculated as a function of the coefficient of variance (CV). Values of CV were found for a similar type of brick in the literature (Zhao *et al.,* 2015). Descriptive statistics of material properties of the specific old brick material are presented in Tables 2 and 3.

Table 2. Deterministic parameters of brick.

Material property	Unit	Mean
ρ	[kg/m^3]	1842.47
c	[J/kgK]	772.224
λ	[W/mK]	0.7975
θ_{por}	[m^3/m^3]	0.304727
θ_{cap}	[m^3/m^3]	0.255
A_w	[kg/m^{2}s$^{0.5}$]	0.0668929

Table 3. Stochastic parameters of brick.

Material property	Unit	Mean	Std dev	CV (%)
θ_{eff}	[m^3/m^3]	0.28399	0.00954	3.36
μ	[-]	37.5558	9.8734	26.29
k_l	[s]	2E-8	5.248E-09	26.24

2.4 Wall Orientation

This study was carried out for the orientation with the highest amount of annual wind-driven rain calculated according to ASHRAE (ANSI/ASHRAE, 2016). In Ottawa, a wall facing South-South-West (202.5°) was considered. Note that a North-facing wall (receiving least solar radiation) was not included in this analyis; but will be further investigated.

2.5 Boundary Conditions

2.5.1 Indoor boundary conditions

The indoor relative humidity was computed using the ASHRAE 160 simple method (ANSI/ASHRAE, 2016). The indoor temperature was also calculated using the same model for heating only. As for the indoor vapour diffusion and the indoor heat conduction coefficients, they were assumed as $1.52*10^{-8}$ s/m and 8 W/m^{2}K, respectively.

2.5.2 Outdoor boundary conditions

Outdoor boundary conditions include heat conduction, vapor diffusion, wind driven rain, short wave radiation and long wave radiation. To compute the longwave radiation, the boundary layer method was selected in Delphin. The required longwave emission coefficient of the building surface was set to 0.9. And the convective heat transfer coefficient was calculated based on Equation (1):

$$h_{ce} = 4 + 4.v \quad (1)$$

Where, *v* is the wind speed. The reflection coefficient of the surrounding ground (albedo) was 0.2 and the absorptance coefficient of the brick cladding surface was equal to 0.6.

2.5.3 Wind-driven rain

WDR is calculated using ASHRAE method (ANSI/ASHRAE, 2016) for a 3.5 storey building located in the suburban area. Assuming a medium exposure factor, the rain exposure factor (F_E) and the rain deposition factor (F_D) were set to 1.0 and 0.5, respectively.

2.6 Initial Conditions

Initial temperature and relative humidity conditions were selected as constants and set to 21°C and 50%, respectively.

2.7 Performance Indicator for Assessing Wall Performance

One of the most important damage mechanisms in porous materials is caused by the action of freezing and thawing inside materials (K.R. Lisø *et al.,* 2007 G.; Wardeh and B. Perrin, 2008). The onset of freeze-thaw damage in porous materials requires that the value of moisture saturation is exceeded simultaneously with the occurrence of freezing temperatures. According to Straube *et al.* (2006), the critical degree of moisture saturation (Scrit) of masonry can vary considerably among different types of historical brick. For instance, following an experimental study using frost dilatometry, the Scrit of three brick stones found in Canada was found between 0.25 and 0.87 (Straube *et al.,* 2010). In this paper, values of (Scrit) equal to 0.25, 0.35, 0.5 and 0.8 were considered. Also, freezing is considered to occur at temperatures below -5°C within the material (Straube and Schumacher, 2006). The risk of freeze-thaw damage is computed using the critical number of freeze-thaw cycles (FTC). One cycle is counted when temperature decreases below the freezing temperature and moisture content exceeds its critical level.

2.8 Simulations

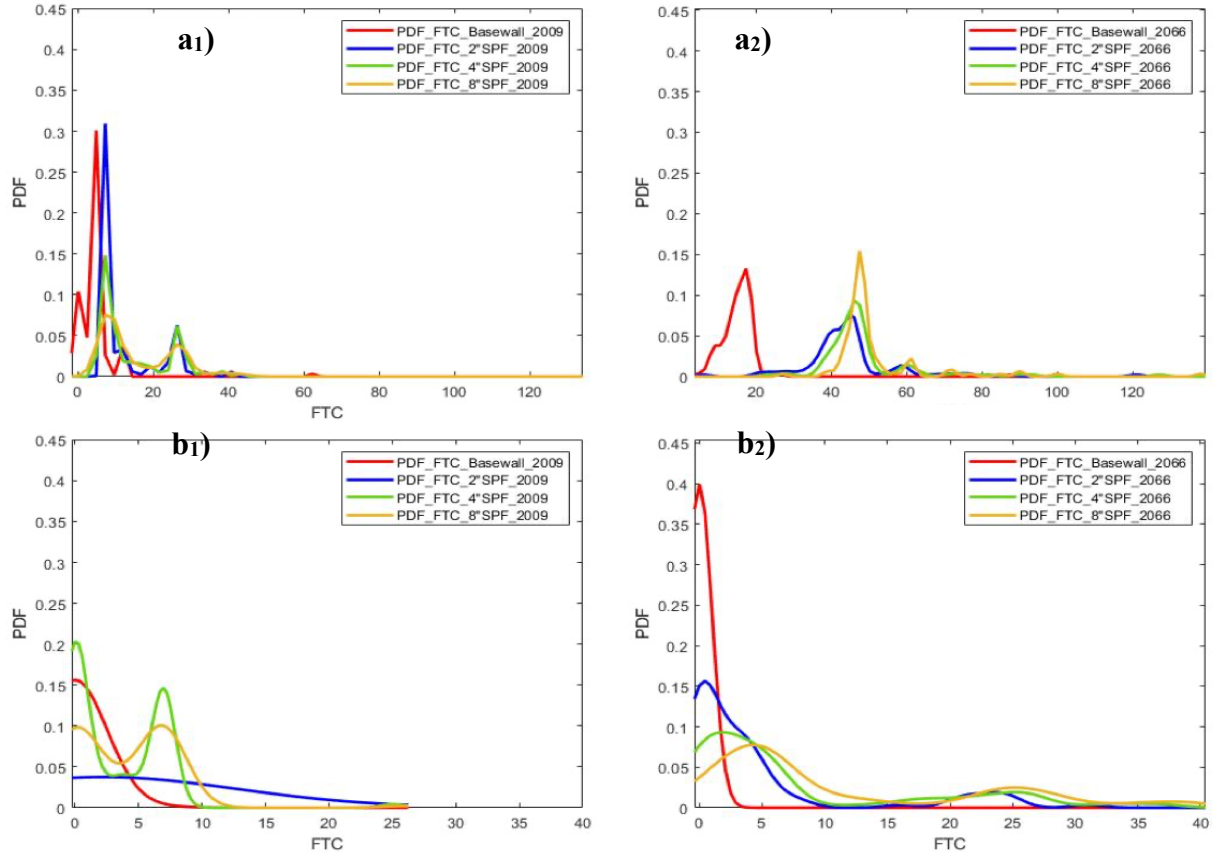
Simulations were performed for the base and retrofitted walls under historical and future loads, using hygrothermal simulation program Delphin 5, v5.9.4. No air and moisture leakage source were assumed. Simulations were executed over a period of five years using the reference year for each time-period; meaning that each selected year is repeated 5 times. However, only the results of the 5th year are evaluated.

A fine variable discretization, with a minimum element width of 0.5 mm and a stretch factor of 125 was used to set up the meshing of the materials. The point of investigation was placed at a depth of 5mm of the brick surface.

3 Results and Discussion

Figure 3 shows the impact of interior insulation thickness on the estimated number of freeze-thaw cycles (FTC) of an old brick masonry wall located in Ottawa and modelled for historical and future climatic loads. The brick was tested for different critical degree of saturation: 0.25, 0.35, 0.5 and 0.8. However, Figure 3 shows stochastic results for Scrit equals to 0.25 and 0.35 only. For higher saturation degrees, i.e., brick having higher resistance properties, the insulation thickness did not have any influence on the durability of the masonry wall. Estimated FTCs

indicated zero; therefore no potential risk to freeze-thaw damage to occur. Therefore, only results for a brick with Scrit equal 0.25 and 0.35 will be discussed.



PDF = Probability density function; SPF = Spray polyurethane foam; [1]Historical year (2009); and [2]Future year (2066).

Figure 3. Stochastic results – the impact of insulation thickness on the estimated number of freeze-thaw cycles (FTC) for brick masonry having a critical degree of saturation of a) Scrit = 0.25; and b) Scrit = 0.35.

In general, after interior insulation was added, the number of FTCs increased, indicating a higher potential of freeze-thaw to occur. For instance, FTC values varied between 0 and 12 for a base wall with Scrit = 0.25. These values increased to range between 5 and 30 FTCs when 2" of insulation was added. When adding a larger insulation thickness of 4" and 8", the number of FTCs reached a range of [5 – 42] and [5 – 50], respectively (Figure 3-a_1). The probability distribution of FTCs for the same type of brick under future climate denoted a larger difference between the base wall and the retrofitted options. While values of FTC varied between 0 and 22 for a base wall, added insulation has caused the FTC to range between 0 and 100, with a higher probability around 50 cycles (Figure 3-a_2). When the Scrit is 0.35 (Figure 3-b_1 and Figure 3-b_2), adding insulation still has increased the number of FTC; however, with less discrepancies.

Table 4 represents the deterministic results of the predicted number of freeze-thaw cycles. Comparing results obtained by the deterministic and the stochastic methods, they seem in good agreement. Values of FTCs calculated using the deterministic approach corresponds in most of the cases to the FTC number having the highest density within the stochastic results range.

Table 4. Estimated number of FTC results for the deterministic method.

	Basewall			2" added insulation			4" added insulation			8" added insulation		
Scrit	0.25	0.35	0.5 – 0.8	0.25	0.35	0.5 – 0.8	0.25	0.35	0.5 – 0.8	0.25	0.35	0.5 – 0.8
2009	*5*	*0*	*0*	*24*	*2*	*0*	*29*	*6*	*0*	*32*	*7*	*0*
2066	*5*	*0*	*0*	*49*	*2*	*0*	*52*	*9*	*0*	*56*	*21*	*0*

Figure 4 illustrates the impact of climate change on the potential risk to freeze-thaw damage. Stochastic results clearly show that FTC increased in number and spread under future conditions. Deterministic results in Table 4 demonstrated the same as well.

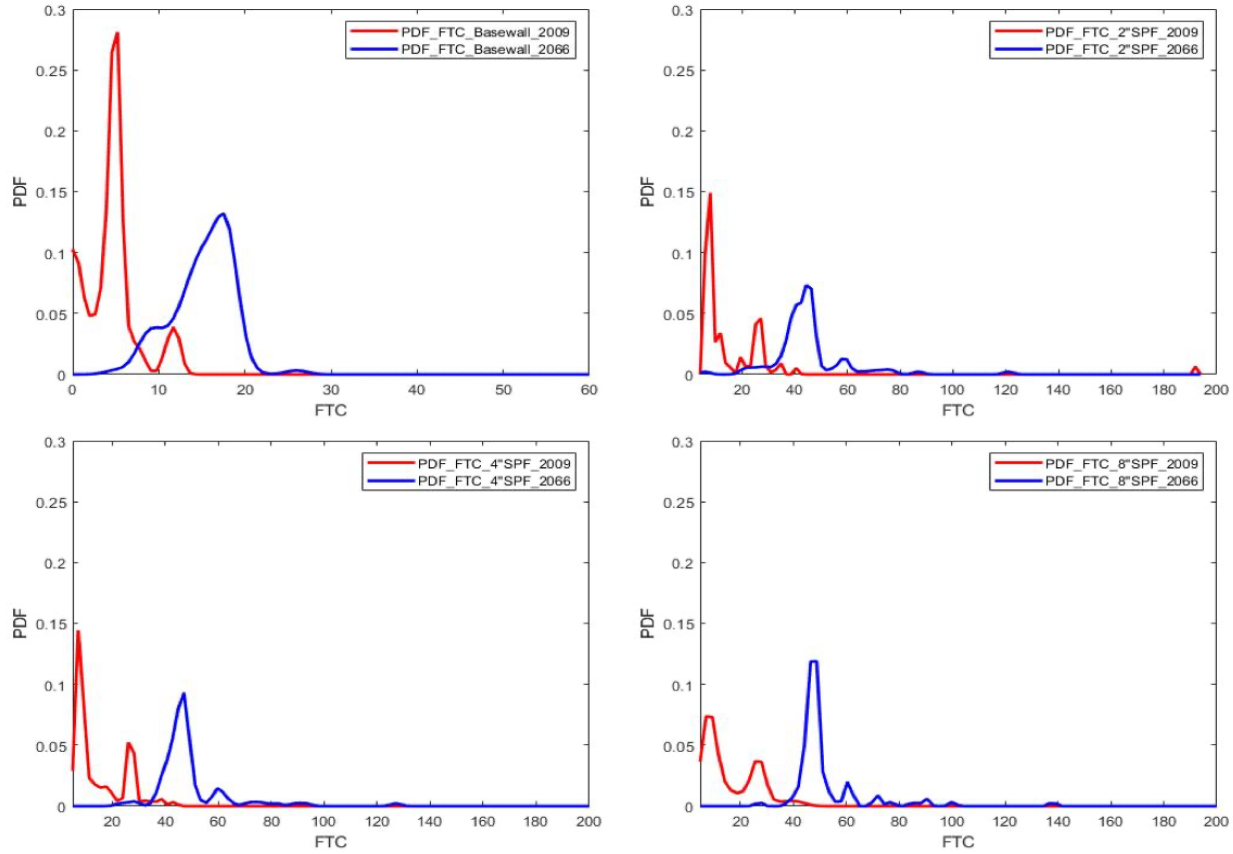


Figure 4. Stochastic results – the climate change effect on the estimated number of FTC for brick masonry having a Scrit of 0.25.

4 Conclusions

The durability performance of a masonary basewall and three retrofit alternatives of the same wall, having three different insulation thicknesses were evaluated using both a deterministic and a stochastic method. This study took into account the uncertainties in brick masonry properties under historical and future climate conditions. The brick was tested for different critical degree of saturation: 0.25, 0.35, 0.5 and 0.8. The insulation thickness did not have any influence on the durability of the masonry brick with better frost resistance, i.e. higher critical degree of saturation of 0.5 and 0.8. However, for a Scrit of 0.25 and 0.35, the number of FTCs

increased, indicating a higher potential of freeze-thaw to occur. Results obtained by the deterministic and the stochastic methods were in good agreement, as values of FTCs calculated using the deterministic approach correspond to the number of FTC having the highest probability within the stochastic results range. In addition, both methods showed an increase in FTCs' number and spread under future conditions; thus, a higher risk to frost damage. To provide a safe insulation type and thickness range for the retrofit of masonry walls and to account for the uncertainty of future climate, a study will be carried out later.

Earth Construction Durability: In-Service Deterioration of Compressed and Stabilized Earth Block (CSEB) Housing in Algeria

Adel. Benidir, M'hamed. Mahdad and Ahmed. Brara

National Center of Integrated Studies and Research on Building Engineering (CNERIB), 16201, Souidania, Algiers, Algeria, abenidir.cnerib@gmail.com

Abstract. *The present work deals with a unique in-service valuation of CSEB structures in Algeria. The inspection tries to bring out the impact of long time exposure under different and opposite climate and micro-seismic contexts. The diagnosis methodology is inspired by the approach largely adopted for the rehabilitation of traditional architecture. It involves the compilation of the previous survey reports, visual inspection of the structures, in-situ and laboratory tests to assess the residual CSEB mechanical properties. The CSEB constructions are located in the coastal north and the desertical south part of Algeria and were exposed respectively to a long-term Mediterranean and Saharian climate. The results of the investigation show that the CSEB in the construction located in the northern region is increasingly altered by the humidity. As the relative humidity rises, the fouling layers grow over some level. The surface pitting which is the consequence of long exposure to the wetting/drying cycles is also observed. The outer surfaces of the walls were honeycombed which reduce drastically the block resistance against the abrasion test. In some cases, differential erosion appears in the front of the walls, which indicates that the alteration does not proceed at the same rate from one area of the block to the other. However, owing to highly cementitious mortar used to join the earth blocks, the edges and corners remain unchipped. In the southern region where the arid climate dominating, the degradation of the CSEB is less prone to water attack but roughly exposed to the effect of the wind-dust frequent in this region and to the unawareness of the population. The paper presents also some recommendations to improve the earth construction durability with CSEB technique.*

Keywords: *Earth Blocks, Durability Valuation, Weather Exposure.*

1 Introduction

Among the eco-friendly building materials, the Stabilized and Compressed Earth Block (CSEB) is considered the most promising. Hence, improving the sustainability of this material deserves more attention and study. If the durability at the scale of the unit and the structural element in CSEB (Guettala *et al*., 2006), the scientific literature is prolific, it is not the same for constructions in the field with this material. Regular monitoring of CSEB building in the aim to assess the durability of the materials has received little formal research. The returns are generally based on a review or reported after a large building degradation or collapse. For instance, the document elaborated by Arandara and Jayasinghe (2007) on the durability of the CSEB construction gives prominent insight. The project focused on the report of the degradations observed on a group of 50 houses, 59 % of which were built in Matara (Sri Lanka) with stabilized earth blocks. This appraisal shows that the pathologies identified are mainly due to climatic factors, in particular, heavy rainfall and wind. It has been observed the appearance of water absorption by capillarity caused by the inappropriate stabilization of the

earth blocks. In addition, more erosion of the walls composed with the weakly stabilized block was noticed.

Based on previous experience, in 1949, India launched a program of construction of several hundred housing units (Bangalore), in which earth blocks manually compressed and stabilized with 5% of the cement was used. Some of these houses are still occupied to this day. Certain blocks from the demolished buildings were found to have a wet compressive strength of the order of 1.5 MPa. On the African continent, the survey reported by Oppong and Badu (2012) revealed that the walls (built with CSEB) exhibit considerable damages due to their exposure to high water absorption in Ghana. The recurring cycles of wetting/drying have inevitably caused their cracking alterations. Moreover, the blocks have been found to have low tensile strength and abrasion. In Uganda, where the projected housing backlog by the year 2000 was estimated at 3 million dwellings, an inventory of CSEB structures has been achieved by Kerali (2017). The author confirmed that in humid tropical areas, rainfall and temperature variations can adversely affect the performance of a block exposed to the elements. It was further related to the extensive appeal to this kind of construction in low income urban and rural areas.

2 Methods

The chosen diagnosis methodology is inspired by the one recommended by the Réhabimed guide (RéhabiMed, 2007) concerning the approach to be followed for the rehabilitation of traditional architecture. This guide is the work of a consortium of Mediterranean experts. In the present context, the investigation is sequenced in three stages: pre-diagnosis, multidisciplinary studies, and diagnosis. The first step ensures a brief location of the disorders and defines their nature and their extent. Herein, the classification of the construction according to the state of degradation could be partitioned into i) The building lost its structural stability or ii) The building suffers from structural disorders or other ageing pathologies. The second stage considers all historical and documentary studies that lead to the identification, the evolution and the transformation of the construction. Accordingly, that delimits and locates the factors of degradations. Finally, the diagnosis is developed following the analysis of the whole collected information to determine the causes of the disorders in order to define in fine the appropriate remedies. The diagnosis is supported by the analysis of the recorded climatic and seismic activity data of each region over the last decades.

Furthermore, laboratory and in situ tests have been performed to assess the block residual mechanical properties with both destructive (crushing) and non-destructive tests (mass rebound, abrasion). The compressive test using an universal press were extracted from the cornice and acroterion and replaced by new CSEBs in the building. The in situ tests rely on the use of pendulum sclerometer, consisting of the measurement the return of the rebound of a mass impacting a vertical surface. Abrasion tests has been performed on the block at different locations of the wall. Using a steel brush, the technique undertakes surface brushing along the entire length of the block for about a minute, which equals 30 round trips.

3 Location of the Sites, CSEB Buildings and Climate Environment

The figure 1 shows the geographic locations of the different sites assigned to the earth constructions studied throughout this investigation program.

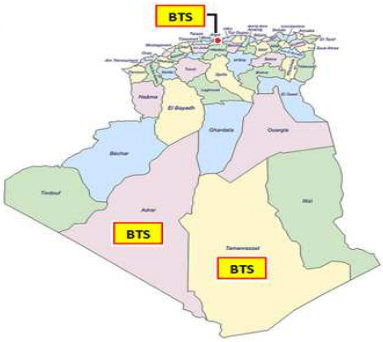

Figure 1. Geographic locations of sites.

The buildings are ground dwellings except in one residential site situated in the north region (see figure 2.c). The stabilisation of the earth blocs are both chemical and mechanical. The portion of cement exceeds 7 % and could be in some places more than 10 %. The second stage of stabilisation relies on reducing the pores volume by applying a compactive effort with at least 7 MPa of stress, using as a matter of fact a manual or a hydraulic semi-automatic press. This moulding pressure raises the bulk density of the block as it improves the block performance against the water runoff erosion phenomenon. The cure process involves a storage of the blocks under roofing or hat for 28 days. It requires also a light watering for a week with a wrap. The dimensions of the blocks used in these constructions are different from one site to another. For instance, the dimensions of the blocks manufactured and used to build the first bioclimatic prototype at Souidania in 1984 (Algiers, figure 2.a) are 250 mm in length, 125 mm in width and 70 mm in height. In 2007, blocks with the dimensions of 295 mm in length, 140 mm in width and 90 mm in height were prepared to construct the second bioclimatic prototype (figure 2.b). Over all the surveyed houses, the earth blocks are entire except in the site of Beni Messous where compressed earth hollow blocks were used.

Figure 3. Load bearing soil–cement block residential building in the northern region.

The appraisal concerns three departments (Wilaya): Algiers (Capital), Adrar and Tamanrasset. The temperature, the relative humidity and the accumulated rainfall amounts referring to these regions are respectively depicted in figure 4, 5 and 6. In summer, the maximum temperature (not the peak) reaches 44 °C in Tamanrasset and 33 °C in Algiers The relative humidity is up 78 % in the north and less than 40 % in the south. The maximum accumulated rainfall amounts in the coastal region is around 1000 mm where the value of this parameter is extensively in decrease in the south region.

4 Results

Ageing-related pathologies observed in stabilized earth constructions (CSEB) in the coastal northern region are mainly caused by weather element. Water (rain, humidity) is considered as the main cause of damage. For instance, the abundant rain in the northern region has three main effects:

i) The direct and repeated impact of the violent rain alters the surface of the external elements and causes a crumbling,

ii) The flow of rainwater on a surface (runoff phenomenon) causes surface erosion of the blocks which thereby provokes detachment of render,

iii) The splashing and infiltration generated by the indirect and repeated impact of rain on the ground, awning, exterior pavement, salient or re-entrant elements, followed by weathering, crumbling and digging.

As depicted on figure 7.a, the crumbling due to the impact of splashing attains generally the area close to the ground where the runoff phenomenon could provoke erosion in a large surface above the base (figure 7.b).

a) Splashing b) Surface erosion

Figure 7. Impact of the mechanical action of the rainwater.

The inattention on removing the element likely to cause seasonal variations in humidity in particular the vegetation near the building participate actively on the development of humid pathology (figure 8).

Figure 8. Degradation observed in the north region (humid pathology).

Furthermore, due to the high humidity rate, the pollution released in the air is fixed on the structures' external envelopes by dirtying the contact surfaces and favouring biological colonization (figure 9).

Figure 9 : Wall Pollution.

The structural degradation of the CSEB housing ascribed to the micro-seismic activity is not evident to distinguish. Although the coastal area is subjected to an important micro-seismic activity (about 60 micro-earthquakes per month), the noticed structural defects could be assigned to the differential settlement.

For the southern region, the investigation has ultimately identified very little pathologies due to exposure to climate, characterized by very low rainfall. On the other hand, the very frequent winds activity in this region has a stronger mechanical action when they carry suspended particles, such as the sands. The most common defects observed included: surface roughening, erosion and surface pitting. However, the inspection in the North and South regions has highlighted significant degradation resulting from poor design, production and implementation of the blocks, as well as others due to human intervention such as undertaking fitting out works or installation of air conditioning equipments.

Figure 10. Direct impact of the mechanical action of the wind.

5 Conclusions and Contribution

In this contribution, an evaluation of the in-service earth housing degradation in Algeria is reported. The investigation consists of an in-field visit including visual inspections supported by in situ and laboratory tests on CSEB. The visited earth constructions are long-time exposed to varied micro-seismic and climate contexts. In the coastal region where the high rainfall frequency and important humidity rate prevails, the CSEB constructions defects included: black fouling, due to pollution and biological colonization, efflorescence, detachment of render and erosions caused by the effects of whipping rains. On the one hand, the housing experiencing arid climate condition, the blocks are less prone to humid pathology. The observed defects concern surface roughening and pitting. On the other hand, the degradation caused by the inhabitant unawareness adversely affects the performance of the blocks. From the analysis of the degradations unveiled by the in-field investigation, some recommendations to improve the durability of the CSEB constructions are made:

Maintenance of the terraces according to the geographical situation and the climatic conditions.

Cleaning walls affected by fouling and biological colonization.

Checking the correct drainage of rainwater (avoid stagnation of water) to provide a good circulation and evacuation of the collected rainwater.

Removing the element likely to cause seasonal variations in humidity in particular the vegetation near the building.

Elevating the base, putting a sufficient roof overhang or installing an anti-capillary barrier especially in the North region.

Resorting to the earth construction guide in the selection of the soil nature and the process of stabilization.

Installing a windbreak and / or choosing an appropriate orientation of the structure minimizing the direct exposure to the winds.

Abstract. *Textile-reinforced mortar (TRM) composites have received extensive attention as a sustainable solution for seismic strengthening of masonry and historical structures. This new system is composed of textile fibers embedded in an inorganic matrix and is applied on the masonry and the concrete substrate surface as an externally bonded reinforcement (EBR) system. The bond at the textile-to-mortar interfaces is the main stress-transfer mechanism and, therefore, should be thoroughly investigated. Furthermore, the effectiveness of TRMs in improving the seismic performance of existing structures is highly dependent on the durability of its components, materials, textile-to-mortar bond, and their long-term behavior. Due to the novelty of these materials in application to masonry structures, several aspects related to the durability and long-term performance of them are still not clear. To that end, a new study has been launched that looks at the time effect on the mechanical properties and bond behavior between fiber and mortar. For this purpose, two different hydraulic lime-based mortars, as well as steel and glass fibers, are used to investigate the effect of mortar age on the TRM system after 180 days. The results show that at the early age of mortars, their mechanical properties, and the bond behavior of textile-to-mortar have been increased. Another critical point to remember is that by increasing the mortar age, textile-to-mortar bond and mortar strength are decreased.*

1 Introduction

The advantages of textile reinforced mortar (TRM) composites to fiber-reinforced polymers (FRPs) are the fire resistance, the vapor permeability, the removability, and the compatibility with masonry and concrete substrates (Carozzi and Poggi, 2015; Papanicolaou, Triantafillou, Papathanasiou, and Karlos, 2007). Thus, these advantages have made TRM composites very interesting for externally bonded reinforcement of masonry and reinforced concrete structures.

Mechanical properties of the TRMs and structural components strengthened with TRMs are strongly dependent on the properties of both the mortar and the fiber, the interfacial bond behavior of the fiber-to-mortar, and the interfacial bond behavior between the TRM composite and masonry substrate (Ghiassi, Oliveira, Marques, Soares, and Maljaee, 2016). Although mechanical characterization of TRMs (Leone *et al.*, 2017; Lignola *et al.*, 2017), or the bond between TRM and masonry substrate (Ascione, De Felice, and De Santis, 2015; Razavizadeh *et al.*, 2014) have been the subjects of several studies, the fiber-to-mortar bond

response has not received the attention (Dalalbashi, Ghiassi, Oliveira, and Freitas, 2018a; Ghiassi *et al.*, 2016). The fiber-to-mortar bond response of TRMs made of cementitious composites has been the subject of several studies, but this mechanism in case of lime-based TRMs that are usually used for strengthening of masonry structures is relatively unknown. The fundamental differences between the mechanical properties of lime-based and cementitious mortars indicates that a different bond behavior should be expected. Therefore, there is a clear need for understanding of this mechanism in lime-based TRMs and the parameters affecting that for fit-for-purpose design of TRMs, as well as, fully utilization of this strengthening system when application to masonry structures.

The age of mortar for performing pull-out tests (or any other mechanical characterization tests) on TRM composites seem to be a critical issue. Hydraulic lime-based mortars usually used in TRMs for application to masonry, and historical structures harden over prolonged periods. It means that probably the bond and mechanical properties of the TRM composite is also developed over longer periods, compared to the 30 days curing time commonly used for cementitious materials. In this study, to better understand the role of mortar age on the bond behavior of the fiber-to-mortar, pull-out tests are performed from 15 to 180 days of curing, and the results are compared and discussed.

2 Experimental Program

The experimental program consists of evaluating the role of mortar age on the pull-out response of single fibers embedded in lime-based mortars. For this purpose, two commonly used fiber types (steel and glass) with their counterpart mortars are used for these investigations.

2.1 Materials

Materials consisted of two commercial hydraulic lime-based mortars referred to as M1 and M2 throughout this paper. Mortar M1 is a high-ductility hydraulic lime mortar (Planitop HDM Restauro), and mortar M2 is a pure natural NHL 3.5 lime and mineral geo-binder base (GeoCalce).

The reinforcing materials are glass and steel fibers. The glass fiber is a woven biaxial fabric mesh (Mapegrid G220), and based on the technical datasheets, the elongation at breakage, modulus of elasticity, and tensile strength are 1.8 %, 72 GPa, and of 45 kN/m, respectively. The steel fiber is a unidirectional ultra-high tensile steel sheet (GeoSteel G600) and is made by twisting five individual wires together. The density and effective area of one cord (five wires) is equal to 670 g/m^2 and 0.538 mm^2, respectively. Additionally, its tensile strength and elastic modulus are equal to 2800 MPa and 190 GPa, respectively.

The fiber/mortar pairs are selected from the same provider in this study. It means that the glass fibers are used with the mortar M1 and the steel fibers with the mortar M2.

2.2 Material Characterization Tests

Mechanical characterization tests on mortar included compressive and flexural tests, according to ASTM C109 and EN 1015-11. The changes in the mechanical properties of mortar with curing age are evaluated by performing the tests at the ages of 14, 28, 60, 90, 180 days.

The compressive tests are performed on five cubics (50×50×50 mm^3) specimens at each age with a Lloyd testing machine under force-controlled conditions at a rate of 2.5 N/s. A pair of Teflon sheets with a layer of oil in between is placed between the specimens and the compression plates to reduce friction near the boundaries (Figure 1a). The flexural tests are performed on five prismatic (40×40×160 mm^3) specimens, at each age, following a three-point bending test scheme (Figure 1b). The tests are performed with a Lloyd testing machine under force-controlled conditions at a rate of 10 N/s.

(a) (b)

Figure 1. Mechanical characterization tests: (a) mortar compressive test; (b) mortar flexural test.

2.3 Pull-out Test

The single-sided pull-out test setup developed and presented by the authors in (Dalalbashi *et al.*, 2018a) is used in this study for investigating the fiber-to-mortar bond performance. The specimens consist of fibers embedded in disk-shaped mortars with a thickness of 16 mm (see Figure 2). The free length of the fiber is embedded in an epoxy resin block with a rectangular cross-sectional area of 10×16 mm^2, as shown in Figure 2. For detailed information on the procedure followed for the preparation of the specimens, the reader is referred to (Dalalbashi *et al.*, 2018a). The embedded lengths of steel and glass fibers are equal to 150 and 50 mm, respectively. These embedded lengths are corresponding to the sufficient embedded length of each composite system (Dalalbashi, Ghiassi, Oliveira, and Freitas, 2018b). The specimens are demolded after 24 hours of preparation and are stored in the lab environmental conditions (20°C, 60% RH) until the test day. Both glass and steel-based specimens are tested at the ages of 15, 30, 90, and 180 days ,to evaluate the role of mortar age on the fiber-to-mortar bond behavior.

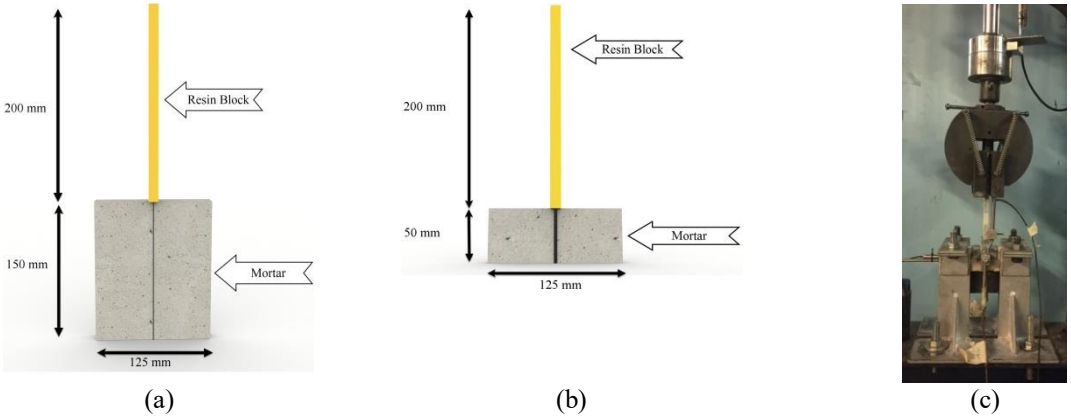
U-shape steel support is utilized for supporting the specimens (Figure 2). A mechanical clamp is used to grip the epoxy resin from the top. Also, two LVDTs with a 20 mm range and 2-µm sensibility are located at the side and in front of the epoxy block, at the vicinity of the mortar edge, to record the slip. All the tests are carried out using a servo-hydraulic system with a maximum capacity of 25 kN at a displacement rate of 1.0 mm/min.

3 Experimental Results and Discussion

3.1 Material Properties

Table 1 presents the changes of mortars' mechanical properties with age. Although both mortars show similar value for the maximum compressive strength (8.31 MPa for M1 and

9.53 MPa for M2), the peak values are reached at different times. Mortar M2 shows the maximum gain of compressive strength in the first 30 days, and after that, a slight decrement of compressive strength is observed until 180 days. Meanwhile, mortar M1 reaches its peak compressive strength in 60 days, and after that, the changes in the compressive strength are negligible.



(a) (b) (c)

Figure 2. Details of pull-out specimens and test: (a) steel-based TRM; (b) glass-based TRM; (c) test setup.

Mortar M2 reaches its peak flexural strength in the first 30 days, but the flexural strength of mortar M1 increase until 180 days. As flexural strength is indirectly related to the tensile strength of the mortar, an evolutionary bond behavior should also be expected in the experimental pull-out curves until 180 days. Additionally, mortar M1 shows a higher flexural strength (6.0 MPa), in contrast to M2 (2.62 MPa), even if it has a smaller compressive strength that is an indication of a more ductile response of M1 mortar.

Table 1. Mortar mechanical properties with age.

Mortar	Test [MPa]	Mortar age [days]				
		14	28	60	90	180
M1	Compressive strength	5.91 (8)	7.07 (9)	8.31 (11)	7.84 (4)	7.46 (10)
M1	Flexural strength	4.03 (3)	4.71 (7)	5.10 (3)	4.66 (8)	6.0 (10)
M2	Compressive strength	8.76 (7)	9.53 (10)	8.81 (12)	8.89 (5)	7.48 (5)
M2	Flexural strength	1.79 (12)	2.54 (9)	2.09 (7)	2.33 (9)	2.62 (13)

Coefficients of variation (%) are provided in parentheses.

3.2 Pull-out Response

3.2.1 Steel-based TRM composite

Figure 3 and Table 2 present the evolution of the pull-out response of steel-based TRMs with time and the summary of the main characteristics of the pull-out curves of different ages.

A typical three-stage of the bond behavior of the fiber-to-mortar (linear, nonlinear, and dynamic stage) is shown by the pull-out response of steel-based TRM at all ages. The linear elastic range terminates with the first debonding at the interface occurs that leads to a concave-downward shape in the pull-put curves (D'Antino, Carrozzi, Colombi, and Poggi, 2017). Once the peak load is reached, which is corresponding to the full debonding along the embedded length, the pull-out load is dropped, because the bond force is larger than the frictional force in this system (Li, Wu, and Chan, 1995). The pull-out curves, then, show a strain hardening behavior (forming a second peak load) and then a softening response until the end of the tests.

By comparing the average curves, a slight increase in the pull-out response can be observed in the first 30 days, followed by a slight decrease until 180 days. A possible explanation for this phenomenon is due to the changes in the mechanical properties of the mortar M2 that followed a very similar trend with time. Table 2 shows the bond properties of steel-based TRM. While the toughness follows a similar trend as the peak load (increases initially and then a decrease), the slip corresponding to the first peak load is almost constant. At the same time, the initial stiffness of the pull-out curves seems to be decreasing with time.

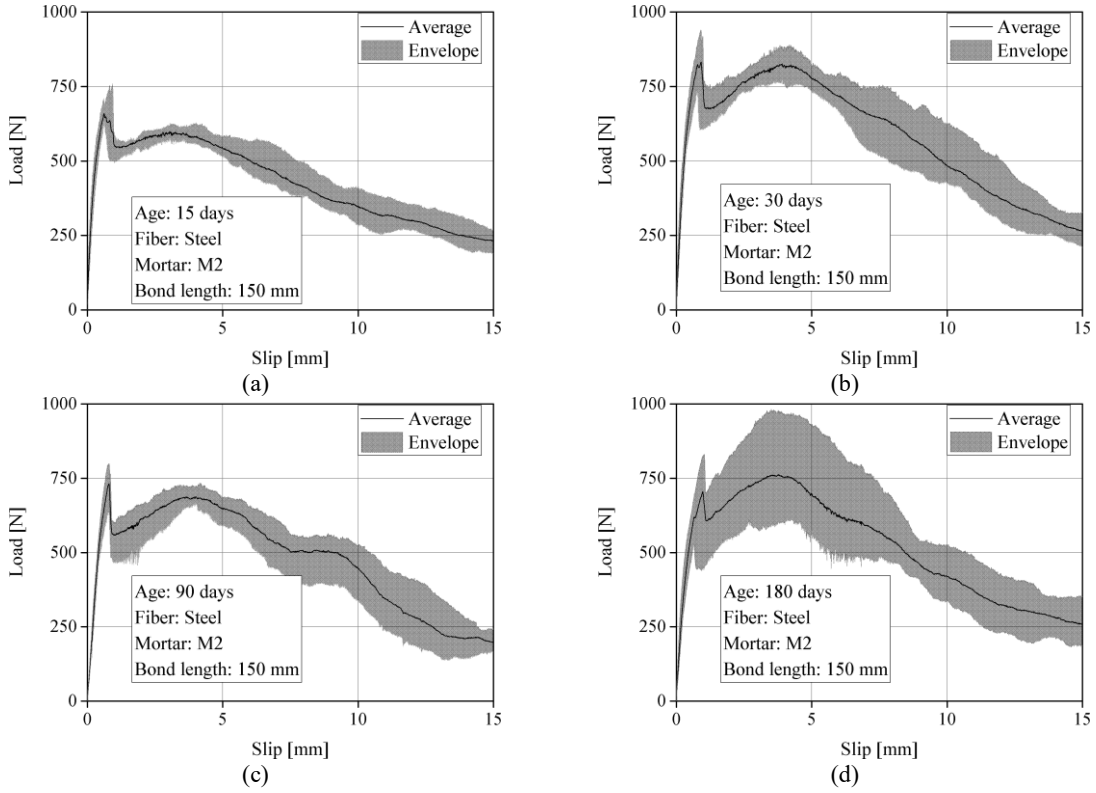


Figure 3. Envelope load-slip curves of steel-based TRM at different mortar ages: (a) 15 days; (b) 30 days; (c) 90 days; (d) 180 days .

Table 2. Effect of mortar age on the pull-out response of steel-based TRMs.

Age [days]	Slip corresponding to peak load [mm]	Peak load [N]	Toughness at a crack opening of [N.mm]			Initial stiffness [N/mm]
			1 mm	4 mm	8 mm	
15	0.8 (16)	711 (7)	511 (8)	2238 (4)	4236 (5)	1903 (19)
30	0.9 (9)	872 (9)	599 (10)	2861 (5)	5745 (6)	2076 (23)
90	0.8 (3)	741 (9)	474 (8)	2372 (7)	4747 (7)	1277 (10)
180	0.9 (16)	731 (17)	476 (16)	2581 (15)	5143 (17)	1360 (14)

Coefficients of variation (%) are provided in parentheses.

3.2.2 Glass-based TRM composite

It can be observed that the pull-out response of the glass-based TRMs shows a significant change with time, as shown in Figure 4. At the mortar ages of 15 and 30 days, after complete debonding (at peak load), a descending trend in the pull-out force can be observed. In contrast, at the age of 90 and 180 days, the pull-out force increases after complete debonding, showing a slip hardening behavior. This behavior, again, is in-line with the observed changes in the mechanical properties of mortar M1. The flexural strength of mortar M1 continuously increased until 180 days, and therefore increasing bond strength is also expected to be developed during this period.

The summary of the pull-out curves presented in Table 3 shows the slip corresponding to the peak load is relatively constant. In contrast, the peak load, toughness, and initial stiffness of the pull-out curves increase with time until 180 days.

Table 3. Effect of mortar age on the pull-out response of glass-based TRMs.

Age [days]	Slip corresponding to peak load [mm]	Peak load [N]	Toughness at a crack opening of [N.mm]			Initial stiffness [N/mm]
			1 mm	4 mm	8 mm	
15	2.6 (12)	285 (10)	154(11)	914 (10)	1778 (4)	456 (4)
30	1.9 (31)	251 (30)	156(18)	805(24)	1540(27)	815 (22)
90	2.3 (13)	379 (16)	227(9)	1727 (12)	2476 (16)	858 (22)
180	2.3 (27)	391 (12)	191 (17)	1252 (3)	2673 (9)	909 (35)

Coefficients of variation (%) are provided in parentheses.

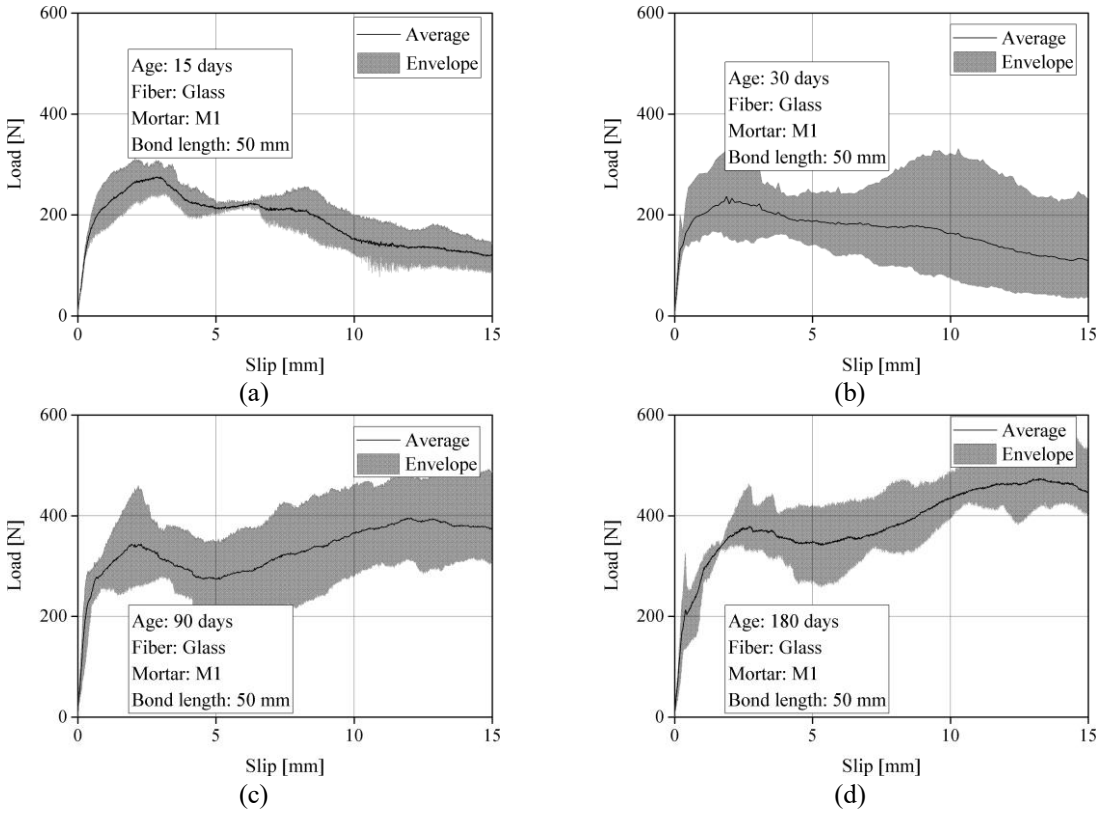

Figure 4. Envelope load-slip curves of glass-based TRM at different mortar ages: (a) 15 days; (b) 30 days; (c) 90 days; (d) 180 days .

4 Conclusions

A comprehensive experimental study is presented in this paper on the role of mortar age on the pull-out response of single fibers embedded in lime-based matrices. The following conclusions can be drawn from the obtained experimental results:

- The results show the significant effect of mortar age on the bond response. In particular, it seems that the 30 days curing period that is usually used for cementitious mortars is not suitable for lime-based mortars.
- It is difficult to propose a generic curing time for performing the pull-out tests when lime-based mortar is used as the matrix. In one of the studied mortars, 60 days of curing seemed to be sufficient for obtaining realistic bond behavior, while in the other mortar 90 days is found to be the minimum required aging time.
- The changes of flexural strength of the mortar seemed to be a good indication of the changes in the bond behavior and are suggested to be considered in investigations for estimating the suitable curing age for evaluating the mechanical properties and bond response of these systems.

Electro-Desalination of Sandstones With Cracks

Lisbeth M. Ottosen

Department of Civil Engineering, building 128, Technical University of Denmark, 2800 Lyngby, Denmark, LO@byg.dtu.dk

Abstract. *Historical stone monuments and buildings are lost due to salt induced decay. This paper deals with a method, electro-desalination (ED), in which an electric DC field is applied to the infected stones. The method utilizes that ions are transported (electromigrating) in the pore solution in the electric field. In the experimental work here, sandstone prisms were spiked with NaCl to high concentrations prior to ED. During the application of current, the Cl ions are electromigrating into a poultice at the anode, and Na ions into a poultice at the cathode. Damaged stones are often fragile and cracked, and the focus of this paper is to investigate experimentally if the salts are removed effectively from the stone parts next to a crack. In the lab experiments performed, a crack was cut half through the rectangular sandstone prisms perpendicular to the electric field. The results showed no delay on the ED process from the crack. All through the stone, very low concentrations of Na and Cl were reached. The concentration were even lower than the concentrations before the spiking. This finding of effective desalination around a crack is important, as it means that during ED, the poultice with electrodes can be placed around the cracked and fragile surfaces, and thus further damage from physical contact between poultice and fragile stone can be avoided.*

Keywords: *Salt Induced Decay, NaCl, Sandstone, Electro-Desalination, Historical Buildings.*

1 Introduction

Soluble salts cause damage to many historic stone buildings and monuments, and cultural heritage is lost. When water accesses the pore network of a stone, it may carry various salts in solution. Several mechanisms can subsequently cause crystal growth and crystallization-dissolution cycles, which can result in severe stone damage. The techniques to remove the damaging salts are few, and an overall effective method is lacking. The use of poultice materials to reduce the salt content of salt deteriorated objects is a long established technique in conservation (Sawdy-Heritage *et al.,* 2008). However, due to the complex nature of salt problems within historic structures the result of such interventions can be variable and unpredictable. The amount and depth to which salts are mobilised, and where they are transported to, is dependent on the inter-relationship between the poultice and the substrate, the drying conditions and also the initial salt distribution (Sawdy-Heritage *et al.,* 2008).

Another option is electro-desalination (ED), which is a method under development. ED is based on application of an electric DC potential gradient to the salt contaminated stone. The method utilizes that ions in the pore solution are transported by electromigration towards the electrode of opposite polarity when the electric field is applied. The electrodes are placed externally on the stone surface in electrode compartments with poultice, and the ions from the salts concentrate in the poultice during the treatment. When the poultices are removed after the ED, the ions of the salts are removed with them.

Electrolysis of water occurs at both metallic electrodes: at the anode $H_2O \rightarrow 2H^+ + ½\ O_2\,(g)$

doi:10.23967/dbmc.2020.210

+ $2e^-$ and at the cathode $2H_2O + 2e^- \rightarrow 2OH^- + H_2$ (g). As seen, pH decreases at the anode and increases at the cathode. It is necessary to neutralize the pH changes to prevent severe damage of the stone. The work by (Herinckx *et al*., 2011; Skibsted, 2013) underlined the importance of avoiding stone acidification, as in ED experiments without pH neutralization, the stones were severely damaged next to the anode. Use of a calcite rich clay poultice offers neutralization of the acidification from the anode (Rörig-Dalgaard, 2013). The calcite buffers the acid and the clay gives workability, so the poultice can have optimal contact to the stone surface during the treatment.

Previous research has shown that ED can be removed from high and damaging concentrations to very low concentrations in laboratory scale from different types of sandstones: Posta and Cotta sandstones (Ottosen and Christensen, 2012), Gotland Sandstone (Skibsted, 2013), Nexø sandstone (Pedersen *et al*., 2010), and granite (Feijoo *et al*., 2013). No limitation posed by the stone type has been reported. Also successful removal of different salts of chlorides (Ottosen and Christensen, 2012), nitrates (Skibsted *et al.,* 2013) and sulphates (Ottosen, 2016) have been obtained.

An advantage of ED over poultising is that whereas in poulticing the poultice needs to be covering the surface of the object, inclusive the most fragile parts, this is not necessary in ED. In ED, the poultice with electrodes can be placed around the fragile parts, and the electric field will distribute into the stone material. It has been shown experimentally that the salts can be removed from stone parts, which are not placed in the direct line between the electrodes, which means that e.g. carvings can be desalinated (Ottosen *et al.,* 2014 ; Feijoo *et al.,* 2017;Ottosen, 2017).

Damaged stones are often cracked, and thus it is relevant to investigate if the salts are removed efficiently around the cracks. The electric field can pass only through the moisture of the pores and in case the crack is air-filled, it acts as an insulator, which the electric field lines cannot pass. This work is an experimental investigation of the influence from a major crack on the ED process. Laboratory experiments are conducted with single sandstones, where a major crack is cut perpendicular to the electric field lines, and the salt concentration around the crack is measured after different durations of the desalination.

2 Materials and Methods

2.1 Experimental Stones

The experimental work was conducted with Gotland Sandstone. This type of stone was chosen, as it is relatively homogeneous and it is commonly used in Denmark. All sandstone pieces in this work were cut from the same block.

2.2 Measuring Techniques

For the measurement of pH, conductivity and concentration of soluble Cl and Na, the dried stone samples were grinded in a mechanical mortar. Following 10 g powder was suspended in 25 ml distilled water and agitated for 24 h. The samples settled for 10 min and pH was measured. The samples were filtered through 0.45 µm filter. Na concentrations were measured by ICP-OES. Cl concentrations were measured by ion chromatography (IC, Dionex DX-120). The concentrations for each segment was measured as single determination.

The open porosity and density of the Gotland Sandstone used in this work were determined (five replicates). Sanstone pieces of 170-190 g were dried (105 °C for 24 hours), weighed (m_{dry}), and placed in a desiccator under vacuum for approximately 3 h. After 3 h, distilled water at room temperature was led into the desiccator, so that the discs were completely submerged. Vacuum was maintained for 1 h. Hereafter, air was let into the desiccator and the submerged discs were left at atmospheric pressure overnight. The water-saturated pieces were weighed in water (m_{sw}) and in air after wiping excess water of the surface (m_{sa}). The open porosity was calculated as $(((m_{sa} - m_{dry})/(m_{sa} - m_{sw})) *100\%)$; and apparent density $(((m_{dry}*\rho_w)/(m_{sa} - m_{sw}))$, where ρ_w (970 kg/m3) is the density of water.

To have a uniform distribution of the salt prior to the experiments, the stone samples were contaminated with the salt in the lab: the stone prisms were dried at 105°C and vacuum saturated by 80 g/l solution of NaCl in a desiccator prior to the ED experiments. The dry weight of the stone prisms before vacuum saturation (m_d) and the stone weight after vacuum saturation (m_0) were measured and from these the initial water content was calculated as $(m_0 - m_d)/m_d)*100\%$.

2.3 Electro-Desalination Experiments

Four rectangular stone prisms were cut from the same stone block. The prisms were 13.5 cm x 7.5 cm x 5.5 cm. A crack was cut half way through each prism in the middle, perpendicular to the longest side (and the electric field lines) (Figure 1). The width of the void was about 1 mm.

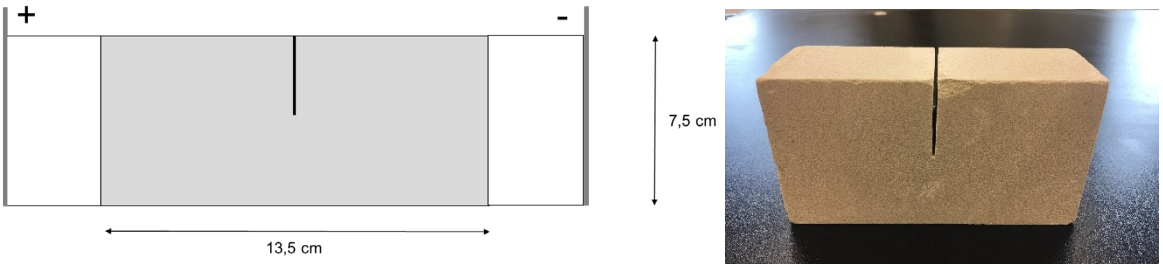

Figure 1. The setup for electro-desalination. The electrodes are placed in clay poultice on each end of the stone, and a crack is cut half into the stone perpendicular to the electric field.

Electrode compartments were placed at each end of the rectangular stone prism as illustrated in figure 1(a). For the electrode compartments a frame was folded in thin plastic to fit the surface of the stone at each side. The frames were filled with poultice; a mixture of kaolinite and CaCO3 [3] with an initial water content of 54%. Inert platinum coated electrode meshes were placed at the end of each electrode compartment. The sandstone and electrode compartments were wrapped in plastic film to hinder evaporation. A reference stone (REF) was made with no applied current. The REF stone was wrapped in plastic film for 14 days. Three ED experiments were made differing only in duration: 2, 4 and 5 weeks (ED_2, ED_4 and ED_5). A constant current of 10 mA was applied to the electrodes all through these experiments. Table 1 shows the dry weight (m_d) of the different stone prisms, the water content after the vacuum saturation and the duration of the experiments in weeks.

Table 1. REF and ED experiments. Dry weight of stone, initial water content after vacuum saturation and duration of experiment.

	Stone weight, m_d (g)	Initial water content (%)	Duration (weeks)
REF	1072	10.2	2 (no current)
ED_2	1056	10.4	2
ED_4	1084	10.5	4
ED_5	1079	9.4	5

After the REF and ED experiments, the stone prisms were segmented with hammer and chisel into 8 segments (Figure 2). The upper row of segments were named a-segments and the lower b-segments. All segments were weighed and dried (24 hours at 105°C), and the water content calculated. The dried segments were grinded in a mechanical mortar (FRITSCH – pulverisette 9) for 10 seconds. Following, 10 g powder was suspended in 25 ml distilled water and agitated for 24 h. The samples settled for 10 min and pH was measured. The samples were filtered through 0.45 µm filter. The Cl concentrations were analyzed by ion chromatography (IC, Dionex DX-120).

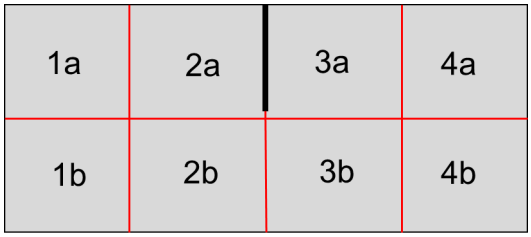

Figure 2. Segmentation of stone block after electro-desalination.

The poultices were changed every 7th day. The poultices were weighed. The Cl and Na concentrations, water content and pH were measured using the same methods as for the stone segments.

3 Results and Discussion

3.1 Characteristics of the Sandstone

The porosity of the Gotlandic sandstone used in the experimental work was 20.4% ± 0.03%, which is higher than previously reported (15%) by (Nord and Tronner, 1995). The difference shows a natural variation in the porosity of Gotlandic sandstone. Nord and Tronner (1995) reported that the grey, calcitic Gotland sandstone is composed of about 60 wt% quartz grains, cemented together by 7-10 wt% calcite, and with lower amounts of clay minerals, micas, feldspar minerals, pyrite, and glanuconite.

The concentrations of Cl and Na before and after spiking with NaCl is shown in table 2 together with pH and conductivity. The salt concentration is similar to previous investigations with the same type of sandstone and concentration of NaCl in the spiking solution (Ottosen *et al*. 2014).

Table 2. Concentrations of Na and Cl, pH and conductivity of the stone before and after spiking with NaCl.

	Na (mg/kg)	Cl (mg/kg)	Conductivity (mS/cm)	pH
Before spiking	23.3 ± 0.3	21.4 ± 4.2	0.46 ± 0.04	8.6 ± 0.04
After spiking	2520 ± 230	4200 ± 130	5.33 ± 0.16	9.1 ± 0.1

3.2 Electro-Desalination Results

The concentrations of Cl and Na in the different segments after the REF and the three ED experiments are shown in figure 3. The decrease in concentrations is clear and the average concentrations were already about halved after two weeks.

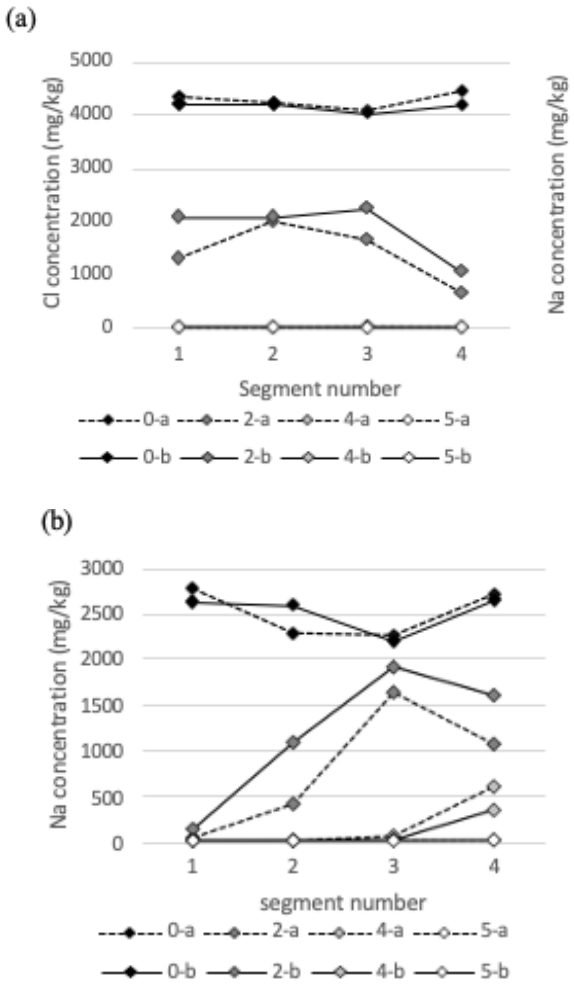

Figure 3. Concentration profiles of (a) Cl and (b) Na in the stone segments at the end of the experiments. The dotted lines are the profiles in the segment row with the crack (a-segments) and the full lines are the lower row of segments (b-segments).

The final Cl concentration in all segments in ED_4 was between 14 to 19 mg Cl/kg (figure 3), which corresponds to a reduction of more than 99.5% in comparison to the 4200 mg Cl/kg, which was the initial concentration in the ED experiments (Table 2, concentration after spiking). The final Cl concentrations were even lower than the concentration in the stone before the spiking (21.4 mg Cl/kg; table 2), and the Cl removal was successful all through the stone. Thus, the final Cl concentration in the segments next to the crack was not negatively influenced by the crack.

The Na removal was not finished in ED_4 since the concentration was still 340 and 600 mg Na/kg in the segments closest to the cathode, 4a and 4b, respectively (figure 3). Thus, the removal of Na was slightly slower than the removal of Cl. However, within one week longer treatment, the Na removal was successful, as in ED_5 the concentrations in the segments were between 7 and 11 mg Na/kg, which was also less than before the spiking (2520 mg Na/kg).

The successful desalination was supported by the conductivity, which in the segments after ED_5 was 0.096 ± 0.007 mS/cm was also less than the 0.46 ± 0.04 mS/cm prior to the spiking.

The pH in the segments after ED_5 was between 9.7 and 10.3. Since the initial pH was 9.1 (table 2), the pH was increased all through the stone, and the acidic front was thus prevented in developing into the stone by the poultice.

In summary, Na and Cl were removed to very low concentrations in all stone segments during the ED treatment and after 5 weeks, the concentrations were lower than before the stones were spiked. Thus, the crack did not prevent successful desalination.

Results from experiment ED_5 are in figure 4 as the accumulated moles of Cl removed into the poultice at the anode and Na into the poultice at the cathode. The number of moles were calculated from concentrations measured in the poultices when they were changed every 7 day. In figure 4, the electrical resistivity is shown as well (calculated as voltage divided by current). During the first approximately three weeks, the removed mass of Cl and Na is almost linear with the duration of the treatment, and in this period, the electrical resistivity is very low. After about 3 weeks, the removal rate decreased as result of a lower concentration of the ions in the stone. After a little more than 3 weeks of treatment, it is also seen that the electrical resistivity increases dramatically corresponding to the low level of removal indicating lower salt content left in the stone. Thus, the time for the desalination to be finished is indicated by an increase in electrical conductivity.

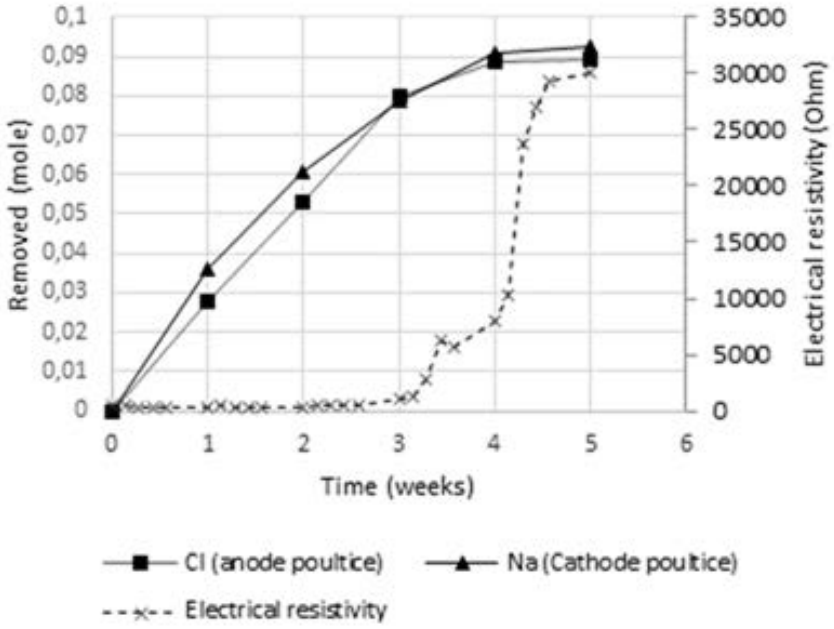

Figure 4. Number of moles Cl removed into in the anode poultice and Na into the cathode poultice over time in experiment ED_5. The electrical resistivity over time in ED_5 is shown as well.

4 Conclusions

Electro-desalination was experimentally shown to effectively remove Na and Cl from stone parts next to a crack. A crack was cut half through rectangular sandstone prisms (13.5 cm x 7.5 cm x 5.5 cm) and electrode compartments were placed in each end of the prism. The prisms were spiked with NaCl to high concentrations prior to the electro-desalination, and after 5 weeks of treatment, the salts were removed again and even to concentrations lower than present in the stone prior to the spiking. The concentrations in the stone next to the crack were as low as in the other parts of the stone, and thus the interference of the crack on the overall desalination is minor.

Freeze-Thaw Deicing salt Attack on Concrete: Towards Engineering Modelling

Charlotte Thiel, Vadym Lomakovych and Christoph Gehlen

Centre for Building Materials, Technical University of Munich, Franz-Langinger-Str. 10, 81245 Muenchen, Germany, charlotte.thiel@tum.de

Abstract. *In order to reduce carbon dioxide emissions, the construction sector is increasingly using clinker-reduced concretes. Concrete with high amounts of ground granulated blast furnace slag (GGBFS) show increased durability performance in certain environmental conditions compared to concrete with Ordinary Portland cement (OPC). However, in laboratory studies, concrete with GGBFS show an increased initial scaling rate in comparison with OPC concrete. Changing weather conditions and high relative humidities > 70 % in field lead to less carbonation and thus, to a better freeze-thaw deicing salt resistance (FTDSR). Therefore, the current lab performance test penalizes GGBFS concrete. This contribution studied the impact of carbonation and intermittent dry periods on FTDSR of GGBFS concrete compared to that of OPC concrete. It could be shown that for concrete with OPC, intermittent dry periods lead to an accumulation of salt in the near surface, which causes a reduction of the scaling. GGBFS concrete, on the other hand, shows an opposite behavior: carbonation causes an increase in scaling after the dry period. GGBFS concrete samples with CO_2-free pre-storage show the lowest scaling of all samples investigated. A better simulation of the behavior of GGBFS concrete could lead to economical as well as optimized solutions for the local environment conditions and enable the large-scale use of more environmentally-friendly concretes. Therefore, by taking the effect of carbonation and intermittent dry periods into account in a simple engineering model, the prediction of concrete scaling under consideration of real climatic conditions is possible in an eco-efficient manner.*

Keywords: *Freeze-Thaw Deicing Salt Attack, Carbonation, Durability, Service Life Prediction, Combined Attack.*

1 Introduction

With the increased use of clinker-reduced concretes, the evaluation of durability design methods remains a topical issue. There are mainly three design strategies:

- Deemed to satisfy rules: Avoidance of damage by complying with the requirements from the exposure classes, and
- Lab-Performance concept: Compliance tests with accepted limit criteria provide a yes/no decision on the suitability of a material for a certain environment; see (Thiel and Gehlen, 2018).
- Performance based durability design: The condition of a structure remains with a certain reliability below selected limit states (Gehlen, Schießl and Schießl-Pecka, 2008.; fib, 2006).

Performance based durability design can be further divided into fully probabilistic approaches, and the partial safety approach derived from the probabilistic concept. Probabilistic service life design require deterioration-time-laws that account for statistical uncertainty. An important input parameter is the material resistance, which is usually determined in compliance tests in the laboratory, (Thiel and Gehlen, 2018). Those engineering models should be as simple as possible in order to promote acceptance. In addition, different attack intensities, i.e. different

climatic conditions should be realistically displayed. They should also be flexible so that new materials, new knowledge or new situations (*e.g.* climate change) can be accounted for. The use of performance based design concepts offer the following advantages

- Quantification of deviations between execution and planning
- Optimized maintenance strategies through service life prediction
- Optimized choice of material as well as curing time and type
- Simplified use of new building materials through proof of performance

Djuric successfully combined the critical saturation model from Fagerlund (Fagerlund, 2004) with the transport mechanism of the micro ice lens pump (Setzer, 1999) for pure freeze-thaw attack, thus developing a model for the evolution of internal structural damage (Djuric, 2017). For the durability assessment of structural components under combined freeze-thaw deicing salt attack (FTDSA), different approaches exist. For example, a simple performance concept based on the CDF method was proposed by Guse (Guse, 2009). The glue-spall model developed by Valenza (Valenza and Scherer, 2007) is able to explain most observations during FTDSA. An easy and structured factor approach was proposed by Sarja *et al.* (Sarja and Vesikari, 1996) and further developed by Lowke *et al.* (Lowke and Brandes, 2008). Currently, Müller *et al.* (Mueller; Ludwig and Erhardt, 2019) are combining the cryogenic suction model with frost suction in order to model the scaling evolution under FTDSA.

However, evidence of large-scale practical applications of these concepts is still missing. The aim of this contribution is to demonstrate, by means of practical experiments, how the strongly varying attack intensity under field conditions can be taken into account.

2 Materials and Methods

Two concrete mixes using quarzitic sand and gravel were produced, Table 1. C1 contained Ordinary Portland Cement (OPC) with the European label CEM I 42.5 R, while C2 labelled CEM III/B 42.5 N contained 75 % ground granulated blast furnace slag (GGBFS). For carbonation to occur, a rather high w/b-ratio of 0.55 was used. Therefore, the concrete composition is neither XF2 nor XF4 conform, see (DIN 1045-2:2008-08).

Table 1. Concrete composition, air content and compressive strength.

	C1	C2
Binder type	OPC	GGBFSC
Binder amount (kg/m³)	320	320
w/b-ratio	0.55	0.55
Sand + Gravel (kg/m³)	1732	1724
Air content	1.9	2.0
28d compressive strength	42.5	38.5

Entrained air is the dominant factor in ensuring high FTDSR for OPC based systems (Powers, 1949). However, Auberg showed that the FTDSR of concrete with GGBFS ≥ 58% in the cement was largely unaffected by entrained air voids (Auberg, 1999). Furthermore, entrained air is not required in the exposure class XF2. As this contribution intends to exploit the potential of non-entrained concrete more effectively, no air-entraining agent was used. Carbonation leads to increased initial scaling and is the dominant parameter for concrete with

GGBFS cement. Ludwig justified this observation with the coarsening of the pore structure due to the formation of metastable aragonite and vaterite, which are dissolved by FTDSA. 25 cubes (edge length 150 mm) were cast against PTFE slides, immediately covered with moist cloth and stored at 20±2°C. After demoulding at an age of 1 d, the samples were stored further 6 d under water. Then the samples were cut according to the CDF method (DIN CEN-TS 12390-9:2017-05) and divided in five different series of five samples each, Fig. 1.

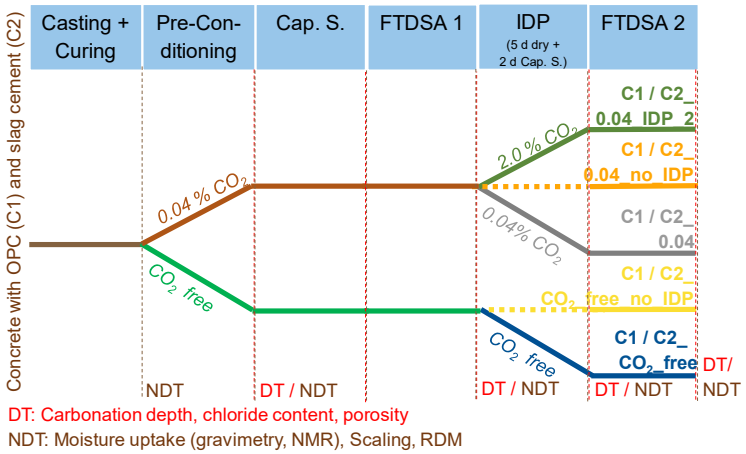

Figure 1. Overview of experimental program (FTDSA: Freeze-thaw deicing salt attack, Cap. S.: Capillary Suction; IDP: intermittent dry period, DT: destructive testing, NDT: non-destructive testing, RDM: relative Young's modulus).

Three series were stored according to the CDF method at 20±2°C and 65±2 % RH and natural CO_2 content of 0.04±0.005 % by vol. Two series were preconditioned under the same temperature and humidity conditions but in argon flooded chambers creating a CO_2 free atmosphere. All samples were exposed to a seven days period of capillary suction followed by freeze-thaw cycles in 3 % NaCl solution. The setup followed the guidelines of the CDF method, however the temperature cycle was changed. In order to reduce damage, the minimum temperature was increased to -10°C, which is closer to field situation in Germany, see (Siebel *et al.*, 2005). Here, the holding times remained constant but cooling and heating rate were lowered from 10 K/h to 7.5 K/h. Before, during and after FTDSA nondestructive tests as well as destructive tests characterized the evolution of damage, Table 2. For porosity measurements, the samples were manually broken, immediately exposed to isopropanol for 12 - 24 h and then oven dried at 40°C for 24 ± 2 h.

Table 2. Experimental methods.

Test	Goal	Device	Reference
Modified CDF (-10°C): Scaling, Relative Young's Modulus (RDM), solution uptake	Determination of scaling rate and possible relation to moisture uptake	Chamber, Balance, US-equipment (Pundit)	(DIN CEN-TS 12390-9:2017-05)
Carbonation depth (colour indicator spray test)	Determination of the effect of carbonation	Spray bottle with 1% phenolphthalein in 70% ethanol	(RILEM CPC-18, 1988)
Mercury Intrusion Porosimetry (MIP)	Determination the effect of carbonation and FTDSA on pore structure	AutoPore III, hammer for crushing	(Lomakovych, V., 2018)

3 Results and Discussion

Fig. 2 shows scaling, moisture uptake and RDM of the concretes. Especially the accelerated carbonation leads to a five times higher scaling rate for C2. The orange line (C1/2_0.04_no_IDP) represents the standardized procedure (DIN CEN-TS 12390-9:2017-05), which is quite in the middle of the different series. Despite the significant effect of the different storage conditions, the carbonation depth in general was very low. Thus, Table 3 shows only the carbonation depth of the series with which a color change occurred at all. For the C1 samples, for example, only the surface was usually uncolored, while the carbonation depth for the C2 was 0.1 mm, which disappeared in the course of the 14 freeze-thaw-cycles (FTCs). No carbonation was detected before the intermittent dry period (IDP) indicating that the carbonated layer scaled off.

Table 3. Carbonation depth (mm).

Series	Exposure time (d)			
	0 (before FTC)	7 (after 14 FTC)	14 (after either 28 FTC or after IDP)	21 (after 28 FTC
C1_0.04_IDP_2	0.0*	0.0	0.1	0.0
C2_0.04_IDP_2	0.1	0.0	0.4	0.0
C2_0.04	0.1	0.0	0.0*	0.0
C2_0.04%_no IDP	0.1	0.0	0.1	0.0

*Surface was colorless (carbonation depth < 0.1 mm)

The solution uptake shown in Fig. 2 middle correlates neither with the external damage nor with the drop of the RDM (bottom). After an IDP, the samples very quickly reabsorb moisture; however, for all series the total solution uptake remains below the level of the continuously exposed series. The RDM of the C1 only decreases for samples that have not been dried in the meantime ("no_IDP"). The high scatter of the reference series (C1/2_0.04_no_IDP) is most likely due to detaching of the sealing of two samples. This is also reflected in the RDM.
C2 did not show any significant changes in RDM. This could be due to the finer pore structure,

Fig. 3. C1 has a lower total porosity before and after the FTDSA compared to C2.

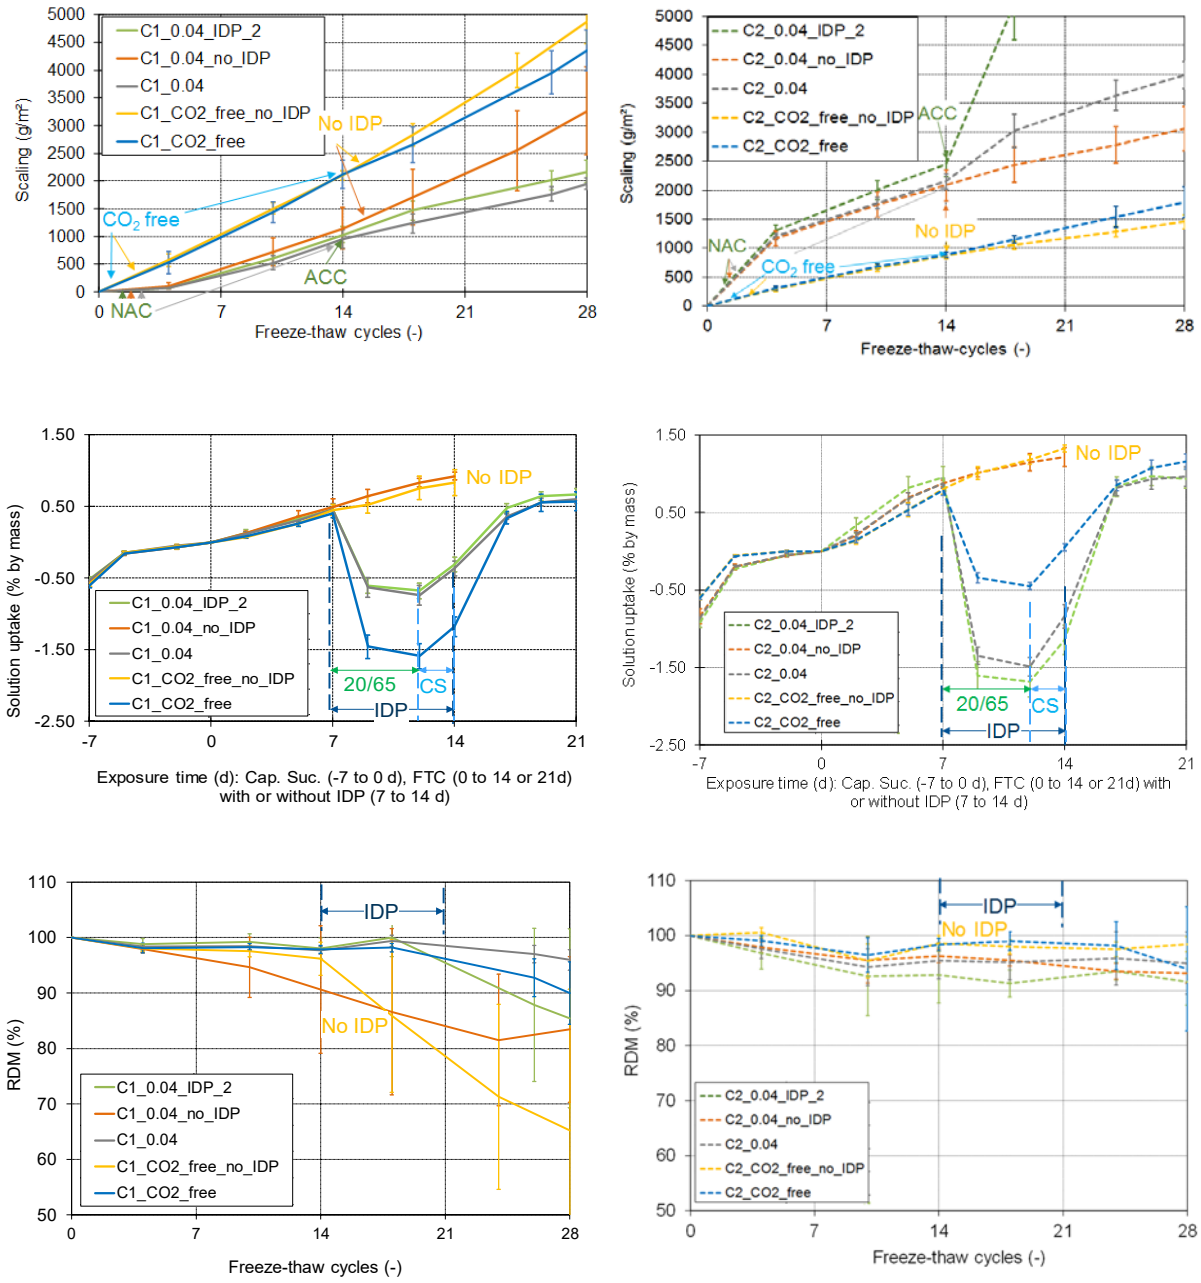

Figure 2. Top: Scaling of C1 (left) and C2 (right), middle: solution uptake of C1 (left) and C2 (right) (note: x-axis starts with dry state before capillary suction and represents the exposure time); bottom: Relative Young's modulus of C1 (left) and C2 (right). (NAC: Natural Carbonation; ACC: Accelerated Carbonation, CS: Capillary suction).

In all cases, FTDSA led to an increased total porosity. Note that only concrete exposed to three weeks of natural carbonation was measured as "before FTDSA". The carbonation front was already scaled off which explains why the well described coarsening of the pore structure

due to carbonation in C2 was not found here. C1_0.04_no_IDP had the highest total porosity and a clear increase in the capillary pore range. This clearly indicates micro-cracking which is also confirmed by the RDM (Fig. 2 middle left).While a coarsening of the pore structure occurred for C1, the pore structure became finer in all C2 series, Fig. 3. This is most likely due to ongoing hydration. To simplify matters, if the carbonated surface layer is scaled off, GGBFS concrete show higher FTDSR than OPC concretes with otherwise identical composition. However, IDPs can cause the exposed surface layer to carbonate again, resulting in high initial scaling, corresponding to the carbonation depth. With OPC the behaviour is reversed. This shows that a test according to 28d is not sufficient to describe the damage behaviour in practice and that it is absolutely necessary to consider the age and the degree of carbonation and hydration.

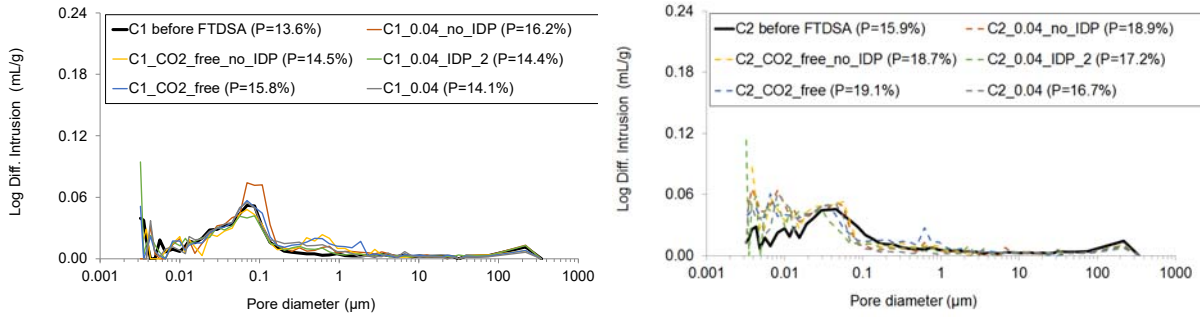

Figure 3. Pore size distribution and total porosity (P) of C1 (left) and C2 (right) before and after FTDSA.

The following options are available for considering our findings when designing or maintaining structural components exposed to FTDSA:

- Deemed to satisfy rules: Further subdivision of the exposure classes XF2 and XF4 according to the expected time in which a critical saturation occurs.
- Performance based durability design: Implementing the effect of IDPs and carbonation on scaling rate in an engineering models

4 Engineering Model

For chloride-induced corrosion as well as for carbonation validated probabilistic models exist (Gehlen, 2000). For carbonation induced corrosion, the effect of changing moisture conditions is taken into account by a parameter for considering the effect of micro-climatic conditions (relative humidity) and a parameter for considering the macro-climatic conditions (time of wetness and probability of wind-driven rain for vertical components. A similar procedure could be used for scaling due to FTDSA: The scaling rate over time $s_r(t)$ can be described by including the initial scaling rate and a later scaling rate determined in a lab performance test. The initial scaling rate $s_{r,ini}$ accounts for the effect of carbonation while the later scaling rate $s_{r,prog}$ represents the evolution of scaling of the uncarbonated material under damage-relevant environment. The environment only leads to scaling when sufficient moisture, rather low chloride content and a minimum Temperature below - 5°C are present at the same time. This is included in the environment factor f_e, which depends on the number of damage-relevant freeze-thaw-cycles in one winter period as well as on the outer salt concentration and the minimum

temperature. As the resistance of the concrete is affected by curing, the curing factor f_c is also introduced, Equation 1.

$$s_r(t) = (s_{r,ini} + t \cdot s_{r,prog}) \cdot f_c \cdot f_e \cdot f_a \quad (1)$$

This approach allows a weighting of the different scaling rates. The exact statistical distributions as well as dependencies need to be quantified in future. Moreover, suitable limit states need to be defined. Scaling not only leads to visual defects, it also reduces the concrete cover. Cracking reduces mechanical performance and might accelerate other mechanisms relevant to durability. Therefore, a much lower scaling depth than the concrete cover is certainly tolerable.

5 Conclusions and Outlook

FTDSA is very versatile. It strongly depends not only on the material resistance but also on the macro- and micro-climatic conditions. Recent investigations (Aßbrock *et al.*, 2019) showed that for most European locations, freeze-thaw deicing salt attack (FTDSA) is milder than displayed in laboratory tests. Consequently, there is a need for eco-efficient and economic methods to design and maintain structures under FTDSA despite the current deemed to satisfy rules. The most important findings of this contribution are summarized as follows:

- Damage evolution strongly depends on the climatic conditions. The scaling rate can change considerably for structural components that can dry in field during periods without precipitation.
- For concrete with OPC, the scaling rate was reduced by intermittent dry periods with and without carbonation. The main reason for the reduction of the scaling rate is probably salt crystallization, which should be further investigated.
- Carbonation was the dominant influencing parameter for concrete with GGBFS. Here, after an IDP concrete with GGBFS will always exhibit a new increased initial scaling rate until the carbonated layer is scaled off. Afterwards, the scaling rate is lower than for concrete with OPC. Concretes with high amount of GGBFS could be used in building components that are exposed to low carbonation (few dry periods, high relative humidity).
- Palecki (Palecki, 2005) and others found a correlation between inner damage and moisture uptake for freeze-thaw attack without deicing agents. This correlation could not be confirmed for FTDSA. Although concrete with GGBFS absorbed more solution than concrete with OPC, the finer pore structure caused only minor changes in the RDM while concrete with OPC showed a significant drop in RDM.
- IDPs significantly reduce the occurrence of inner damage.
- A new concept was proposed to consider the effect of real weather data and include the effect of carbonation. With the help of this, a weighting of the different scaling rates of the carbonated and non-carbonated layers would be possible.
- Taking into account the actual performance of the material as well as the actual expected intensity of attack would enable more economic and eco-efficient design of concrete structures.

Abstract. *Mexico City is located at a seismic region with a complex soil. That condition had an impact on buildings and their conservation; it requires to know their structural state to control strain and cracks that could cause severe damages. To accomplish that objective this research contemplates the evaluation of concrete elements to propose an alternative to restraint antique concrete deformations using FRP system.*

Keywords: *Architecture, Reinforced Concrete, Plastic Flow, Textile Composites, Carbon Fiber.*

1 Introduction

Construction has always been complicated as the city is located on a seismic region (Servicio Geológico Mexicano, 2017), which also has a subsistence ground (Marsal J. and Mazari, 2016); specially during 1940, when technical information about the city complex soil was starting to be studied, and new constructive methods were developed for skyscrapers. Specialized research on the geotechnical and seismic engineering started in 1955 and 1962, respectively; twelve years after the Mexico City building code was used for the construction, about 1942- 1966. Thus, all RC structures built before 1960 have a probability of exhibiting some damage. The aging of RC structures could be accelerated due to soil and seismic stresses. Permanent axial load causes plastic flow on RC (Park and Paulay, 1988), creating disbalance between the load/stress distribution of the structural system and producing fissures, structural cracks, or increasing the one that exists (Muñoz and Mendoza, 2012). Another critical factor for RC frames built on seismic areas is ductility of columns, which is provided by reinforcing bars (rebars), but buildings constructed before 1970 are considered as non-ductile (Al-Mahaidi and Kalfat, 2018) while their columns have not enough rebars to accomplish with current regulation codes (Moehle, 1997).

Today most of these 1940-1960 buildings are still operative. The aim of this project is to improve the structural performance of historic buildings without affecting their patrimonial integrity. To accomplish the last objective, this study proposes the use of Fiber Reinforced Polymers (FRP) as a rehabilitation/reinforcement system. This method is selected because if

doi:10.23967/dbmc.2020.220

its correctly applied, FRP could increase RC life-service by improving ductility and control plastic flow (Metha and Monteiro, 1998; Park and Paulay, 1988). The following variables will be analyzed to confirm the hypothesis:

a) The evaluation of FRP composites attached to a standard concrete mix will be made while analyzing the adherence between phases and the performance of FRP;

b) Analysis of the adherence between FRP composite and old concrete specimen;

c) Comparison between the previous data obtained with a weathering reinforced concrete specimen

2 Method and Materials

For this research FRP method refers to the use of a composite material made with carbon fiber impregnated with epoxy resin, applied to rehabilitate a structural member (American Concrete Institute, 2008). Carbon fiber CF) is the most commonly type of concrete reinforcement sections because its range of tensile properties allows an acceptable mechanical performance between phases (Hull, 2010; Park S.-J. , 2018), its semi crystalline microstructure exhibit an tensile strength over 1200-2250 MPa (Teng, Chen, Smith and Lam, 2002). Wet lay-up is the preferable method to applied CF because it has major advantages for *in situ* installation wherefor CF sheet can adapt to complex geometries (Teng, *et al*, 2002). Composites materials are based on mechanical adherence amid epoxy resin and concrete surface, so previous applied carbon FRP over the concrete section, it must be cleaned free of dust, oil or solvents. To increase phase adherence, it could be peel off the surface until it is removed, a thin layer with an average thickness from 0.5mm to 2mm. For the experimental campaign it selected 12K unidirectional carbon tow sheet thus one direction cloth has the strongest tensile resistance (Chanda, 2018). To attach the fiber, it is used an epoxy adhesive indicated by the manufacturer, Quintum ©. Their mechanical properties on Tables 1 and 2.

Table 1. Mechanical Properties of Carbon fiber.

Material	Ultimate Tensile Strength	Young Modulus	Weight
QuintumWrap-300©	875 MPa	34, 500 MPa	302 g/m^2

Mechanical properties of carbon fiber imbibed into epoxy resin. The cloth physical characteristics are: 0.5mm thickness, 500mm wide and 12K tow.

Table 2. Mechanical Properties of Epoxy Resin.

Material	Compressive Strength	Lap shear Adhesion Strength	Tensile Strength
Q102R ©	121 MPa	12 MPa	42 MPa

Epoxy adhesive is formed by two components: part A, bisphenol resin type and part B, ammonium adduct as hardener. Both shall mix in a 100g :10gr relation.

2.1 Manufacturing Specimens

Concrete specimens were designed considering a structural resistance of 25Mpa (CEMEX) using the standards C192/C192M (ASTM, 2002). For the experimental campaign they were made six concrete cylinders of 150mm radius and 300mm height, using Portland Composite Cement (IMCyC, s.f.). Three of them were selected for control of the mix and three more for FRP reinforcement.

2.2 Confined Concrete with Carbon Fiber

After 20 days of demolding concrete cylinders, three specimens were prepared to attach CF by scabbling a 2mm layer from the surface using an angle grinder. FRP method consisted of five steps that were made considering the combined action principle (Callister, 2009). The first step was applying a uniform layer of epoxy resin over the concrete surface. The second step was immersing the CF sheet ultimately into epoxy resin to reduce the air content and dry zones. The third step was wrapping to confining specimens with an impregnated fiber sheet with overlapping of 10 centimeters. The fourth step was removed the air trapped into the tows dragging a palette knife over the wrap. The fifth step was applied another uniform epoxy layer.

3 Compression Test

The compression test consists of applied a uniaxial increasing load on the material to deformed it until it's ultimate strain. If carbon fiber is correctly attached to concrete, it shall restring the lateral pressure and radial expansion, assuming that epoxy layer has the same thickness on both sides of fiber; tensile stress shall be equal in the hoop direction. Specimens were tested 28 days after manufacturing. Tests were made in an INTRON universal testing machine, screw-type UTM model MII 400WHVL with capacity for 200 tons.

4 Results

Control specimens showed average compression strength of 22MPa and for the FRP it was an average strength over 38 MPa. CF almost doubled the compressive strength of concrete. In Table 3 shown test results.

Table 3. Results of compression test for Control and FRP specimens.

Specimen	Maximal Load	Ultimate Compression Strength	Strain
Control 1	38,514 kgf	21 MPa	2.1 mm
Control 2	43,154 kgf	23.5 MPa	3.6 mm
Control 3	39,791 kgf	21.7 MPa	2.9 mm
FRP 1	65,914 kgf	36.5 MPa	5.1 mm
FRP 2	66,235 kgf	36.7 MPa	5.2 mm
FRP 3	73,090 kgf	40.5 MPa	5.5 mm

Table 3 shows the maximal values obtained from data bases of test machine.

Mechanical behavior of FRP specimens is shown in Figure 1. The three curves have a similar development with a semi-ductile trend, and all of them showed a small dropping when concrete reached its maximal compressive strength, as it is shown on figure 1 (left). All curves had the same geometrical composition, also, according with data in table 3: FRP 1-2 had a very similar mechanical behavior. On the other hand, FRP 3 continues growing asymmetric. The average FRP ratio was calculated using a sixth-grade polynomial trend line to correct each curve. After that, corrected data were put on the same base to define another trend line and made one more correction. The final result was the edited stress-strain curve, which had the average behavior of FRP specimens, it is shown in Figure 1 (right). Physical analysis shown in Figure 2-4.

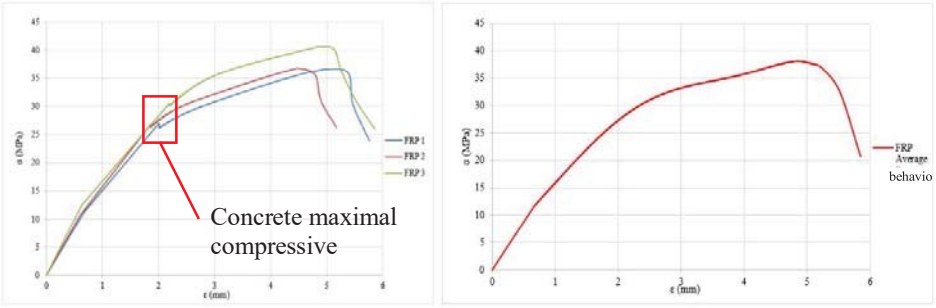

Figure 1. Stress-strain curves of FRP specimens and edited curve after statistical analysis.

On Figure 1, it is presented, from left to right, stress-strain curves of all FRP cylinders; stress-strain curve performed with edited compression data base.

Figure 2. FRP specimens after compression test.

On Figure 2 it is shown, from left to right, FRP 1 with total detachment of CF; FRP 2, total detachment of CF; FRP 3, partial detachment of CF.

Specimens FRP 1 -2 failed because a delamination from overlap section, it shown on Figure 3A. The revision of the pulled off carbon layer showed the presence of a considerable quantity of voids at overlapping area, Figure 3B. While the rest had concrete residuum, Figure 3C. For those two cases, the matrix layers were detached because the distribution of stress was discontinuous

due to voids. Internal stress at borders generated micro tangential tensions which broken the matrix, then shear produced by pressure delaminates the overlap. Concrete aggregate exposed refers to such good phase adhesion. According to the partial uniform state of the concrete section, specimens FRP 1-2 can not reached their ultimate compression strength; otherwise, residual concrete would be abundant cracks on the cylinder section; checking numerical data at Table 3, load stress was transmitted by both phases only before delamination of FRP, after that each phase was working by itself: CF jacket was just restrung cylinder bulge until epoxy matrix was completely broken.

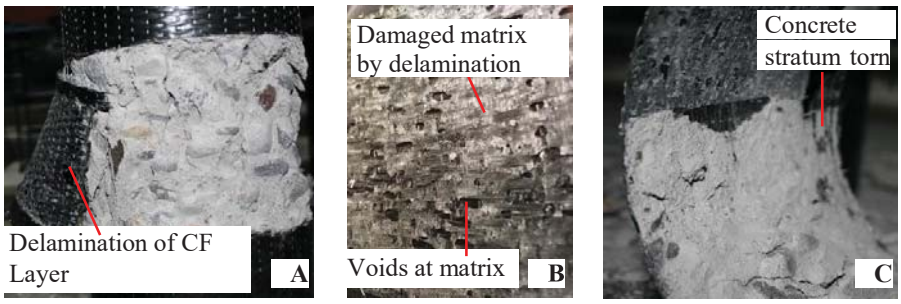

Figure 3. Detail of delamination in FRP at compression test.

On Figure 3 showed: (A) delamination of FRP matrix; (B) detail of voids at overlapping; (C) detail of adherence between phases.

FRP 3 reached its ultimate compressive strength. In this case, tangential tension was uniformly distributed over the cylinder's section until pressure shear the carbon layer causing an explosion. The tested specimen had small delamination on overlap area, Figure 4D. Then, it assumes less void contain at matrix and a uniformly epoxy coat on each side of layer. The explosion also produced the tearing of CF cloth, shown in Figure 4E; it observes parts from the concrete section who were torn by the adhesive and remained attached to the epoxy matrix, Figure 4F. In FRP 3, serious cracks were caused by stress distribution, which means that when the concrete reached its maximal compressive strength, it still transmitting load. That indicates the simultaneous transmission of stress from both phases; this specimen already worked as a composite material.

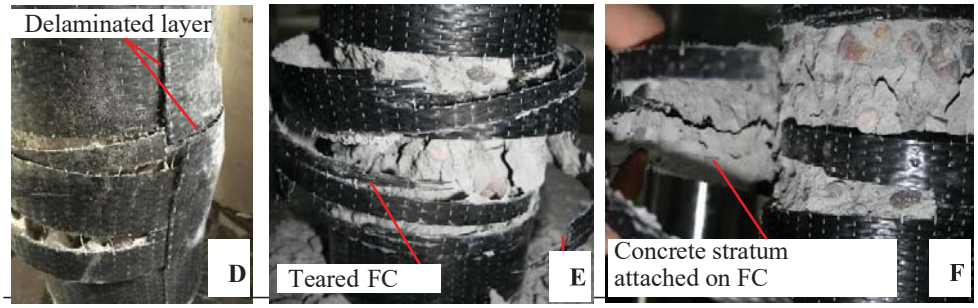

Figure 4. Detail of failure in FRP at compression test.

On Figure 4 it can be seen: (D) Partial delamination of FRP matrix; (E) detail of CF teared by shear strength; (F) detail of adherence between phases.

Below its presented, on Figure 5, the results of concrete and FRP cylinders to contrast the influence of CF cloth. On this figure observes that carbon fiber actually extend the plastic zone of concrete allowing it major load resistance.

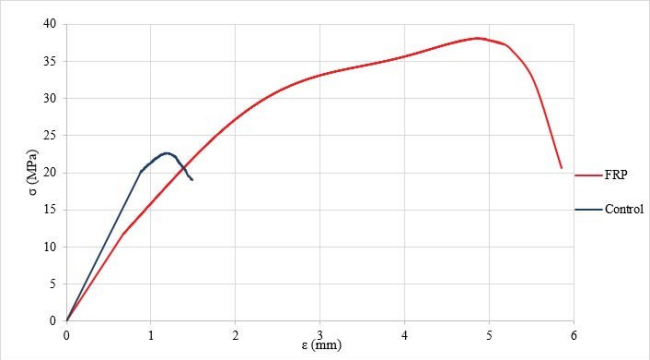

Figure 5. Comparation between FRP and pure concrete specimens.

Based on the current normative of the ACI (American Concrete Institute, 2008), the FRP manual of SIKA (SIKA, 2015) and current investigations about carbon fiber (Hernández Pérez, 2019), the theorical compressive strength results for FRP cylinders are compared with the practical test results. On Table 4 shown the results.

Table 4. Results of compression test for Control and FRP specimens.

Specimen	Theorical Confined Compressive Strength	Practical Confined Compressive Strength
FRP 1	30.92 MPa	36.5 MPa
FRP 2	30.92 MPa	36.7 MPa
FRP 3	30.92 MPa	40.5 MPa

Theorical confined compressive strength at table 4 only consider the design target compressive strength of 25 MPa for the three specimens.

Comparison of numerical results at table 4 expressed an increment of 40% in practical tests compared with the theorical calculation, even with the cylinders whose FRP was detached.

5 Conclusions

- Based on the numerical data provided by the mechanical test, the method of manufacture, and the physic analysis of the FRP concrete specimens it concludes that the fiber reinforcement polymer method increases the compressive strength of concrete even if FRP is not well attached. This condition means that quality control at FRP application

must be hardly supervised.

- The surface treatment had successful results on adherence between epoxy-concrete interphase. Mechanical adhesion between phases was strong to keep them together after radial pressure pull off the epoxy matrix. Considering that, significant attention must be put on overlapping while FRP method is applied. Delamination at this zone is the common cause of failure at confining, the matrix is easy to fracture by shear strength if there is a high void percent.
- The adherence range of service is such enough to control longitudinal and transversal deformation and consequently adding partial ductile properties. So then, carbon fiber is capable of retarding plastic deformation on concrete by full confining. The compression test is an accelerate process to deforming concrete until it is destroyed, then considering that plastic flow is a slow process it can conclude CF could stop deformation by aging.
- At service, FRP could produce some elasticity to concrete because its tensile resistance parallels to the axis. However, the characteristic of its materials still having a fragile trend. Under that premise, the porous matrix at the overlapping area is vulnerable to shear, torsion, impact, etc. As an optional experimental purpose to improve adherence in epoxy-epoxy interphase, it could use a compatible polymeric adherence bridge.

Abstract. *This paper deals with the investigation of properties of Czech fortification concrete bunkers built before Second World War (WWII). The Czech defense system consisted mainly of light bunkers type No. 37. The vast numbers of these bunkers have been preserved in various conditions to nowadays. The light bunkers type No. 37 were designed to last limited lifetime of decades. According to the preserved test protocols, strength of used concrete varied from 40 to 50 MPa, measured on cube specimens with dimensions 200×200×200 mm. There is an information, in general public, about high quality and strength of used concrete. The non-destructive analysis of compressive strength, determined by Schmidt hammer was performed. This method was used to maintain a historical value of the structures. Three were analyzed different bunkers type No. 37 located in Western Bohemia – Pilsner region. Tested bunkers are preserved in various conditions with various quality of concrete. The measurements by Schmidt hammer took place in several locations especially in the interior part. The exterior was also investigated but only in the locations of surface which were not covered with camouflage plaster. Non-destructive testing had shown high quality of concrete older than 80 years old concrete, with compressive strength between 50 to 60 MPa. On the other hand, based on the visual assessment, the concrete showed very different characteristics, especially in compactness and the quality of surface layer. We can find places with insufficiently compacted concrete with exposed steel reinforcement.*

1 Introduction

The European continent has a great historical, cultural and architectural heritage, which includes monuments dated back several centuries and even millennia. The architectural heritage contains relicts of ancient civilizations, medieval buildings, sacral and also profane buildings. In the terms of building monuments, materials used most frequently are bricks or stone masonry, timber and steel (traditional and proven materials). The field of architectural heritage is closely connected with the restoration, reconstruction and, if necessary, strengthening. The strengthening and conservation of widely used structural elements (column, pillar, vault, beam etc.) made with traditional materials is well described and mastered. Even modern materials with high utility properties are successfully implemented into the strengthening process – we can find the application of carbon rods or fabrics (Witzany *et al.,* 2016, Jongsung *et al*., 2005). Even very modern material – textile reinforced concrete can be used for stabilization or

strengthening of masonry structures (Garmendia *et al.,* 2014).

Even relatively new buildings and structures are in the center of interest of exploration and conservation. We can see a growing interest in exploring industrial heritage as a reflection of its time. This brings new challenges for historians, architects and engineers. A very good example of this phenomenon is the system of the Czech fortification system, built by former Czechoslovakian government in years before the WWII. This example of widespread use of concrete has been extensively preserved in various conditions till today. For general public, concrete is not the representative of historical material (Heinemann *et al.,* 2008).

1.1 Czech Fortification System

The system of fortification was built in relatively short time during 1930s by incurring high financial and material costs. The whole system consisted of several defensive lines of light bunkers for seven soldiers. In this way, the strategic disadvantage of defending very long borders with Germany, Poland and later with Austria and Hungary, with limited human capacity, had been solved. This system of light bunkers had been supplemented in certain places, usually in mountainous terrain by artillery fortresses. The support of the defense system contains large number of smaller fortresses, usually connected by system of underground corridors. Unlike the bunkers type No. 37, these fortresses were intended for long-term stay of military crews. The bunkers type No. 37 were designed for short stay of soldiers only at the time of threat. Due to their cramped space, longer stay of crews was not possible. In the event of war crash, bunkers No. 37 were designed for indirect firing, when individual fire fans of each bunker overlap with the fire fans of its neighbor. The front wall was the strongest part of fortification and it was also protected from exterior part by a stone flat with loam (also used as camouflage).

The vast majority of the preserved bunkers No. 37, according to cadastral information, are owned by the Army of Czech Republic. More extensive preserved complexes and artillery forts have a status of official cultural heritage and are open to the public. A large number of objects of varying size and technical conditions are also owned by private persons or group of WWII fans. These organizations or individualities usually try to restore the bunker to its original state, including camouflage, armament and equipment. However, with more intensive use and reconstruction works, there are many challenges that need to be solved. The bunkers were not designed for long-term stay of military crew. Various problems are connected with the actions of capillarity and moisture penetration. An extensive experiment and numerical simulation on this topic performed Pazderka *et al.,* 2016. The problem with massive water ingress can be solved by using modern crystallizing coating (Pazderka *et al.,*2019). On these two examples we can see that the issue of defensive structures gains its importance, therefore the theoretical investigation and field in-situ survey are also significant and important.

2 Performed Investigation and Observation

Three preserved examples of bunkers No. 37 located in the “Pilsner line” in West Bohemia region were chosen for the purpose of this contribution. The designations of investigated bunkers are D-19/22/A-160, D-19/47/A-160 and D-20/4/A-160. This number has its systems and contains the information about location and type of object. The first part “D-19” or “D-20” means the construction section, in this case “Nové Městečko” respectively “Blažim”. It was

usually named about the nearest important city or village. The next number, in our case “22”, “47” and “4” means the order of the bunker in the particular construction section. The last part, in this case “A-160” means the type of bunker. Letter “A” means, that the investigated bunkers represent the most commonly used type with ordinary ballistic resistance. There were also bunkers with letter “Z”, which describes the bunker with higher ballistic resistance with stronger front wall. The last number characterizes the angle of coverage with installed machine guns.

2.1 Testing by Schmidt Hammer

Testing by Schmidt hammer represents commonly used method for non-destructive testing of concrete´s mechanical properties. This method is standardized and allowed by standard systems of many countries. There have been cases where Schmidt hammer was used as representative of non-destructive method for measurement of compressive strength of masonry elements (Aliabdo *et al.,* 2012). However, the most widespread use still represent concrete, as a material usually supplemented by destructive testing if circumstances permit (Holčapek *et al.,* 2014). The standard Schmidt hammer type N was used, according to Czech standard (CSN EN 2013). Due to the preserved external plasters the investigation took place mainly in the interior part. The schematic cross-section of bunker No. 37 with marked location of performed measurements is shown on Figure 1. Minimum of 50 measurements were performed on each place (places in different heights). Also the quality of roof was investigated.

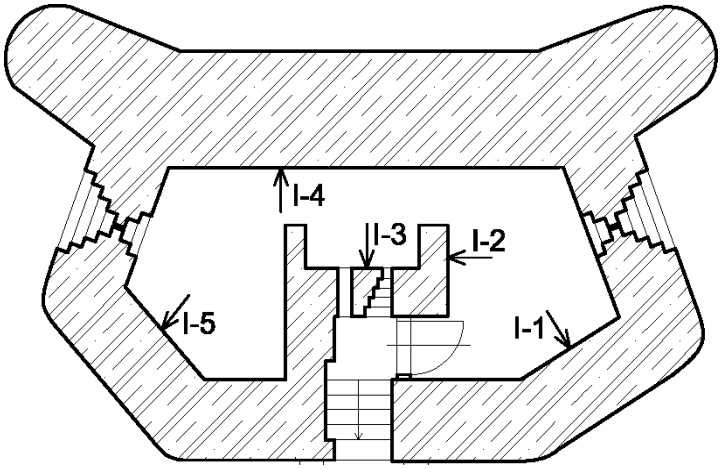

Figure 1. Schematic cross-section with marked places of performed measurements.

2.2 Visual Evaluation

Analyzed bunkers are situated in one location and were built in approximately in the same period of second half of 1937. Their entrances are not locked, which means that the bunkers are not protected against vandalism. We can still observe the residua of original timber cladding in the interior part, as shown on Figure 2 and also on Figure 3. These timber elements were exposed to moisture and the effects of fungi and microorganisms. An important finding is that the quality of concrete within a single object is variable. We can observe excellent quality of surface layer, without any cracks or cluster of aggregate. There are places with very poor quality

of compaction in the same bunker. We can see reinforcement uncoated by concrete, clusters of coarse aggregate and other imperfections. This surface was originally covered by timber cladding and the estimated designed lifetime was only about 20 years, bud if we want to preserved these objects to future generations, we have to deal also with these problems.

Figure 2. Residuum of internal timber cladding, poor quality of surface layer of concrete.

Figure 3. Insufficient compaction with uncovered steel reinforcement.

3 Results and Discussion

As mentioned above, totally six different locations in the interior part were investigated by Schmidt hammer. The investigation in exterior part is limited by the protective earth wall in the front part and also by the residues of masking plasters, but one location was also analyzed.

All results of performed measurements are summarized in Table 1. The first column describes the location according to Figure 1. Following three columns list the values of tentative

compressive strength of three different bunkers No. 37. The last row in the table contains the compressive strength calculated according to destructive test performed in 1937 on cube specimens with dimension 200×200×200 mm.

Table 1. Results of performed non-destructive measurements.

Designation	D-19/22/A-160	D-19/47/A-160	D-20/4/A-160
	[MPa]	[MPa]	[MPa]
Exterior	67.5	59.7	N/A
Interior (I-1)	58.1	54.3	57.8
Interior (I-2)	51.7	48.8	53.4
Interior (I-3)	56.3	63.4	59.6
Interior (I-4)	61.2	68.9	57.8
Interior (I-5)	53.9	59.9	64.7
Interior (roof)	59.4	58.6	53.1
Compressive strength (test performed in 1937	49.5	57.5	51.4

The strength in the exterior part of investigated bunker D-200/4/A-160 could not be measured due to well preserved camouflage plasters on the walls. There were several places on remaining two bunkers, where the plasters did not preserve and it was possible do a measurement of the concrete wall directly. The properties of concrete in the exterior part can be influenced by the carbonation process that caused increased strength of the surface layer, where the measurement took place. It is recommended to mechanically remove thin part of carbonated layer. Considering the non-invasive approach to testing, this recommendation was not chosen. Each value from interior part represents an average of at least 50 measurements. A relatively small spread of values can be observed.

4 Conclusions

Based on performed non-destructive testing of compressive strength, determined by Schmidt hammer, in different location of light bunkers knows as “Model No. 37” and also according to visual evaluation we can obtain following conclusions:

- The non-destructive testing of compressive strength of concrete plays its important role for determination tentative quality of concrete structures. The importance of non-destructive testing is increasing in the case of historically valuable structures that we do not want or cannot damage. Obtained values showed high strength of over 80 years old concrete and confirmed the strength determined in 1930s on specimens with dimension 200×200×200 mm (according to the army methodology used before WWII).
- The quality of concrete from investigated bunkers shows very different properties. On one object, we can find areas with excellent surface quality and well compacted concrete. These locations alternate areas with exposed reinforcement and insufficiently compacted concrete with large gaps. This phenomenon is caused by the originally used method of compaction with rammer in 1930s. The exposed and uncovered reinforcement is not a result of concrete´s degradation.
- Durability of concrete is very important and currently discussed parameter. In the case

of studied bunkers No. 37 the durability is closely connected with long-term properties of concrete and steel reinforcement. All these parameters are connected with the function of waterproofing (foundations and roof). According to performed in-situ investigations the biggest problems connected with durability are leaches of minerals from concrete. Due to the age of structures (over 80 years) extensive carbonation of concrete can be expected, which is also related to the corrosion of steel reinforcement with insufficient concrete cover layer. Based on the performed analysis (visual evaluation and the Schmidt hammer measurements) we can expect long service life and good durability of bunkers No. 37. At the same time is necessary to provide further moisture penetration into the structure - restoration of the waterproofing function of roof and insulation of foundations from moisture. Due to the age of bunkers, we can identify problems, that affect the overall service life and durability which can be solved by repairs and reconstruction works and precautions.

Stability Assessment of Historic Plaster Ceilings on Wood Lath

Helena M. Currie, Matthew B. Bronski, and Rachel M. Lynde

Simpson Gumpertz & Heger, Inc. (SGH), 480 Totten Pond Road, Waltham, Massachusetts 02451, United States of America, HMCurrie@sgh.com, MBBronski@sgh.com, RMLynde@sgh.com

Abstract. *Plaster (often lime plaster, reinforced with animal hair) installed on wood lath secured to wood framing was a common ceiling system for hundreds of years in the Americas, and for thousands of years in Europe. Despite having a relatively good record of stability, some ceilings of this type have collapsed. Given their overhead position, often above large groups of people, when cracks or localized areas of displacement or damage occur in these ceilings, the question often arises as to whether the ceiling is stable and safe. Because procedures for stability assessment of historic plaster ceilings on wood lath are not well quantified in building codes or technical literature, this article proposes key considerations and best practices for assessing these ceilings.*

Keywords: *Historic, Plaster Ceilings, Condition Assessment, Structural Stability, Vibration Monitoring.*

1 Typical Construction

Plaster ceilings on wood lath were a common ceiling system for hundreds of years in the Americas, and for thousands of years in Europe. European plaster ceilings typically consist of lime-based plaster (lime and sand) that is reinforced with animal hair, applied to a network of narrow, closely spaced wood members, that are secured to an overlying structural framework of larger wood members, either by tying in the earlier examples, or nailing in the later examples. Similar plaster ceilings applied to dried wood reeds (aka wattle, or wicker) were constructed over 2,000 years ago, as described by the Roman architect Vitruvius in the first century BCE in his treatise *De Architectura* [Vitruvius]. Multiple 500 year-old examples of this plaster ceiling construction survive from the Italian Renaissance.

Historic examples in the USA survive from as early as the mid-18th century, and were typically constructed of lime-based plaster with animal hair fibers (Fig. 1A), similar to earlier European examples; however, closely spaced wood members are lath (long slender wood pieces) rather than dried reeds. Prior to the early 19th century, the wood lath was typically riven (*i.e.*, hand-split), and from the early 19th to the early 20th century, the wood lath was typically sawn. In both cases, pieces of the wood lath were approximately 6 mm thick by 60 mm wide, with gaps approximately 6 mm wide between the long edges in sawn lath, and approximately 2-6 mm wide between the long edges of riven lath. The lath is secured to the overlying structural wood framing (*e.g.*, the floor framing of the roof or attic above) by smooth shank nails, installed from the underside. Prior to the late 19th century, the nails were either hand-forged wrought nails or cut nails, which both have a wedge-shaped profile, tapering from head to tip. After the late 19th century, the nails are typically wire nails, which have a uniform cylindrical shank and a point only at the tip.

In both European and US examples, the dense network of slender wood members (dried reeds or lath) are intentionally spaced with gaps between the long edges to provide space for the wet plaster to be forced between the gaps and create hardened plaster "keys" on the topside

of the lath or reeds, that are wider than the gaps, and thus form lines of mechanical interlock between the plaster and the topside of the reeds or lath. In both European and US examples, whether tied or nailed from below, the connection of the dried reeds or wood lath to the overlying structural wood framing is a tensile connection.

2 Typical Failure Modes

Failures of these historic plaster ceilings in the US typically fall into one of two primary failure modes: 1) failure of plaster keys (Fig. 1B), or 2) tensile failure or "pull-out" of the nailed connections of the lath to the overlying wood framing (Fig. 1C).

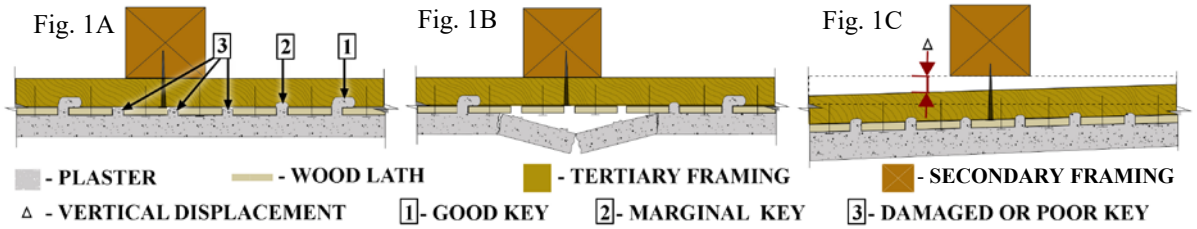

Figure 1. Typical historic plaster ceiling construction on wood lath (Fig. 1A) and two primary failure modes: plaster key failure (Fig. 1B) and fastener "pull-out" (tensile) failure of supporting framing connections (Fig.1C).

Multiple causes (*e.g.*, impact damage, structural over-loading, moisture-related deterioration, excessive deflection, or lateral movement, excessive vibration, etc.) can contribute to the two primary failure modes for historic plaster ceilings, failure of the plaster keys and tensile failure of nailed connections, which are described below in more detail.

2.1 Failure of Plaster Keying

Deteriorated, damaged, insufficient or otherwise failed keying of the plaster can lead to loss of mechanical interlock with the wood lath and localized failure of the plaster. However, this failure mode does not tend to lead to progressive widespread collapse of entire ceilings. Rather, this failure tends to be self-arresting. As unkeyed, debonded plaster starts to separate and displace downward from the wood lath, the self-weight of the debonded area may exceed the remaining interlock capacity of the remaining plaster keys, if any, and cause a relatively small (< 0.1 m^2) displaced piece to break off (as a result of the low shear strength and flexural strength of the plaster) before the displaced piece becomes relatively large (Fig. 1B). Generally, this failure mode tends to result in the falling of relatively small pieces of plaster alone (with no wood lath or framing). Given the light weight and friability of the lime plaster, plaster pieces of this size (< 0.1 m^2) generally do not pose a significant life safety risk when they fall. When evaluating the condition of plaster keys, it is helpful to distinguish between the original condition and current condition of the plaster keys, because the severity and extent of currently damaged keys, compared to the condition and performance of the original plaster keys, will inform to what extent one can or cannot rely on the track record of performance of the keying as testament to its current stability.

Original Adequacy of Plaster Keys: The adequacy of the plaster keying through the lath, as originally constructed, depends on how well-keyed (mechanically interlocked) it is with the topside of the wood lath to which it is applied. Substantially interlocked plaster keys are clearly

wider than the corresponding gap in the lath, and thick enough where they pass over the back edge of the lath to resist a shear or flexural failure within the plaster key. Keys that are at least twice the width of the gap, and with a thickness of plaster of at least 6 mm above the top edge of the lath, we consider to be "good" keys. By contrast, we consider "marginal" keys to be barely wider than their corresponding gap in the lath, with minimal thickness (less than 6 mm) where they pass over the top edge of the lath. We consider "poor" keys to be equal to or less than the width of their corresponding gap in the lath. In any ceiling installation, the best keys tend to occur at more vertical portions of the ceiling, where the wet plaster keys were applied with more ease and sagged down and over the topside/backside of the wood lath during the original installation. In the more horizontal portions of a plaster ceiling, where gravity does not aid in the formation of keys, good keying was achieved only when the workers forced sufficient plaster through the gaps in the lath with sufficient hand pressure on the trowel. Thus, the quality of the original keying in horizontal (overhead) conditions relied heavily on workmanship.

A common approach in evaluating ceilings is to conservatively consider marginal keys as not contributing to the reliability of the plaster ceiling attachment. However, in our experience, reviewing the performance of plaster ceilings a century or more old, good keys are quite reliable, and even marginal keys may perform well long-term. One historic ceiling we examined that is constructed primarily of marginal keys has performed relatively well for 200+ years, with only a few highly localized failures (*e.g.* locations where less than 0.1 m^2 pieces of plaster have fallen from the ceiling). While clearly not as strong or reliable as "good" plaster keys, marginal plaster keys likely still contribute to the reliability of the plaster ceiling attachment, unless there is evidence of marginal key failure or site-specific testing is performed. While there is no definitive research indicating whether "poor" plaster keys contribute to the load-carrying capacity of the ceiling attachment through friction between the sides of the plaster key and the wood lath, we conservatively consider "poor" plaster keys as not contributing to the overall reliability of the plaster ceiling attachment, regardless of whether displacement is evident, unless site-specific testing is performed.

Current Condition of Plaster Keys: Where keys are cracked, deteriorated, separated, or otherwise damaged, their current condition (*e.g.*, of good, marginal or poor) should be based on their remaining intact section, rather than their original width or thickness**.** In cases where relatively little damage has occurred to the keys since their original construction, one can more reasonably rely on the track record of performance of the keying as a testament to its current stability, since the adequacy of the keying has not been significantly diminished**.** Conversely, in cases where extensive damage has occurred to the keys since their original construction, one cannot reasonably rely on the track record of performance of the keying.

2.2 Failure of Supporting Wood Framing

Failure of the overlying structural wood framing, and/or its connections can potentially lead to progressive collapse of the entire plaster ceiling. Indications of this failure mode are often visible at the topside plaster framing and include gross withdrawal ("pull-out") of nailed wood-wood connections (often smooth shank or tapered nails), or gross displacement of wood members or connections (Fig. 1C). When an individual connection pulls out, the loads and stresses tend to redistribute to the adjacent connections, potentially causing them to become overstressed and more likely to pull out, which can cause a "domino effect" leading to

progressive collapse of the entire plaster ceiling (*i.e.*, the plaster, wood lath and wood framing, not just the plaster). As such, this failure mode presents a far more significant risk to life safety than the more common (and generally self-arresting) failure mode of inadequate plaster keying.

3 Stability Assessment: Current Common Practices

Numerous publications we reviewed emphasize that visual survey is the initial step for plaster evaluation. However, visual survey of plaster is subjective and damage is not consistently defined. Multiple publications also agree that damage visible at the underside of a plaster ceiling often correlates with damage on the topside of the plaster ceiling (Stewart H., 2011; Goeke, 2008). While some practitioners employ destructive tactile tests (*i.e.*, prying of plaster keys from the topside with light hand pressure to determine whether the plaster breaks) to evaluate topside conditions, in our opinion this test is problematic and ill-advised because it is destructive, non-qualitative and highly subjective. If deemed necessary, hands-on assessment, testing, and/or instrumented monitoring may supplement the initial visual assessment of plaster.

Current literature does not clearly define the condition of plaster keys (*e.g.*, "good", "fair", "poor"). While most publications agree that the percentages of damaged plaster keys are an *approximate* indicator of the overall condition of the plaster (Stewart. R, 2013), percentages that define plaster conditions vary widely in currently available literature, ranging anywhere from 30%-70% loss of plaster keys in a given area as meriting repair. Further, the pattern of plaster damage (*e.g.* whether plaster key loss is highly concentrated or uniformly distributed over a given area) that distinguishes "good" from "fair" or "poor" is not consistently considered as a factor in the overall condition or stability of plaster ceilings.

4 Recommended Best Practices for Stability Assessment

4.1 Three Step Approach to Initial Visual Assessment

Visual Assessment: An initial visual assessment of plaster ceilings is a generally accepted part of plaster evaluations. We recommend the visual assessment is best achieved using the following three step approach:

- Visual review of the underside plaster surface to document cracking and out-of-plane displacement (*e.g.*, sagging, vertical offsets) that may indicate damage or deterioration. This survey is best done first, so that areas of damage at the underside can be examined more closely and correlated with damage identified at the topside.
- Visual review of the topside wood framing to document any indications of gross withdrawal ("pull-out") of nailed wood-wood connections, or gross displacement or deterioration of wood members or connections.
- Visual review of the topside plaster keys to categorize the adequacy of mechanical keying of the plaster into the lath as good, marginal or poor (as previously defined).

Correlating Visual Review of Plaster keys with Tactile Assessment: The visual assessment of the topside plaster should include gentle, non-destructive tactile assessment of a localized area of plaster keys, after a visual-only assessment of the same area. The goal is to correlate the two methods in a representative area and confirm that the visual-only survey of

the plaster keys does not overlook concealed damage to plaster keys that was found in the tactile survey. If visual and tactile assessment of representative areas yield similar results, proceeding with a visual-only survey (with intermittent tactile testing) is appropriate.

Documenting Current Conditions: Clear, consistent documentation of the existing conditions is critical. Documentation should include clear definitions of each condition (*e.g.*, good, marginal, poor), and indicate the location and condition of keys or panels. Any imminent safety hazards should be identified on-site during the visual assessment, not postponed until synthesis.

4.2 Additional In-Situ Testing or Monitoring

In-situ "pull" testing (tensile testing conducted from the underside) of representative types of keys and derivative calculation to determine the actual factor of safety in representative areas can be used to refine the initial approximate criteria for critical percentages of plaster damage with respect to stability. If the ceiling is vaulted, it is preferable to conduct pull tests data on both horizontal and approximately vertical applications of each plaster condition type to get the full range of existing conditions. Pull-testing is most prudent when conservative assumptions and approaches would otherwise lead to invasive recommendations. If vibrations are suspected to be contributing to plaster damage, vibration monitoring may be prudent (Section 5).

4.3 Synthesis

Synthesis of the information gained from the in-situ assessment is needed to evaluate the overall stability of the plaster ceiling, to identify any potential risks, and to develop recommendations for repair. We divide the synthesis into the following steps:

Initial Categorization – As a first step, classify areas of plaster keys into condition categories (*e.g.*, "good", "marginal", "poor") based on the percentage of poor keys in a known area. Initial categorization should also include review of the overlying framing and connections. We often graphically depict condition categories as distinct colors on a ceiling plan, to help visualize patterns and areas of concern.

Review Performance History – Understand the performance history (*i.e.*, "track record") of how the plaster keying has performed over time (*e.g.*, few or many areas of previous repair or fallen plaster) to evaluate to what extent undamaged original keying can be relied upon, especially undamaged original "marginal" keys. Compare the current conditions to those of other plaster ceilings of similar construction and the track records of those ceilings.

Assess Sources of Deterioration – For areas where plaster and/or supporting framing is deteriorated or damaged, assess whether source(s) for deterioration are active (*e.g.*, a roof leak), and if so, whether they can be mitigated.

Calculate the Factor of Safety – To assess whether plaster keying conditions are at risk of failure, calculate the ceiling-specific factor of safety for the range of typical conditions and orientations present. The factor of safety (FS) under gravity-loading conditions (not seismic) consists of $FS = P_{fl}/P_{sw}$, where P_{fl} is the failure load applied to the plaster during the tensile "pull" test, and P_{sw} is the self-weight of the plaster for the same surface area. Standard structural engineering procedures and calculations can be used to evaluate the safety and stability of the supporting wood framing and connections.

5 Recommended Best Practices for Vibration Monitoring

5.1 Standards for Protection of Historic Buildings from Vibration Damage

There are numerous guidelines and publications for the protection of historic buildings from vibrations; however, various factors make it difficult to directly apply the criteria in these guidelines to evaluating the stability of historic plaster ceilings:

- Criteria for minimizing the probability of damage to existing buildings vary widely (*e.g.*, typical values for peak particle velocity range from 0.06 to 2.0 in./sec.).
- Criteria tend to be conservative, in that they are typically created to define low vibration levels at, or below, which damage almost certainly will NOT occur, to be relatively certain that vibrations from nearby construction will not damage an historic building. Thus, they are NOT intended to define a threshold at which damage WILL occur.
- Furthermore, these criteria tend to be based on vibration measurements taken at grade outside the historic building, closer to the external source of vibration, not inside the building or at a plaster ceiling itself (where the same external vibrations would measure at lower levels). Thus, these criteria are even more conservative when applied to internal vibration sources as measured at the interior.

Based on our review of various articles (Johnson, Hannen), as well as common vibration standards (*e.g.*, the British, German, and Swiss Standards), the vibration guideline values listed in the Swiss Standard for Building Class 4 (*i.e.*, the most sensitive class for historic and protected buildings) is often referred to as the most appropriate standard for evaluation of historic or sensitive materials. Further, the vibration criteria provided in the Swiss Standard are generally more conservative than other commonly referenced standards. Thus, by selecting the most conservative vibration criteria (*i.e.* 0.06 in./sec.), in one of the most conservative standards as the threshold vibration limit for monitoring and further review, it is highly unlikely that aesthetic or structural damage will occur if vibration levels in the plaster are less than 0.06 in./sec. Because the Swiss Standard and others are not directly applicable and likely highly conservative, these standard values should be treated as initial values that will likely require further evaluation and refinement. In some cases, ambient vibrations (*i.e.* vibrations experienced by the plaster ceiling regularly) or anticipated vibrations exceed these conservative limits. In these cases, project-specific vibration monitoring and/or testing may allow less-conservative project-specific threshold vibration criteria to be established for specific ceilings.

5.2 Continuous and Discrete Vibration Monitoring

A successful vibration monitoring program must achieve two primary objectives: 1) quantify the vibration levels experienced by the plaster over time and 2) evaluate specific vibration sources that pose a potential risk of damaging the plaster. Continuous vibration monitoring over an extended period of time, at the point of interest (*i.e.* at the topside of the plaster) quantifies both the ambient (typical) and atypical vibrations at the plaster ceiling. When ambient vibrations fall below the conservative industry thresholds, vibrations are highly unlikely to cause plaster damage. Where ambient vibrations levels are higher than these thresholds, however, vibrations will not necessarily cause damage to the ceiling. By contrast, this may confirm that the industry standard vibration criteria are not appropriate. Additionally, the type

and regularity of occurrence for each vibration source that coincides with high vibration levels should be taken into consideration (some standards do not account for these factors).

All potential vibration sources identified during continuous monitoring as exceeding the ambient or industry-standard threshold should be further assessed by discrete vibration testing of those specific sources, isolated to the greatest extent possible. Consider vibration monitoring information jointly with the plaster condition assessment to determine whether any of the plaster damage is likely associated with suspect vibrations sources. For example, where damaged plaster keys are highly concentrated adjacent to walkways at the topside of the ceiling, vibration monitoring can help to evaluate whether the damage is from accidental direct impact (*e.g.*, individuals bumping into the plaster) or transferred vibrations (*e.g.*, from footsteps on the walkway transmitted through rigid connections to the ceiling framing) (Fig. 2).

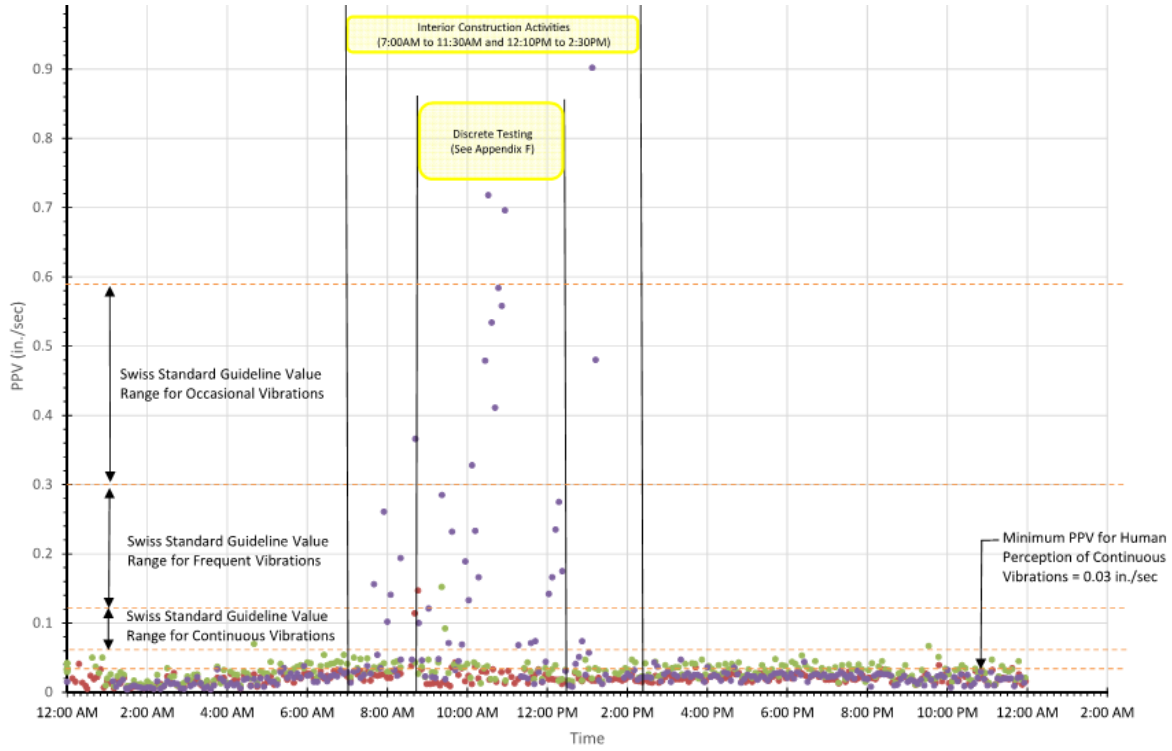

Figure 2. Example of vibration measurements collected at the topside of a plaster ceiling (where plaster damage was concentrated adjacent to attic walkways) during targeted vibration monitoring of an historic plaster ceiling.

In turn, this diagnosis should inform the recommendations to mitigate the problem (*e.g.*, implementing a protection system to mitigate accidental impact, or developing a dampening system to mitigate walkway vibrations, respectively).

6 Conclusion

Historic plaster ceilings on wood lath have been used for thousands of years, in many countries on multiple continents, and are a valuable historic resource well worth preserving. Despite some failures, plaster ceilings on wood lath generally have a reliable track record. The two most

common failure modes are failure of plaster keys and failure or "pull-out" of the supporting wood framing, the latter of which can result in progressive or whole-sale collapse. While vibrations are seldom the driving mechanism for failure, vibration monitoring is helpful in some cases where vibrations are a suspected cause of damage. In the US, the lack of guidelines or standards on how to evaluate historic plaster ceiling stability, and relatively little technical literature on the topic has been a hindrance to their proper evaluation of life safety/stability. Based on our experience, we utilize and recommend the condition and stability assessment procedure described herein, which includes documenting the original and current condition through visual assessment and correlation of visual observations with intermittent tactile assessment and empirical comparisons, in-situ testing and/or monitoring where prudent, and development of evaluation criteria and recommendations through post-processing and synthesis.

The Stone Masonry Contribution in Greek Industrial Buildings' Typology and Construction Durability (Late 19th to Early 20th Century)

Georgia G. Cheirchanteri

Department of Civil Engineer, Faculty of Engineering, University of West Attica (UNIWA), Ag. Spyridonos 28 p.c. 12243 Egaleo, Athens, Greece, geoxeirr@gmail.com

Abstract. *Stone masonry is the oldest form of construction in the world until the beginning of the 20th century. The first stone walls were constructed by farmers and primitive people by piling loose field stones into a dry stone wall. Later, mortar and plaster were used, especially in the construction of city walls, castles, and other fortifications before and during the Middle Ages. These stone walls are spread throughout the world in different forms. Stone walls are usually made of local materials varying from limestone and flint to granite and sandstone. However, the quality of building stone varies greatly, both in its endurance to weathering, resistance to water penetration and in its ability to be worked into regular shapes before construction. Also, the majority of buildings in Greece at the end of 19th century up to the use of concrete in constructions are load-bearing stone masonry structures. Moreover, research shows that it is the most widely construction material in industrial buildings, that era. As it is known, stone masonry has high compression strength under vertical loads but has low tensile strength (against twisting or stretching) unless reinforced, while the tensile strength of masonry walls can be increased by thickening the wall. In general, industrial buildings constructed of stone masonry, from late 19th to early 20th century, have particularities in their typology because they were directly dependent on their mechanical equipment and production line. The aim of this study is to investigate the contribution of stone masonry as a construction material in the typology of these industrial buildings concerning their durability.*

Keywords: *Stone Masonry, Durability, Stone Masonry Properties, Traditional Constructions, Industrial Buildings' Typology.*

1 Introduction

Stone masonry is a traditional form of construction practiced for centuries in the regions where stone is locally available (Khan, Lemmen, 2013). Until the emergence and wide use of steel around the mid-20th century, load-bearing masonry was the only building material up to date in the construction of various works around the world. Exceptions were areas where wood was used exclusively for building. In countries with a tradition in using masonry constructions and where there was no strong seismicity such as Great Britain new buildings up to four floors using bearing masonry techniques are still constructed.

This type of masonry is still found in old historic centres, often in buildings of cultural and historical significance, and in developing countries where it represents affordable and cost-effective housing construction. This construction type is present in earthquake-prone regions of the world, such as Mediterranean Europe and North Africa, the Middle East, India, Nepal, and other parts of Asia.

Houses of this construction type are found both in urban and rural areas. There are broad variations in their shape and the number of storeys. Houses in rural areas are generally smaller in size and have smaller openings since they are typically used by a single family. Buildings in urban areas are often of mixed use, that is, with a commercial ground floor and a multifamily residential area above. Houses in the countryside are built as stand-alone

structures, while the neighboring houses in old town centers often share a common wall.

Moreover, research shows that it is the most widely construction material in industrial buildings, after the first Industrial Revolution. Between the end of the 19th and the beginning of the 20th century, industrial buildings constituted a large part of the cities' urban fabric, especially ports, such as Piraeus in Attica, Volos in Thessaly, Syros in the Cyclades etc., constituting an important chapter in the architectural development of each area. Therefore, their typological structures as well as their morphology, in relation to their structural construction system, which is bearing stone masonry and its durability, need special study.

2 Stone Masonry: Building Materials and Construction Technology

The main components of stone masonry are simple stones and synthetic mortar. Stones come mainly from sturdy rocks, which after a short or a long process get the proper shape to be suitable for the construction of the project. From a geological point of view, and depending on the way the rocks are formed, the natural stones used in building construction can be classified according to their origin as igneous, sedimentary and metamorphic.

The igneous stone principally used in building is granite, which was formed from the fusion of minerals under great heat below the earth's surface many thousands of years ago. Sedimentary stone was formed gradually over thousands of years from particles of calcium carbonate or sand deposited by settlement in bodies of water. Gradually layer upon layer of particles of lime or sand settled into depression in the earth's surface and in course of time these layers of lime or sand particles became compacted by the water or earth above them. Metamorphic stones have been changed from igneous or sedimentary stone or from earth into metamorphic stone by pressure, or heat, or both in the earth's crust. Examples are: a) marble which was formed from limestone and slate and b) shale formed from clay (Anmol, J.-10: 2019).

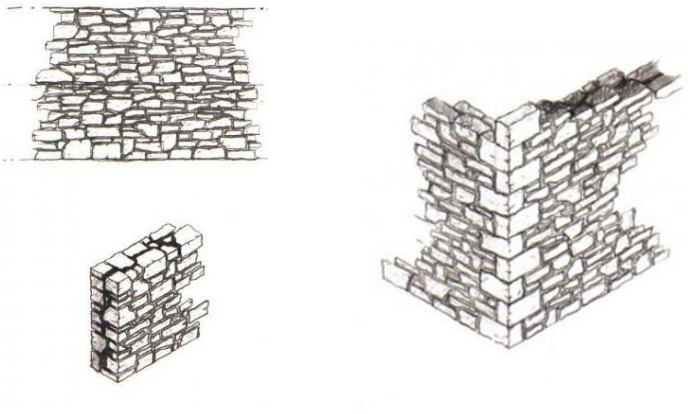

Figure 1. Stone masonry constructions.

Stone masonry is the most common type of masonry in Greek traditional architecture due to the abundance of stone in many places in Greece. They can be distinguished in coursed rubble masonry and uncoursed rubble masonry (Fig1.). The coursed rubble masonry walls have more durability due to the better fitting of the stones and homogeneity. However, they require larger and better quality of stones, in order to have quantity and quality material for achieving the best possible fitting. Furthermore, highly skilled craftsmen are required to carve

the stones properly. The highest level of coursed rubble and durability, was achieved by the creators of the marble buildings in the Acropolis rock, in Athens. The carved stones were so well fitted together that no mortar was needed and their interconnection was finalized with internal metal fasteners.

On the other hand, uncoursed rubble masonry has the disadvantage of less durability, due to the poor adhesion of the stones and the high proportion of mortar required to fill the gaps. Another factor of less strength is the heterogeneity of the stones, since their irregular shape requires the use of different sizes to fill the gaps. Typical traditional architecture adopts an intermediate state using the coursed rubble stones are in the most sensitive parts of the building (corners, base, crown), and the uncoursed rubble stones in the least sensitive or visible parts of the building. Although brick masonry is very common in lowland areas where stone is scarce, as well as in northern Europe, in areas where the stone is abundant, there are brick masonry constructions, because they have some advantages over stone masonry such as the light weight of the bricks compared to the stones and the standardization of their dimensions (Ravi *et al*., 2014; Francis *et al.,* 1971).

Mortar, the binder material between the stones in masonry, is called the mixture consisting of fine aggregates (maximum aggregate grain diameter 4mm), cements such as binder and treatment water, having a wide variety of compositions and strengths (ASTM C 270-10:1019). Generally, the use of mortars makes the stonewall a comprehensive body, carrying safely the loads it was designed for and remaining also unchanged over time. Mortar's mechanical properties have a catalytic effect on the masonry characteristics. An additional factor of diversity is the construction type or otherwise the "knitting" way of masonry construction, giving to the stone masonry a distinct character and some additional features, such as better bonding and stone durability.

Structural walls are supported either by stone masonry strip footings or not. Floor structures in towns and historic centers are vaulted brick masonry at the ground floor level and timber joists at the upper floor levels. Timber joists are usually placed on walls without any physical connection. The original floor structures in historic buildings have typically been replaced either by a precast joist system or by solid reinforced concrete slabs especially in Italy (WHE Report 28-8:1019) and Slovenia (WHE Report 58-8:1019).

3 The Structural Stone Masonry Mechanical Behavior and Durability Under Vertical and Seismic Loads

The mechanical behavior of masonry is characterized by:
-Relatively high compressive strength.
-Extremely low tensile strength.
-Relatively satisfactory shear strength.
-Strongly anisotropic behavior.

The high compression strength of the masonry compared to its other mechanical properties also determined its use as a mainly compressed load bearing component (Stylianidis *et al.*-10:2019). Both the strength and type of failure of compression masonry are strongly influenced by the angle of the compression force as to the direction of horizontal joints (anisotropy).

When a masonry construction is being pressed perpendicularly to the main horizontal joints, usually, fails due to transverse splitting of the stones, due to the development of tensile

strength in transverse directions. These tensile strengths are caused by the reconciliation of the large transverse deformations of the mortar joints with the smaller ones of the bricks, which causes corresponding transverse adhesion in the mortar. Thus, under axial compressive loading of the masonry, triaxial strength is developing on the stones and joint mortar. When using the term masonry strength refers to the compressive strength perpendicular to the horizontal joints (Tensing *et al.,* 2013).

The compressive strength of the masonry depends on:

1. The properties of stones, such as their strength, type and geometry.
2. The characteristics of the mortar such as its durability and composition.
3. The prevailing conditions in masonry i.e. the manner of engagement of masonry.
4. The material and the thickness of the joint.
5. How to apply and effect concentrated loads.
6. The quality of construction.

On the other hand, features of weaknesses in masonry are due to the behavior of the contact interface, mainly, along the repeated horizontal joints that have been characterized as "weak levels of masonry". The tensile strength of the masonry is clearly much lower than the compression, varying and depending on the angle of the tensile strength in the horizontal joints. In particular, the tensile strength of the bearing masonry is low, being perpendicularly to the horizontal joints and greater when is parallel to them. In case there is tensile strength on the joints, the mortar will be detached. Usually, the tensile strength being parallel to the joints is greater the tensile strength is greater, because of the resistance to sliding mortar or stone, as well as, the tensile strength of masonry.

Factors affecting tensile strength of masonry:

A. Joint resistance to detachment
B. Tensile strength mortar.
C. Mortar coherence.

Masonry's behavior in shear compression is more satisfactory, as the incurred structure passes through various stages, until reach the crash stage. Pressing under vertical loads is clearly defined, but it is not the same in case of seismic pressing. Even after the simplification of the earthquake action in the two main directions of the building, the size and distribution of the seismic intersection (also between the vertical load-bearing elements of each floor) depending on the geometric and dynamic mechanical characteristics of the bearing organism, remains unpredictable (Kaaki, 2013).

The most important factors affecting the seismic performance of these type of buildings are the strength of the stone and mortar, the quality of construction and the density, distribution of structural walls and wall intersections and floor/roof-wall connections (Costa *et al.,* 2011).

Stone masonry construction generally shows very poor seismic performance. Poor quality of mortar is the main reason for the low tensile strength of rubble stone masonry. Timber floor and roof structures are usually not heavy and therefore do not induce large seismic forces. However, typical timber floor structures are made of timber joists that are not properly connected to structural walls. These structures are rather flexible and are not able to act as rigid diaphragms. Due to their large thickness, stone masonry walls are rather heavy and induce significant seismic forces.

Typical damage patterns for built rubble stone masonry are delamination and disintegration, infilling in weak mud mortar with many air voids. Out-of-plane failure can occur when the connections between the exterior and interior walls are inadequate. When the

connections between the perpendicular walls are strong, the wall shear capacity can be exhausted, thus causing typical shear cracks can be developed.

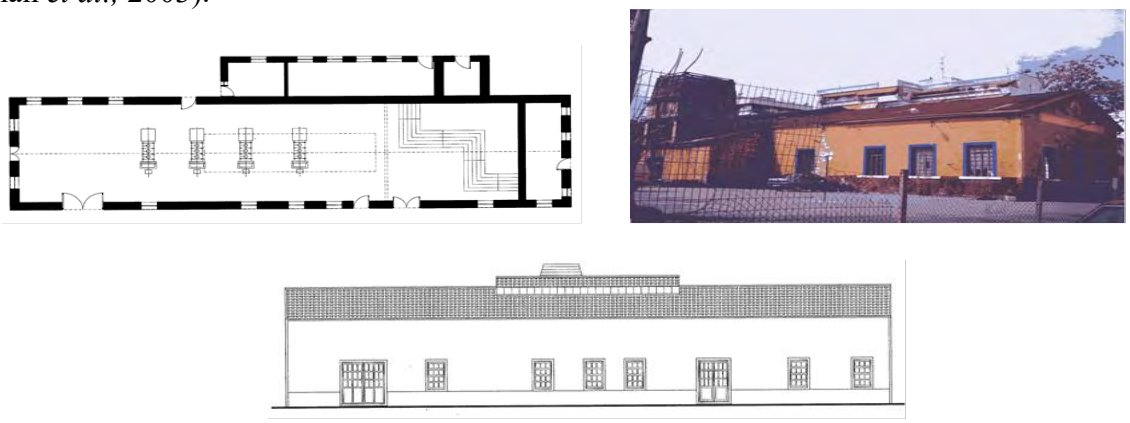
4 Typological and Material Characterization of Stone Masonry Durability in Industrial Buildings

Basic properties of stones for stone masonry are strength and durability, while economy and appearance are additional values. The main considerations for durability are the lasting qualities of stone itself and the locality where it is going to be used. Porous stones are unsuitable for areas prone to heavy rainfall and frost. Stones, e.g. marbles having low porosity and low coefficients of expansion and contraction should be used in areas subjected to large variations in rainfall and temperatures. Generally, lime and cement mortars are used for stone masonry, providing a workable matrix and ultimately a hard building material, which renders masonry into a monolithic unit.

As a matter of fact, the typology of traditional industrial buildings has been characterized by the elongated rectangular shape of the ground plan (Fig 8,9.), which contained the mechanical equipment for the production of the products. These elongated rectangular industrial buildings must have very thick walls (from 0,50 to approximately 1,00 meter, depending on the building's size: height and length) in order masonry durability to be increased. Also, this building's shape proves that the layout of the machines was not random, but was arranged in a linear layout to facilitate the production line. Using the perimetric bearing stone masonry, which was the structural construction system until the early 20th century, it was possible to construct most of the rectangular elongated buildings, or even having a square ground plan (Cheirchanteri, 2014).

The entrance of this type of buildings was most often located in the center of the narrow or longitudinal side, in such a way, that the production line was not interrupted. In this construction building system, although the openings were large, symmetrical, repetitive and sometimes arched, interior lighting was not sufficient in the middle of the building. As a result, elevated skylights were installed along the roof in order to enhance lighting (Fig 7,10,11.), (Cheirchanteri, 2014).

Masonry advantages, usually, include thermal insulation, fire safety, durability, ecological recycling materials of the building at the end of its lifetime and the elegant façade appearance. Among the disadvantages is the diversity of the stones, which makes its mechanical behavior unpredictable, contributing in the great difficulty of standardizing materials and methods (Phan *et al.,* 2003).



Figures 9, 10, 11. Power Plant building in Larisa, Greece (1913).

4.1 Stone Masonry Greek Industrial Buildings' Typology and Construction Durability

Until World War I, the typology of industrial buildings in Greece was the same as in Europe. The architectural volumes of these buildings were adapted to the shape and size of the mechanical equipment, as well as to the needs of the production cycle, unlike to other private and public buildings of that era, in which the shape, size, and layout were following strictly by the stereotypes, dictated by neoclassicism.

The basic type of these industrial buildings was the elongated rectangular shape, while the facilities were formed by the layout of many similar units. The machines were positioned across the production area, due to the motion transmission way and the side windows location, which were the only source of natural light for the workforce. Most of them were constructed using traditional techniques. It should be noted that industrial buildings were morphologically influenced by neoclassicism. According to their characteristics they were classified into three categories: the traditional industrial buildings, the monumental and the ragged in shape.

The industrial ground floor buildings constructed until 1900, were usually using in masonries stones cut and dressed to proper shapes, as well as, double incline roofed contractions, with small rectangular repeated openings. The stone masonry of these buildings was load-bearing, made of traditional materials such as wood, stone, tiles, and in many cases cast iron and steel. But their dominant feature was the incorporation of local architectural elements, achieved using traditional materials and construction methods. Concerning construction durability, bearing walls used to be very thick, about 1,00 meter, because of their very big height and length, which were demanded for their mechanical equipment.

A typical example of a traditional industrial ground floor building, built in 1882 in Athens, is the Drakopoulos Textile House (Fig 2.). It was one of the rare occasions among the first factories that the building was outstanding (variety of apertures, classic pediment on the façades, elaborate details, characteristic patterns), as opposed to the simple form of other factories in Greece. Also, the Politis factory in Piraeus (Fig3.), built between 1907 and 1916, had the same treatment as the first ground floor industrial buildings. The arched openings were dominant, while the consecutive double incline roofs had jagged architraves, with double skylights windows in the center, forming small, rectangular openings (Cheirchanteri, 2014).

The Turbine House of the Larissa's Power Plant in Thessaly (1913, Fig 9,10,11.), was a building with an oblong rectangular ground plan and a double incline tiled roof elevated on its central part, completing natural lighting and ventilation of the building. On the other hand, the Power Plant in Karditsa city, also in Thessaly area (1909, Fig 4,5,6.) was an industrial complex of two buildings, one and two-storey, correspondingly. Additionally, noteworthy is the monumental Water Pumping Station building in Thessaloniki (Fig 7,8.), built by Belgian engineers in 1890–1892. The metal elements in combination with the bricks in the prominent masonry of the building formed a radical façade appearance (Cheirchanteri, 2014).

5 Conclusions

- Stone masonry as the oldest traditional form construction in the world was also the most popular construction material in industrial buildings, after the first Industrial Revolution. The typology of industrial buildings in Greece was the same as in Europe, where the architectural volumes of these buildings were adapted to the shape and size

of their mechanical equipment and production needs.

- The typology of traditional industrial buildings in Greece was characterized by the elongated rectangular shape of the ground plan, which depended on the stone masonry load-bearing construction system and the mechanical production equipment.
- Stone masonry has high compressive strength under vertical loads, but has low tensile strength (against twisting or stretching) unless reinforced, while the tensile strength of masonry walls can be increased by thickening the wall.
- Concluding, the stone masonry contribution in Greek industrial buildings' typology and construction durability has been proved by the elongated rectangular shape ground plan, which includes the arranged linear machines layout, in order to facilitate the product line. Concerning the industrial buildings construction durability, it was achieved by the big thickness of bearing walls, despite their length and height. In many occasions they were big enough due to the requirements of the mechanical equipment, which was located inside the buildings.

The Structural Strengthening of a Masonry Heritage Shop House using Glass Fibre Based Materials

Kribanandan Gurusamy Naidu

JTK Consult Sdn Bhd, Kuala Lumpur, Federal Territory, Malaysia, drkribangn@jtkconsult.com.my

Abstract. *A two-storey masonry pre-war shop house in Taiping, Malaysia was badly affected by construction being undertaken at an adjacent lot. The building was in a serious state of disrepair and on the verge of collapse at the time of the investigation and temporary propping and a stoppage of adjacent works had to be imposed. For the remedial intervention a rapid approach was critical with materials and methodologies selected to incur minimum additional impacts on the building in terms of physical works and with flexibility on site. Several innovative techniques developed for the structural intervention of masonry buildings was considered. In this case the masonry wall cracks were repaired by a stitching method using the glass fiber rod maperod g which was considered a suitable material due to the compatibility of modulus of elasticity (40,800N/mm2) to the lime mortar, having good tensile strength of 760 N/mm2 to help bridge the cracks in case of further movement and is also corrosion resistant and will remain protected in future even though it is embedded in a highly porous masonry substrate. The materials used were easily transportable, flexible (ie) could be prepared to requirements on site and could be delivered to site quickly despite this being imported. The approach taken resulted in a rapid reinstatement of the building, minimised the risk of losing heritage features and matched the client's overall objectives. The paper provides details of the approach taken and the basis for the remedial intervention.*

Keywords: *Masonry, Structural Cracking, Remedial Intervention, Glass Fibre Materials.*

1 Introduction

1.1 Project Background

A masonry shop house in Taiping, Perak in Malaysia was badly affected by construction being undertaken at an adjacent lot. There was significant evidence of settlement at the front and back of the building, leading to significant cracking of a party wall, front and rear walls and the main walkway Arch Supporting the upper floor and wall.

The building is a 2 storey pre-war shop house with an overall layout plan as shown in Figure 1. The building housed a family business until adjacent construction activity forced the owners to move from the premises due to an eviction order imposed by the local authority arising from the dangerous state of the building. The actual construction details of the adjacent building was not made available but the site visit confirmed that the original 2 storey building next door had been torn down to make way for a 3 storey structure on piled foundations with a lift at the rear.

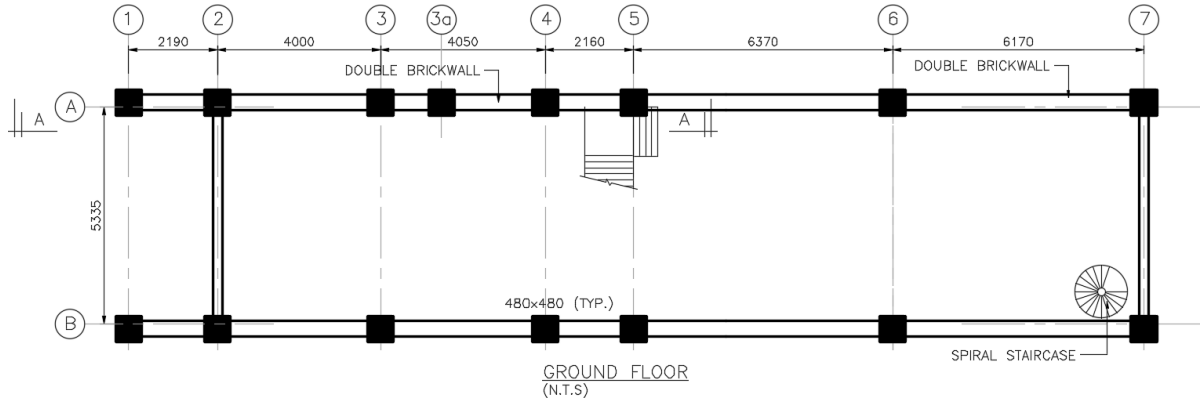

Figure 1. Plan View of Shop House.

The only precaution taken to protect the shop house was an attempt to support the common corridor arch at the front of the building with Timber Props which was totally inappropriate for a structural masonry arch and had potentially accentuated the serious damage caused by imposed stress concentrations due to the settlement and vibration. The structural Engineer who designed the new adjacent 3 storey shop house was asked by the local authority to provide a report and a basis for remedial intervention. The initial suggested approach to epoxy inject the cracks were considered wholly inadequate and not a serious measure of what was required to reinstate the shop house to its original design intent and to guard against long term settlement and cracking associated with the disturbed foundations. A site walk through was undertaken to view the condition of the structure and this is discussed below.

1.2 Condition Audit

There was considerable evidence of settlement of the columns in gridline A/1-3 as shown in Figure 2. This led to uneven loads on the masonry columns causing the characteristic structural cracking of the Arch, where cracks of up to 50 mm in width were noted. A closer examination of the party wall from the adjacent shop house confirmed that the structural cracking extended to this wall along Gridline A2- A5 where cracks of up to 30 mm were noted. In general the party wall away from the new development was structurally intact. An immediate intervention was proposed to structurally reinstate the front Arch, the common party wall along gridline A and other settlement and cracking points. It was noted that the building was not loaded with the full complement of live loads which can be expected. The cracking on the walls and the Corridor Arch were clearly to do with settlement and vibration loads associated with the adjacent construction, rendering the building unsafe to use at the time of the investigation. There was also a considerable amount of water ingress into the building particular at gridline A-B'/5-7 and also at the building corners at gridline A1 and A5 which had not been a problem previously. Based on the visual survey the key defects noted are summarised in Table1.

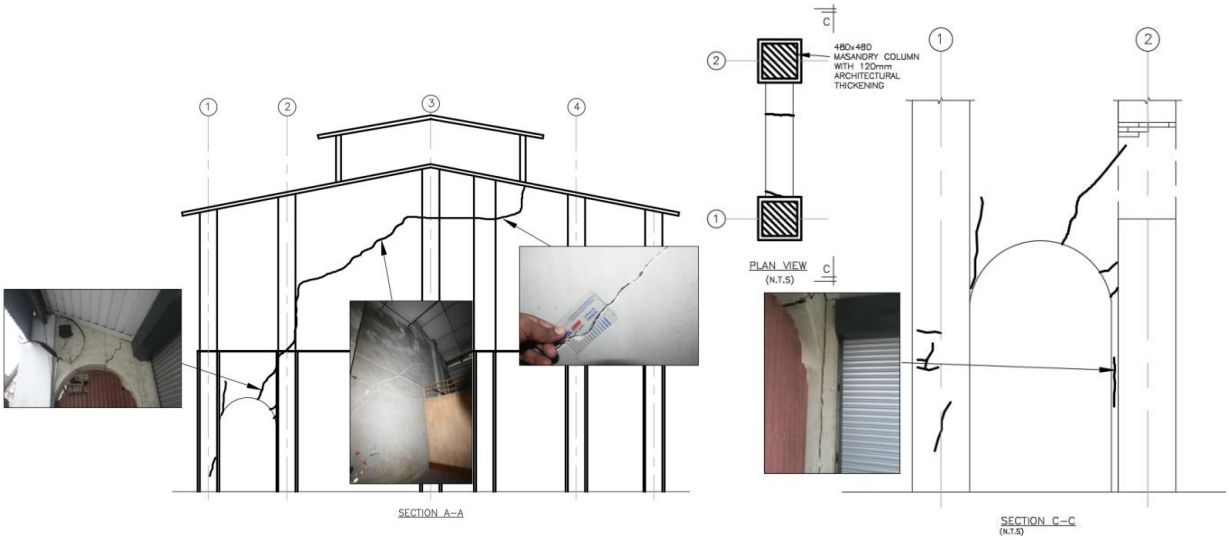

Figure 2. A Record of the defects at the Main Arch at the Shop House Front and at the Party Wall.

2 Engineering Features

2.1 Overview

Demolition of masonry shop houses and rebuilding is often considered the preferred option when such structures come into disrepair. Increasingly however repair and refurbishment is seen as a more sustainable option in terms of architectural value, materials use, neighbourhood disruption, waste disposal and overall cost. By avoiding expensive demolition and rebuild, the development of repair and refurbishment techniques retains the aesthetic and historic value of a building including its appearance and providing a sustainable structural solution. It also potentially reduces costs.

Where defects are related to settlement, it is necessary to repair or underpin the foundations before any stitching of the cracks on the brick masonry. In historic buildings, it is important to preserve as much of the original materials as possible and consider repair options which are relatively reversible and do not damage the original building fabric.

2.2 Options for Structural Reinstatement

The building was in a serious state of disrepair and on the verge of collapse. Temporary propping and a stoppage of adjacent works had to be imposed. A rapid approach was critical for the intervention, with materials and methodologies selected to incur minimum additional impacts on the building in terms of physical works and with flexibility on site.

Table 1. Summary of Condition Audit Findings.

Item	Type of Damage	Location of Damage	Options for Reinstatement
1	Damage to Footings Leading to Settlement	Party Wall between unit 150 and 152, Gridline A1-7	Compensation Grouting was done for all footings at the common Boundary between the Shop House 150 and 152 from Gridline A/1 to 7 to guard against future movement and settlement.
2	Structural Cracking of the Arch and associated Party Wall	At the Front Corridor Gridline A/1 - 3	The Arch was fully supported with a radial support structure and props to facilitate repairs. The remedial works involved reinforcing the whole span of the masonry arch across the crack with Carbon Fibre Rods and an appropriate mortar effectively introducing structural beams above the arch opening so that load shedding is directed to the columns. The remedial intervention also involved stitching of structural cracking which extended to the party wall and columns to cover the full extent of cracking
3	Wall Crack	Party wall between Gridline A/2 - 4	The remedial works consisted of stitching the cracks with Carbon Fibre Rods and a structural grade epoxy. The stitching was extended to the full extent of cracking
4	Window Lintol and wall Cracks	Gridline A-B/1	Epoxy Injection and Borehole Suspension' Grout used
5	Settlement Cracks at the Rear of Building	Gridline A-B/7	Epoxy Injection and Borehole Suspension' Grout used
6	Level 1 Cracks Leading to Water Ingress	A-B'/5-7	Flexible Acrylic Gel to Seal the Cracks with the Option of Reinjection if the problem is not resolved in the first instance
7	Other Areas of Water Ingress	A1 and A5	Further investigation was required at roof level to ascertain the source of the water leakage problems. Repair as per 6 was required and in this case replacement of damp plaster works was also necessary.
8	General		Replastering, Overall Repainting and Replacement of Internal fittings affected by moisture ingress adjacent to party wall was done.

Several innovative techniques have been developed for the structural intervention of masonry buildings. Among the key developments in this area includes the use of stainless steel helical ties and slim ties developed by Helifix (www.helifix.com). These form very strong axial ties to resist lateral forces, yet are flexible enough to accommodate natural building movement without introducing further stresses in the substrate. The associated concealed, non-disruptive installation techniques provide many outstanding benefits, from the simplicity of their design to ease of installation and their long term performance. At the time of the investigation the options for repair had been further advanced by Mapei using alternative materials with glass fibre as the base ie Maperod G and Mapewrap Foccio. Where masonry wall cracks are to be repaired by a stitching method, the glass fiber rod maperod G is a suitable material due to the compatibility of modulus of elasticity (40,800N/mm2) to the lime mortar. It also has a good tensile strength of 760 N/mm2 to help bridge the cracks in case of further movement. As glass fiber is also corrosion resistant it will be protected in future even though it is embedded in the highly porous masonry substrate. In the case of the Taiping shop house the latter approach *i.e* Mapei rod was used as the materials were easily transportable, flexible *i.e* could be prepared to requirements on site, and Mapei had the infrastructure to deliver the materials to site quickly despite this being imported.

2.3 Approach to Reinstatement

The extent of the remedial works was confirmed based on the visual examination and following hammer tapping and hacking to confirm the extent of the problem. The final remedial works undertaken between gridlines 1-5/A included the following:

a) Stabilization of six column foundations A/1, A/2, A/3, A/4, A/5 and A/6 with soil grouting using OPC and Intraplast –Z.
b) Stabilization of six column foundations A/1, A/2, A/3, A/4, A/5 and A/6 with soil grouting using OPC and Intraplast –Z.
c) Removal of wall plaster and re plastering using Mape-Antique MC a prebagged lime based plaster
d) The full reconstruction of one column at gridline A/3 by re-using the existing bricks which were carefully dismantled piece by piece.
e) The columns at gridline A/2 and A/5 were partially removed and the bricks reinstated and injected using Mape-Antique I by a low pressure injection method.
f) The Arch and wall cracks were repaired by a stitching method using Maperod G a glass fibre rod which is inert within the matrix but providing structural strength.
g) Mapewrap G Fiocco was used allowing stitching to be performed at one-side with minimum impact to the overall wall with the anchors planted deep into the masonry wall to provide the full anchorage.

In this case the stitching could only be performed at one-side and for this reason Mapewrap G Fiocco was selected as an appropriate method. Mapewrap G Fiocco is made into an L-shaped anchor using epoxy impregnator Mapewrap 31 SP and is bonded at both ends of the Maperod G.

The anchor is planted deep into the masonry wall, ie approximately to a depth of 140mm to provide the full anchorage. To structurally bond the Maperod G and Mapewrap Fiocco to the masonry wall, epoxy adhesive Adesilex PG2 TG was selected. Epoxy has high durability and good mechanical properties in terms of compressive, flexural, tensile and shear strength.

To enhance the bonding to the masonry wall, all contact surfaces of the masonry were primed with Mapewrap Primer 1 SP to consolidate the porous surface and eliminate dust. The crack lines were reinforced at every 4-5 brick intervals and inserted into the pointing layer for a minimal impact on the existing masonry wall. The full extent of the repairs is illustrated in Figure 3.

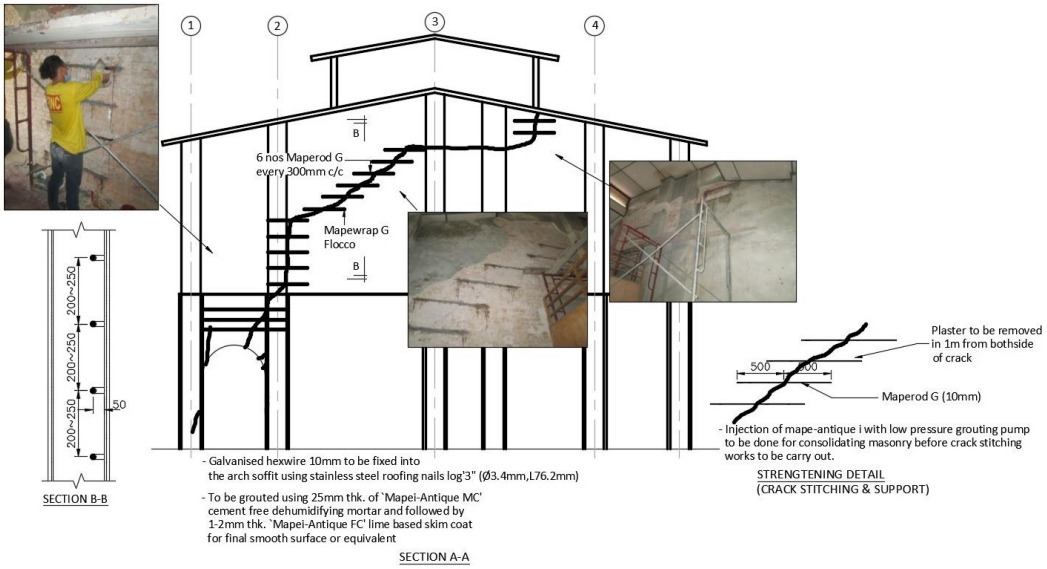

Figure 3. Significant Cracking of the Arch and Party Wall and the proposed approach to crack repair.

The remedial work was carried out by a specialist contractor and the repair materials were supplied by Mapei. The works were carried out successfully and the shop house was reinstated to its original condition within 3 weeks (see Figure 4).

Figure 4. Additional Illustrations of the Remedial works.

3 Project Accomplishment

3.1 Client Needs

The remedial works were undertaken rapidly and reduced the impact of the loss of access to the facility. The alternative which was on the cards was demolition and rebuilding. The engineering solution entailed using modern materials developed specifically for heritage upgrading which had never been used in a practical project application before for structural restoration. The work was done with little impact on the overall heritage value of the building.

3.2 Budget and Project Time Line

The project was successfully controlled with the implementation of proper documentation in the form of detailed method statements and pre-selection of materials to be used directly from a specialist supplier (Mapei). In conjunction with Mapei an off-site training was undertaken of key personnel involved in the project to minimise delay on site.

The arches and key structural components had been temporarily propped using specially designed timber props to guard against collapse and this was removed progressively. The stabilization of the foundation was undertaken within a week and as the injection works were completed in a particular area masonry strengthening works proceeded in the associated area. The crack repair works and stabilisation of the masonry walls proceeded over a 2 week period. The finishing works and painting was then undertaken by the main contractor.

The works were successfully undertaken at approximately a quarter of the cost and 1/3 of time compared to rebuilding of the structure which was the only other option. As this was the full responsibility of the adjacent works contractor as per the court order, the approach taken was a win-win for all parties (ie) in terms of time and cost. This met the client's requirements for speed and minimisation of the disruption after a lengthy delay due to the legal action.

3.3 Overview

This work demonstrated the validity of the use of modern materials for a non-invasive low maintenance reinstatement of a heritage building badly affected by settlement and structural movement with little impact on its heritage value. This was considered to be the most cost-effective solution and appropriate, where speed of reinstatement to manage structurally compromised masonry buildings are concerned. As the structural rods used in strengthening are made with glass fibre reinforcement these are not affected by corrosion which is a problem in porous Masonry structures particularly if rebars are used for strengthening. In this case life cycle issues outweighed initial capital expenditures particularly as a period building was concerned and the approach minimised the risk of any repeat intervention which would have in a rapid reinstatement of the building, minimised the risk of losing heritage features and matched the client's overall objectives.

3.4 Budget and Project Time Line

The project was successfully controlled with the implementation of proper documentation in the form of detailed method statements and pre-selection of materials to be used directly from a specialist supplier (Mapei). In conjunction with Mapei an off-site training was undertaken of key personnel involved in the project to minimise delay on site.

The arches and key structural components had been temporarily propped using specially designed timber props to guard against collapse and this was removed progressively. The stabilization of the foundation was undertaken within a week and as the injection works were completed in a particular area masonry strengthening works proceeded in the associated area. The crack repair works and stabilisation of the masonry walls proceeded over a 2 week period. The finishing works and painting was then undertaken by the main contractor.

The works were successfully undertaken at approximately a quarter of the cost and 1/3 of time compared to rebuilding of the structure which was the only other option. As this was the full responsibility of the adjacent works contractor as per the court order, the approach taken was a win-win for all parties (ie) in terms of time and cost. This met the client's requirements for speed and minimisation of the disruption after a lengthy delay due to the legal action.

3.5 Overview

This work demonstrated the validity of the use of modern materials for a non-invasive low maintenance reinstatement of a heritage building badly affected by settlement and structural movement with little impact on its heritage value. This was considered to be the most cost-effective solution and appropriate, where speed of reinstatement to manage structurally compromised masonry buildings are concerned. As the structural rods used in strengthening are made with glass fibre reinforcement these are not affected by corrosion which is a problem in porous Masonry structures particularly if rebars are used for strengthening. In this case life cycle issues outweighed initial capital expenditures particularly as a period building was concerned and the approach minimised the risk of any repeat intervention which would have in a rapid reinstatement of the building, minimised the risk of losing heritage features and matched the client's overall objectives.

Abstract. *Reinforced concrete structures are commonly used in civil engineering. However, the number of deteriorations in these structures is increasing, especially problems related to steel corrosion. Also, according studies, corrosion is responsible for about 3.5 % of annual GDP with recovery costs in world. Thus, this study analyzed the corrosion of steel bars at 70-year-old, which are in corrosion process by natural aging. Tests were performed to analyze the bars microstructure, using SEM and EDS, as well as analysis of the current mechanical characteristics, with tensile test. Through SEM, it was possible to measure the layer of the corrosion products formed at the samples edge, and to observe the fragility of this region, with the presence of several microcracks. EDS test contributed to verify the oxygen difference from the nucleus until to the specimen edge. It was possible to notice that in the edge, presence of oxygen is much greater. In the mechanical tests, by the tensile test, the samples do not reach the minimum elongation and the limit of resistance prescribed in the standard. Thus, it is believed after 70 years of natural aging, the samples are in advanced process of corrosion, with edges worn out, and no comply with the minimum mechanical requirements.*

Keywords: *Corrosion, Steel Bars, Microstructure, Deterioration, Natural Aging.*

1 Introduction

Reinforced concrete is one of the structural elements most used in construction worldwide. Consequently, the incidence of pathological manifestations that deteriorate this type of structure is increasing, mainly problems related with corrosion. In addition, corrosion causes a lot of damage to the global economic sector, generating a high cost of recovery. It is estimated that around 3.5 % of world GDP is spent annually on corrosion (SCHMITT *et al*., 2009; KOCH *et al*., 2016).

Corrosion is considered a destructive interaction of a material with its environment, usually occurring in aqueous environment, known as electrochemical corrosion. In this degradation, oxidation and reduction reactions occur, forming an electric current and an ionic current. Insomuch, it is possible to form iron oxides and hydroxides, which deposit on rebar surface and are called corrosion products.

One of variables that favor corrosion is the pH of the environment, which is responsible for enhancing this degradation. As stated by Mehta and Monteiro (2006), from the moment the concrete pH becomes lower than 11.5, the passivation film on rebar is broken, which

allows the beginning of corrosion. After the steel depassivation, the corrosion propagation phase begins, with the development of the corrosive process, in which each material reacts and has a particular deterioration velocity (SOUZA and RIPPER, 1998).

Thus, there is a relation as pH function, which is represented in E-pH diagram, known as the Pourbaix diagram (1974). In this diagram, the pH conditions are established in relation to the potential that take the material to three distinct situations: the immunity region, which independent of pH, the steel has a very low corrosion potential, being protected; the passivation area, which the armor has the protective layer; and corrosion, located in circumstances of more acidic pH, which the reinforcement depassivation occurs and, consequently, its deterioration.

Also, there are two main aggressive agents helping in reinforcement depassivation: the carbonation of concrete and the presence of chloride ions. Carbonation involves the penetration of carbon dioxide (CO_2) into the concrete by diffusion, resulting in a gradual decrease of pH. It is ranging from 12.5-13.5 to a pH close 9, thus losing its high alkalinity (LIMA, 1996).

Other aggressive agent is chloride (Cl^-) ions, penetrating or embedded in the concrete, which reach the steel, resulting in the reinforcement depassivation even with the high pH (LIMA, 1996). Thereby, the presence of chlorides ions especially in marine exposure and the loss of alkalinity due to the carbonation of the concrete can destroy the passive film that protects the steel and induce its corrosion (BOSSIO *et al*., 2015).

Tuutti (1982) proposed what currently is considered the classical model of reinforcement concrete structure life cycle, which period of life cycle is considered as the sum of the corrosion initiation and propagation periods, until the moment the structure needs correction. Moreover, any loss of rebar protection affects significantly the durability and service life of reinforced concrete structures and may compromise and even induce to collapse.

Necessity to better understand this degradation process, in order to improve the quality and performance of structures, resulted in the microstructural study of steel bars at 70-year-old, which were in corrosion process by natural aging.

Scanning electron microscopy (SEM) was used to analyze the material's microstructure. Energy Dispersive X-Ray Spectroscopy (EDS) was utilized to examine the difference in chemical composition between the grains and the layer of corrosion products formed on the surface. In addition, the mechanical tensile test was performed to obtain the current mechanical state of the specimens.

2 Materials and Methods

This chapter will present the materials that composed the sample of the study, as well as the methodology used to achieve the intended tests.

2.1 Materials

Three bars composed the specimens, belonging to foundation block of ITA’s building. The bars were smooth, originally had a nominal diameter of 15.88 mm (5/8”), and were named B1, B2 and B6.

Figure 1. Specimen B2 before preparation and cutting.

These bars remained underground and unloaded for approximately a period 60 years, from their construction to 2008, when the samples were collected and stocked in the Materials Laboratory of the Civil Engineering Department. Currently, these bars have about 70 years of natural aging.

2.2 Methods

Methodology used in this study searched the analysis of steel bars with about 70 years of age, which were in corrosion process by natural aging. Figure shows the flowchart of the proposed analyses.

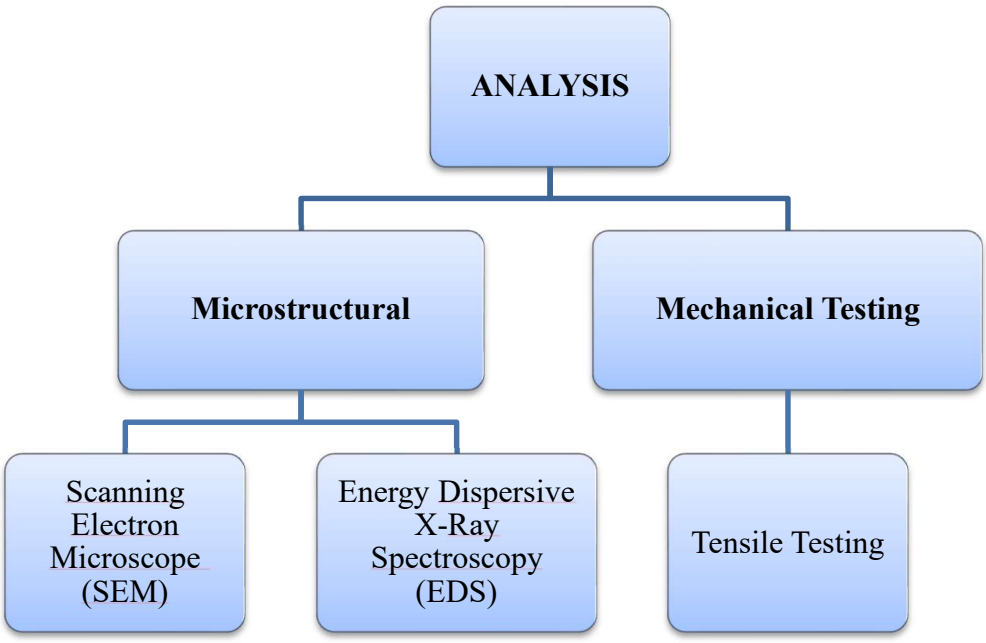

Figure 2. Flowchart with studies performed.

2.2.1 Microstructural Analysis

Scanning electron microscopy (SEM) was used to analyze the general structure of the samples, allowing the visualization of grains and grain boundaries. Thus, the bars were cut to 10 mm (0.39 in.) in length and metallographic preparation was performed to preserve the corroded edges.

Analysis by energy dispersive X-ray spectroscopy (EDS) using the Linescan technique allowed the comparison of samples chemical composition between the grains not corroded in relation to the layer of corrosion products. For this test, were used the same samples of the SEM.

2.2.2 Mechanical Testing

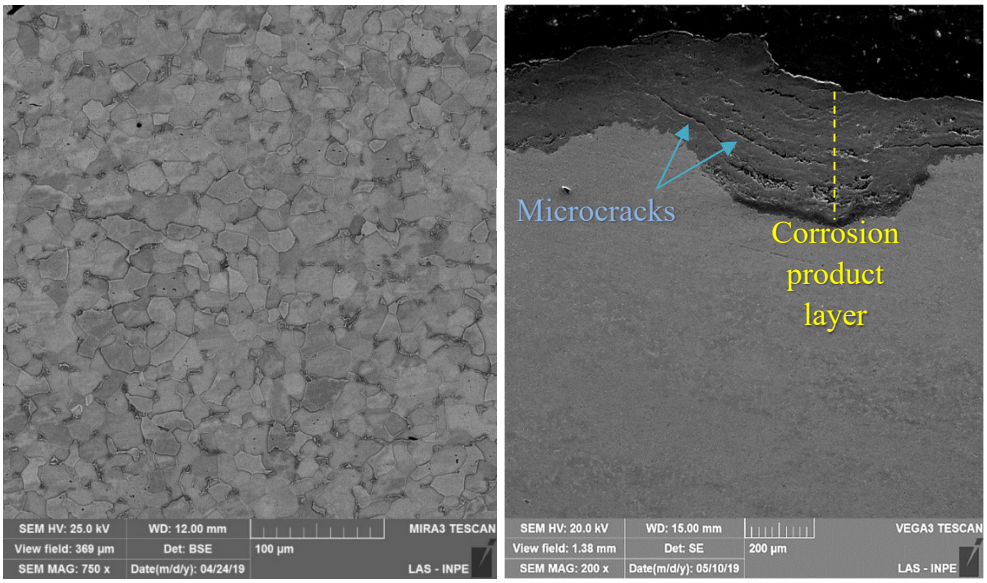
Tensile test was carried out on samples of 210 mm in length, seeking to analyze the behavior of the material during the test until its rupture. Therefore, it is possible to analyze the current resistance of the bars and compare with the minimum resistance required by the standard.

3 Results and Discussion

This chapter will present and analyze the results obtained from the methodology described in the previous chapter.

3.1 Microstructural Analysis

Scanning electron microscopy resulted in a more detailed study of the material, with verification of the structure formed by the grains and their boundaries. It was possible to observe the homogeneity in the grain structure of sample. Still, two distinct grain tones were observed, some grains are lighter than others, characteristic of different phases (PANDOLFO, 2006). The following image shows the result obtained by microscopy.



(a) (b)

Figure 3. SEM image (a) at center of the sample (b) of corrosion product layer.

Figure (a) was obtained through the backscattered detector, which allows verifying broadly the material configuration. SEM also showed the presence of the corrosion product layer formed on surface of the samples, as shown in (b). Corrosion product layer found in the bars showed irregular wear at the edges, as well as different corrosion depths. Thickness of corrosion layer ranged from 62.38 µm to 381.20 µm. Also, several microcracks and various micropores were visualized in this corrosion layer, showing fragility of this material.

Through X-ray dispersive energy spectroscopy analysis, using the Linescan technique, verified the variation in concentration of main chemical elements. For this, was defined in sample a line from the center to the corrosion layer, as shown in Figure .

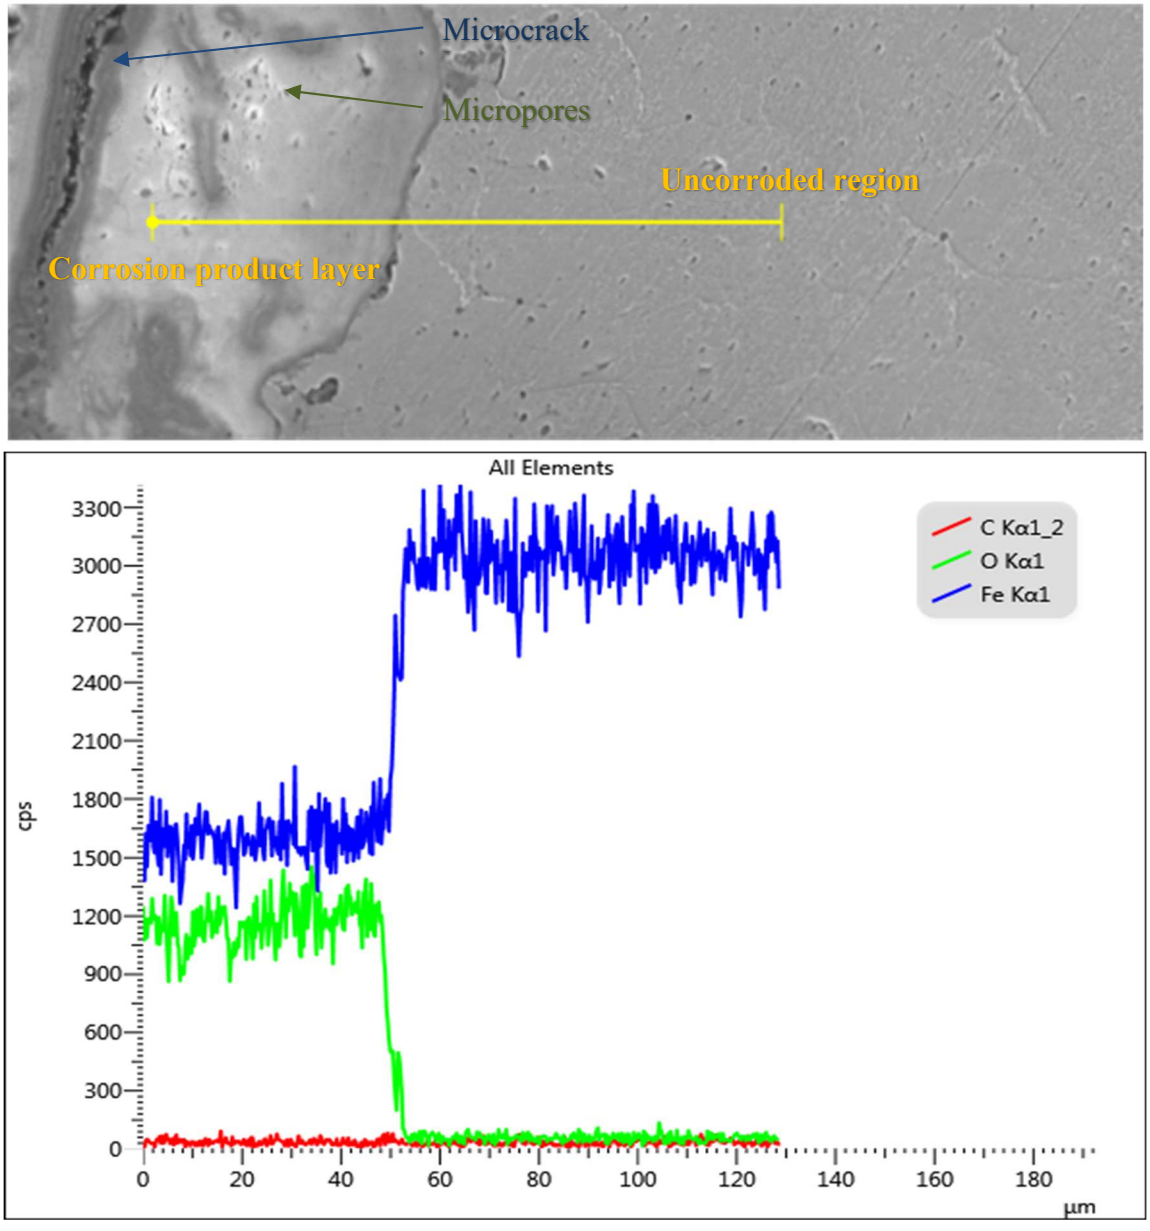


Figure 4. EDS Linescan image.

Linescan technique showed variation in concentration mainly of oxygen and iron. Non-corroded region of the three samples resulted in high iron concentration and insignificant amount of oxygen. Where the analysis reaches the corrosion layer, the iron concentration drops abruptly and the oxygen concentration rises, thus remaining throughout the corrosion product layer. As the corroded layer is formed by corrosion products, which are composed of different types of oxides and hydroxides, according Gomes and Barreto *apud* Helene (1993), this high presence of oxygen identifies the presence of these products in the corroded layer.

3.2 Mechanical Testing

To finalize the bars analysis, mechanical tensile test was performed, in order to obtain the bars strength limit. It was followed the criteria established by ASTM E8.E8M:2016, which resulted in the following data:

Table 1. Mechanical tensile test.

Sample	Tensile Strength (MPa)	Tensile Rupture (MPa)	Elongation (%)
B1	385	290	17,14
B2	355	352	19,18
B6	338	264	14,79

Comparing the results of the three samples obtained from tensile test, the strength values differed by about 12 %, ranging between 338 MPa and 385 MPa. Regarding the minimum elongation, a difference was greater, 23 %. Standard ABNT EB 3:1939 defines the minimum strength tensile of 370 MPa for these steel bars (37-CA class). Only the specimen B1 comply with the standard resistance. Still, this standard determines the minimum elongation of 18 %. In this parameter only the specimen B2 corresponds the value. Specimen B6 did not reached any of the standards requirements.

Therefore, in terms of mechanical characteristics according to tensile test performed, the steel bars are not presented in conformity to the current rules, given their state of degradation after about 70 years inside the concrete structure.

4 Conclusions

Through microstructural studies, it is possible to visualize the configuration of the material, which presented itself in a homogeneous way, with irregular grain size and shapes. In addition, the presence of grains with two different shades was observed, possibly presenting two distinct phases.

The microstructural analysis also allowed to observe a generalized corrosion process in the studied bars, with some more accentuated corrosion pits. As the corrosion occurred and progressed irregularly from the surface, points with very superficial corrosion depth and other more advanced points were found. This irregular wear can best be seen through the contrast caused by bakelite, showing that the corrosion front in this case did not act uniformly.

Another microstructural analysis was the layer of corrosion products formed on the surface of the bars. This layer presented with varied thickness, from 62.38 μm to 381.20 μm,

emphasizing that the corrosion does not occur in a uniform way. Still, the fragility of the corrosion products was observed on the surface of the bar, since the layer presented several microcracks and micropores. As shown by Zhang (1996), corrosion products may differ in their composition, structure, morphology and properties, and this will depend on the specific conditions under which the corrosion process occurs, and some are thicker, more voluminous and more porous than others.

Chemical evaluation by EDS, using the Linescan technique, it was clear the high presence of oxygen in the corroded layer, and the abrupt fall as soon as this barrier is overcome, reaching the steel that does not show signals of corrosion. This is justified because the oxygen penetration into the corroded layer is facilitated, due the presence of microcracks, differently of more conserved steel that has less porosity. Furthermore, the corrosion products formed on the surface of the steel bar are various oxides and hydroxides, which provides a high presence of oxygen in this region.

Through the tensile test, sample B1 meets the minimum strength and sample B2 corresponds to the minimum elongation indicated by the standard. However, none of the tested bars showed all results according to the established values.

Finally, all these results showed that, it was possible to notice their advanced corrosion process, after 70 years of the bars aging naturally and with no records of repair in the structures in which the bars were inserted.

Analysis of the Variation of Thermal Conductivity of Rigid Polyisocyanurate Foam (PIR) in The Context of Aging

Tomas Makaveckas, Raimondas Bliūdžius and Aurelija Levinskytė

Institute of Architecture and Construction, Kaunas University of Technology, Tunelio 60, LT-44405 Kaunas, Lithuania, asi@ktu.lt

Abstract. *For most building insulation materials, dependency of the thermal conductivity on temperature is close to linear, and it increases with rising materials temperature, but the thermal conductivity of the polyisocyanurate foam (PIR) increases in the lower temperature range, so the heat transfer through the partition insulated with this material is increased in the cold season. The thermal conductivity of PIR also increases during the aging process, especially during the later operating period, which is not covered by the standard aging procedure used to determine the declared thermal conductivity value. Also, there is a lack of information how PIR reacts to the certain temperatures and other climate conditions, and how fast it loses its thermal properties. The aim of this experimental research was to analyse the change of the thermal conductivity depending on aging temperature. 30, 50 mm thick PIR samples were prepared for the test, and the thermal conductivity of all specimens was measured at the standard conditions prior to the start of the test using the heat flow meter FOX 314, and again after each stage of aging, when the samples were kept at the certain temperature for 21 days. The results showed that the thermal conductivity of PIR increases more (up to 10 %) when kept at higher temperatures (+50 °C, and +70 °C), and after specimens undergo negative temperatures (-18 °C) it has a minor influence to the change of thermal conductivity of PIR.*

Keywords: *Polyisocyanurate Foam Insulation, Thermal Conductivity, Aging.*

1 Introduction

Thermal insulation for buildings is used to create indoor thermal comfort using as little thermal energy as possible. The thermal insulation in building envelope extends the periods of indoor thermal comfort, and by keeping buildings with smaller temperature fluctuations, it helps to preserve the integrity of building structures, increasing their lifetime (Berardi and Naldi, 2017). Long-term performance is an important consideration for choosing the best insulation material for each application (Alvey *et al.*, 2017). Change of thermal conductivity over time has been extensively studied for different thermal insulation materials such as mineral wool, expanded polystyrene foam (EPS), and extruded polystyrene foam (XPS) which are used in building insulation layer (Berardi, 2017; Khoukhi *et al.*, 2016). Current environmental issues require intensive research on energy efficiency and energy savings in buildings to reduce consumption of conventional fuel and CO_2 emissions that generate greenhouse effect (Paraschiv *et al*., 2017). Therefore, the use of rigid polyisocyanurate-polyurethane foam (PIR/PUR) in construction has recently significantly increased due to its excellent mechanical properties and low thermal conductivity (Jin *et al.*, 2014). However, changes in the thermal properties of this thermal insulation material due to environmental influences have not been sufficiently investigated.

Polyurethanes are urethane bonded polymers and are made by reacting diisocyanates with polyols, and some additional chemicals and catalysts. Polyurethane foams are one of the most effective thermal insulation materials because blowing agent gas with extremely low thermal

conductivity is trapped in the closed porous structure (Zhang *et al.*, 2017). Thermal conductivity of this material at its standard measurement temperature is low due to the blowing agent trapped in the insulation cells, which is more inert and has a lower thermal conductivity than air. This reduces heat transfer through the cells by thermal conduction and convection, however, if the temperature falls below the condensation point of the blowing agent, the gas condenses in the cell space, and since the liquid phase of the blowing agent is more conductive than its gaseous phase, the heat transfer increases (Berardi and Naldi, 2017). These phenomena result in a continuous reduction of thermal resistance (i.e. aging) of the foam over period of time, resting to a long-term equilibrium value (Mukhopadhyaya *et al.*, 2004) For a gas to function as an insulating gas in the cell of polyurethane and polyisocyanurate foam, it must be in a gaseous state (Bogdan *et al.*, 2005). Bogdan *et al.* (2005) gives few diagrams showing thermal conductivity of gases versus temperature. Few researchers showed that the thermal conductivity of porous insulating materials strongly depend on their moisture content (Berardi, 2019).

Tests have shown that the thermal resistance R, ($m^2 \cdot K/W$) of PIR decreases when the ambient temperature drops below 0 ^oC, reaching a peak when the material temperature is like the indoor air temperature (i.e. between 2.2 ^oC and 42.2 ^oC). During the winter, when the temperature falls below 0 ^oC and the time when a PIR-insulated roof is heated by the sun and the material temperature rises higher than 45 ^oC, the R-value of the thermal resistance decreases (Building Science Corporation, 2013). However, Finch *et al.* (2014) noted that in roof assembly using other insulation materials, such as mineral wool, together with PIR may significantly improve the effective R-value of the polyisocyanurate as it keeps it near optimum temperatures (near room temperature). Berardi (2019) performed an experiment with several foam materials showing that the aging of the foams and the operating temperatures have higher impacts on the polyisocyanurates than on polyurethanes. His study showed that different aging mechanisms impact mainly the polyisocyanurate which increased their effective thermal conductivity significantly.

Standard methods for predicting the change in thermal properties of polyurethane foam: aging at high temperature and thin PUR/PIR slice aging were found to be inconsistent with the actual material use conditions. Increased temperature changes the diffusion intensity of the gas trapped in the pores of the material in a non-uniform manner (pentane-foamed material gases are CO_2, air, and different pentane isomers) (Christian *et al.*, 1995; Stovall *et al.*, 2013). Thin slicing and weighing do not appreciate the fact that the surface layers of PIR with facing are denser than the inner layers (Singh *et al.*, 2003). The main standard for rigid polyurethane foam (PUR/PIR) products is EN 13165:2012+A2:2016, and the aged value can be determined in one of two ways according to this standard. The first is the thermal conductivity measured after 175 days aging at 70 °C, with the addition of safety factor which depends on the type of facing, the blowing agent of the foam and the thickness of the product. The safety factor may be adjusted on the basis of a comparison between the aged values at 23 °C and 70 °C. The second is the thermal conductivity measured after 21 days of exposure at 70 °C with addition of a fixed increment. Fixed increment depends mainly on the type of facing and is different for different blowing agents.

As PIR thermal insulation material is rapidly gaining popularity in the Northern Europe, which has a wide range of ambient air temperatures, it is important to investigate its thermal properties under operating conditions, and to predict the influence of temperature, and aging effects on the thermal properties of buildings insulated with PIR.

2 Research Methodology

2.1. Sampling and Sample Preparation for Testing

In this experiment, samples are aged like in the standard fixed increment procedure, but the samples are used at full thickness as fabricated, i.e. without cutting a 20 *mm* sample from the core of the product. This is done to find out how the entire product is aging at different temperatures and how the (non)presence of a facing affects the change in thermal conductivity. For this experimental study, PIR specimens were obtained from the producer. The dimensions of the specimens are 300x300 *mm*, thicknesses 30 and 50 *mm*. Samples of each thickness are taken from products of three different production dates. There are three types of specimens for each date of production: the first specimen is with a factory-made composite non-diffusion facing; the second sample is sealed with a diffusion-tight film from all sides; the third sample has its facing removed. Products are stored at (23±3) *°C* and (50±10) *%* relative humidity for at least 16 hours before cutting. Prior to thermal treatment, the value of the thermal conductivity of each sample is measured using FOX 314 Heat Flow Meter in conformity to ISO 8301. Two tests are performed in parallel: first - successive effects of temperature on specimens, maintaining the same specimens at different temperatures and measuring their thermal conductivity after each step corresponding to the temperature environment over the year; second - measuring different specimens after storing in different temperature environments, to determine certain temperature impact on thermal conductivity.

2.2 Influence of Successive Thermal Treatment on Thermal Conductivity of Specimens

The algorithm for this experiment is presented in Figure 1. The specimens are placed at (70±2) *°C* for a period of (21±1) days. After certain period, specimens are reconditioned for 16 *h* at (23±3) *°C* and (50±10) *%* relative humidity, then the aged values of thermal conductivity are determined using FOX 314 Heat Flow Meter. The measured value is compared with the value obtained from a standardized measurement (Fixed increment procedure). Later, using the same procedures the specimens are treated at (50±2), (23±2), (0±2), and (-18±2) *°C* for (21±1) day, and their thermal conductivity is measured after each stage. Table 1 shows the mean values of the measured thermal conductivity before and after each exposure at different temperature conditions.

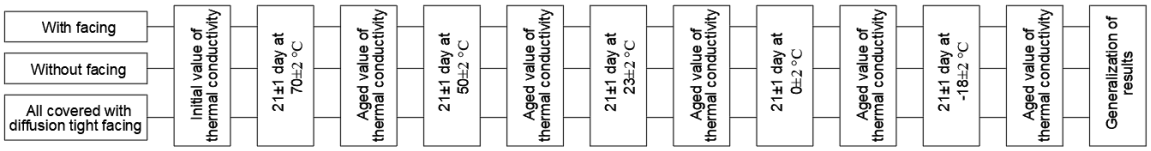

Figure 1. Algorithm of the experiment.

Table 1. Average thermal conductivity values after successive aging in different temperature conditions.

Thickness, *mm*	Type of facing	λ value, *W/m·K*

	Without facing	0,0207	0,0230	0,0232	0,0231	0,0230	0,0232

2.3 Influence of Particular Thermal Treatment on Thermal Conductivity of Specimens

This experiment is conducted to investigate the effect of ambient temperature conditions on the thermal conductivity of specimens. The specimens are kept at different temperature environments: (70±2), (50±2), (23±2) and (-18±2) °*C* for (21±1) days, after which the specimens are reconditioned for 16 *h* at (23±3) °*C* temperature and (50±10) *%* relative humidity, and the change in thermal conductivity is measured. The results of the measurements are given in Table 2.

Specimens without facings

3 Results and Discussion

The thermal conductivity values of PIR specimens measured in both experimental studies were

compared with the declared thermal conductivity value, which is determined by standard procedures, i.e. aging and measuring a 20 *mm* sample cut from the core of the product.

Figure 2 shows the thermal conductivity variation of 30 *mm* thick PIR specimens using a successive thermal treatment procedure. All types of specimens show a significant increase in thermal conductivity after heating at 70 *°C*. This change could be explained by the intense diffusion of gas out of the material pores into the surrounding environment. It can be noticed, that when the same specimens are kept at a lower positive temperatures, the increase in the thermal conductivity is insignificant, while for specimens with facing it is close to linear. This indicates that the emission of gas into the environment at this stage is largely dependent on their movement from the inner layers of the material to the superficial layers. The thermal conductivity of the unfaced samples ceases to increase earlier than that of the faced samples, and it depends on the diffusion possibilities, which are limited by the facings.

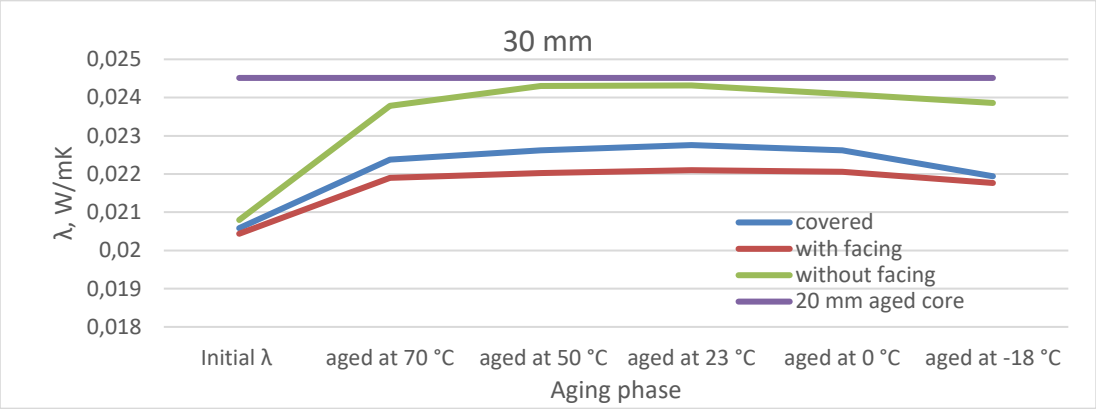

Figure 2. Variation of average thermal conductivity coefficient of 30 *mm* thick samples during successive aging.

The results of this experiment also show that the thermal conductivity of unfaced specimens at the average operating conditions is close to the declared thermal conductivity of the product, and significantly lower than that of the faced specimens. This shows that when standard procedure is applied, even for 30 *mm* thick products with facing thermal properties can be unreasonably degraded.

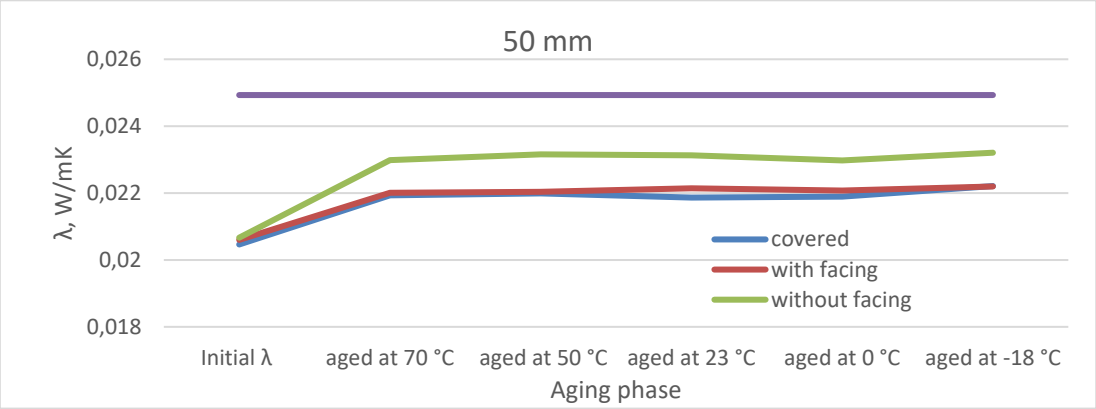

Figure 3. Variation of average thermal conductivity coefficient of 50 *mm* thick samples during successive aging.

The tendency of the PIR thermal conductivity change is similar for 50 *mm* thick specimens (Figure 3). In this case, it has been found that the post-production side facings of the specimen do not affect its thermal conductivity because they do not ensure a gas-tight permeability. It can also be seen in this graph that the increase in the thermal conductivity of the specimens stabilized earlier (already after heating at 70 °*C*), than that of the 30 *mm* thick specimens. This may be due to the larger lateral area of the test specimens, which could have released more gas during the same period. Examination of 50 *mm* thick specimens also showed that the thermal conductivity of the specimens with removed facing remains lower than that of the same 30 *mm* thick specimens during the successive aging. This difference may be due to the fact that the surface layers of the material are compacted to such an extent that they significantly stop the gas diffusion into the environment, and at the end of the experiment, the remaining gas concentrations in the pores of 50 *mm* thick specimens is higher than in the 30 *mm* thick specimens. Only further investigations could determine the effect of the thickness on the rate of gas diffusion and consequently on the increase in thermal conductivity for specimens with removed facing.

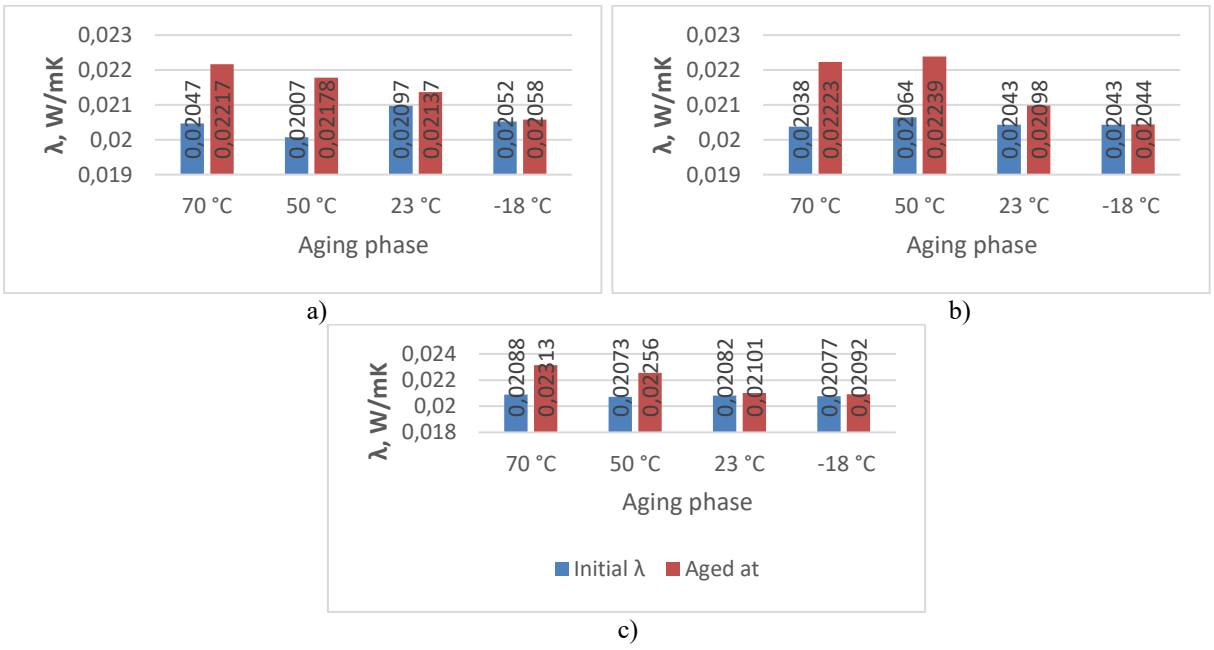

Figure 4. Influence of temperature conditions on the thermal conductivity of PIR (50 *mm* sample: a) covered, b) with facing, c) without facing).

The influence of specific temperature environmental conditions on the variation of PIR thermal conductivity is presented in Figures 4 and 5. Analysing changes in the thermal conductivity of 50 *mm* thick specimens showed that temperatures 70 °*C* and 50 °*C* has the greatest influence. For both types of specimens with diffusion-tight facing, the thermal conductivity increases by 8-9 *%* after exposure to higher temperatures (50 °*C,* 70 °*C*), and to 11 *%* for specimens with removed facings (Figure 4c). This confirms the effect of diffusion of the gases, present in the pores of the material, on the thermal conductivity of the material. Exposure to negative temperatures (-18 °*C*) does not alter the thermal insulation properties of all specimens.

Examination of 30 *mm* thick specimens showed that in all three cases aging at 70 °*C* had the greatest influence (up to 10-15 %) on their thermal conductivity (Figure 5). The influence of 50 °*C* on the thermal conductivity of the 30 *mm* samples with facings is smaller (only 3-4 %), while that of the samples without facings was slightly higher – 7 % (Figure 5c). As with 50 *mm* thick specimens, the change in the thermal conductivity of the 30 *mm* thick specimens is not affected by the negative temperature. This indicates that the gas condensation in the pores does not change the thermal properties of the material.

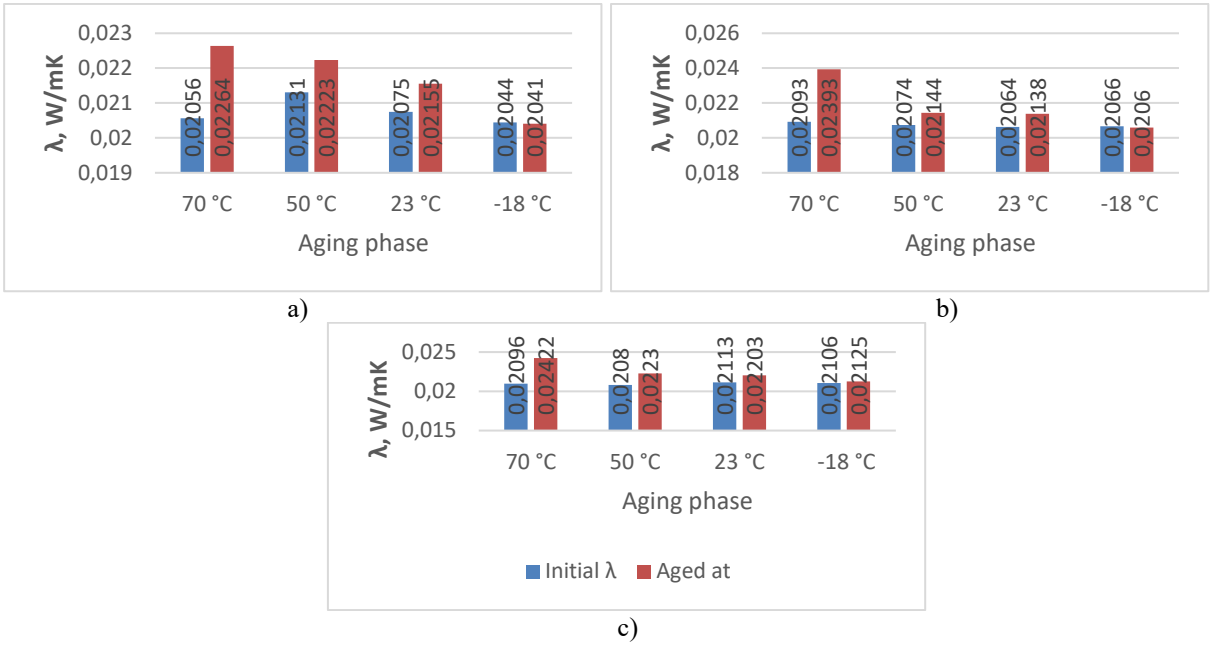

Figure 5. Influence of temperature conditions on the thermal conductivity of PIR (30 *mm* sample: a) covered, b) with facing, c) without facing).

4 Conclusions

- The standard methodology for determining the declared value of the thermal conductivity of PIR, when a specimen is cut from the core of a product, does not meet the conditions of use of products faced with diffusion tight facings, and must be adjusted providing aging and measurement of the specimens with such facings.
- The thermal conductivity of PIR is mostly changed after storage at 70 °*C*. The higher growth in thermal conductivity was measured for thinner specimens - 30 *mm*. Experiments showed that the 21 days aging period at the high temperature is enough for the samples to have a thermal conductivity settling down. After storage at -18 °*C*, the thermal conductivity of the material does not change under standard conditions. From the point of view of thermal insulation of structures, it is important to determine the thermal conductivity of PIR at negative temperatures, for which further studies are carried out.
- The removal of the facing results in up to 8 % greater change in thermal conductivity after exposure to high temperatures, compared to specimens faced with diffusion tight facings. The application of diffusion tight film to the sides of the specimens does not affect the change in thermal conductivity of the specimens after aging, because it is not as tightly pressed to the foam core as for factory made faced insulation boards.

- The results of this study are important to get knowledge about the aging of PIR insulation when it is installed in building envelope, so further research is being conducted on different facing materials on boards open ends to select a reliable technology to prevent thermal conductivity increase through the open ends (e.g. wall corners).

Are Mineral Toppings of Asphalt Roofing Sufficient to Protect Flat Roofs and Roofing Felt Alone?

Tomasz Szkuta[1] **and Maria Wesołowska**[2]

Abstract. *Mineral surfaces are an integral part of bituminous roofing felt. Their task is to protect less resistant elements from the destructive effects of the environment. Since the first application in 1897, they have been constantly improved in the direction of better functionality and aesthetics. It often turns out that the intended effect has not been achieved. During the first years of operation, there are signs of roof damages on most facilities. Due to the complex interaction of roofing elements, several causes of damages can be defined. A group of processes taking place in mineral roofing toppings is important for roofing felt. Mineral surfaces are exposed to physical, chemical and biological factors. They cause losses due to the unavoidable breaking of adhesion to the modified asphalt. Pulling out caused by factors occurring on the roof is a long-term process with more effects on the covering, in particular its durability and tightness. In the paper, the reasons for the release of mineral topping from the SBS modified asphalt layer were defined. The analysis shows that as a result of significant degradation and harmful impact of mineral coverage, this layer may lose the ability to protect the roofing paper, and long-term changes threaten the durability of roofing materials. Solutions have been proposed to significantly reduce the phenomenon caused by specific factors.*

Keywords: *Mineral-Surfaced Tar Board, Durability of Roofing Felt, Impact of Environment.*

1 Introduction

The subject of the work is the problem of top covering roofing felt. It is visible already in the first years of operation of the roofing felt. Depending on the quality of the roofing felt (price), this process takes place faster or slower, but inevitably occurs.

Figure.1 This is a comparison of mineral topping on new roofing paper and topping on the same roofing paper after several years of use in adverse conditions (on the right photo a drastic example of a significant loss of granules and exposure of asphalt in a roof depression - a periodic puddle).

doi:10.23967/dbmc.2020.166

Figure 2. This is the cross-section of an ordinary polymer-asphalt covering roofing felt, on polyester nonwovens using typical roofing felt.

Mineral surfaces protect the roof against atmospheric influences and to some extent against mechanical influences. They have been known, used, modified and improved for years. They are getting better and prettier really. They are absolutely necessary but do they fully fulfill their role on flat roofs? They were invented and began to be used a hundred years ago. Is the inertia of the solution justified and does it have to be continued?

Despite the objections of producers and some specialists outraged by such a suggestion, it must be made. Mineral surfaces are an ad hoc invention, an added element. They used to be a cheap and quick solution to the problem, but today they is not. Today we find improper cooperation with roofing felt and no cover durability guarantee. This is especially visible in the light of the changes that are taking place in the climate around us. Roof temperatures up to almost 90^{o}C is an examined fact. It turns out that the problem is not only the temperature, there are many more.

Due to the location of the place of work or residence, we rely on data from Poland. However, the principles of analysis are universal.

Roofing granules are released during the operation of roofs covered with roofing felt from polymer-modified asphalt (mainly SBS in Poland). The applicable European standard EN12039 from July 2016. regarding possible defects on up to 30% of the mineral topping, during tests, is significant. Such large roof defects are real, as shown in the above photos. The defect itself is one thing but the effects of the way they are formed are a much broader topic.

The purpose of the work is to analyze the reasons for the deterioration of roofing materials over time. Due to the possible volume of occurrence content, limited only to roofing granules.

Analyzes of other elements of cover materials on flat roofs should be expected in subsequent publications.

2 Method

To find out the reasons for the appearance of roofing defects and the effects on the roofing felt and roofs, an analysis of processes and phenomena occurring on the roofs is needed. For the purposes of the study, the processes were divided into groups depending on the seasons.

General description of processes, impact on roofs (roof granules):

Autumn, winter, spring: snow retention; melting and freezing of snow in contact with the covering surface and stands (!), deepening effect (increased hydrostatic pressure), penetration into asphalt cracks and between granules and disintegration; the bottom layer of thawed and frozen snow turns into ice, the top layer from thawed snow (sun) and frozen turns into ice, after freezing it in whole we have a thick layer of ice with a significant mechanical breaking strength (linear expansion of the ice when the temperature drops below $0^{o}C$) ; passing through "$0^{o}C$" up to 100 times per year (deepening effects).

Summer: rainfall on a hot roof (hydrophobization is less effective - Table 1, significant energy of falling drops - Figure 4), soaking of mineral topping; rapid temperature changes, water, hail falling on the roof heated to almost $90^{o}C$; chemical impact on toppings - decomposition, leaching, formation of chemical solutions; leaching of soluble components of roofing felt (*e.g.* sulfur), solutions effecting on roof granules and other cover elements; crystallization of water chemical contaminations in crevices and soaked granules, destruction of granule-asphalt adhesion and cohesion of granules, increasing the concentration of solutions at subsequent precipitation; wet and dry deposition of media enabling the development of living organisms (lichen, algae, other).

Regardless of the season: linear expansion of roof materials and their interactions affecting mineral toppings; additional impact, wind pressure and suction transporting loose material; capillary penetration into granules, theoretically reduced by hydrophobization, practically depends on temperature (Figure 3), water pollution (*e.g.* PH, Table1) and other phenomena associated with the shape and number of open pores may also occur.

Identification of the main physical phenomena generating the indicated processes:

Weather conditions and their changes together with climate changes: precipitation; humidity; winds; insolation; temperature changes; wet and dry deposition of mineral, chemical, organic and inorganic compounds and substances.

Physical properties of materials used to make coverage, precipitation and deposits, and their interactions: linear expansion (discontinuous linear expansion); adhesion and cohesion; humidity; solubility; hygroscopicity; surface tension; changes in physical state; density; melting and softening point; copolymer uncoupling temperature; viscosity stiffness; ductility; flexibility; thermal conductivity; brittleness; reflection; radiation absorption.

Chemical properties of materials used for covering, precipitation and deposits, and their interactions (as additional): PH; causing chemical corrosion; change in physical properties (*e.g.* surface tension).

Research and analysis carried out:

We focused primarily on long-term observations and research of flat roofs in situ. An important observation during the tests turned out to be the quality of roofing, often correlated with the quality of the materials used. It should be emphasized here, that perfectly made covers made of the best materials on the market are not often the subject of expertise. They are much less frequently and more slowly damaged and constitute a small part of the market. We focused on the greater part of the market where the important measure of the quality of materials used and the quality of workmanship is the criterion of a lower price.

Analysis of the impact of differences in linear expansion of polymer-asphalt layers reinforced with polyester nonwovens and mineral topping immersed in puddles formed in an improperly shaped roof surface: expansion of polymer-asphalt felt; ice expansion; thermal shock with rapid temperature changes (summer downpours, hail).

Analysis of the effect of crystallization of chemical compounds found in puddles on roofs: chemical compounds found on roofs; crystallization of chemical compounds between the granules; crystallization of chemical compounds in the joints of roofing felt sheets.

Analysis of weakening of roof paper sheets joints by the presence of granules embedded in joints in the context of linear expansion and crystallization in puddles: quality of joints and the way they are made; facilitating the possibility of water getting into the contacts areas; blasting through ice, the effect of temperature shrinkage of roofing felt.

Analysis of the impact of hydrophobization on the number of granules defects in real conditions on roofs: phenomena eliminating increased surface tension on hydrophobized materials (Table 1, Figure 3, Figure 4, Table 2), surfactants, the occurrence of these phenomena on roofs, the impact of these phenomena on defects of granules

Table 1. Surface tension values of sulfur-contaminated water PH dependant (Janocha, 2014) .

Surface tension [mN/m]	pH
74	6,5
52,6	6,8
49,2	7,2

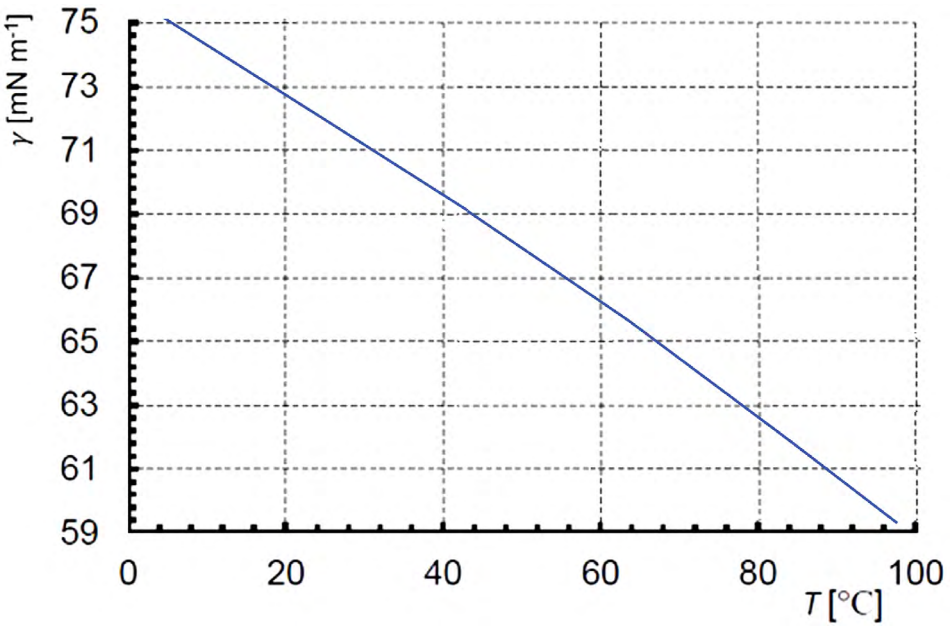

Figure 3. Surface tension of pure water as a function of temperature (at saturation pressure) (Vargaftik *at al*., 1983).

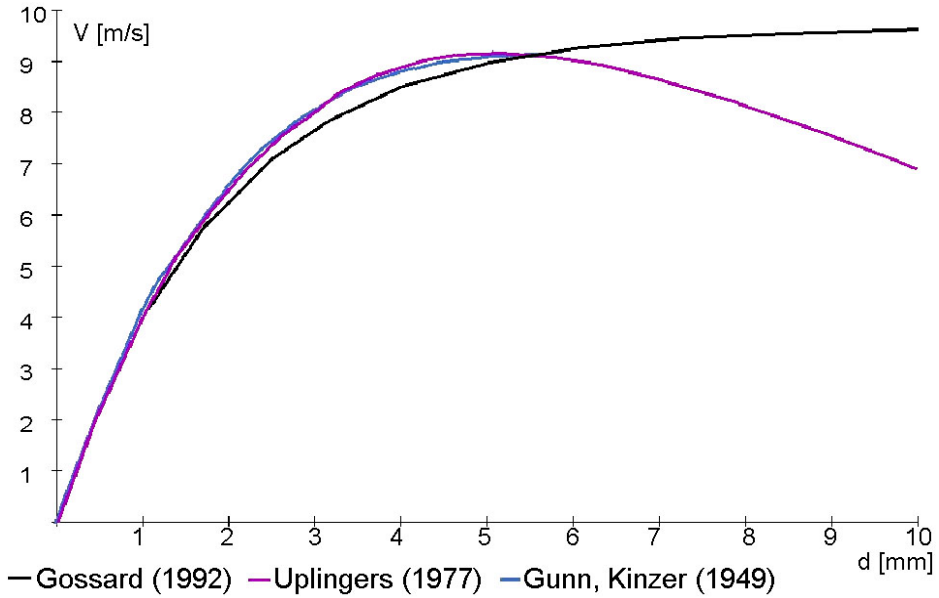

Figure 4. Water drop falling rates for ideal conditions (Van Boxel *et al.*, 1998).

Analysis of released granules accumulation places and the impact on the destruction of these places; location of accumulation of unbound granules; phenomena occurring at places where pellets accumulate; the impact of these phenomena on the durability of roofing felt and roof.

Figure 5. Accumulation of released granules (roof after one year of operation)

Analysis of the impact of granules accumulating in the gutters on gutter durability: transport for gutters - mechanical impact; transport in gutters - mechanical impact; slowing down the flow of water and prolonging the impact of chemical compounds present in the water flowing from the roof (influence of rainfall intensity on corrosion).

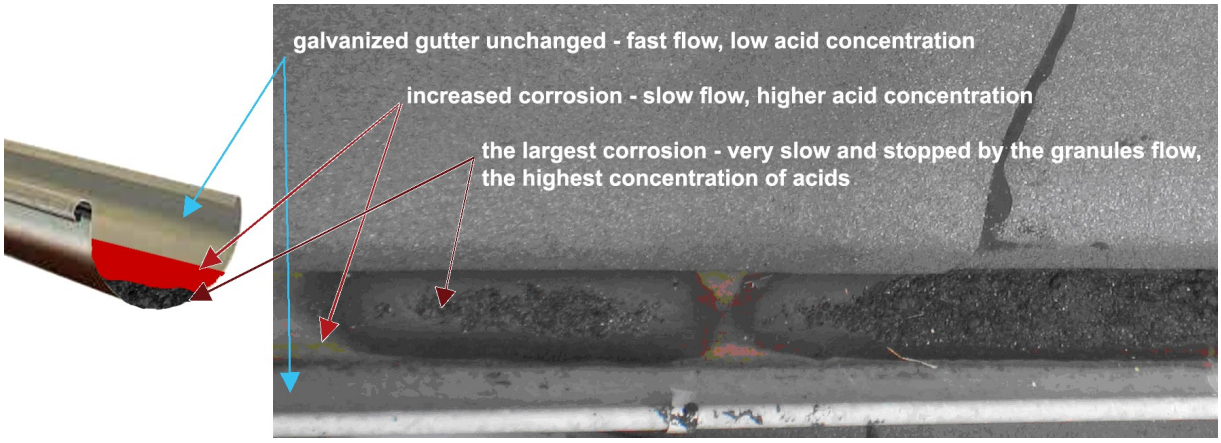

Figure 6. Accumulation of free granules in the gutter, retention of chemically polluted water and corrosion. The rust level determines the water flow rate at which the acid concentration is sufficient to cause rapid corrosion. The concentration of chemical pollution increases during low runoff from the roof surface.

Analysis of the impact of granules transported with water on the durability of downpipes: topping transport in downpipes; clogging of pipe inflows and outflows.

Analysis of the impact of hail rainfall on driving the topping into the polymer-asphalt layer at a significantly heated roof surface.

Table 2. Energy of falling hail (Heymsfield *at al*., 2014).

Diameter [cm]	Mass [g]	Speed [km/h]	Energy [J]
1	0,5	52	0,05
3	13	90	4
5	59	116	31
7	162	138	118
10	471	164	491

Effect analysis of contacts of polymer-asphalt felt with elements of different thermal expansion (flashings, batten protections ...) on defects in granules: way of contacts interact; resistance of roofing felt to contacts; increased granules defects at the contact points and consequences for exposed polymeric asphalt.

Analysis of the impact of roof loading elements (*e.g.* roof bases for lightning and ventilation systems) on indentation of granules in the places of contact edges at high temperatures: quality of loading elements - eccentricity for small elements, edge action and wind action for large elements; the effect of high temperatures on roofs for puncturing asphalt roofing felt with granules.

Analysis of the impact of exposing polymeric asphalt mass by tearing off the topping and releasing mainly sulfur compounds as a prolonged process: sulfur compounds as a component of polymer-asphalt mass; long-term release of sulfur compounds; the impact of sulfur compounds on roof elements (Figure 6).

Analysis of the influence of granules on the possibility of accumulation of deposits constituting the basis enabling the growth of living organisms: topping structure that holds deposits; collecting water.

Analysis of the impact of living organisms (algae, lichen, mosses, plants) on pulling out roofing powder: colonization by living organisms; method of long-term extraction of granules (growth of mosses, lichen, plants).

Analysis of the impact of temperatures on roofs on the possibility of sinking the granules in the top layer of roofing felt and the possibility of penetration into the layer of polyester nonwoven fabric: polymer decoupling temperature for lower quality roofing paper; impact on the decomposition temperature of polymers in roofing paper resulting from the lack of obligation to carry out direct tests and to specify the composition of polymer-asphalt; methods of kneading the granules (shoes, storage of renovation materials).

Analysis of the shape and size of the granules influence for possible damage to roofing felt: granules used by roofing felt producers and their most common shapes; size, thickness of topping; the possibility of causing damage.

3 Results

As a result of research and analysis we have determined:

The positive functions of roof granules – as the protective layer are: mechanical protection; UV protection; now also enabling, by means of adhesion, the use of additional roofing protection measures (*e.g.* expensive paints increasing the reflection of heat radiation); architectural and decorative functions.

Negative impacts of roof granules - the "protective layer" on the roof are: uncertainty of attachment in polymer-asphalt and protection losses; too high porosity of the layer and the possibility of retaining deposits and water in the layer; systematic and unavoidable release of pellets during roof operation; leaching of sulfur compounds from asphalt resulting from the method of releasing the granules (pulling out, UV exposure, slow destruction of the surface); too much heat radiation absorption; possibility of mechanical destructive impact on polymer-asphalt; making it possible to transfer the destructive effects of freezing water to polymer-asphalt (the protective layer is a tool of destruction); accumulation of released pellets in different areas of the roof increasing the amount of deposits and water retained on the roof; mechanical impact of granules transported by rain and wind on other roof elements; participation in clogging water outflows; weakening of torched joints between transverse joint of the roofing felt.

4 Conclusions

Elimination the negative effects of roof granules on existing roofing felt is possible by: coating with materials that reduce the porosity of the layer; covering with materials increasing the reflection of solar radiation; increasing resistance to the development of living organisms; coating with materials that reduce the release of primarily sulfur compounds. Such actions are effective but expensive and labor-intensive.

Elimination of the negative effects of granules layer is possible by replacing it in the production process with materials characterized by: inability to accumulate in the layer wet and dry deposits; reflection of a significant part of solar radiation; limiting or eliminating the possibility of harmful chemical compounds emission from modified asphalt, above all sulfur; high adhesion to asphalt; the possibility of periodic and cheap renovation - enabling the use of cheap spray paints; enabling the effects of texture and colors for small visible roofs; gives possibility of obtain flat and smooth self-cleaning surfaces for large-area roofs. Such actions are more beneficial, cost effective and introduce the possibility of cheaper and simpler systematic renovation of roof coverings, increasing their durability.

In connection with the climate change, there is an urgent need to redefine the territorial aapplication of cover materials and their required characteristics for these areas.

The authors team is in the process of developing and patenting a new material solution for the surface layer of asphalt felt for flat roofs. The solution should, basing on existing production technology, enable the production of a new generation of roofing felt.

Abstract. *Chemical reactions that lead to decreased durability in concrete structures may result from chemical interactions between aggressive agents present in the external environment and cement paste compounds or may result from internal reactions. The chemical reactions are manifested by the physical properties of the concrete, such as porosity and permeability and the decrease of resistance and cracking. Among the several aggressive agents that attack the reinforced concrete structures it can be highlighted chloride ions, sulphate ions and carbon dioxide. In this context, the study presents the analysis of different traces of mortar executed with cement type CPII-F-32 (OPC Cement, in Brazil one of the most used cements) with w/c ratios of 0.4 and 0.7, when subjected to the attack of sulphates, chlorides and carbonation. The analyzes quantitatively evaluated the amount of ions present after exposure to the agents and demonstrate the importance of evaluating the dosage of water in the mortars to minimize future problems with durability.*

Keywords: *Mortars, Sulphate Attack, Chloride Attack, Carbonation, Porosity.*

1 Introduction

Chemical reactions leading to decreased durability in concrete structures may result from chemical interactions between aggressive agents present in the external environment and cement paste compounds or may result from internal reactions like alkali-aggregate reaction, or from reaction of delayed hydration CaO and MgO crystalline, if present in excessive amounts in Portland cement, or electrochemical corrosion of concrete reinforcement. Chemical reactions manifest themselves through the physical failures of concrete such as porosity and permeability, decreased strength and cracking.

Among the various aggressive agents that attack reinforced concrete structures, chloride ions, sulphate ions and carbon dioxide can be highlighted.

Sulphate can be found in soils such as landfills and is a major cause of degradation of cement-based materials. The attack by sulfate ions stands out especially when dealing with marine, underground or sewage handling structures (Mehta and Monteiro, 2014; Wei *et al.*, 2019).

When dissolved sulfate ions (SO_4) react with hydrated cement paste the two main means of

sulfate attack are: reaction with hydration products of unhydrated tricalcium aluminate (C_3A) producing ettringite and reaction with calcium hydroxide producing gypsum. Sulfate attack on concrete can manifest as expansion or cracking, leading to increased concrete permeability, structural problems and initiating corrosion processes of reinforcement (Mehta and Monteiro, 2014).

According Mangat and Ojedokun (2019) the chloride concentration of concrete exposed to a chloride environment is a parameter used to characterize the long term chloride resistance of concrete. The presence of chlorides is a cause of the corrosion process in reinforcement of reinforced concrete structures. The structure in an environment that has seawater, sea salt and thaw salts is subject to attack by chlorides. The rate of chloride penetration from the surface to the interior of the concrete depends on: the amount of chloride ions in the environment, the permeability of the concrete and the humidity of the environment (Aguiar, 2011).

Carbonation of concrete is directly linked to the CO_2 diffusion coefficient that is determined by Fick's first law, but there are limitations in some parameters, for example CO_2 diffusivity varies over time and strongly depends on the moisture content of the pores. concrete, as well as other variables that may also influence the microstructure of the concrete, such as cure condition, moisture content, location, elapsed time and mixing parameters (Yoon *et al.*, 2007).

In this context, the objective is to analyze different traces of mortars made with type CP II – F32 cement with w/c factors of 0.4 and 0.7 when subjected to the attack of sulfates, chlorides and carbonation.

2 Materials and Methods

To evaluate the durability, the specimens were exposed for 70 days to aggressive agents to verify their performance against the attack of sulfate ions, chlorides and carbonation. For the evaluation, quantitative tests were performed. The tested mortar has a 1:3 trait (cement: sand), varying the water/cement ratio in two levels, being 0.4 to obtain less porous mortar and w/c of 0.7 for a more porous mortar. In samples with w/c of 0.4, 1% hyperplasticizer was added to aid in the consistency of the mortar.

The binder used was Portland Cement CP II – F32, chosen for its wide availability in the market. The choice of producing mortars is due to the fact of ease in smaller samples, in this case it was decided to mold 10 x 5 cm cylindrical specimens. According to some authors such as Papadakis (2000), Kulakowski (2002), Gervais *et al.* (2004), Pauletti *et al.* (2007), Pauletti (2009) and Neville (2015) explain about better results that the use of mortar brings in the carbonation front analysis, such as the influence of the presence of coarse aggregate.

For durability analysis against the aggressive agents the specimens were submitted after cure of 28 days in a humid chamber, for the sulfate solution was used 10% magnesium sulfate ($MgSO_4$). For the accelerated chloride attack, 10% sodium chloride (NaCl) solution was added and for carbonation depth evaluation, the specimens were deposited in a carbonation chamber with 10% controlled CO_2 concentration, without the control of humidity and temperature.

2.1 Sulphate Content

The samples were fully submerged in magnesium sulphate ($MgSO_4$) solution of 10% for up to 70 days. The chemical test to determine the sulphate ions content in the samples was made according to an adaptation of the standard APHA Method 4500-SO_4^{2-} (1997). The procedure consists to submit the ground sample, whose diameter is less than 600 μm, to a solution of hydrochloric acid (HCl), shown in Figure 1, with barium chloride ($BaCl_2$), which will form a precipitate of barium sulphate ($BaSO_4$), which after calcination at 800°C is heavy ($M_{calcined}$).

Figure 1. On the left the sample mixture with hydrochloric acid and on the right the filtered solution.

To determine the percentage of sulphate in the sample, the equation is:

$$SO_3(\%) = \frac{34{,}3045 \cdot M_{calcined}}{M_{standard}} \quad (1)$$

Where the mass of the standard sample is weighed prior to the test in grams.

2.2 Chloride Concentration

The chloride concentration of the mortar powder sample was obtained Volhard's titration method. The procedure consists an indirect titration to determine the chloride ion that precipitates with silver ion (Figure 2).

The acid soluble chloride content was calculated as a percentage of chloride ions by weight of the binder, by the following equation:

$$Cl^-(\%) = 0{,}1773 \cdot \frac{V_2 - V_1}{m_1} \quad (2)$$

Where V1 is the volume of ammonium thiocyanate of a standard sample in ml, previously determined to be 0,07; V_2 is the volume of ammonia thiocyanate in the concrete sample in ml; and m_1 is the mass of the concrete sample in grams.

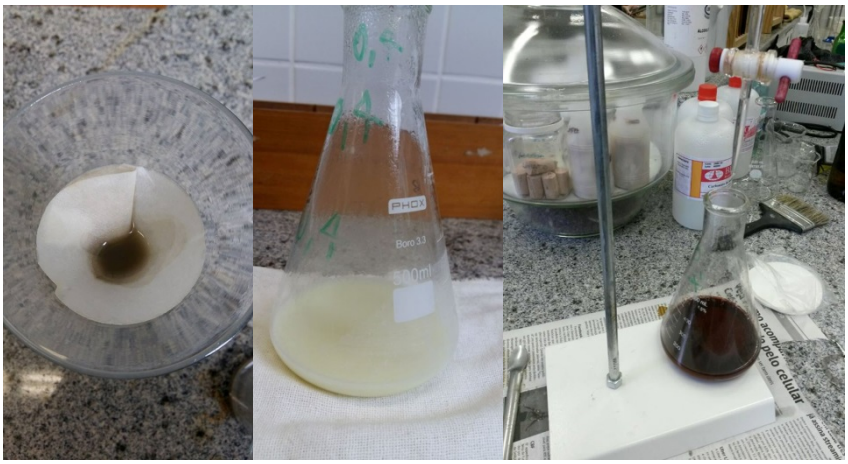

Figure 2. Silver chloride solution filtration and coagulation after boiling and then titanium ammonium titration.

2.3 Carbonation Penetration

Carbonation tests were performed by cylindrical mortar samples**.** Phenolphthalein was used as test to carbonation penetration. It is in the initiation phase that it was intended to verify the occurrence of carbonation, because generally the typical appearance of carbonation is the occurrence of light spots produced by refraction of calcium carbonate, it is necessary to verify the carbonation using colorimetric indicators that point the pH. The lower the pH, the lighter its appearance, tending to colorless in the less alkaline regions. A non-carbonated concrete in the most alkaline region turns purple when using this same indicator. The most commonly used carbonation or pH indicator is the phenolphthalein solution or equivalent, being successfully used for pH between 8 and 11.

Figure 3 shows the color of the specimen when the phenolphthalein solution is sprayed.

Figure 3. Specimens submitted to the phenolphthalein spray test.

3 Results

The average values of the analyzes of the three tests performed for the sample group, considering the w/c variations are presented in Table 1.

Table 1. Mean values for durability analyzes.

Specimens		Sulphate content (%)	Chloride content (%)	Carbonation Penetrarion (mm)
CP II – F32	w/c 0.4	6.28	0.55	-
	w/c 0.7	8.39	0.69	2.1

Sulphate content increased by more than 33% when the water factor used in the mortar was added.

CP II – F32 cement analysis for chloride determination by chloride submerged samples resulted in chloride content of 0.69% for samples with water/cement ratio of 0.7 and 0.55% for samples with water/cement ratio of 0.4. According to NBR 12655 (ABNT, 2015) the maximum chloride content for reinforced concrete exposed to chloride in the service conditions of the structure is 0.15% (considering aggressive classes III and IV, which includes marine and industrial environments with chemical agents). Therefore, all the samples exceeded this reference.

It was not possible to measure the carbonation depth for the samples with water/cement ratio of 0.4 because no sufficiently measurable points were observed for the caliper measurement. For the trace with w/c 0.7 the average carbonation point was 2.1 mm.

4 Conclusions

- OPC cement mortars using w/c fractions of 0.4 show better durability results when compared to 0.7 water dosing.
- The proposed tests serve as durability indicators for previous considerations due to the attack of sulfates, chlorides and carbonates.
- The service life of concrete structures depends mainly on the durability of the concrete. Concrete made from traditional Portland cement is considered a durable material for the non-aggressive environment, however water should be carefully considered as a direct influence on the durability of mortars and concretes, due to the increased porosity.

Abstract. *The service life of buildings can be associated with the durability of enveloping the elements, e.g., the flat roofs that are constantly exposed to environmental agents. Waterproof membranes, produced with bituminous or polymeric materials, usually protect these elements. This paper presents an experimental study of waterproofing systems subjected to environmental agents of degradation. Four types of membranes were tested: bituminous, polyurethane, acrylic and acrylic with polyester mesh. All membranes were applied to concrete substrates and exposed to cycles of 48 hours in 70°C oven and 24 hours in immersion vats with 23°C water. The specimens were subjected to 0, 4, or 8 cycles and submitted to pull-off tests. The results demonstrated that the waterproof system behavior change when subjected to cycles of the temperature gradient. The tests show that the different thermal deformation between the membranes and the concrete substrate results in loss of adhesion.*

Keywords: *Waterproofing System, Durability, Environmental Agent, Adhesion.*

1 Introduction

The waterproofing layer of the roof system can be considered as a building protection system since it prevents damaging actions of water as well as aggressive elements of the atmosphere (Gonçalves *et al*., 2019). It is related to the building service life and it is the first principle of their durability (Henshell, 2000). The loss of properties of its materials can cause premature degradation in other building systems (Navratilova Rovenska, Jiránek, and Kačmaříková, 2015).

The roof is one of the building envelope part that requires the design of a system to predict the service life. The durability of the roofing system depends on several parameters (Cash, 2003) because it involves choosing proper design and materials considering the detrimental effects of natural agents (Henshell and Griffin, 2000).

The materials used in waterproofing systems, mainly those for flat roofs, are exposed to environmental agents like ultraviolet radiation, mechanical actions, contact of the organic solvents, moisture, and cycles of the oxygen, carbon and temperature (Bertolini, 2014; Marques, Lopes, and Correia, 2011; Pirondi, 1988). Due to these factors, the waterproofing systems are subject to natural and accelerated degradation processes of their mechanical water-tightness characteristics (Walter, De Brito, and Lopes, 2005).

The main factor for material degradation is temperature according to Patterson and Mehta (2001), the heat transference by radiation occurs because every object produces electromagnetic

waves by virtual temperature. The membranes and sheets of the weatherproof system are polymeric materials like polyurethane, polyvinyl chloride, bituminous, acrylic, polypropylene (Cash, 2003; Marques *et al*., 2011). This class of material is known for its temperature instability due to its thermoplastic characteristics. The internal energy of polymers rises with the increase in temperatures, reducing weak bonds between macromolecules (Callister and Rethwisch, 2001). It leads to lower elastic modulus and higher flexibility (Bertolini, 2014). However, at high temperatures, covalent bonds are broken, leading to irreversible chemical degradation of the material. With this regard, it is important to understand the behavior of these materials when working together with building as a system, not just as a material.

In this work, the main objective is to analyze the behavior of four waterproofing materials applied in a concrete substrate submitted to weathering actions by temperature, air and wetting.

2 Methodology

This work evaluated the behavior of waterproofing systems when submitted to wetting and drying cycles. In the experimental study, four waterproofing systems adhered to the substrate were evaluated: acrylic with and without polyester mesh, polyurethane, and bituminous. The substrate used was concrete with steel mesh, produced according to the Brazilian standard ABNT NBR 14081-2: 2015.

The specimens were submitted to the aging process by wetting and drying cycles, placed in a forced air circulation oven at a constant temperature of (70 ± 1) ºC for 48 hours and moved to a water vat at (23 ± 1) °C for 24 hours. So, each cycle corresponds to 72 hours. Four substrates were tested for each waterproofing system, varying the number of cycles: 0, 4, 8 and 16.

Visual analyses were performed at each cycle stage. After finishing the cycles, the membranes were submitted to pull-off tests, using 10 samples for each substrate.

2.1 Materials

The selection of the waterproofing materials for the experiment was based on their relevance and application in the Brazilian market, their adhesion to the substrate and their distinct chemical composition and mechanical behavior. Table 1 presents the Brazilian standard and manufactures characteristics of the materials to compose the waterproofing systems: acrylic membrane, polyurethane membrane and bituminous sheet adhered with heated asphalt.

Table 1. Characteristic of waterproofing materials tested.

Characteristics	Acrylic Membrane	Polyurethane	Bituminous sheet
Color	White	Green	Black
Density (g/cm³)	1.40	1.4-1.6	Undeclared
Elongation (%)	200	70	30
Touch drying (h)	4	6	-
Consumption (kg/m²)	1.2	1.7	1.15m²/m²
Thickness (mm)	0.50-1.00	Undeclared	4.00
Application state	One-component liquid	Two-component viscous	Solid

The Systems composed of acrylic membrane received structural reinforcement with polyester mesh, table 2 present its physical and mechanical properties.

Table 2. Physical and mechanical properties of polyester mesh.

Physical and mechanical properties	Unit	Standard	Specifications
Longitudinal tensile strength	kgf	EN-ISO 1421	25±5
Transverse tensile strength	kgf	EN-ISO 1421	25 ± 5
Stretching	%	EN-ISO 1421	Max. 25
Resistance to longitudinal tear	kgf	DIN 53.363	15 ± 5
Tear Resistance	kgf	DIN 53.363	15 ± 5
Grimace	g/m²	EN-ISO 2286	15 ± 5
Thickness	mm	EN-ISO 2286	0.25 ± 0.05

The structural reinforcing mesh has the function of resisting the tensile forces when it is requested from the system (Pirondi, 1988). The bituminous sheet is prefabricated, modified with SBS (styrene-butadiene-styrene), structured with nonwoven continuous filament and sand-finished on both sides, with a thickness of 4 mm.

2.2.2 Specimens Preparation

The waterproofing systems were applied to the previously prepared substrate. The application process differs when the material is prefabricated or molded on-site. The membranes were applied using a brush and the material quantity is controlled by weighing it on a precision scale (0.01 g). For thickness control, a measurement was performed using a wet layer thickness gauge (25 to 3000 µm). Figures 1 to 4 demonstrate the procedure for specimens preparation.

Figure 1. Preparation of Bituminous sheet.

Figure 2. Application of the Bituminous sheet adhered with heated cement asphalt.

Figure 3. Application of Polyurethane membrane and inspection the thickness.

Figure 4. Application of the Acrylic membrane with polyester mesh.

The wetting and drying cycle started with the specimens in an air circulation oven at (70 ± 1) ºC. After 48 hours at a constant temperature, the specimens were removed and submerged in a water vat at (23 ± 1) ºC.

3 Results and Analysis

The test results were analyzed qualitatively and quantitatively. The first was performed by visual observations of changes in the systems during each cycle and the second by pull-off tests. The analysis of variance method (ANOVA) was used to evaluate if differences between the cycles are statistically significant.

3.1 Visual Analysis

Figures 5 to 10 illustrate the visual observations made in the test specimens throughout the 16 cycles. The visual inspection shows the occurrence of microbubbles, air bubbles, apparent pores, melting and debonding.

Figure 5. Air bubble disrupted and microporous in the Acrylic membrane with mesh.

Figure 6. Microbubbles and microporous in the Acrylic membrane.

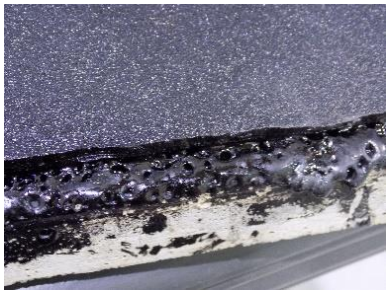

Figure 7. Increase in viscosity (melting) and microbubbles in the asphalt cement between the bituminous sheet and substrate.

Figure 8. Debonding of the bituminous sheet of the substrate with increase the temperature.

Figure 9. Air bubble in the Polyurethane system.

Figure 10. Microbubbles and apparent porous in the Polyurethane system.

3.2 Pull-off Analysis

The adhesion strength was measured using pull-off tests that were performed at the end of each wetting and drying cycle. Figures 11 to 12 demonstrate the preparation and performance of the test.

Figure 11. Preparation of the samples to the pull-off test.

Figure 12. Pull-off test in the polyurethane membrane.

The adhesion strength is given by the following equation:

$$Ra = \frac{F}{A} \tag{1}$$

Where *Ra* is the adhesion strength, expressed in Megapascal (MPa), *F* is the force, expressed in Newton (N), and *A* is the tested area, expressed in square millimeters (mm²).

In Figures 13 to 16 should be noticed that all waterproofing systems presented a decrease in adhesion strength when at least 4 wet-dry cycles were applied.

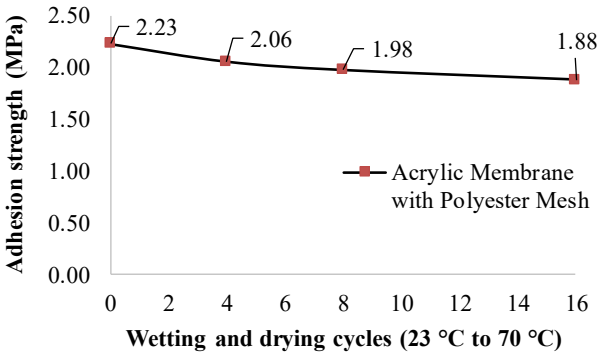

Figure 13. Adhesion Strength of Acrylic membrane with Polyester mesh.

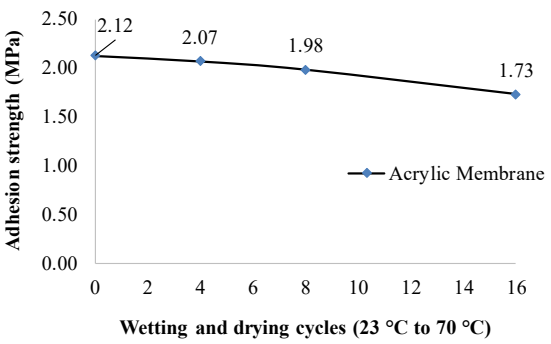

Figure 14. Adhesion Strength of Acrylic membrane.

Comparing Figures 13 and 14, it is can be seen that the reinforcement has no influence at the adhesion strength of acrylic membranes. Also, a decline of adherence with number of cycles is presented in both systems. Figures 15 and 16 indicates that the bituminous sheet and the polyurethane membrane show no significant decrease in adhesion strength after 4 cycles.

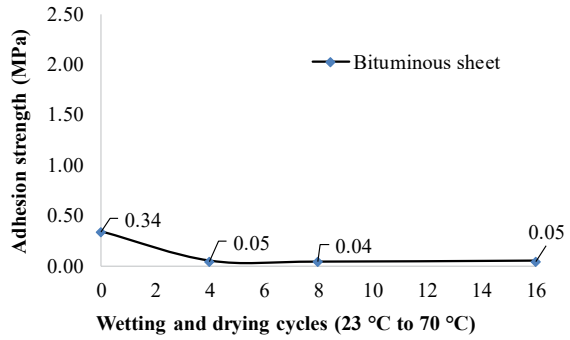

Figure 15. Adhesion Strength of Bituminous sheet.

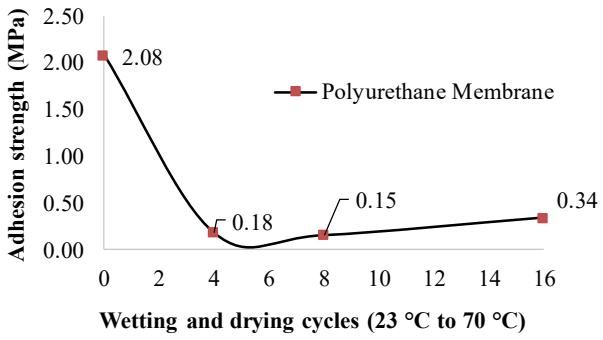

Figure 16. Adhesion Strength of Polyurethane membrane.

In Figure 17, the variability of the adhesion strength results is presented. Each result is an average of 10 specimens tested in each substrate plate. It is observed that polyurethane systems presented a larger deviation. It was observed that specimens located in points where air bubble formation results adhesion next to zero. Also, in the case of bituminous system, the penetration of fluids in the polymer-modified asphalt pores causes a debonding process.

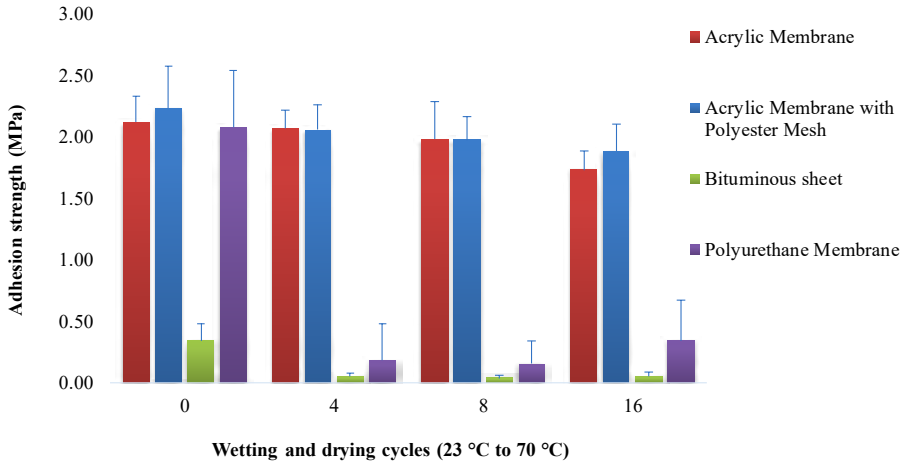

Figure 17. The Standard deviation of each waterproofing system.

It is noted that the behavior of the bituminous and polyurethane systems proved to be highly sensitive to temperature actions and wetting cycles. Additionally, it is noticeable that the adhesion strength of the bituminous sheet is the lowest, even in cycle 0. This factor is related to the adhesion shape, thickness, and type of material used to adhere the layers. The system consists of 3 layers: primer, polymer-modified asphalt cement and the bituminous sheet itself, resulting a 6 mm thickness. So, there is a larger area for energy dispersion when the system is stressed. In cycle 0, the adhesion strength of the polyurethane system was considerably high comparing to the other systems. However, the cycles of weathering result a loss of this initial behavior. As shown in Figure 9, during the wetting and drying cycle, air bubbles were formed between the substrate and the polyurethane system. In this process, the system had a loss of adhesion in some parts of the substrate.

Table 3 presents the comparison of adhesion strength of the tested systems using the analysis of variance (ANOVA), the level of significance considered is 5%.

Table 3. Analysis of variance and Tukey's paired comparisons of adherence strength.

System	Cycle	Value-P	Media	Group	
Acrylic Membrane	0	0.002	2.12	A	
	4		2.07	A	
	8		1.98	A	B
	16		1.73		B
Acrylic Membrane with Polyester Mesh	0	0.024	2.23	A	
	4		2.06	A	B
	8		1.98	A	B
	16		1.88		B
Bituminous sheet	0	0.000	0.34	A	
	4		0.05		B
	8		0.04		B
	16		0.05		B
Polyurethane Membrane	0	0.000	2.08	A	
	4		0.18		B
	8		0.15		B
	16		0.34		B

It can be seen that for all the systems the weathering cycle is significant for the decrease in adherence (value-P is less than 5%). Also, a Tukey's method is used to compare all possible pairs of results for each system. With this, it is possible to observe in the bituminous sheet and polyurethane membrane the cycle 0 and the others are significant different. Bur, the acrylic membranes do not show a significant difference in the adhesion strength up to the cycle 8.

4 Conclusions

Waterproofing systems as an integral part of the building need to provide weathering resistance. Through tests on wetting and drying cycles, it was possible to understand the behavior of waterproofing systems when adhered to the substrate. From the tests performed and materials used the following conclusions are drawn:

- The adherence of the acrylic membranes to the substrate is less influenced by weathering cycles than other systems. In addition, the use of reinforcement mesh does not influence significantly in this pattern.
- Despite the high adhesion strength of acrylic membranes, it was observed over the cycles the manifestation of air bubble disrupted and microporous. This may compromise the system in terms of watertightness.
- The polyurethane membrane system and the bituminous sheet system lost their bonding characteristic to the substrate after 4 cycles. In view of this behavior, it is necessary to evaluate previously the place where it will be applied; therefore, it is not indicated for regions susceptible to severe weather conditions, such as cycles of intensive rain and extremely high temperature.
- The results demonstrate the importance of the thermal protection layer in waterproofing systems that will be exposed to weather cycles. Moreover, a special attention should be taken in the design and execution of this layer.

Abstract. *The aim of the current study is to investigate the carbonation behavior of cement hydrates at different environments. Hardened cement pastes are prepared using OPC and BFS and crushed into ~90μm powder. The powder samples are carbonated at 5/20% CO_2 and at 60/85%RH. TGA, XRD and phenolphthalein tests are conducted before and after carbonation. The results show that CH remain uncarbonated even after CO_2 uptake apparently ended and that the amount of the residual CH affects the results of phenolphthalein test. External humidity strongly affects the carbonation behavior of both CH and other hydrates. The degree of CH carbonation is greater at higher humidity, while the degree of other hydrates carbonation is greater at lower humidity. This conflicting effect can occur at surface of bulk concretes and changes in its properties (coarsening of pore structure and cracking) can be caused without apparent carbonation detected by phenol phthalein test. The effect of relative humidity on CSH carbonation should be taken into consideration when estimating long-term performance of carbonated concretes.*

Keywords: *Carbonation, OPC, BFS, Relative Humidity, Phenolphthalein Test.*

1 Introduction

Carbonation of concrete leads to significant changes in its chemical and physical properties. During the process, gaseous CO_2 diffuses through pore network of concrete and react with cement hydrates. When Portlandite (CH) is carbonated and consumed, pH value of pore water decreases, which causes depassivation of steel bars embedded in RC structures. CH carbonation also contributes to reduction in concrete porosity because precipitated calcium carbonate ($C\hat{C}$) clogs up the pore space. The clogging of porosity results in a decrease of diffusion path, which improves weight transport resistance in general (Houst *et al*., 1994). In terms of porosity change, it has been reported that carbonation of calcium silicate hydrate (CSH) has greater impact than CH carbonation (Morandeau *et al*., 2014). CSH carbonation also alters pore size distribution of cement pastes, which can cause coarsening of pore structure (Auroy *et al*., 2014). Furthermore, it has been known that CSH carbonation is responsible for carbonation shrinkage and subsequent cracking (Chen *et al*., 2006).

Summarizing the above, carbonation reaction of cement hydrates governs the property changes of carbonated concrete. Better understanding on both the reaction behavior and the impacts can help us to estimate the long-term performance of carbonated concretes. Up to the

present, the impacts of cement hydrate carbonation has been widely investigated (Borges *et al*., 2010; Auroy *et al*., 2014), and the changes in physical properties can be related to the degree of carbonation (Morandeau *et al*., 2014). On the other hand, data on carbonation behavior of cement hydrates are lacking.

As has been already known, carbonation behavior of cement hydrates is strongly affected by external environment (Castellote *et al*., 2009; Galan *et al*., 2013). Thus, the aim of the current study is to investigate the carbonation behavior of cement pastes at different humidity and CO_2 concentration. Also, cement hydrates inside bulk concretes are carbonated under changing environments (humidity and CO_2 concentration), because concrete carbonation basically occurs during drying process. In order to estimate the carbonation degree at any environment, it is desirable to remove the bulk effect and to obtain direct relationship between the carbonation degree and external environments. Considering the above, powdered samples (hardened cement pastes) are employed in this study.

2 Materials and Experiments

3 types of cement pastes were prepared. 2 of them were made with OPC (LOI: 0.97%, SiO_2: 21.41%, Al_2O_3: 4.84%, Fe_2O_3: 3.20%, CaO: 65.01%, MgO: 1.08%, SO_3: 2.02%) and their water to cement ratio were 0.45 and 0.60 (N45 and N60). The other was made with OPC and BFS (50:50) and its water to cement ratio was 0.60 (BB60). The pastes were cast into prismatic molds (40×40×160mm) and demolded after 24 hours. They were cured until 91 days under water, and then crushed into powder. In order to uniform their particle size, crashed powders were sieved with 90μm mesh. The powder samples were dried in N2-purged desiccators, where temperature and humidity were controlled at 20℃ and 60/85%RH. After drying, the samples were carbonated at 4 different environments (Relative humidities were 60/85% and temperature was 20℃, CO_2 concentrations were 5/20%, and they are denoted as 6005, 6020, 8505 and 8520.). In order to monitor CO_2 uptake rate, sample weight was measured during carbonation, and the tests were finished after 24 hours at CO_2 concentration of 20% and 72 hours at CO_2 concentration of 5%.

After accelerated carbonation, TGA tests were performed on carbonated and non-carbonated samples. Measurement temperature ranged from 105℃ to 1050℃ at the heating rate of 10℃/min. The amount of CH and C$\hat{C}$ were calculated from TG curves and their decomposition was detected from inflection point of ΔTG curves around 400℃ to 550℃ and 550℃ to 800℃. Before the tests the samples were soaked in acetone for 48 hours and dried in vacuum desiccator. XRD tests were also performed on the same samples. Patterns were obtained from 2θ of 5° to 65°. In addition to TGA and XRD tests, phenolphthalein tests were carried out so as to compare apparent carbonation and the degree of carbonation. The powders are packed into sample holder (10×10×0.2mm), and phenolphthalein solution was dropped onto them. Sample color was measured by means of color difference meter before and after phenolphthalein was dropped.

3 Results

3.1 Weight Change and CO_2 Uptake

Figure 1. shows the results of monitoring of the sample weight during carbonation at 5% CO_2 concentration. Sample weight shapely increased in first 8 hours, but the change slowed down

quickly and was completed within 24 hours in most samples. The weight increase is mainly due to CO_2 uptake and evaporation of water generated through carbonation reaction. In the case of OPC system, larger amount of CO_2 was absorbed when water to cement ratio and external humidity is higher. On the other hand, little difference can be found in OPC-BFS system, although gentle weight increase continued after 24-hour carbonation at 60% RH. In Figure 2, influence of CO_2 concentration on the weight change is compared. As expected, increase in sample weight was higher when CO_2 concentration is higher. and the influence is more obvious in higher relative humidity.

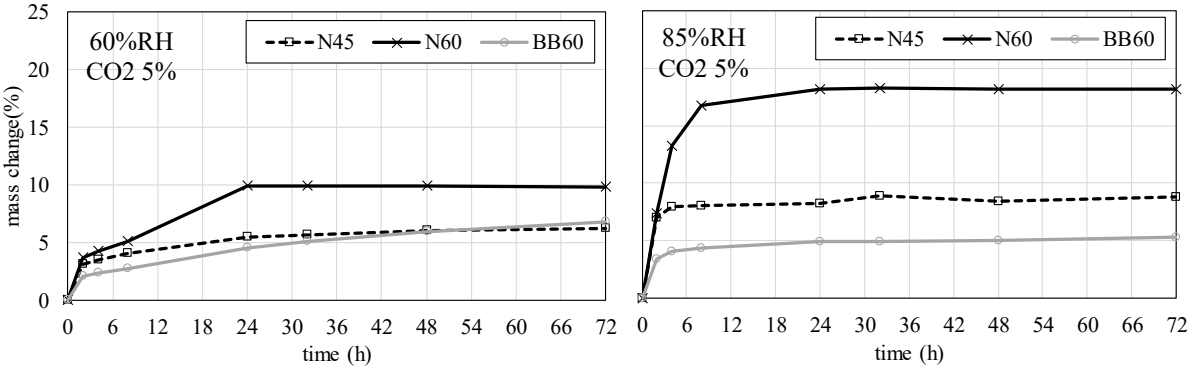

Figure 1. Sample weight monitored during carbonation (5%CO_2).

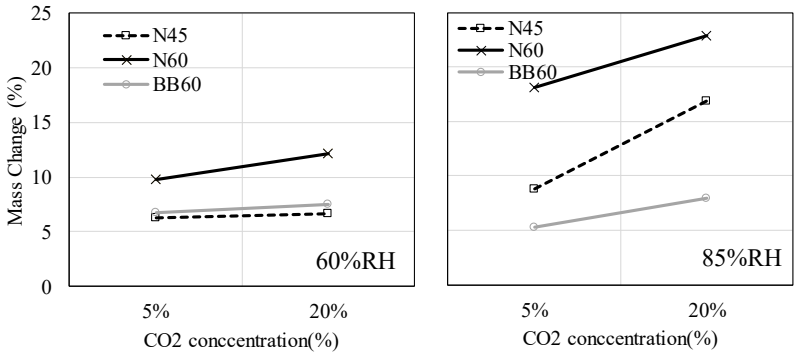

Figure 2. Weight change after carbonation. Carbonation time was 24 hours for 20 % CO_2 and 72 hours for 5% CO_2.

3.2 Carbonation Behavior of Cement Hydrates

Figure 3. shows the results of TGA tests before and after carbonation. In some cases, especially in lower relative humidity, CH dose not reach full carbonation even after CO_2 uptake apparently stopped (Figure 1.). It has been pointed out that degree of CH carbonation is strongly affected by external humidity and that larger amount of CH is carbonated in more humid environment (López-Arce *et al*., 2011; Galan *et al*., 2015). In Figure 3, the results of 5% CO_2 concentration are coincide with the reported behavior of CH carbonation, although little difference can be found in the residual CH of 20% CO_2 concentration.

In addition to the TGA results, the amount of $C\hat{C}$ generated from CH carbonation ($n_{C\hat{C}}^{CH}$) and other hydrates carbonation ($n_{C\hat{C}}^{others}$) is calculated using the following equations.

$$n_{C\hat{C}}^{CH} = n_{CH,nc} - n_{CH,c} \quad (1)$$

$$n_{C\hat{C}}^{others} = n_{C\hat{C},c} - n_{C\hat{C},nc} - n_{C\hat{C}}^{CH} \quad (2)$$

Where $n_{CH,nc}$ and $n_{CH,c}$ are the amount of CH contained in non-carbonated and carbonated samples respectively (mmol/g). $n_{C\hat{C},nc}$ and $n_{C\hat{C},c}$ are the amount of $C\hat{C}$ before and after carbonation (mmol/g).

The calculation results (grey and yellow lines in Figure 3.) illustrate that relative humidity also has impact on other hydrates carbonation. In most cases, larger amount of $C\hat{C}$ is generated from other hydrates at 60% RH than at 85% RH, and the amount of $C\hat{C}$ from other hydrates exceeds that from CH carbonation at 60% RH. This general tendency is similar to carbonation behavior of synthesized CSH reported elsewhere (Kim *et al*. 1995), where it has been pointed out that CSH carbonation continues longer and greater amount of CO_2 is absorbed at 60% RH than at 80%RH. In summary, higher humidity promotes CH carbonation and larger amount of CH is consumed. On the other hand, lower relative humidity contributes to other hydrate carbonation and larger amount of CH remain uncarbonated.

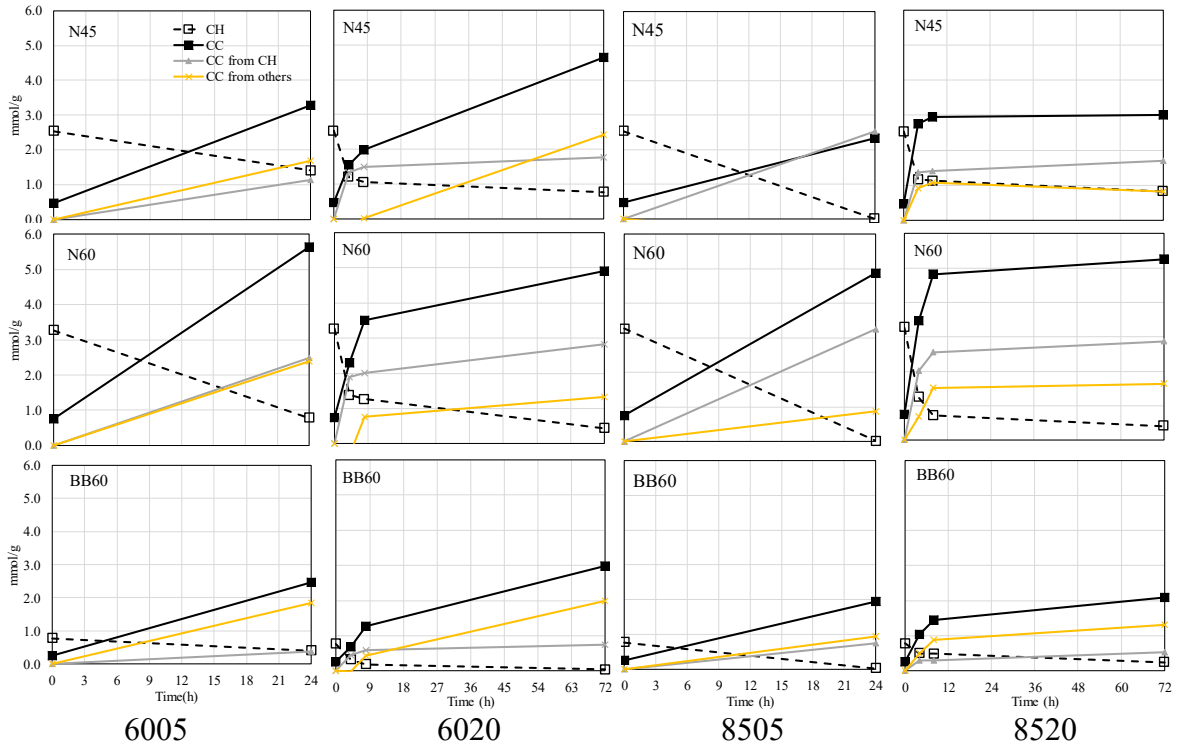

Figure 3. Changes in the amount CH and $C\hat{C}$. The amounts of $C\hat{C}$ coming from CH carbonation and other hydrates carbonation are also illustrated in grey and yellow lines.

3.3 Difference in Calcium Carbonate

Figure 4. shows XRD patterns for carbonated and non-carbonated samples. To compare the presence of CH and three polymorphs of CĈ, only the range from 25° to 35° is shown in the figure. In general, CH peaks do not disappear after carbonation and their peak height is higher when samples are carbonated at 60%RH, which agrees with TGA results. In regard to CĈ calcite and vaterite peaks are observed in every pattern, but their proportion of peak height is different depending on relative humidity. At Vaterite peak height of 60%RH (orange) is higher, whereas at calcite peak that of 85%RH (grey) is higher. Aragonite can be found only in 5% carbonation (N45_6005 and BB60_6005).

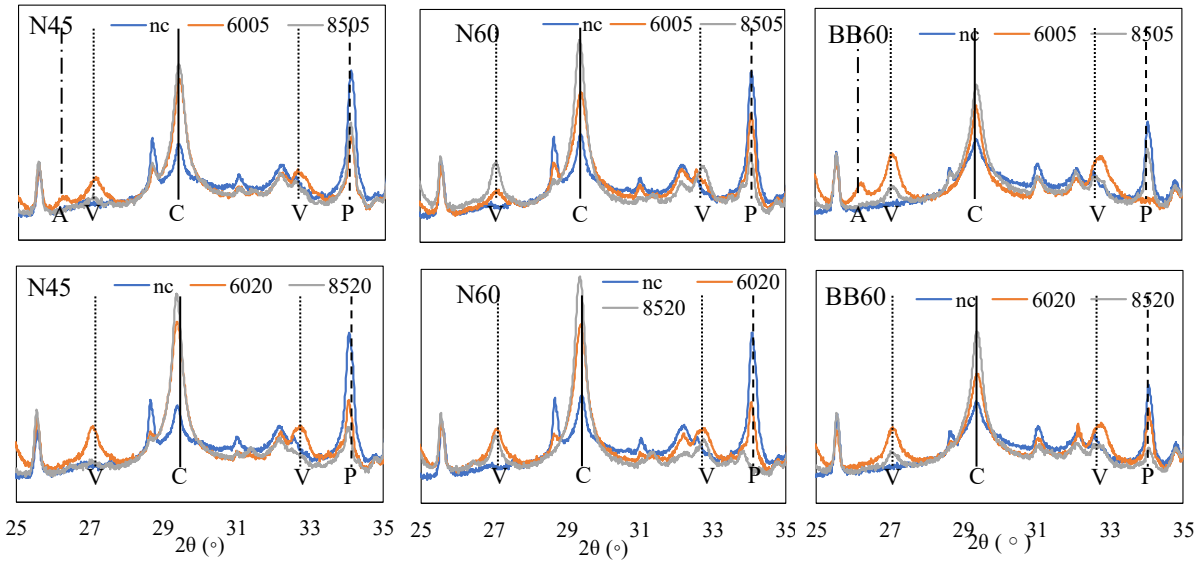

Figure 4. XRD patterns for carbonated (6005, 8505, 6020 and 8520) and non-carbonated (nc) samples. A, C, V and P denote aragonite, calcite vaterite and portlandite respectively.

3.4 Color Change During Phenolphthalein Test

Table 1. and Figure 5. show the results of the phenolphthalein tests. Here, the color difference before and after phenolphthalein addition is determined based on CIE L*a*b* color space, where a* coordinate indicates red (positive) or green (negative). The color of non-carbonated samples turns red immediately and Δa* value reach around 50 whereas, color change of carbonated samples is slower and their Δa* value is below that of non-carbonated. The results of carbonated samples also indicate that carbonation environment (both external humidity and CO_2 concentration) affects the sensitivity to the indicator, that is to say, Δa* value is smaller when relative humidity and CO_2 concentration are higher. In addition, the effect of relative humidity is greater than that of CO_2 concentration.

Table 1. Photographs of compacted samples 60 minutes after phenolphthalein indicator was dropped. Color difference index Δa* (positive: redder and negative: greener) is also shown below each photograph.

	Non-carbonation	carbonated 6005	6020	8505	8520
N45	 Δa*=49.8	 Δa*=46.6	 Δa*=44.5	 Δa*=26.6	 Δa*=24.6
N60	 Δa*=51.2	 Δa*=18.9	 Δa*=14.0	 Δa*=2.93	 Δa*=2.64
BB60	 Δa*=48.4	 Δa*=3.58	 Δa*=18.4	 Δa*=13.6	 Δa*=12.1

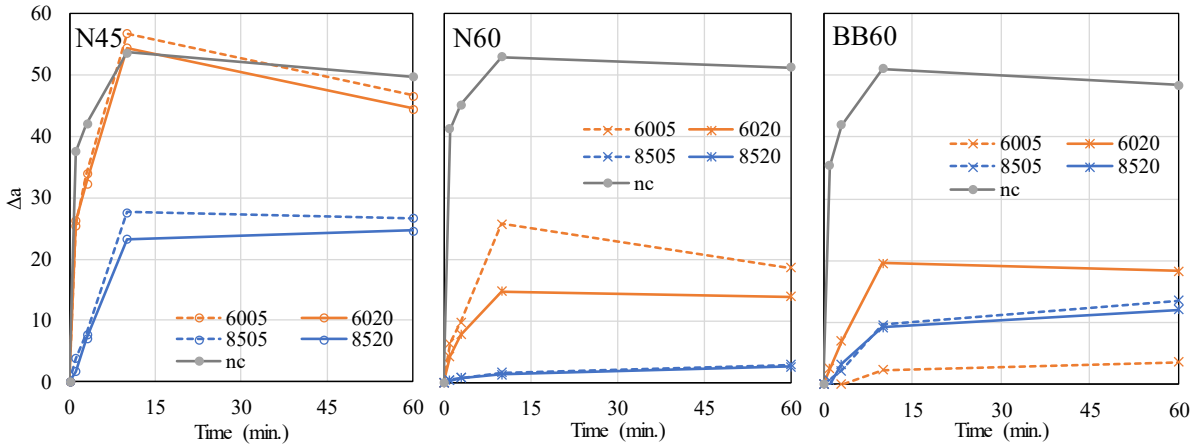

Figure 5. Changes in Δa* after phenolphthalein indicator was dropped. Non-carbonated (nc), carbonated at 60%RH and carbonated at 85%RH are illustrated as grey, orange and blue lines respectively.

4 Discussions

Based on the obtained results, carbonation behavior of cement hydrates and their impact on concrete properties are discussed. First of all, the results of weight increase (Figure 2.) do not agree with the increase in $C\hat{C}$ amount after carbonation (Figure 3.). In other words, TGA results indicate that less amount of CO_2 is absorbed at 85%RH, whereas the weight increase is greater at 85%RH. According to natural carbonation tests (Galan *et al*., 2012), larger amount of water is released from CSH when it is carbonated at lower relative humidity (about 38%RH and 58% are compared). Although the carbonation environment is different from that of the current study, this carbonation behavior of CSH can explain the reason for the disagreement in the figures 2 and 3. When the powder samples are carbonated at lower relative humidity, more H_2O can be released from CSH due to drying and weight increase due to CO_2 uptake is canceled.

Regarding to carbonation behavior of CH and other hydrates, the impact of relative humidity is clearly observed. As has been pointed out, CH carbonation is promoted at higher relative humidity (85%RH) and less amount of CH remain uncarbonated. Compared to the results of phenolphthalein test, the amount of residual CH can be related to color change of phenolphthalein. On the other hand, other hydrates carbonation is promoted at lower relative humidity (60%RH). As a result, at 60%RH, other hydrates carbonation proceeds without enough CH carbonation. Because other hydrates carbonation is more responsible for pore structure changes and carbonation shrinkage, changes in cement paste properties can occur without color change of phenolphthalein in such environments.

As mentioned in the first section, carbonation occurs during drying process. Especially around surface of bulk samples or in small samples, drying proceeds immediately. In such situation, carbonation reaction proceeds under lower relative humidity, which leads to other hydrate carbonation without CH carbonation. In the previous research, CO_2 concentration is main factor for CSH carbonation and decomposition (Castellote *et al.*, 2009). Relative humidity also affects CSH carbonation, and this factor should be taken into account when estimating long-term performance of carbonated concretes.

5 Conclusions

- Powdered cement pastes were carbonated in order to investigate the impact of external environment on carbonation behavior of CH and other hydrates.
- The results of weight increase do not agree with that of TGA tests. The disagreement can be related to the effect of relative humidity on stoichiometry coefficient of H_2O CSH carbonation reaction.
- CH remain uncarbonated even after CO_2 uptake apparently end and the amount of the residual CH affects the results of phenolphthalein test. External humidity strongly affects the carbonation behavior of both CH and other hydrates. The degree of CH carbonation is greater at higher humidity, while the degree of other hydrates carbonation is greater at lower humidity. The conflicting effect above can occur at surface of bulk concretes, and changes in its properties (especially coarsening of pore structure and cracking) can be induced without apparent carbonation detected by phenol phthalein test.
- Relative humidity, as well as CO_2 concentration, strongly affects CSH carbonation, and

this factor should be taken into account when estimating long-term performance of carbonated concretes.

Abstract. *The so-called works of special arts, are constructions of high complexities that allow the advancement of widening gaps and overcoming obstacles previously unthinkable. With the increase in magnitude of these structures, in addition to greater investments, the maintenance of these structures becomes an increasingly important factor for engineering. Among the elements of bridge structures, the support devices are components with important structural functions, being essential for their proper functioning and especially the durability of the entire structure. This paper aims to evaluate the pathological manifestations in support devices so, according to inspections performed and the diagnosis of causes, define their best practices and treatments for the maintenance and mitigation of the pathologies found. In the practical study the following steps were performed: survey and selection of the structures currently under maintenance of MetrôRio; selection of criteria for the evaluation of pathologies; carrying out inspections; comparative analysis between the viaducts to determine the priority order for negotiations; and definition of conduct. The results obtained were the result of evaluation of the field analysis, diagnosis and comparison with tests performed in support devices. Having as input the tests in the support devices, the best treatments and suggestions to avoid new pathologies were proposed.*

Keywords: *Support Device, Infrastructure, Pathological Manifestation, Maintenance.*

1 Introduction

Throughout history, bridges have been built to exemplify the engineering prowess of a civilization, many enduring longer than the empires that built them (Wilson, 2009).

Bridges and infrastructures systems, due to their inherent vulnerability, are at risk from ageing, fatigue and deterioration process due to aggressive chemical attacks and other physical damage mechanisms (Biondini, 2015). The preventive and corrective maintenance should be part of a comprehensive management process, including periodic surveys aimed at identifying any existing structural anomalies and failures, diagnosing them and then defining recovery and treatment actions, if necessary (Kainuma *et al.*, 2014).

The culture of inspection and maintenance of road bridges, railroads and viaducts in Brazil is recent, being from the 80's the first studies of pathologies in the structures (Araujoa, 2017).

There is a specific standard for the inspection work on bridges, viaducts and concrete walkways, ABNT / NBR 9452/2016 (ABNT NBR 9452, 2016).

Support devices are components with structural functions essential for the proper functioning and durability of the structure, but not just a sample of the entire structure, the support device alone can already represent a maintenance point of the structure, so its monitoring continuous inspections are considered very important in the bridge maintenance management process (Freire *et al.*, 2015).

It can be said that knowledge of the state of the bearing apparatus is a good sign and well represents the state of the bridges in their entirety in structural terms. Therefore, the analysis of their pathologies, causes and origins is of great importance in defining the treatment and maintenance of bridges, elevations and viaducts. (Freire *et al.*, 2014).

Metal and concrete support devices expose some problems that discourage their use, either in terms of maintenance difficulty, poor property of materials or even the built-in cost. Therefore, over time, it was searched for elements that could cover all the needs of a support device, this way arose the support devices in elastomer, based on polychloroprene, whose widespread trade name is neoprene which as a product industrialized, it presents greater uniformity of physical characteristics, as well as exceptional resistance to light and ozone, thus providing durability significantly superior to that of other types of elastomers (Cordeiro,2014).

This paper aims to present approaches towards improving some specific infrastructure maintenance principles, strategies, models and practices, based on a recent study to evaluate the pathological manifestations in neoprene support devices, of the structures currently under maintenance of *MetrôRio*.

The novelty of this work is in proposing a systematic approach to condition assessment, deterioration forecasting, and maintenance decision making over the life-cycle of the built asset. Given the importance of *MetrôRio* to society in Rio de Janeiro, it is essential that the entire system works continuously as there is no margin to support major service disruptions.

2 Methods

In the methodology the following steps were used: survey of the viaducts, elevations and bridges existing in the subway railway; selection of structures to be inspected; selection of criteria used in the evaluation of pathological manifestations; conducting visual inspections based on ABNT NBR 9452/2016; and suggestions for future interventions.

2.1 Inspection of Bridges and Support Equipment

Inspections are paramount to characterize the bridge's constituent elements and, therefore, their classification according to criteria established in ABNT NBR 9452 (2016). Each element is evaluated according to specific visual aspects defined in the standard. According to the same standard, the following types of inspections are considered: cadastral, routine, special and extraordinary.

ABNT NBR9452 (2016) provides in Annex A, a basic roadmap for tokens and cadastral inspections, the proposed initial documents are described such as project data, execution record and changes in the construction phase, previous inspections, among other elements that may provide more inputs for the definition of the causes and better dealings.

Inspection of assistive devices may not be limited to the space in which they are positioned and to the element. It is necessary to identify the general functioning of the studied artwork and to verify the compatibility with the current behavior of the support devices.

Because of their location, support devices are structural elements that are difficult to inspect, but their behavior must be monitored by inspectors according to the following general procedures in Table 1 (DNIT, 2004).

Table 1. Items to be inspected on assistive devices (DNIT, 2004).

Visually inspect the accessible faces of the appliance; After a few years of service, small cracks 2 to 3mm deep and 2 to 3mm long are tolerable;	Check that the support device has been correctly vulcanized and that there are visible and oxidized charter steel sheets;
If there is displacement of the structure, measure the angles between the surfaces of the structures in contact with the support apparatus;	Check for defective expansion joints on the superstructure, very close to the support device or directly above the device.
Measure distortions of the support apparatus;	Check that the support device has been moved from its original position;
Check for the presence of oils, greases or any other substance harmful to the elastomer;	Measure the heights of the support apparatus at the edges and center points;

According to ABNT NBR9452 (2016), Table 2 can be considered as a parameter for evaluating support equipment, given its condition and the scenario to which it is exposed.

Table 2. Device Classification (ABNT NBR9452, 2016).

Condition	Description
Critical	Support devices and / or their surroundings present breakdowns at risk of structural collapse requiring repair intervention and / or immediate device replacement.
Bad	Support devices and / or their surroundings present damage that compromises structural safety without risk of collapse, requiring repair intervention and / or short-term device replacement. All devices with breakage with charter exposure fall into this classification. Follow-up is recommended and interventions may be needed in the short term.
Regular	Support devices and / or their surroundings present malfunctions that may generate some structural deficiency, but there are no signs of deterioration of the devices, nor compromise of the stability of the work. Follow-up is recommended and interventions may be necessary in the medium term.
Good	Support devices and / or surroundings are not malfunctioning. Interventions may be necessary in the long run.
Excellent	Support devices and / or their surroundings are not damaged and the devices were manufactured from 1987 following the recommendations of ABNT NBR 9783 (1987).

2.2 Pathological Manifestation in Neoprene Support Devices

Although it has excellent performance compared to other types of support equipment, especially when not in need of maintenance, the neoprene device also requires some care. Table 3 shows recurrent pathological manifestations in neoprene supports.

Table 3. Pathological Manifestations in Neoprene Apparatus (Cordeiro, 2014).

Most Common Pathological Manifestations - Neoprene Apparatus
High Neoprene Distortion
Neoprene cracking or creep
Frame contact zone shutdown
High compression on neoprene
Loss of serviceability and distortion
Variations in rubber layer thickness
Unsticking of vulcanization of inner sheets
Degradation of sliding plates, guides or stops
Oxidation of steel elements

The causes for the deterioration of structures can be as diverse as the natural "aging" of the structure to the irresponsibility of some professionals who choose to use materials that are out of specification (Souza and Ripper, 1998).

The causes of pathologies in structures have their origins in two groups: intrinsic causes - referring to the processes of deterioration inherent in the structure itself, *i.e.* its origin is in execution, use, human failures, etc. and extrinsic causes - external to the material body, can be understood as factors that attack the structures from the outside inwards, throughout the process of conception, execution or the useful life. The most common causes of decreased service life in assistive devices are listed in the Table 4 (DNER, 2006).

Table 4. Causes of Pathological Manifestations in Support Devices (DNER, 2006).

Most common causes of pathological manifestations	
Intrinsic damage not detected during installation	Irregular seating causing additional localized overload
Displacements, rotations and loads in service much higher than estimated	Unintended aggressiveness of the environment
Attack by chemicals	Badly nesting in the crib

The treatment of a pathological manifestation should be done according to the inspection report, condition and definition of the causes of the given manifestation.

As it is a synthetic structure, of specific manufacture, it is more common that if it presents anomalies, it will be replaced by a new device. Except in the case of incorrect positioning of support devices or displacement of a Teflon sliding plate, for example.

Table 5 presents some common types of repair methods according to each pathology in neoprene support devices (Cordeiro, 2014).

Table 5. Neoprene Support Devices Treatments – adapted (Cordeiro, 2014).

Damage to Support Devices	Repair Dealer
Corrosion, presence of dust and moisture	Cleaning and use of protective paint.
Massive corrosion leading to section loss	Replacement
Offset or misalignment	Component replacement or total
Neoprene deterioration or wear	Replacement
Fissures	Crack sealing or replacement
Fragmentation of concrete in support	Removal and execution of new concrete

3 Results – Case Study of Pathological Manifestations, Their Causes and Treatments in Neoprene

All *MetrôRio's* assets are cataloged according to an asset tree ABNT NBR ISO 55000 (2014), which aims to give an overview, keep all history of interventions, corrective or preventive, and maintenance plans in force combined with each group of systems and equipment. Thus, the support devices studied in this work are under the structures system.

The object of case study was the support devices and their surroundings. The elevations between São Cristóvão and the *MetrôRio* Maintenance Center and between the Triagem and Maria da Graça stations are the oldest in the system, and their construction dates back to the late 1970s, or about 35 years of operation.

The recommendations of DNIT inspections were followed (DNIT,2004). Field information has been posted in a specific form for this service. A specific inspection campaign was carried out for the support devices of each structure. As an input for maintenance decision-making, 1228 neoprene support devices were performed along the entire railway structure. The inspections were performed by specialized technicians using the visual method, with the naked eye, and the access was made by stairs with a reach of 9.00 meters in height. The fieldwork was accompanied by a professional specialized in occupational safety, all safety procedures were complied with in accordance with current legislation. No device has been classified in the Excellent Class because it is over 30 years old and has not been manufactured (ABNT NBR 9783, 1987).

The CNV - SCR Elevated is located between the Maintenance Center - MC and the São Cristóvão station (later, there was also the connection of the elevated with Cidade Nova station). The old elevation has a total length of 970m and consists of 30 spans, 4 spans with 4 beams, 1 span with 3 beam and 25 spans with 2 beams. The trays are seated on 28 pillars and two staked joints at the longitudinal ends, constituting isostatic spans. In the beam x pillar and beam x encounter interface there are chartered neoprene support devices with regular dimensions of 700 x 250 x 40 mm. In this elevation, 30 pillars and 138 support devices were evaluated, two of which were not inspected for being covered. It was found that most of the assistive devices (79 units) inspected at this stage were classified as being in a regular state of conservation (57%). Supporting devices fitted with poor condition total 57 units (42%), as shown in Fig. 1.

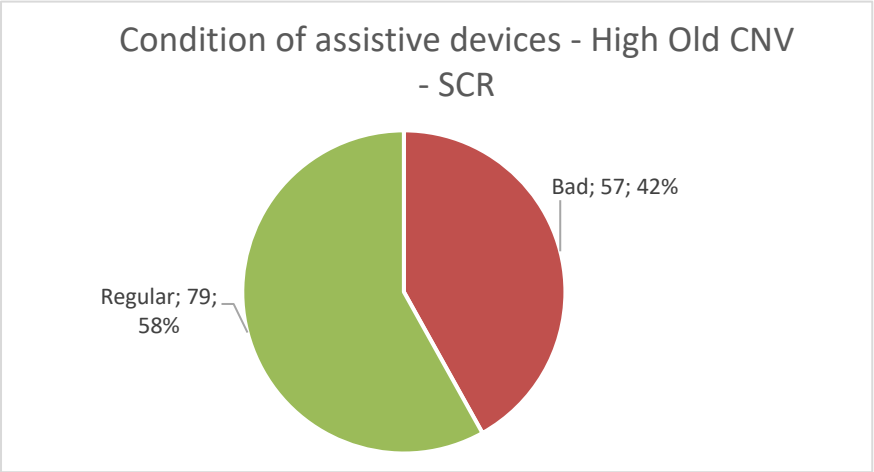

Figure 1. Support Device Conditions - CNV – SCR.

Elevated TRG -MGR is mostly located between the Triagem (TRG) and Maria da Graça (MGR) stations and starts after leaving the Bernold tunnel next to the Mangueira Olympic village. The Elevado has a total length of 2,925 meters and is formed by 84 spans, mostly with 4 precast beams each, with chartered neoprene appliances with dimensions 750 x 200 x 40 mm. In this elevation, 361 support devices were evaluated, and 37 pillars were not inspected because they were in a risk area where access could endanger the inspection team. It was found that most of the support devices (269 units) inspected at this stage were classified as being in a regular state of conservation (75%). Poorly classified support devices total 78 units (22%), 9 units (2%) were considered in good condition and 5 critical support devices (1%), as shown in Fig. 2.

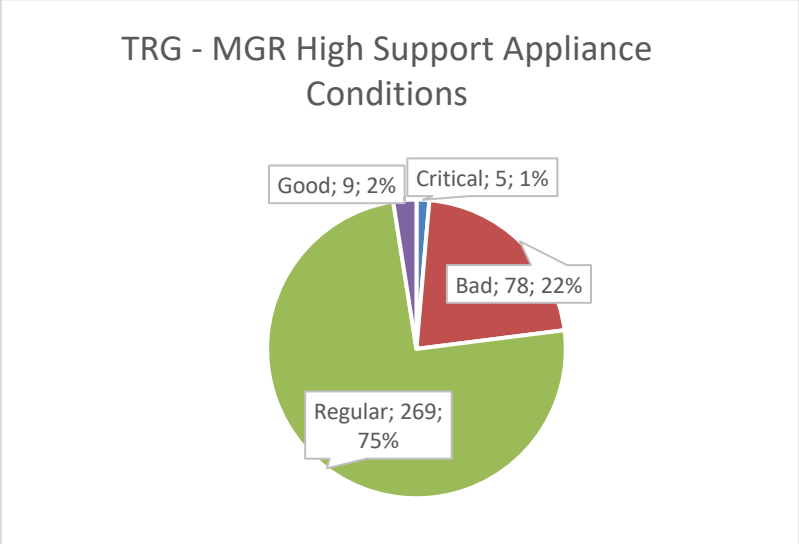

Figure 2. Support Device Conditions - TRG – MGR.

With the definition of the pillars that concentrated the largest number of critical devices, aiming at a better use of the operation, the decision was made to replace 12 units, from the perspective of urgent replacement. Tables 6 present this pathological manifestation, with the degree of risk, possible cause and the indicated treatment.

Table 6. Pathological manifestations in the devices and support.

Pathological Manifestation - Cradle Degradation (Plinth)	
Pathology	Anomaly around the support apparatus, but caused by malfunction of the element. 
Risk	Critical risk - severe pathological manifestation with compromised structural safety
Cause	From a malfunction of the supporting bond between the superstructure and the mesostructure of the elevation.
Treating	The treatment, in addition to the replacement of the support apparatus, should include reinforcement of the plinth with its recomposition at the bottom, called the cradle. As said, in neoprene support devices, it is not common to perform maintenance and treatment interventions on the element, but rather its immediate replacement.

4 Conclusions

The concern with the maintenance of structures such as those of special artworks was motivating for the work and allowed to relate the pathological manifestations in support devices with the pathological manifestations of the structures, the intrinsic and extrinsic causes as a whole, allowing an analysis, albeit superficial in the field of subject matter, sufficient for decision. The novelty was the proposal of a systematic approach to condition assessment, deterioration forecasting, and maintenance decision making over the life-cycle of the built asset.

Supporting devices are structural connecting elements which allow forces to be transmitted between the superstructure of the artwork and its support and are therefore essential elements for the proper functioning of the structure into which they are inserted.

The inspection processes took place exactly in accordance with all the literature found, allowing great inputs for subsequent decision making. Thus, the pathological manifestations were quite explicit.

As for the causes of the manifestations, it is a complex study and although there is literature, it is not trivial to understand the reason why two support devices, theoretically manufactured under the same process, of the same age, suppose stored in the same form, are adjacent to each other, exposed to very close loads and exhibit behaviors so distinct in terms of behavior in service.

Even with breakage and chartering exposed in the corrosion process, the devices can still perform satisfactorily without causing movement restriction of the part. But in these cases, annual monitoring is essential to follow up on a case-by-case basis to make sure that the performance and operation of the chartered neoprene parts is still adequate.

As for the process of negotiations, in cases where no substitution was considered, monitoring will take place in accordance with the first inspection. Thus, the big point of the issue of support devices is to understand their operation not individually but in conjunction with adjacent structures, as it is evident that despite some anomalies found, support devices, except those that had signs of degradation around them, they were still able to remain in service, provided they were well monitored.

Abstract. *A compact fatigue testing machine to quantitatively evaluate the effects of this complex degradation of sealants and the load change of the sealant under dynamic fatigue has been developed. The developed fatigue testing machine is compact with dimensions of (width) 100 × (length) 135 × (height) 110 mm. It can be installed in an outdoor exposure test site or in a chamber. Thus, this machine can be used for performing various compounded accelerated degradation tests. We report the use of this testing machine to examine the effects of this complex degradation of sealants and the load change of the sealant under dynamic fatigue.*

Keywords: *Fatigue Testing Machine, Sealant, Joint, Fatigue Resistance.*

1 Introduction

The factors contributing to the degradation of the construction sealants used in exterior walls can be broadly classified into weathering (heat, ultraviolet rays, moisture, etc.) and joint movement and they work simultaneously in a complex manner. Especially, for dynamic joints, these factors work simultaneously and in a complex manner, and they continue to take effect from the moment that they are filled in the joint until the end of their life.

Current evaluation tests for the sealants mainly evaluate properties after curing in relation to a single degradation factor. No evaluation method for the effect of movement during curing process or one in which complex degradation can be applied had been established yet.

For this reason, we worked on developing a compact fatigue testing machine for the sealant to quantitatively evaluate the effect of complex degradation and load change in the sealants at the time of dynamic fatigue.

Using the developed compact fatigue testing machine the effects of the joint movement during curing on the physical characteristics and the shape of the sealant and the changes in physical properties of the cured sealants were evaluated. The changes in compression and tensile stress of the sealant when repetitive expansion/contraction fatigue (deformation) was applied to the sealing joints with variable fatigue cycle, displacement, and temperature were also measured and examined.

doi:10.23967/dbmc.2020.154

2 Overview of the Fatigue Test

2.1 Overview of the Fatigue Testing Machine

Conventional fatigue test machines are all large devices with low versatility and high price. When developing the current fatigue machine, the following points were paid attention to (a) compact size, lightweight, installable in a chamber; (b) easy mechanism; and (c) the price range is such that concerned parties can use the machine in round-robin fashion.

An overview of the developed testing machine is shown in Figure 1 and Table 1. It comprises of (1) fatigue testing machine unit, (2) load measurement device, and (3) PC for measurement purposes. It is capable of measuring the stress (load) on the sealants simultaneously while applying repetitive expansion/contraction deformation.

The dimensions of the fatigue testing machine are 100 mm (Width) × 135 mm (Length) × 110 mm (Height) mm and it weighs only 1.3 kg and can be held by one hand. The device runs on AC 100 V power source or a DC 12 V battery, so it can be installed for outdoor exposure test and can also be placed in a chamber.

Two types of machines with different fatigue cycles were made. One was a fixed-cycle (one cycle/24 hrs) type, in which the number of rotations was controlled only by the combination of a motor equipped with a decelerator and a worm gear. Another was a variable cycle type, in which the number of rotations could be electronically changed with a stepping motor which was combined with the reduction gear ratio of the worm gear. The main unit is separated into the test unit on the upper fixed platform and that on the lower control unit. A test specimen was fixed between the movable section jig and the fixed section jig in the test section, and the load generated by the reciprocal motion of the compression and tension displacement of the movable section was detected by a load cell. In the control unit, high torque is realized by the motor equipped with the decelerator or the combination of the stepping motor and the worm gear, and it rotated within the specified range controlled by a displacement control cam attached to a rotation axis. The load method is explained as follows. In the displacement mode we used, the compression and tension displacement were applied alternately in a sine wave. The displacement was set at ± 1.2 mm (± 10%), ± 2.4 mm (± 20%), and ± 3.6 mm (± 30%) in relation to the joint width of 12 mm. For joint movement cycle, with this machine two levels could be selected, i.e., once per day (24 hrs) and 5 cycles/min (approximately 12 s). The latter is the range specified in JIS A 1439.

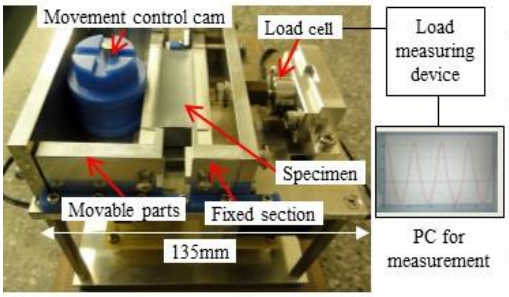

Figure 1. Compact Fatigue Testing Machine (Variable cycle type).

Table 1. Compact Fatigue Testing Machine Specification.

Testing machine type	Fixed Cycle type	Once per day: Decelerator-attached motor control
	Variable Cycle type	Once per day to 5 times/minute: Stepping motor + electric control
Load method	Drive method	Motor + worm gear
	Displacement mechanism	Displacement control by cam eccentric motion
	Displacement mode	Compressed tensile displacement: ±1.2, 2.4, 3.6mm
	Cycle	Once per day, 5 times/minute (sine wave)
Load	Load resistance	Maximum 100N
	Load measurement	Tensile compression load cell (Max.200N)
Environment used	Temperature	-10 to +50°C (depends on motor spec)
	Power	AC100V, DC12V battery (for low load)
Others	Dimensions/weight	Width 100 × length 135 × height 110mm, 1.3kg

2.2 Sealants Used in the Test

Silyl-terminated polyether (STPE) type sealants having a silylated polyether main chain with reactive silyl terminal groups as the main ingredient, which forms siloxane bonds through moisture-curing and thereby exhibits rubber elasticity, were selected. It has excellent weatherability, durability, heat resistance, workability, and good paintability on the surface and is widely used for construction sealing materials and elastic adhesives. General structural formula of STPE is shown in Figure 2.

In the test, the two types of sealants were used, i.e., 1-component type (MS-1) and 2-component type (MS-2, F-25LM-9030), with tensile properties and relaxation rate shown in Table 2. The tensile properties were measured according to JIS A 1439 (tensile velocity was 5.5 ± 0.7 mm/min). The stress relaxation rate was obtained from Equation 1. The larger the stress relaxation rate is, more is the reduction in tensile stress generated in the sealant with time.

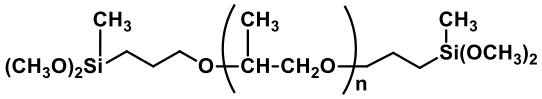

Figure 2. General structure of silyl-terminated polyether.

Table 2. Tensile test results and stress relaxation rate of the sealant used.

Sealant	M_{50} (N/mm^2)	T_{MAX} (N/mm^2)	E_{MAX} (%)	Stress relaxation rate (%)
MS-1	0.06	0.25	580	68
MS-2	0.12	0.25	410	28

$$Stress\ relaxation\ rate = Tensile\ stress\ immediately\ after\ 30\%\ tension - \frac{Tensile\ stress\ after\ 30\%\ tension\ being\ held\ for\ 15\ hrs}{Tensile\ stress\ immediately\ after\ 30\%\ tension} \quad (1)$$

2.3 Specimen Shape

As shown in Figure 3, the test specimen was an ISO type (W 12 mm × D 12 mm × L 50 mm) using anodic oxide coated aluminum as the substrate. The substrate was coated with a primer exclusive for sealants.

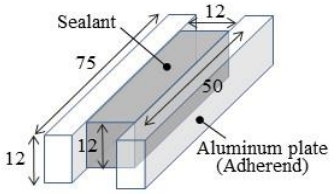

Figure 3. Specimen (ISO type) shape /dimensions (unit:mm).

3 Effect of Repetitive Deformation on Curing Sealants

3.1 Fatigue Test Method

Tests were carried out on two types of test specimens for MS-1 and MS-2, i.e., the cured test specimen in accordance with JIS A 1439 (also called specimen after curing) and the test specimen immediately after the sealants had been applied to the joints (also called specimen before curing). In order to measure the load change in the joint, backup material was not used in the specimen, and Teflon tape was attached to the bottom of the rear side so that the sealant could be peeled off. The deformation rate of the joint was set at ± 20%, and the test was started from the compression side. The cycle was set at once per day in accordance with the actual joint behavior. The test period was set to two weeks (total number of deformations: 14). Load (stress) changes in case of movement applied to sealants during curing were evaluated.

3.2 Fatigue Test Results

3.2.1 Load changes and damage state of the sealant

Figure 4 shows the load changes in each specimen related to the repetitive deformation. For both MS-1 and MS-2, we can see that the specimen before curing had a reduced load amplitude compared to the specimen after curing, and that it was affected by the movement during the curing. In particular, the MS-1 specimen before curing showed these tendencies prominently. The conditions of the front and rear face of each pre-cured specimen subjected to fatigue test did not show any change. Meanwhile, the front face of the specimen before curing swelled in a convex shape, as shown in Table 3. The MS-1 specimen before curing had a large hole in the center of the rear side. It was considered that the sealant was damaged due to significant effect of the movement applied during curing. Additionally, the rear face of the MS-2 specimen before curing was deformed to a convex shape.

	MS-1 Specimen before curing	MS-2 Specimen before curing
Surface		
Side		

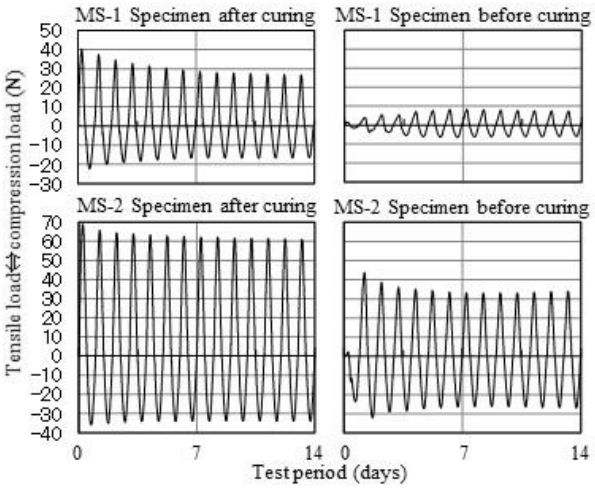

Figure 4. Changes in load against repetitive deformation.

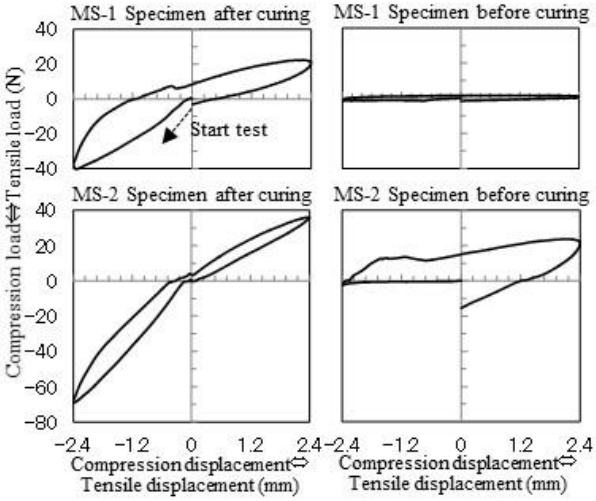

Figure 5. Displacement and load hysteresis curve for the first repetitive deformation.

3.2.2 Hysteresis curve of the displacement and load after first fatigue cycle

Figure 5 shows the hysteresis curve of the displacement and load of the sealants after first repetitive deformation cycle. The initially uncured specimens were slow in expressing the strength compared to the cured specimens, and the load zero value before and after one fatigue cycle did not match. This may be due to change in shape of the sealants or due to damage. Meanwhile, for the cured MS-1 specimen, the difference in the load before and after the tension/compression round-trip was greater compared to that of the cured MS-2 specimen, presumably due to fatigue.

3.3 Observations Concerning Fatigue Resistance

3.3.1 Effect of curing state due to repetitive deformation

In case of the uncured MS-1 specimen, the sealants hardened gradually from the surface (Figure 6). Since the shape coefficient D/W (D: joint depth, W: joint width) decreases in the initial

curing period, the sealant was rendered into a state being easily deformed outward, as shown in Figure, once the compression movement was incurred during the curing. Additionally, when the movement occurred during the curing of MS-2, the compression/tensile load ratio changed (Figure 7). This also suggests that the change occurred similarly in the joint cross-section. That is, when it receives the movement during the curing, the subsequent fatigue resistance would be affected.

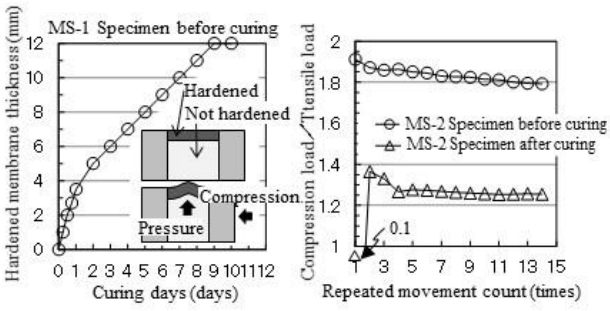

Figure 6. Changes in membrane thickness and joint cross-section change.

Figure 7. Changes in compression /tensile load (cycle day 1).

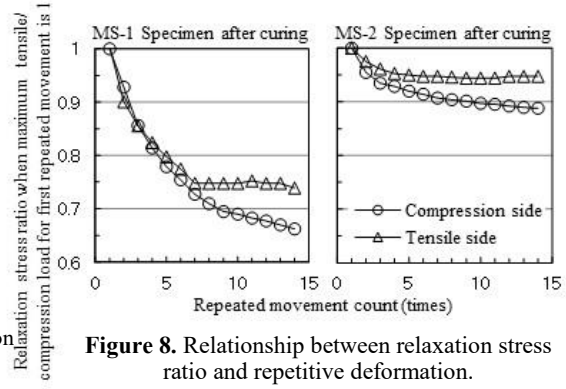

Figure 8. Relationship between relaxation stress ratio and repetitive deformation.

3.3.2 Effect of stress relaxation due to repetitive deformation

The relaxation stress ratio (fatigue stress ratio) has been defined as the ratio of the generated stress under the repetitive deformation to the maximum stress (load) at the first movement cycle expressed as the reference value 1. Its relationship with the number of repetitive deformations is shown in Figure 8 above. The reduction in relaxation stress ratio of the cured MS-1 specimen is larger, compared to the cured MS-2 specimen. Additionally, the relaxation stress rate greatly decreased after applying repetitive deformation. For both specimens, the decrease in the stress relaxation ratio on the compression side was greater than that on the tensile side, and it can be considered necessary to carry out repetitive fatigue tests to evaluate the effect of stress relaxation in the sealants.

4 Effect of Repetitive Deformation in Relation to Cured Sealant

Next, different repetitive deformation were applied to the cured sealant and the compression and tensile stress of the sealant were measured and observed.

4.1 Fatigue Test Method

MS-1 and MS-2 described in Section 2.2 were used. The compression and tension deformation rate of the joint was 20% of joint width, and the fatigue test started from the compression side. The cycle was 12 s, and the maximum number of the fatigue cycles were 10,000.

4.1.1 Viscoelasticity Properties of Sealant

The changes in the stress of the sealant at the first fatigue deformation is shown in Figure 9. For MS-1, maximum compression stress was 2.2 times greater than the maximum tensile stress, and this ratio was 2 times for MS-2. For MS-2, at the displacement zero point (at 6 s

where the joint changed from contraction to expansion), the stress became zero, indicating the elasticity. Meanwhile, for MS-1, the changes in the stress preceded the movement, and the tensile stress was generated at the displacement zero point, indicating the tendency to easily undergo compressive setting and the viscoelasticity.

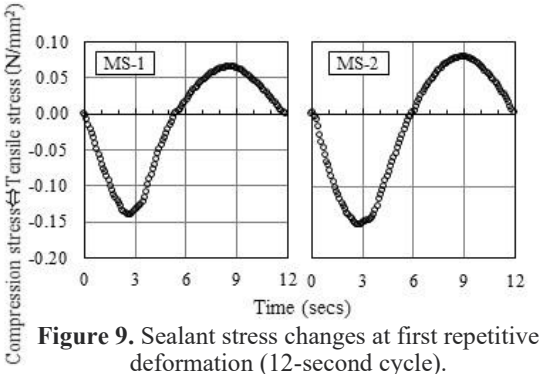

Figure 9. Sealant stress changes at first repetitive deformation (12-second cycle).

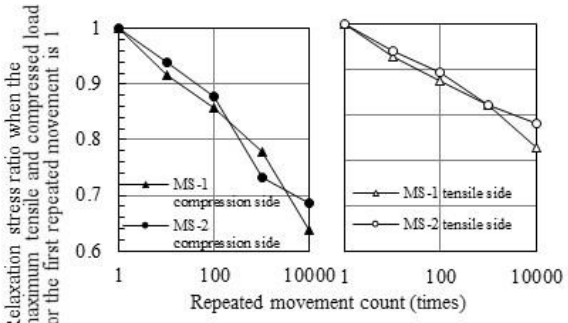

Figure 10. Relationship between relaxation stress ratio and the number of deformation (12-second cycle).

4.1.2 Sealant Stress Reduction Characteristics in Relation to Repetitive Deformation

The relationship between the relaxation stress ratio and the number of the repetitive deformation (when maximum tension and compression load for the first repetitive deformation cycle = 1) is shown in Figure 10. For both MS-1 and MS-2, the stress relaxation ratio in the compression side became smaller compared to that in the tensile side as the number of the repetitive deformations increased. This is particularly prominent in the case of MS-1. Figure 11 shows the hysteresis curve of the displacement quantity and stress for each fatigue cycle.

When the repetitive deformation was applied once, the phase differences for both displacement and stress for both MS-1 and MS-2 were large. The difference was particularly large in MS-1, compared to MS-2. Additionally, in terms of the effect of the joint displacement, the effect of the compression side is greater than that of the tensile side. Therefore, MS-1 has more viscous properties (dashpot) and less elastic properties (spring) than MS-2. However, as the number of the fatigue cycles increased, phase difference became smaller.

4.1.3 Effect of the Fatigue Cycle

Table 4 shows the relationship between the number of test days and total strain energy under test conditions. The 12-s cycle test had $1/10^{th}$ the duration compared to 1-d cycle test, but the total strain energy was five times greater. Figure 12 shows the relaxation stress ratio for the 12-s and 1 day fatigue cycle tests. For MS-2, the stress relaxation ratio at the 14th fatigue cycle in both cases was almost the same. This is because the number of repetitions of the joint deformation may be dominantly influencing the MS-2 stress reduction characteristics, as shown in Figure 10. Meanwhile, for MS-1, the stress relaxation ratio at the 14th fatigue cycle in the 1-d duration cycle test is small, compared to that of the 12-s cycle. This is assumed to be because the fatigue loading time exerts a dominant influence on the MS-1 stress reduction characteristics.

From the above, MS-2 was able to bear the effect of 1 cycle/day fatigue (the actual cycle) based on the test method using a fatigue cycle of 5-6 cycles/min specified in JIS A 1439 under temperature conditions of 23 ± 2ºC. However, for MS-1, it is may be necessary to execute fatigue tests in accordance with the actual cycle.

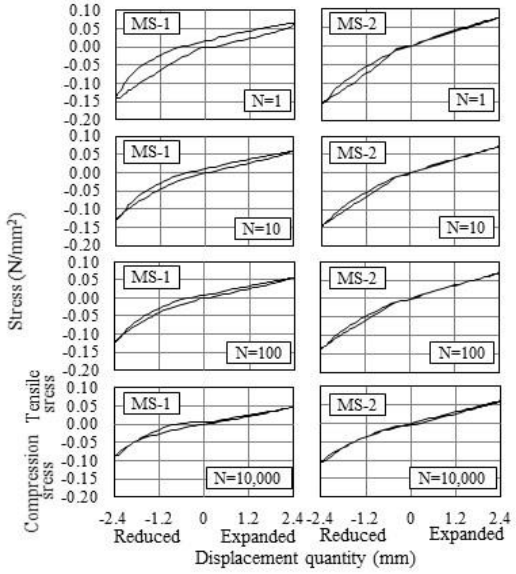

Figure 11. Hysteresis curve for displacement and stress (12-second cycle).

Table 4. Relationship between the number of test days and the strain energy under the load cycles and the maximum deformation cycle in this study.

Test conditions		Days (ratio)	Total strain energy
Cycle	Movement count (ratio)		
12 secs	10,000 (714 times)	1.4 (1)	5 times
1 day	14 (1)	14 (10 times)	1

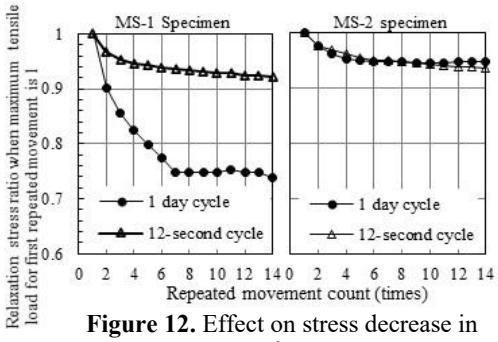

Figure 12. Effect on stress decrease in sealants

5 Effect of Displacement Quantity, Temperature Conditions and Repetitive Elongation/Reduction Deformation

Next, the changes in the compression and tensile stress of the sealant when the repetitive expansion/contraction reformation was applied to the cured sealants while changing the displacement and temperature were measured and examined.

5.1 Fatigue Test Method

After installing MS-2 specimen in the compact fatigue testing machine, it was kept for sufficient time under arbitrary temperature conditions (5, 23, 40°C). Then the repetitive expansion/contraction fatigue with a deformation rate of ± 10% or ± 20% in relation to the joint width was applied from the compression side. The repetition cycle was 12 s, and the maximum number of fatigue cycles were 8,000 to 10,000 (at 23°C, ± 20% 30,000 times maximum).

5.2 Fatigue Test Results and Discussion

5.2.1 Sealant Stress Reduction Characteristics in Relation to Repetitive deformation

The relationship between the relaxation stress ratio when the maximum tension stress (load) for the first repetitive deformation cycle was expressed as 1 and the number of the repetitive deformation is shown in Figure 13.

Under the deformation rates of both ± 10% and ± 20%, the relaxation stress ratio became lower for each repetition. Also, the deformation rate of ± 20% had a smaller relaxation stress rate compared to that of ± 10%. Meanwhile, no significant

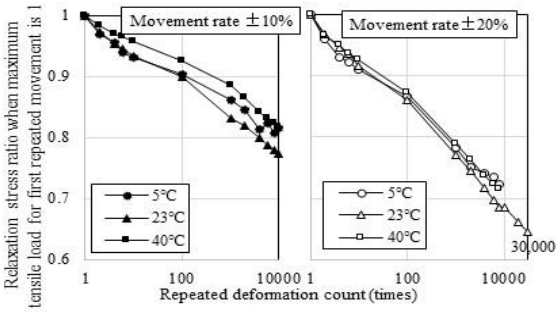

Figure 13. Relationship between relaxation stress rate and the number of deformation (12-second cycle).

temperature dependency was observed for the relaxation stress ratio.

5.2.2 Hysteresis Curve of Displacement Quantity and Load

The hysteresis curves of displacement and the load under various temperature conditions with the deformation rate of ± 20% are shown in Figure 14.

At 23°C, the displacement and the phase difference of the load were small up to a fatigue count of 8,000, whereas the phase difference became large at or above the fatigue count of 20,000. Meanwhile, at 5°C, the phase difference was large even at the fatigue count of 8,000, and it was larger than that at 23°C and 40°C.

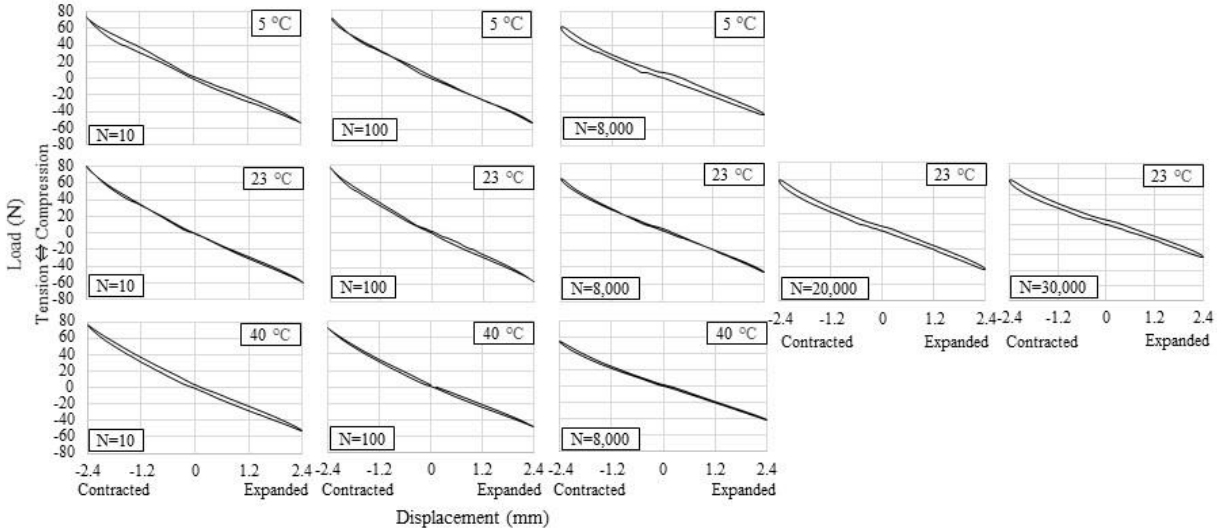

Figure 14. Hysteresis curve of displacement and load under various temperatures (deformation rate ± 20%).

6 Conclusions

This fatigue testing machine was developed to evaluate the durability of sealants against degradation under outdoor environment. Various methods of utilization can be sought according to the user objectives. For example, the testing machine we developed reproduces the movement of the sealants and can be used in combination with outdoor exposure or in an accelerated deterioration test device. This way It is possible to perform a variety of complex degradation tests and further utilization for future sealing technology can be sought.

Abstract. *In the framework of the European project H-House various concrete façade elements were developed with the aim to ensure a long service life by combining a very durable material with self-cleaning properties. The façade elements presented are made of a shell of UHPC filled with blocks of aerated autoclaved concrete as insulating material. Self-cleaning properties were realized amongst others by imprinting a microstructure into the surface during casting. The paper focuses on selected technological aspects of the manufacturing process of prototypes which had to be performed in two concreting sections. Furthermore the challenges faced when upscaling the self-cleaning properties are addressed and the strategy to assess the self-cleaning properties by measuring the contact and the roll-off angel is presented. The results show that a successfull upscalaing process requires detailed planning and that the best results can often be achieved with a moderate work effort or material use.*

Keywords: *Ultra-High-Performance Concrete, Façade Elements, Self-Cleaning Properties, Adhesive Pull-Strength, Microstructure, Architectural Concrete.*

1 Introduction

Highly automated production plants and design methods based on Building Information Modelling (BIM) make the prefabrication of building elements very efficient. Façade elements made from concrete can be produced regardless of weather conditions in variable shapes and at the highest quality and delivered just in time to the building site. Aim of the European project [H]house (Healthier Life with Eco-innovative Components for housing Constructions) was to develop a variety of new multifunctional and flexible building components which are characterized by long service life, reduced maintenance and a long-term improvement of energy efficiency. Within the project part the BAM was involved, self-supporting sandwich façade elements consisting of a thin shell of ultra-high performance concrete (UHPC) filled with an insulation of autoclaved aerated concrete (AAC) were designed (Miccoli *et al*., 2015, Fontana *et al.*, 2016). UHPC allows the manufacture of very filigree, lightweight and resource-efficient building components with high durability and is therefore optimally suited for pre-fabrication. Sustainability of the façade elements was further increased by the optimization of the binder and adding self-cleaning properties to the surface based on either the integration of photocatalytic TiO_2 into the bulk of the thin UHPC layer or by copying the Lotus® effect. Self-cleaning properties referred to as the Lotus® effect are based on the interaction of the specific micro texture and the water-repellent nature of the surface that makes a water droplet taking off

pollutions from the surface when it is rolling off (Barthlott *et al*., 2016, Si *et al*., 2018)

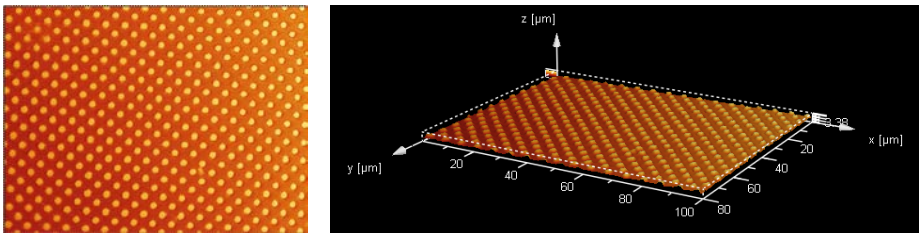
2 Materials and Methods

The concrete mixture specified in Table 1 was designed by the company Dyckerhoff which was one of the industrial project partners. While ensuring a minimum strength requirement of 100 MPa a binder composition named [H]house Compound 5941 based on the Nanodur® fine mix was developed which contains less than 55 % Portland cement clinker and results in a reduction of non-renewable energy and global warming potential (Deuse *et al.*, 2018).

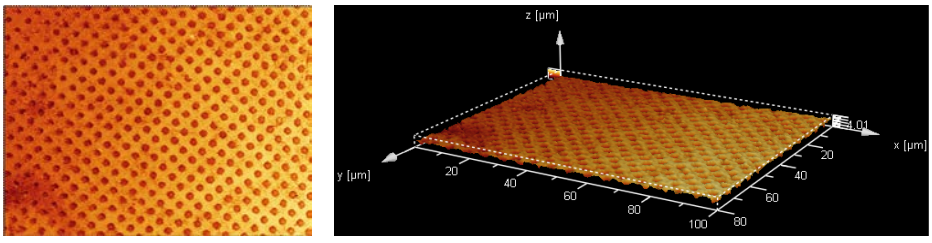
Table 1. UHPC mixture.

Material	Content in kg/m³
[H]house Compound 5941 grey	1050
Aggregate (0-2 mm)	1150
PCE superplasticizer	17,85
Water	178,5

Due to its fineness and fine-tuned granulometry the mixture further allows to imprint a microstructure into the concrete surface with very high quality. Figure 1 shows confocal laser images of a technical fabric with a defined micro texture that was used as substrate for the UHPC cast (a) and the resulting UHPC surface (b), which demonstrate the very accurate and almost defect-free replication of the micro texture (as negative imprint). To achieve a hydrophobic surface a hydrophobing agent was applied to the substrate shortly before concreting and incorporated into the hardening concrete.



a. Substrate with ‘pimples’ (diameter: 3 µm)



b. UHPC cast with holes (diameter: 3 µm)

Figure 1. Confocal laser images of substrate (a) and UHPC surface (b).

Based on structural and economic reasons the façade panels are designed as box shaped UHPC elements which are protecting the shock sensitive AAC insulation (Figure 2). Due to the

support from the edges of the box no shear forces are generated in the interface between load bearing structure and insulation during transport and service life so that additional connectors can be omitted. The frame further increases the stiffness of the box-shaped element so that the cross-section of the UHPC can be decreased. When casting the elements with a single concrete batch the floating body had to be protected against buoyancy which was discarded because of its proneness to errors. Therefore, the façade elements were manufactured in two steps. After initial hardening of the exterior layer a rigid frame was placed as internal formwork on top of the panel and the upturning edges of the box were cast in a second concreting section.

In the following sections selected tests regarding different technological aspects during the upscaling process are presented. They concern the analysis of the bond strength between the two concreting sections, the optimization of imprinting a microstructure with a hydrophobic surface and the assessment of the homogeneity of the self-cleaning surface.

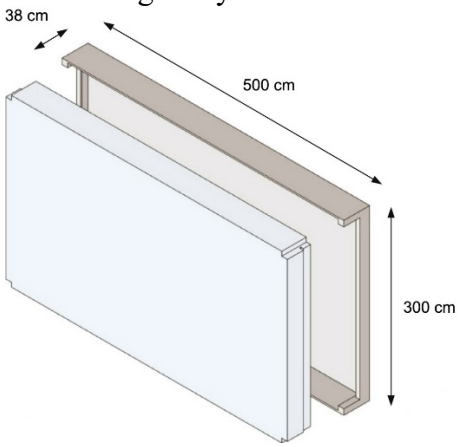


Figure 2. Façade panel consisting of box-shaped UHPC element and insulation of AAC.

3 Technological Aspects

3.1 Adhesive Pull Strength between the Two Concreting Sections

To identify the best surface treatment for an optimum bond between the two concreting sections adhesive pull strength tests were performed at samples sized 30 x 30 cm which were manufactured in wooden formwork coated with a plastic film. After the final setting of the first 2,5 cm thick concreting layer the surface was either left untouched, wetted or roughened using a wire brush (b) in one (1d) or two directions (2d) before the second layer with a thickness of 7,5 cm was poured (Figure 3). After an aeration time of 5 minutes the samples were covered until stripping after 18 hours. The samples were turned around so that the first thinner layer was on the top and the adhesive pull strength was tested according to DIN EN 1542. The surface tensile strength of the monolithic system served as reference. In addition, the effect of a bonding coat (BC) applied to the first layer before concreting the second layer was included into the examination.

The results of the adhesive pull strength (Figure 4) illustrate that without roughening the surface the bond strength between the two concreting sections is only about 12 % of the surface bond strength of the reference sample and wetting of the surface only has a negligible effect.

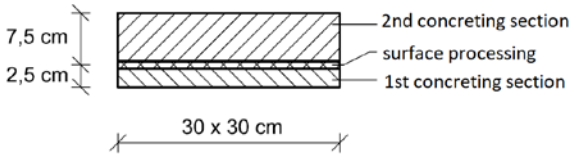

Figure 3. Sample for testing adhesive strength.

Within the "elephant skin" which formed on the first layer ventilation pores are trapped and weaken the cross section (Figure 5, left). After roughening the surface with a steel brush in one direction the loadbearing behavior corresponds to the monolithic reference so that no further measures are necessary. The system fails not in the joint but within the second layer, which was concreted several hours later than the first layer. The application of a bonding coat in contrast lead to an early cohesion failure within the bonding coat.

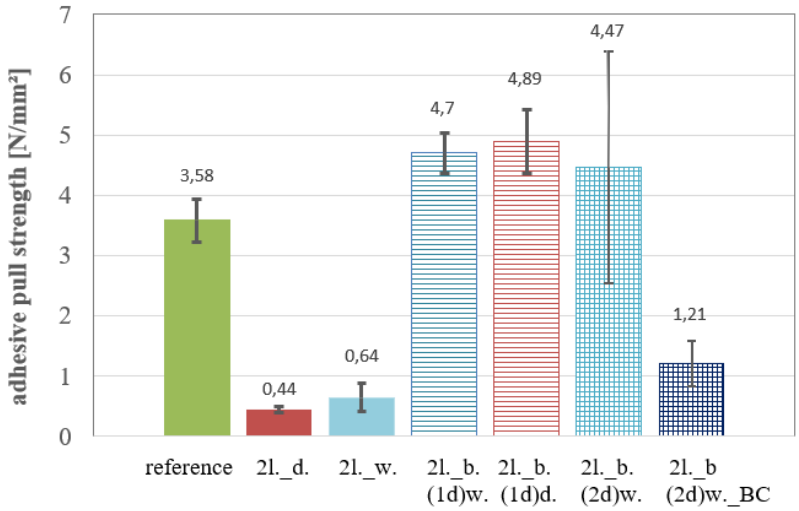

Figure 4. Surface (reference) and adhesive pull strength depending on the processing of the surface before concreting the second layer. 2l = two layers, b= brush, d = dry, w = wet, BC = bonding coat.

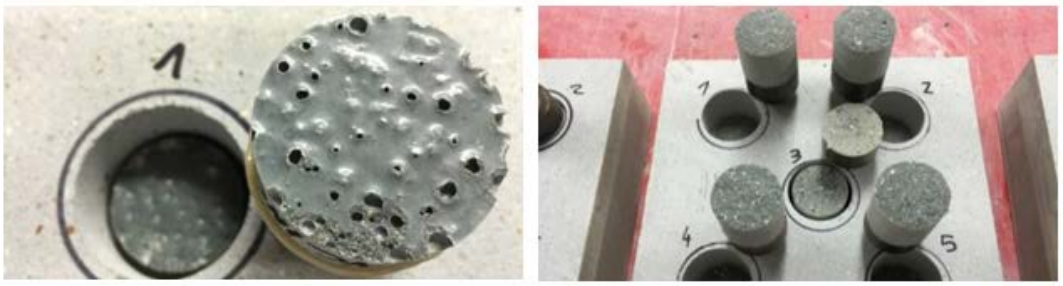

Figure 5. Failure in the joint due to "elephant skin" (left) and cohesion failure within the 2nd layer (right).

3.2 Upscaling of Micro Structured Self-Cleaning Surfaces

For the manufacture of the micro structured surfaces formliners covered with a hydrophobing or releasing agent were integrated into the formwork. In a first step different substrates were analyzed regarding the durability of the surface quality and the hydrophobic properties of the concrete specimens cast in them. For this, measurements of roughness, contact and roll-off angle, lightness and proportion of pores were performed over the course of ten consecutive pours using the same formwork. The root mean squared roughness was measured with a confocal laser microscope and the contact and roll-off angle were determined with a contact angle measuring system. The lightness and the proportion of pores were calculated using a color calibrated scanner whereby the value 255 corresponds to white. Best results were achieved for a substrate of polyurethane rubber to which 80g /m² of hydrophobing agent based on silane and siloxane were applied before the concreting.

All the parameters measured for evaluating the stability of the surface quality for both substrate and concrete exhibit only minor changes over the course of the pours (Figure 6). The contact angle measured on the formliner when using the hydrophobing agent as test liquid is always far below 90 ° ensuring a homogeneous wetting of the substrate. The contact angles of the concrete surfaces in contrast stay always over 140° and are thereby attaining super-hydrophobic properties. The slope angels of the concrete samples cast remain very small throughout the repeated use of the formwork ensuring very good self-cleaning properties. The lightness of the surface does not decrease and the proportion of pores is always below 0,9 % (Figure 6) thereby fulfilling the requirements for architectural concrete class 3 (DBV, 2004).

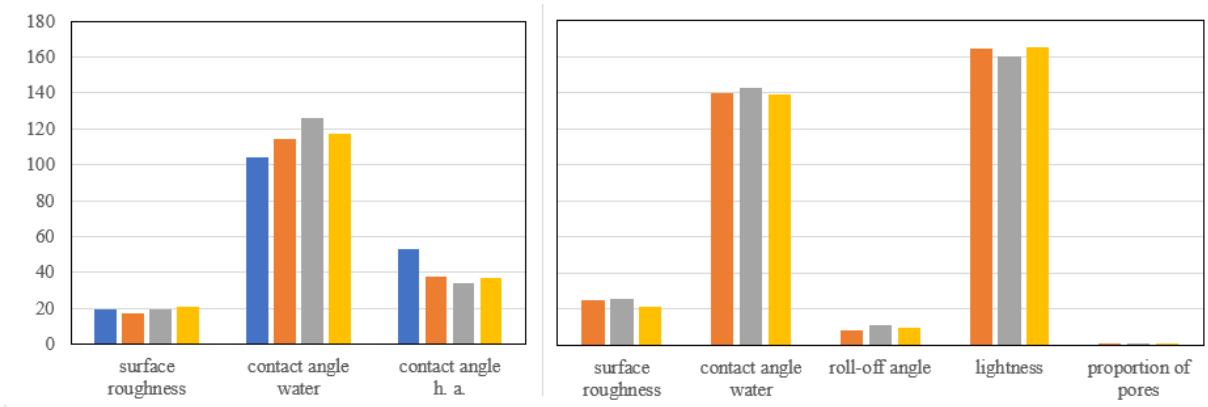

Figure 6. Parameters evaluated for the substrate and the UHPC sample during subsequent concreting.

In a second study the impact of the time span between application of the hydrophobing agent and the concreting was examined in detail using the following test set-up: Ten frame formworks sized 10 x 10 cm were positioned on a micro-structured silicone mat, to which 90 g /m² (45 g of active ingredient) of the hydrophobing agent was applied with a brush. After continuously increasing time intervals the formwork was filled with concrete and after 5 minutes of deaeration covered with plastic sheets for curing. To analyze the evaporated amount of hydrophobing agent in the time span between application and concreting a reference formwork consisting of frame and silicone mat with the equal amount of hydrophobing agent was weighed in the corresponding time intervals.

After stripping the formwork, the concrete surface was assessed visually and by measuring the contact and the roll-off angel (Figure 7).

The results show that even after a time span of 90 minutes between application of the hydrophobing agent and concreting the UHPC surface can be called superhydrophobic. While the contact angel remains on the original level, the slope angel after 30 minutes increases discontinuously from 5 to 37° (Figure 7). The quality of the architectural concrete however deteriorates when the time span between application of the hydrophobing agent and concreting exceeds 10 minutes (Figure 8).

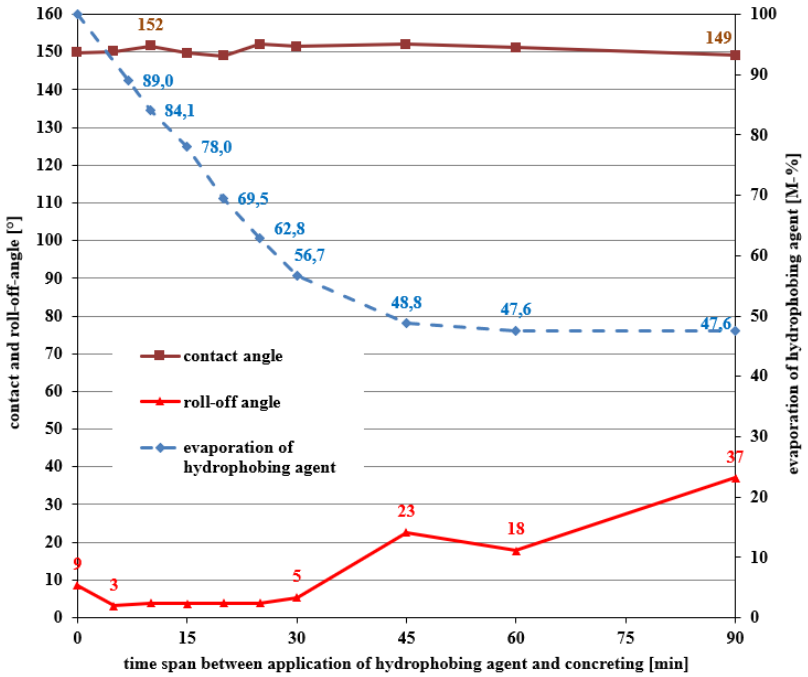

Figure 7. Development of the hydrophobic quality of the surface in dependence of the time interval between application of the hydrophobing agent and concreting.

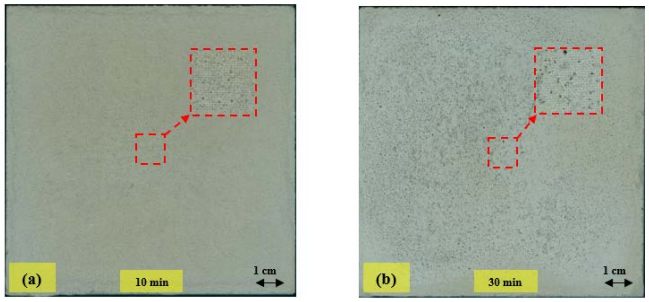

Figure 8. Quality of architectural concrete gained after (a) 10 min and (b) 30 min time span between application of the hydrophobing agent and concreting.

In a further step the impact of the application of the hydrophobing agent and the flow behavior on the hydrophobicity of the concrete surface was assessed by concreting samples sized 160 x 60 cm. Within the test series the hydrophobing agent was applied in different

amounts 160 g/m² and 80 g/m² (active ingredient content 80 g/m² and 40 g/m²) and dilution with water (1:1, none) to the silicon mat at the bottom of the formwork in two different ways (spray and roller application). Maximum 5 minutes after the application of the hydrophobing agent the concrete was cast using a conical discharge hopper positioned 40 cm from the rim of the formwork (Figure 9, left). The formwork was stripped after 24 hours and the elements were stored for 14 days at 23°C and 50 RH. Afterwards 11 cores with a diameter of 10 cm were drilled out of the element (Figure 9, right) and after cleaning with rinsing water stored for another week at 23 °C and 50 RH before the contact and slope angles were measured.

Figure 9. Concreting of test samples (left) and core extractions (right) to assess the self-cleaning properties.

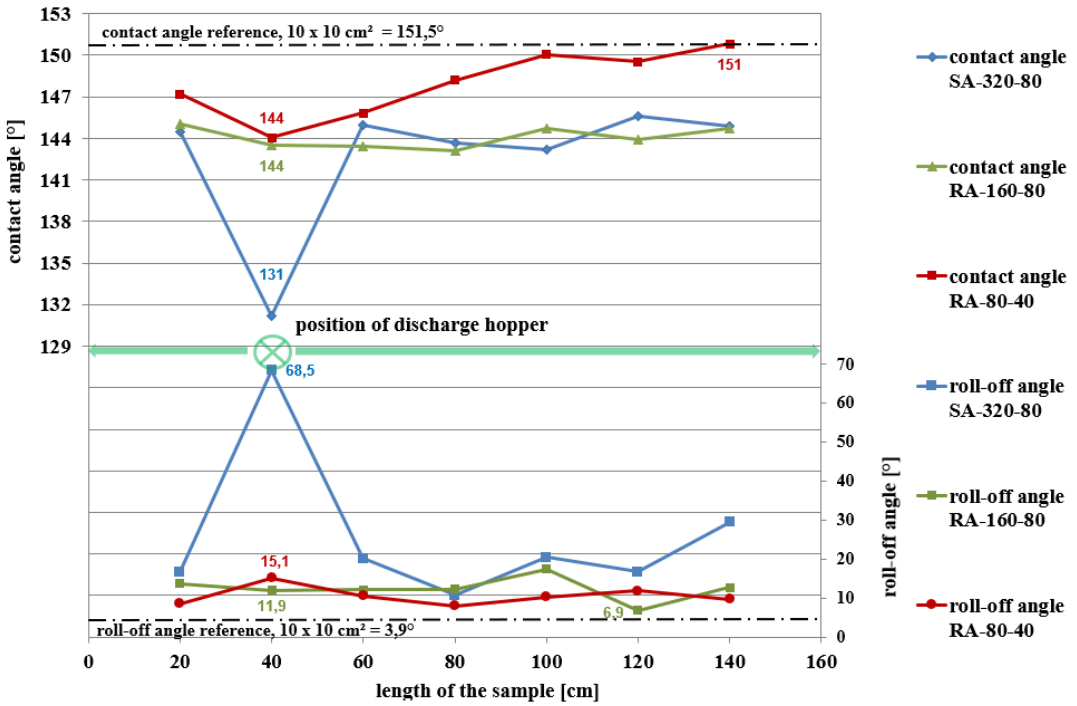

Figure 10. Hydrophobic quality of the surface depending on the distance from the discharge hopper. SA = spray application, RA = roller application; numbers define amount of application / active ingredient [g/m²].

The assessment of the hydrophobic quality (Figure 10) illustrates that the application of a bigger amount of hydrophobing agent diluted in the proportion of 1:1 with water leads to a strong increase of the hydrophobic surface quality at the discharge hopper (blue curve). For the small amount of hydrophobing agent applied undiluted to the silicon mat in contrast only a

small decrease of the contact angle was measured at the position of the discharge hopper (red curve). With increasing distance from the location of pouring the contact angle increased. The specimen further showed the smallest and most homogeneous sliding angels.

4 Conclusions

- The results show that upscaling the production of the façade elements needs detailed planning in order to achieve architectural concrete with self-cleaning properties. The highest bond strength between the two concreting sections is achieved by roughening the surface of the first section with a wire brush. An additional wetting of the surface deteriorates rather than improves the adhesive pull strength between the concreting sections. Also, for the application of the hydrophobing agent it turned out that less is more. The best results regarding the homogeneity of the self-cleaning properties were measured for the application of the smallest amount of hydrophobing agent using a brush.
- The time span between application of the hydrophobing agent and concreting is limited due to the decrease in quality of the architectural concrete.

Abstract. *The structural design of concrete structures has to result in qualities ensuring ordinary structural safety and serviceability, together with durability. Recently, it has become necessary to pursue sustainability as well, and rather newly the issue of resilience has also appeared. It is now apparent that the effects of mechanical load, environmental load and even social coherence need to be reflected and included in the formulation of limit states. This is a complex matter involving the factors of time, service life, degradation effects, modelling, probability analyses, limit states, costs and other phenomena. It has not yet been completely understood, albeit several notions in this context are contained in different codes and regulations, e.g. EN 1990, EN 1992, ISO 13823:2008, ISO 16204:2012, fib MC2010 and fib MC2020 (currently under preparation by the fib committees). According to fib Model Code 2010, the design method most commonly used for concrete structures today is performance-based. Sustainable target value design can be briefly expressed as the comparison of sustainable capacity vs. sustainable impacts. This requires the formulation of a new class of limit states – apart from those of the engineering (or structural) type, also sustainability limit states now need to be specified. The presented contribution briefly mentions traditional and durability limit states, discussing their variants and context, and then concentrates specifically on the formulation of limit states for concrete sustainability at material level. It also presents some examples which apply a full probabilistic approach.*

Keywords: *Durability, Sustainability, Limit States, Concrete.*

1 Introduction

When designing or assessing a RC structure in all situations and/or at all levels, use should be made of the limit state concept and performance models included in ISO 2394 (2015). Generally, possible structural responses are divided into two domains consisting of desirable or undesirable states; the boundary between these domains is called a limit state (LS). The traditional ultimate limit state (ULS) and serviceability limit state (SLS) were initially utilized in engineering practice (ISO 2394:1998) either as part of the semi-probabilistic format (partial factor) or in the fully probabilistic approach, which was mainly applied during research activities. Both material and structural levels were applied.

Limit state design is a common approach in civil engineering practice today. It is described in several international documents, *e.g.* EN 1992-1-1 (2004), ISO 16204 (2012) and *fib* MC2010 (2012). At the turn of the present century, the issue of durability and service life started to be considered important and thus relevant limit states appeared; however, up to now this theme has not yet been fully explored and definitively dealt with. Also, completely new types of engineering tasks have emerged recently, such as the maximising of sustainability

and resilience, which may also need relevant definition and application in terms of limit states. A brief and effective overview of the LS context up to the current stage of progress with regard to sustainability LS can be found in Geiker *et al.* (2019).

Generally, structural assessment/analysis is governed by a LS probability condition which in its general form reads:

$$P_f = P\left[A(t) \geq B(t) \right] < P_d \tag{1}$$

P_d is the design probability (target, limiting, required), t is time, S is the effect of the action being analysed and R is the appropriate barrier (*e.g.* the resistance of the material or structure). Generally, both S and R are time-dependent and hence the probability of failure P_f is time-dependent as well. At the point in time associated with the limit $P_f = P_d$, a design service life t_D can be defined. The combined effect of both structural performance and ageing should be considered wherever relevant. Note that the index of reliability β frequently stands in for the probability of failure P_f in structural design practice (ISO 2394:2015). The present contribution briefly reviews the development of LS issues and concentrates on the formulation of material sustainability limit states, showing some examples.

2 Traditional LS

The traditional ultimate limit state (ULS) and serviceability limit state (SLS) were presented in the nineties in standards – see ISO 2394 (2015).

The ULS concerns the safety of people and/or structures. The ultimate limit state is defined for material deterioration resulting in failure due to loss of resistance when the resistance of the component or structure becomes equal to or less than the relevant internal force.

The SLS concerns the functioning of the structure, the comfort of people and the appearance of construction work. For material degradation, the serviceability limit state is defined by:

- Local damage (including cracking) or changes in appearance which affect the function or appearance of structural or non-structural components.
- Relative displacements which affect the function or appearance of structural or non-structural components.

An allowable value (target, design) P_d for the probability of failure was given in EN 1990, Annex C (EN 1990:2002/A1:2005/AC:2010), differentiating them according to LS type, three reliability classes and three consequence classes. A distinction must be made between the design of new structures and the assessment of existing structures. Note that at the beginning of limit state development the level of reliability in the context of durability was left to the client's decision, together with the definition of the target service life.

3 The Durability Concept

According to Tutti (1982), the durability of reinforced concrete components or structures was later included in the LS concept mainly in connection with the consideration of reinforcement corrosion – (i) an initiation period (reinforcement depassivation leading to corrosion initiation, usually due to carbonation or chloride ingress) and (ii) a propagation period (the

development of reinforcement corrosion with a decrease in the effective reinforcement area, crack formation and spalling). There are numerous research works dealing with the durability of concrete structures, of which only a few of the earliest of them shall be mentioned here, *e.g.* Mehta (1997), Rostam and Schiessl (1994), Keršner *et al.* (1996) and Gehlen (2000). The durability of concrete structures is influenced by degradation effects and exposure conditions, and using appropriate LS the service life L can be assessed as well. This can be performed with a suitable model analysis via the use of effective software tools, *e.g.* Matesová *et al.* (2008), Life 365 (effect of chloride ingress) or Novák *et al.* (2014), Teplý *et al.* (2018) (FReET-D, incorporating a number of different numerical degradation models in a probabilistic format, producing statistical, sensitivity and probability analyses). Broadly accepted models (carbonation, and chloride effect) were included in the Model Code for Service Life Design (2008) and later in fib Model Code 2010 (2012).

The time passing before the initiation of rebar corrosion is usually considered the most conservative limiting state. It is known as the durability limit state (DLS) or initial limit state – see ISO 13823 (2008). Note that this category of LS is referred to the SLS in ISO 2394 (2015). For such a probability condition the basic form (1) can be reformulated as follows:

$$P_f(t_D) = P\{a - x_c(t_D) \leq 0\} \leq P_d \tag{2}$$

The thickness of concrete cover a, x_c is the depth of the carbonated zone, t_D is the design (target) service life and P_d is the design (target) probability of "failure".

Evidently, during a structure's service life the SLS and ULS have to be fulfilled, so the DLS is a "prerequisite" in this respect. All this also has to be considered when determining the relevant failure probability value. To complete such considerations the standard ISO 2394 **(**2015) describes, apart from the SLS and ULS, another LS – the condition limit state (CLS), which corresponds to following situations:

- An approximation to the real LS that is either not well-defined or is difficult to calculate (examples include initiation limit states or LS associated with the propagation period - *i.e.* the corrosion of reinforcement (Matesová *et al.*, 2008)).
- Local damage (including cracking).
- Additional LS thresholds in the case of a continuously increasing loss of function.

The CLS has not yet been fully understood and utilized in practice; this kind of LS is expected to be presented and explained in more detail by the upcoming fib Model Code 2020. Moreover, when dealing with durability tasks this LS is often affected by a particular combination of actions (mechanical, environmental); see *e.g.* Vořechovská *et al.* (2008). Also, the eventual reversibility or irreversibility of the LS has to be taken into account.

4 The Limit State Concept from the Perspective of Sustainability

According to the *fib* Model Code 2010 (2012), the most commonly used method of designing concrete structures today is performance-based design. Sustainable target value design can be briefly expressed as the comparison of sustainable capacity vs. sustainable impacts. This requires a new class of limit state – apart from those of the engineering (or structural) type, sustainability limit states have to be specified as well. This was mentioned in the *fib* Model

Code 2010 (2012), and also in Geiker *et al.* (2019), which states that by means of Eq. (1) the environmental performance of a concrete structure shall be verified by confirming that the retained performance or barrier (R), defined by using appropriate indexes with regard to the environment, is larger (or smaller) than the set value or effect of the action (S) of the relevant performance requirement (Section 7.10) (*fib* Model Code 2010; 2012). Social performance is described in a similar way in this section. Note that in this respect, safety, serviceability and durability are also social aspects (Hájek, 2018), *i.e.* elements of social responsibility, and therefore SLS, ULS and *L* also fall into this category - usually being understood and utilized as basic safety and serviceability criteria as well. Details concerning this class of limit equations and their practical utilization have not yet been specified in the *fib* Model Code 2010 (2012) or anywhere else to the best knowledge of the authors; an overview of the equations and a short literature review can be found in Hrabová *et al.* (2019).

The new *fib* Model Code 2020, which is currently under development, will include an implementation of the sustainability approach (Matthews, 2017): "MC2020 will take sustainability as a fundamental requirement, based upon a holistic treatment of societal needs and impacts, lifecycle costs, and environmental impacts." The limit state approach is not yet commonly used for sustainability analysis and the relevant limit states are not being employed in practice at the present time. A recent paper discusses this without formulating relevant limit state equations. A new design limit state approach is needed, and it has to be based on the probabilistic approach combined with the life cycle approach. It is a highly complex matter, as besides the existing construction limit states, new sustainability LS (environmental and social) need to be addressed together with service life and/or financial factors. These LS have not yet been identified. However, some recent works deserve consideration in this respect and are briefly mentioned below.

Fantilli *et al.* (2019) presented a procedure for RC beam design called "global impact of the beam", which introduces the specific limit state of sustainability (in accordance with the ULS and SLS). It is based on a function relating the mass of CO_2 emitted by the production of a cubic meter of concrete to average compressive strength, while also considering partial substitution of the cement by fly ash. The procedure is an iterative one and deterministic, *i.e.* it does not result in a relevant probability level. The durability issue is not considered, so the LS presented in Fantilli *et al.* (2019) is not a true sustainability limit state.

Geiker *et al.* (2019): in their work a sustainability LS is advocated using a comparison of two potential design scenarios. Considering each scenario´s full design service life, a cumulative emissions envelope can be computed for both scenarios and the actual reduction target (global warming potential emission reduction) is assessed together with the probability of failing to meet a sustainability-focused goal. Reliable and valid models for the assessment of degradation (*e.g.* for corroding structures) are needed to check engineering LS; this also leads to an iterative process. Moreover, there are not yet any approved acceptable failure probability values for a sustainability LS.

Authors of the present contribution have developed a sustainability LS formulation at material level using the sustainability potential indicator k_{SB}, Eq. (3). This combined indicator was recently presented in, *e.g.* Hrabová *et al.* (2019), Teplý *et al.* (2018) and Konečný *et al.* (in revision). Indicator k_{SB} is a normalized form of the Building Material Sustainability Potential (BMSP) defined previously by Müller (2013). In order to transform the BMSP into a normalized form, the quantities *L* (service life), *R* (performance) and *E* (eco-cost) are divided

by the arbitrary reference values L_{ref}, R_{ref} and E_{ref}, thus leading to a dimensionless quantity (3) whose value approximates 1.0. The greater the value of k_{SB}, the higher the sustainability level within the group of studied mixes for concrete production; the ranking of k_{SB} values is the resulting information. It should be noted that the presented method is supposed to enable the comparison of concrete mixture sustainability levels within a group of analysed mixtures under a given degradation effect.

$$k_{SB} = \frac{\frac{R}{R_{ref}} \cdot \frac{L}{L_{ref}}}{\frac{E}{E_{ref}}} \tag{3}$$

Eq. (3) can be further enhanced by considering the costs, C, of concrete (material and production) leading to a modified indicator. More details can be found in, *e.g.* Konečný *et al.* (in revision). Additionally, for any individual concrete composition using k_{SB} as an action and the limiting value indicator $k_{SB,lim}$ as a barrier, the general limit state condition (1) may be rewritten into the sustainability LS form.

$$P_{SB} = \left[\left(k_{SB} - k_{SB,lim}\right) \leq 0\right] \geq P_{d.SB} \tag{4}$$

This equation enables the evaluation of the probability P_{SB}, with which a certain limit value $k_{SB,lim}$ can be exceeded for the concrete mixture in question. However, this value has not yet been discussed and no experience or recommendations are known in this respect. Note that $k_{SB,lim}$ depends on three involved factors, *R, L* and *E*, which makes its determination complex. A less complicated option can be formulated utilizing the individual limit values R_{lim}, L_{lim} and E_{lim} of quantities *R*, *L* and *E*, respectively, or in other words to determine the $k_{SB,lim}$ value as follows:

$$\boldsymbol{k_{SB,lim}} = \frac{\frac{\boldsymbol{R_{lim}}}{\boldsymbol{R_{ref}}} \cdot \frac{\boldsymbol{L_{lim}}}{\boldsymbol{L_{ref}}}}{\frac{\boldsymbol{E_{lim}}}{\boldsymbol{E_{ref}}}} \tag{5}$$

As can be expected, in a real situation factors *R, L* and *E* may often possess different level of dominance. In such a case a more fitting variant of Eq. (5) can be arranged using the weighting coefficients w_R, w_L and w_E:

$$\boldsymbol{k_{SB,lim}} = \frac{\boldsymbol{w_R}\frac{\boldsymbol{R_{lim}}}{\boldsymbol{R_{ref}}} \cdot \boldsymbol{w_L}\frac{\boldsymbol{L_{lim}}}{\boldsymbol{L_{ref}}}}{\boldsymbol{w_E}\frac{\boldsymbol{E_{lim}}}{\boldsymbol{E_{ref}}}} \tag{6}$$

Alternatively only one of the quantities R_{lim}, L_{lim}, or E_{lim} can be employed individually in (5) when $k_{SB,lim}$ is computed (case dependent).

A major obstacle for the effective utilization of the limit state condition (4) is the choice of a suitable value for target reliability $P_{d,SB}$, which is not yet available in any recommendation or standard. The following notes can provide a degree of help when deciding about the $P_{d,SB}$ value:

- in situations when material parameter *R* is dominant (*e.g.* considering requirements for the robustness of the structure or the resilience of its functionality), a $P_{d,SB}$ reliability similar to a relevant one from the ULS group, *i.e.* $3.7 \leq \beta \leq 4.4$ according to ISO 2394 (2015), may be acceptable;

- in cases where L is dominant (if durability is at the centre of interest) then a $P_{d,SB}$ value in the range of $0.8 < \beta_d \leq 1.6$ similar to the SLS or DLS could be relevant;
- if the environmental issue dominates, *e.g.* via the eco-costs E (expenditures on measures to be taken so as to reduce environmental impacts to a sustainable level), then it is not straightforward to decide on a relevant $P_{d,SB}$. Environmental impact targets and/or greenhouse gas reductions must be considered, and also associated human health consequences need to be thought about. In such cases, the involvement of policy-makers at a local or regional level is needed.

Unfortunately, there are no historical bases available for considering an acceptable failure probability for sustainability limit states. A brief discussion of this problem can be found in Geiker *et al.* (2019).

5 Numerical Demonstration of the Presented Approach

A simple example of the sustainability limit state assessment of concrete composition is presented below. The sample consists of 290 kg/m^3 CEM I 42.5 R, 812 kg/m^3 0-4 mm aggregate, 910 kg/m^3 8-16 mm aggregate, 194 kg/m^3 fly ash, and 182 kg/m^3 water. The concrete in question is supposed to suffer from carbonation, so the service life L is calculated according to the initiation period stage of reinforcement corrosion caused by concrete carbonation using an analytical model. The FReET-D tool with model Carb4b are used (Papadakis and Tsimas, 2002). The basic input values were: concrete cover 30 mm; atmospheric CO_2 concentration 820 [mg/m^3]; RH = 70 %; k–value concept k = 0.4 (as stated in EN 206-1, 2013). The strength of the concrete is considered to indicate the performance R in this example. It was gained via sample testing within the grant project GA ČR 103/07/0034 at the Faculty of Civil Engineering, Brno University of Technology. The eco-cost of each concrete mixture element has a unit price obtained from an established database (Eco Costs Data, 2019). Reference values (chosen arbitrarily) used: R_{lim} = 71.9 MPa, L_{lim} = 125 years and E_{lim} = 54.5 €/m^3.

Table 1. Concrete properties.

Property	Pdf	Mean	COV
60-day cube strength [MPa]	Normal	47.2	0.06
Service life [years]	Normal	73	0.16
Eco-costs [€/m^3]	Rectangular	54.3	0.20

Limit values were chosen for the purpose of this illustrative example via the authors' engineering judgement in order to represent the trend of the probability P_{SB} due to limit values R_{lim} while keeping L_{lim} and E_{lim} unchanged. Therefore, three cases (A, B and C) were analysed: A: R_{lim} = 95 % R_{ref}; L_{lim} = 0.66 L_{ref}; E_{lim} = 1.33 E_{ref}; B: R_{lim} = 90 % R_{ref}; L_{lim} = 0.66 L_{ref}; E_{lim} = 1.33 E_{ref}; C: R_{lim} = 85 % R_{ref}; L_{lim} = 0.66 L_{ref}; E_{lim} = 1.33 E_{ref}.

Table 2. Conclusions.

	A	B	C
k_{SB}	1.04	1.04	1.04
$k_{SB,lim}$	0.49	0.47	0.44
P_{SB}	0.04	0.03	0.03
β	1.74	1.84	1.95

The values obtained for k_{SB} and P_{SB} were analysed using a specialized version of FReET software and applying Eq. (3) and (4). As mentioned above, relevant values for the target reliability $P_{d,SB}$ are not available in any recommendation at present. The resulting probability values (and the associated index of reliability β) in the studied ad-hoc case (Table 2) fall into the range "between" usual ULS and SLS values.

6 Concluding Remarks

The paper discusses limit state variants in the context of concrete structures, reviews the current position with regard to traditional Ultimate Limit States and Serviceability Limit States, and mentions Durability LS (initiation and propagation stages) as well as Condition Limit States. It then concentrates on the description and formulation of limit states for material sustainability, noting relevant related documents and attempts at presenting this kind of LS. A general definition of a Sustainability Limit State has not yet been established officially.

This contribution presents a novel form of Sustainability Limit State which utilizes the sustainability potential indicator. This indicator represents an enhanced method for the simple, yet complete sustainability assessment of concrete mixtures, which involves concrete strength, durability measure and eco-costs. The full probabilistic approach is applied and the method illustrated on an ad-hoc case - concrete suffering from carbonation. The resulting probability values and associated values of index of reliability β for different limit values are shown. The study provides engineers and researchers with an emerging tool for effective decision-making concerning concrete mixes that gives consideration to sustainability.

Deformation Velocity Survey in Mortar and Cement Paste Specimens Subjected to External Aggressive Attacks

Cristina Tedeschi and Elsa Garavaglia

Department of Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy.

cristina.tedeschi@polimi.it, elsa.garavaglia@polimi.it

Abstract. *The durability of concrete depends not only on the composition of the material and its resulting porosity, but also on the environmental conditions. Contact between concrete or cement mortars with water and soils containing sulphates, of a natural, biological origin or deriving from pollution, can activate chemical reactions in the cement paste inducing an expansion and degradation of the concrete. To evaluate the behaviour of the cementitious material subjected to various external aggressive attacks, prismatic samples of cement paste and mortar samples produced with the same binder (Portland cement) were immersed in demineralised water and in various solutions containing 5% and 10% sodium sulphates. Their expansion was monitored over time by a direct length measurement. This paper shows the results achieved in a rather long laboratory investigation and a first hypothesis has been formulated on the possible expansion rate in the first 56 test days and in the following 850 days.*

Keywords: *Cement Mortar, Aggressive Environment, Sodium Sulphate Attacks, Experimental Tests, Deformation Velocity.*

1 Introduction

The durability of a concrete structure represents the ability to withstand aggressive environmental stresses, therefore it depends not only on the composition of the material and the resulting porosity, but also on environmental conditions. The different causes of damage to concrete, can be divided into different types depending on whether the aggressive action involves one or more components of the conglomerate (cement paste, aggregate or metallic reinforcement).

In particular, when a concrete structure comes into contact with waters or soils rich in sulphates, a series of complex chemical reactions can occur the sulphates which propagate inside the material and aluminates of cement paste, leading to the formation of leading to the formation of gypsum, secondary ettringite, and in some cases, thaumasite with the consequent expansion and formation of cracks and expulsion of parts of concrete. These phenomena are collected in the general term of the external sulphate attack.

Various researches have been carried out on this subject, many of which were dedicated to the description of sulphate attack from an experimental point of view. There are numerous experimental campaigns carried out on cement paste, mortar and concrete samples, however the results depend strongly on the test conditions, the cement used and the aggregates and their particle size distribution.

On this topic there are researches in the literature that for the most part focus on the evaluation of durability and the evolution of damage (Anzani *et al.,* 2018, Garavaglia *et al.,* 2018, Garavaglia *et al.,* 2017, Garavaglia *et al*., 2016, Anzani *et al*, 2009, Garavaglia *et al*., 2008, Tedeschi and Garavaglia, 2019, Cefis *et al*. 2015, Tedeschi *et al.* 2017).

doi:10.23967/dbmc.2020.027

In this paper, the results of an ongoing experimental campaign are reported, carried out on prismatic samples of cement paste and mortar. An objective of this experimental program is also to highlight the role of the aggregate on the degradation phenomenon, for this reason samples of cement mortar were prepared with two different types of aggregate.

To evaluate the behaviour of the cement material subjected to various external aggressive attacks, laboratory tests were carried out during which cement paste samples (P-CEM), mortar samples with normalised sand (M-nor) and samples of mortar with aggregate (M-agg), were subjected to immersion cycles, thus simulating three different aggressive attacks: from demineralised water, from sodium sulphate at 5% salt concentration and from sodium sulphate at 10% concentration. The expansion was monitored over time by direct length measurements.

The tests were performed in accordance with the UNI EN 12617-4: 2003, but they lasted longer in time in order to verify any changes in behaviour over time.

The results obtained in the 889 days are shown as the variational behaviour of the deformation (shrinkage/expansion) recorded, but also in terms of deformation velocity, variable at each instant of the test process and function of the deformation value recorded.

There are not many approaches to this topic in the literature. The topic investigated is the transmission of waves in the material (Tseng *et al*., 1999, Boyd and Ferraro, 2005), not the deformation velocity of materials subject to degradation. A similar approach is present in Zhanga *et al*., 2012, which stimulates the authors to continue on this path.

Future research developments will be oriented towards probabilistic modelling of the detected behaviours.

2 Laboratory Test Procedure

2.1 Preparation of Specimens

The experimental campaign began 29 months ago and was conducted on prismatic samples of mortar and cement paste of 40mmx40mmx160mm size.

For all the samples a CEM I 52.5R (P_CEM)- type Portland binder cement was used, and for the two series of mortar samples two types of siliceous aggregate were used. The chemical composition of the cement is shown in Table 1.

Table 1. Chemical composition of cement.

Cement	C3A	C4AF	SO3
CEM I 52.5R	4.22%	5.16%	3.61%

The named samples (M_agg), were prepared with a siliceous aggregate for concrete, but used by eliminating the aggregates greater than 2mm by sieving, while the named prisms (M_nor), were prepared with standardised sand used for the certification of mortars (EN 1015-1).

To evaluate the behaviour of the cementitious material subjected to different external aggressive attacks, three prisms for each type of mixture were prepared, and laboratory tests were performed during which the prismatic samples were immersed respectively in deionized water and in a solution of 5 and 10% sodium sulphate. Once hardened, the samples were subjected to measurement to evaluate their variations in length, so as to be able to study their overall expansion, but above all to evaluate the trend and the degradation mechanisms over time.

2.2 Test Procedure

The determination of the expansion was determined according to the standard EN 12617-4: 2003, using an uncontrasted linear measurement method after the immersion in water of prismatic of 40mmx40mmx160 mm size specimens, from 24h after the casting.

The samples were prepared/made in a climatic chamber at temperature T = 20 ° C and relative humidity RH = 65% and subsequently placed in a climatic chamber at T = 20 ° C and relative humidity RH = 90%. After 24 hours from the preparation, the specimens were removed from the moulds and completely immersed in pure water (double-distilled) and in a solution with a concentration of 5% Na_2SO_4 and 10% sodium sulphate.

The prisms were periodically extracted from the solutions, in order to be able to measure the variations in weight and length. Before the initial measurement, the adhesion of the measuring pins was verified. Table 2 indicates the codes of the samples and their corresponding test conditions. In Figure 1, Samples during the measurement phase; b) Samples during the last curing period.

Table 2. Name of the individual specimens and seasoning conditions.

P_CEM Water	P_CEM 5% Na_2SO_4	P_CEM 10% Na_2SO_4	M_agg; water	M_agg; 5% Na_2SO_4	M_agg; 10% Na_2SO_4	M_nor water	M_nor 5% Na_2SO_4	M_nor 10% Na_2SO_4

Figure 1. a) Samples during the measurement phase; b) Samples during the last curing period.

3 Deformation Survey

3.1 Deformation Measurement

In compliance with the standards required in UNI EN 12617-4:2003 the variation in length was calculated in relation to L_0 length detected after 24 hours of immersion of the specimens in water:

$$\Delta L_i = \left(L_i - L_0\right) \quad (1)$$

where: ΔL_i is the variation of the length at time t_i; L_i is the length of the specimen at time t_i; L_0 is the initial length of the specimen after 4 hours of immersion.

The deformation ε_i at each instant of measurement, t_i, is thus expressed by the formula:

$$\varepsilon_i = \frac{\Delta L_i}{L_g} \qquad (2)$$

where ΔL_i is the variation of length expressed by (1) and L_g is the verified length of the specimen before immersion (in the case studied 160mm).

3.2 Observations on the Results Obtained

Figures 2 and 3 show the trend of the average deformations recorded for the tested specimens. In these figures, the deformation values are compared in the three aggressive situations imposed on the test: immersion in water, and immersion in a saline solution with a 5% and 10% concentration, for each type of mixture.

The deformation recorded in the first 56 days of testing shows an initial shrinkage (indicated with a negative numbering in figure 2) more evident in P-CEM specimens.

The continuation of the phenomenon seems to be more rapid for the P-CEM and slower and almost stationary in the M-agg and M-nor. In P-CEM the salt concentration of 5% seems to trigger a process of deformation greater than the processes caused by demineralised water and by the salt concentration of 10%. This is probably due to the porosity of the material. (Fig. 2 a), b) c)).

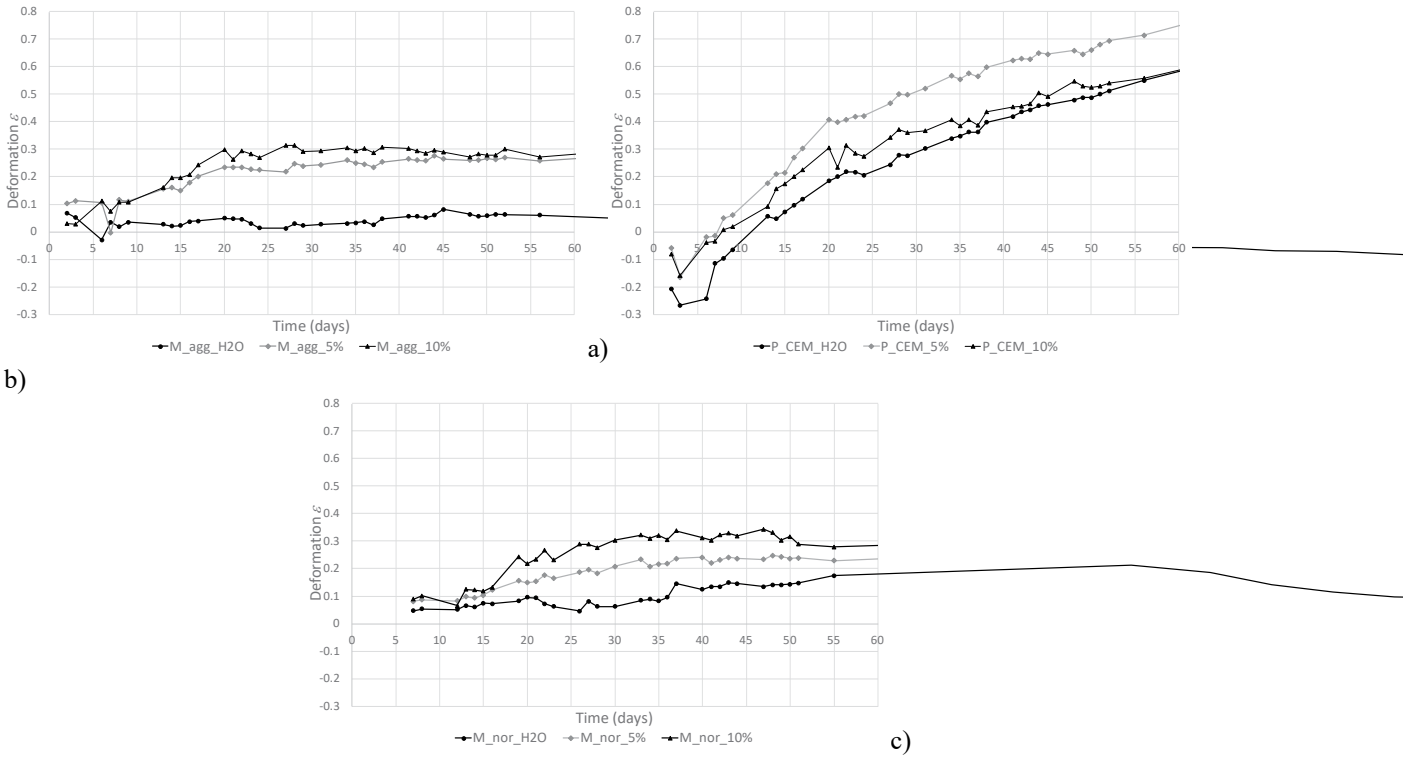

Figure 2. Comparison of the variation of deformation in the first 56 days of testing, referring to the three aggressive agents tested and the mixtures: a) M_agg, b) P_CEM and c) M_nor.

Figure 3 shows the same comparisons but for the entire testing period (889 days).

In this case it is interesting to note that after an initial rather rapid shrinkage of the P-CEM specimens, it stabilises and becomes constant for the entire testing period and for all three aggressive agents. It is not excluded that the continuation of the same test does not lead to different results that are for now unexpected.

Whereas for the M-agg and M-nor mixtures and for the salt concentrations at 5% and 10% after the 500th test day there is an increase in the deformation, perhaps as a consequence of initial cracking of the material for specimens immersed in water, instead, there is an almost constant behavior.

This result indicates that the formation of salt crystals inside of less consolidated pastes does not cause serious problems because they fill the pores and interstices without causing serious pressure on the surrounding material. Over time crystals deposit and during the subsequent immersions they do not have the time to melt, therefore the new attack increases the salt volume and the pressure on the material thus producing micro-fractures which accentuate the deformation, furthermore these results show how the addition of aggregate to the cement paste mixture changes the deformation behaviour of the material.

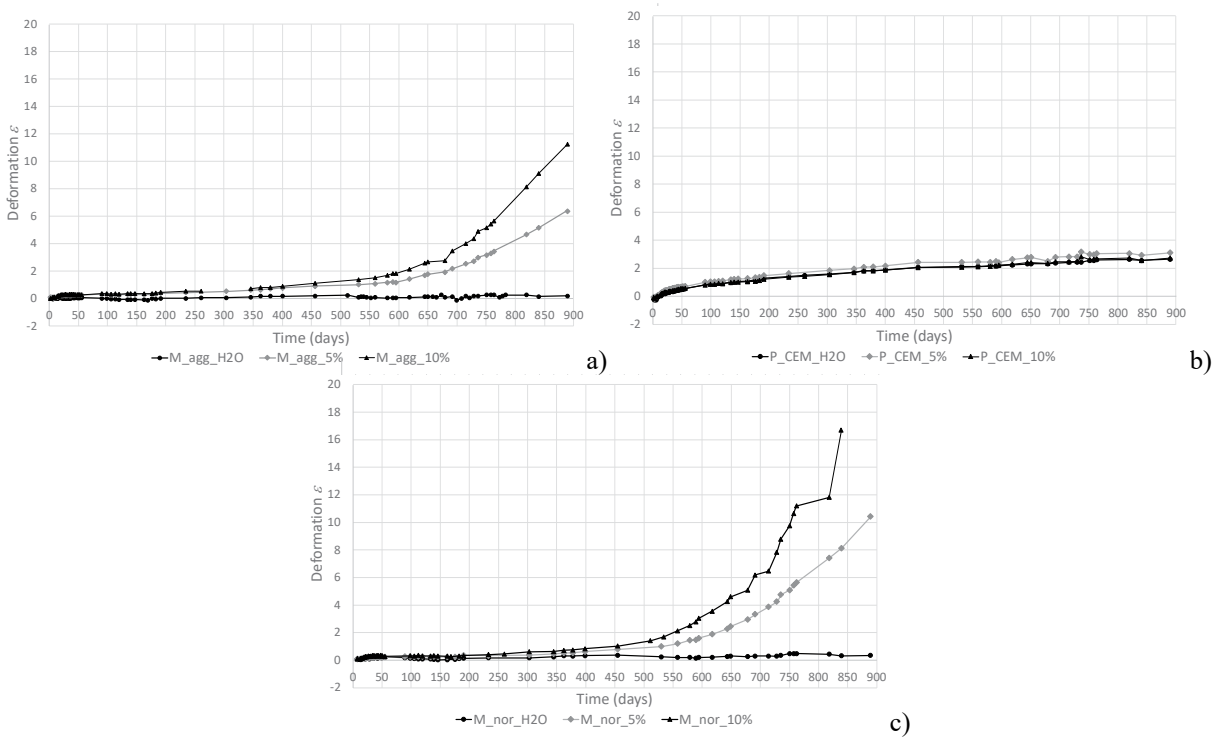

Figure 3. Comparison of the variation of deformation in the 889 testing days, referred to the three aggressive agents tested and the mixtures: a) M_ag: b) P_CEM and c) M_nor.

3.3 Deformation Velocity Survey

From the test procedure adopted and from the results obtained from the quantification of the deformation induced by sulphates attack dissolved in different concentration, the survey and the calculation of velocity were carried out and with which the deformation phenomenon occurred.

The quantification of velocity $\mathbf{v}_i$, relative to each testing cycle, follows the classical definition as reported below:

$$\mathbf{v}_i = \frac{\varepsilon_i}{\left(t_i - t_{(i-1)}\right)} \qquad (3)$$

where: ε_i is the deformation defined in (2); t_i is the instant of testing (measured in days) and $t_{i\text{-}1}$ is the previous instant.

Equation 3 allows to evaluate the variation of deformation velocity instant by instant and to formulate hypotheses on the future of the investigated phenomenon.

3.4. Observation of the Results Obtained.

The calculation of the variations in velocity was performed for all three mixtures investigated in the test (M_agg; P_CEM and M_nor), both for samples immersed in demineralised water (H2O) and for those with a salt concentration of 5% and 10%. The results obtained show interesting aspects that characterise the evolution of the deformation phenomenon.

At first the evolution of the phenomenon was considered in the first 56 days of tests. Figure 4 shows the comparison between the behaviour of the samples at the three different stresses for each type of mixture.

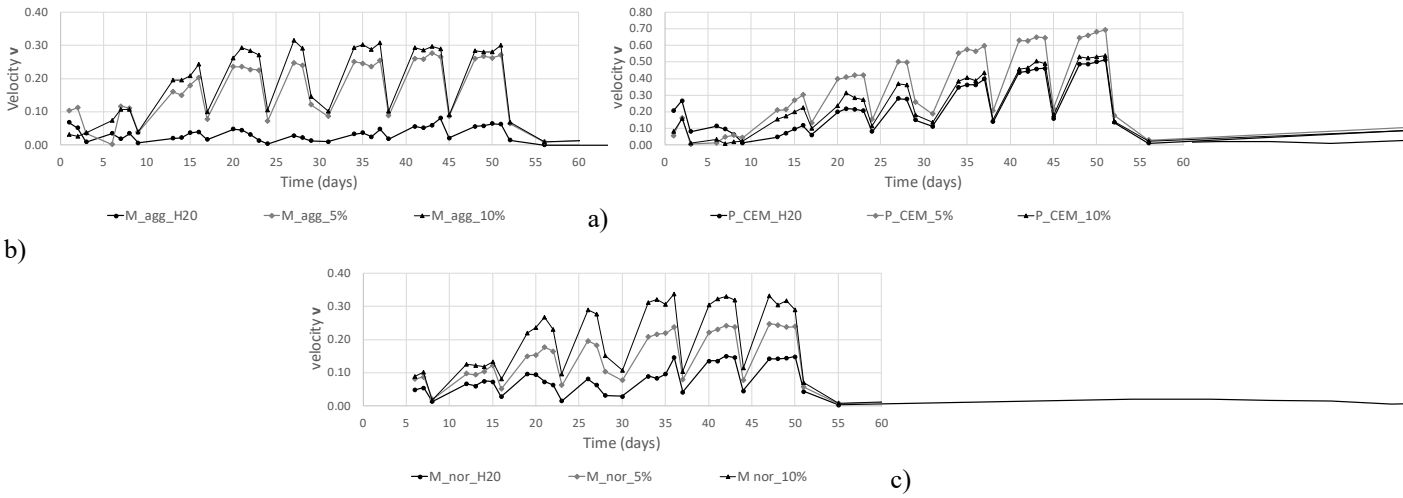

Figure 4. Deformation velocity comparison vs. time for the first 56 days of testing referring to the three aggressive agents tested and for the mixtures: a) M_agg, b) P_CEM and c) M_nor.

Figure 4 clearly shows that for all the mixtures there is a cyclic repetition of velocity increase followed by a stasis phase and subsequently by a velocity decrease phase. This trend seems to be associated with the deformation phases (Figure 2 and Figure 3): when the almost stationary deformation phase ends there is a slowing down of the process which then resumes decisively and with an increase in velocity in the next phase. This behaviour is more regular and marked for the P-CEM mixture.

Figure 5 shows, instead, the trend of the deformation velocity, **v**, for longer test periods.

Here there is a material compromise after 500 days. Test after test, for all the mixtures there is an increase in velocity, a more evident behaviour for the mixtures subjected to saline aggression.

These velocity increases are followed by decreases and subsequent increments. These variations appear to continue to occur every 30 to 70 days. This cyclicality occurs already after the 100th day of the testing.

From the comparison between Figure 4 and Figure 5, the relationship between the increase in deformation velocity and important changes in the deformation phase is even more evident.

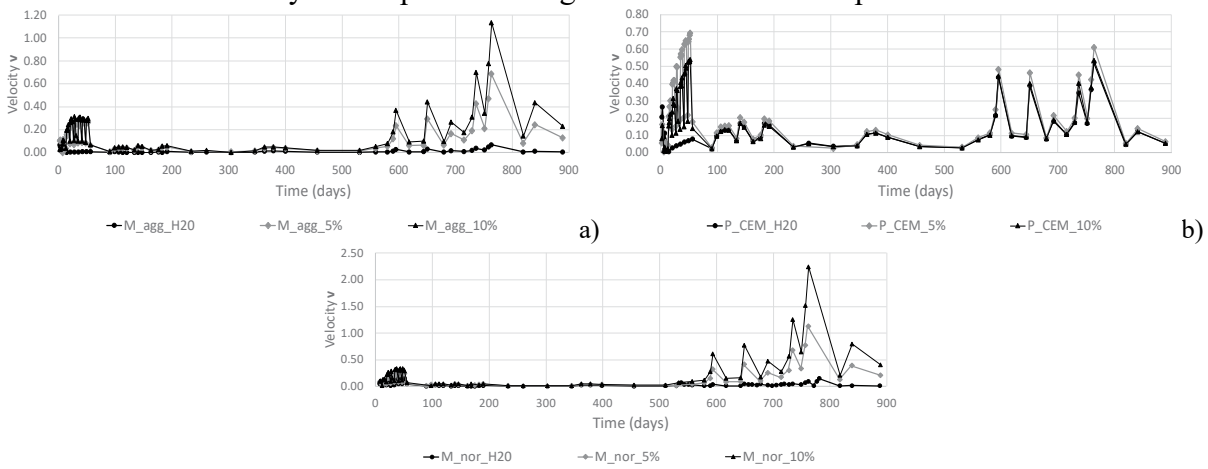

Figure 5. Comparison of deformation velocity vs. time for the 889 days of testing referred to three aggressive agents tested and for the mixtures: a) M_agg;, b) P_CEM and c) M_nor.

5 Conclusions

The laboratory tests applied to specimens of different mixtures and subjected to simulations of different aggressive attacks have shown a propensity to deformation that can be classified in three phases. The first phase takes place in the first 56 test days (test time limit recognised by the legislation). During this phase the velocity shows a periodicity of behaviour that seems to be correlated to the occurrence of a greater deformation after a phase of relative stability; this phase is weekly. The next phase shows a constant deformation behaviour. However, in this phase the velocity shows a certain periodicity and the frequency of the periodicity is in this case variable between 30 and 70 days.

The third phase takes place after the 500-day testing and is typical of the behaviour of saline attacks for M-agg and M-nor. It shows a rather variable deformation velocity (Figure 5a and c), but always with a certain cyclical behaviour, which is matched by a decisive increase in deformation behaviour (Figure 3a and c). Moreover, Figure 3 highlights the different deformation behaviour of P-CEM cement paste compared to M-agg and M-nor mixtures. It is possible that this behaviour is associated with the occurrence of a start of detachment of the material now stressed by the presence of salt crystals inside it. This aspect will be investigated. It is the intention of the authors to proceed with the development of a mechanical test that may monitor this phenomenon.

As for the P-CEM mixture the deformation velocity (Figure 5b) shows the same behaviour recorded for the other mixtures, but with lower values. This is certainly due to a more regular deformation behaviour (Figure 3b).

Abstract. *Cross laminated timber (CLT) are composed of longitudinal layers and cross layers. And as the laminations of the adjoin layers are glued orthogonally deterioration of the laminations such as check and shake and delamination can be rather frequently come out when CLT is exposed to humid and dry cyclic climate. In Japan more than 100 CLT buildings have been constructed and the number of CLT building is increasing. In some buildings the CLT is designed as to be the exterior members and exposed to the outdoor climate. Several CLT buildings that have CLT as exterior members was investigated to make clear what was ongoing on the CLT panels exposed to outdoor climate. Remarkable check and shake, warp and delamination was observed for the CLT in some of the investigated buildings. To bring out the mechanism of the distortion of CLT under humid and dry cyclic climate and to give a solution to prevent deterioration of CLT a series of laboratory tests were conducted. The CLT panels were set in a climate chamber and exposed to a humid and dry cyclic climate. And the moisture content and the movement of the laminations of CLT were measured. The movement was affected by the species of the laminations and also by the direction of the surface, sap-side or heart-side. And the film forming type painting worked well as to prevent the deterioration and the penetrating type painting could slightly reduce the deterioration.*

Keywords: *CLT, Humid and Dry Cyclic Climate, Delamination, Movement, Species.*

1 Introduction

In Japan more than 100 CLT buildings have been constructed and the number of CLT buildings is increasing. In some buildings the CLT is designed as to be the exterior members and exposed to the outdoor climate. And even not exposed to the outdoor climate the surface of CLT in many buildings is exposed to the indoor climate.

Cross laminated timber (CLT) are composed of longitudinal layers and cross layers. And the laminations of the adjoin layers are glued orthogonally. Wood has different swelling and shrinkage ratio for tangential direction and radial direction. It is commonly known that the swelling and shrinkage ration of the tangential direction is approximately two times larger than that of the radial direction. The layer arrangement of CLT cause uneven swelling and shrinkage between the adjoin layers particularly under humid and dry cyclic climate. Oshima, A. (2017) indicated that this uneven swelling and shrinkage between the adjoin layers occasionally cause distortion or deformation of the laminations such as check and shake, warp and delamination.

Lepage, R.T.M. (2012) measured the response of CLT under changing moisture conditions and also simulated the response. CLT produced in Japan are in most cases composed of Japanese species. And there is limited knowledge for the distortion of CLT composed Japanese species. To find a solution to reduce the distortion of CLT the mechanism of the distortion of CLT laminations under humid and dry cyclic climate should be clarified. A series of tests were carried out to estimate the mechanism of distortion of the CLT and to evaluate the capability of surface coating or surface painting against the distortion prevention.

2 Distortion of CLT Exposed to Outdoor or Indoor Climate

Several CLT buildings was investigated to have knowledge of the conditions of the CLT panels exposed to the outdoor or indoor climate. The buildings were investigated 2 to 3 years after their completion. Remarkable check and shake, warp and delamination were observed in some of the CLT panels exposed to the outdoor climate and check and shake were also observed in some of the CLT panels exposed to the indoor climate.

Figure 1 shows a bicycle parking space constructed with CLT panels for their walls and roofs. To protect the CLT panels from the sunshine and rain the panels were painted by some impregnated paint designed to protect wood from the outdoor climate. A certain number of check and shake was observed at the bottom of the wall panels and at the roof panels. And warp and delamination were also observed at the edge of the roof panels. The moisture, rain drop and sunshine (i.e. ultra-violet wave) may have caused these distortions.

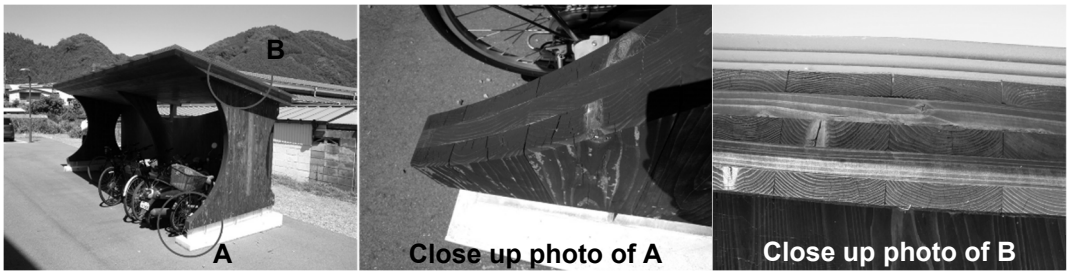

Figure 1. Deformation of CLT exposed to outdoor climate (Bicycle parking space).

Figure 2. Deformation of CLT exposed to outdoor climate (Eaves of CLT flat roof).

Figure 2 shows the eaves of the CLT flat roof. As the edge of the panels was not covered with weather protecting materials such as steel sheet materials or ceramic boards the edge of the panels was fully exposed to the weathering force. And the panels had damages such as check and shake, warp and delamination.

Figure 3(a) shows the delamination of the lamination of CLT panels used for the indoor partition wall. Figure 3(b) shows the check and shake and warp of the surface lamination of the CLT panels located close to the outlet of the air conditioner. The shrinkage of the surface of the CLT panels may have caused these types of distortion.

(a) Delamination of the surface lamination. (b) Check and shake of the surface lamination.

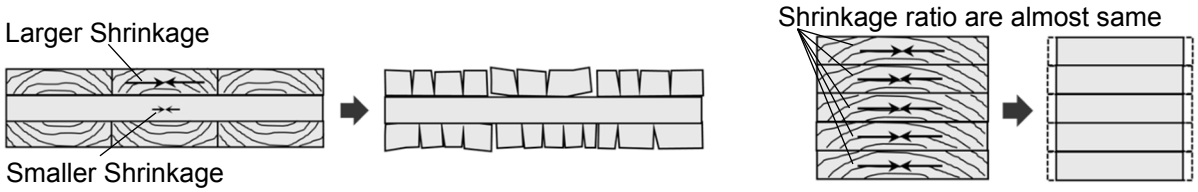
Figure 3. Distortion of the CLT panels under indoor climate.

3 Shrinkage and Swelling of CLT and Glue-Laminated Timber (GLT)

3.1 Assumption of the Deformation

CLT are supposed to shrink as illustrated in Figure 4(a) when it is exposed to a humid to dry climate and the moisture content of the material decreases. This deformation is caused by the composition of CLT (*i.e.* the laminations of the adjoin layers are glued orthogonally) and the shrinkage ratio of wood (*i.e.* the shrinkage ratio of the tangential direction is approximately 20 times larger than that of the axial direction and the shrinkage ratio of the radial direction is approximately 10 times larger than that of the axial direction). This type of deformation also occurs when CLT is exposed to a dry to humid climate.

On the other hand, the direction of the laminations of glue-laminated timbers (GLT) is same for all layers. For this lamination arrangement all the layers will deform in a similar way under humid and dry climate. And the shrinkage or swelling will be same for all layers as illustrated in Figure 4(b).



(a) CLT (b) GLT

Figure 4. Deformation of CLT and GLT under humid to dry climate (Cross section).

The response of CLT under its drying process can be modeled as shown in Figure 5. The different shrinkage ratio of the adjoining layers is supposed to be the reason for the check and shake, warp and delamination of the laminations.

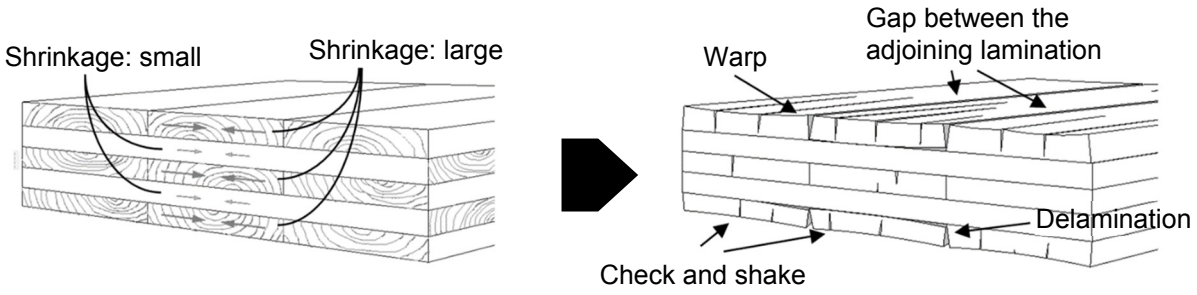


Figure 5. Assumption of the distortion of CLT under its drying process.

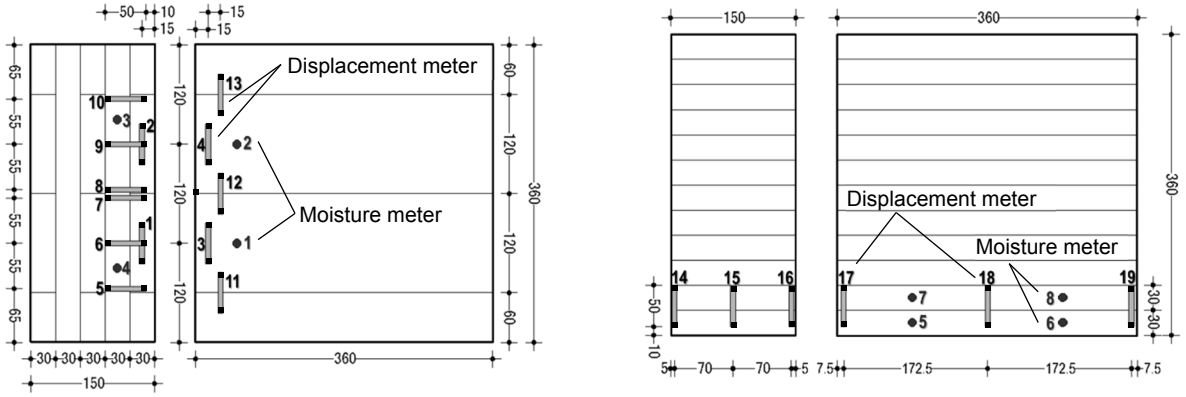
3.2 Testing to Verify the Deformation of CLT and GLT Under Humid and Dry Cyclic Climate

To verify the assumption that CLT and GLT deform differently when they shrink or swell the deformation of both materials were measured under humid and dry cyclic climate. Figure 6 shows the shape and size of the test specimens and the measuring points of the displacement and moisture content. The deformation of the surface and cross section of both materials were measured by displacement meters and the moisture content of both materials was measured by a moisture meter. The species of the test specimens was Japanese Cedar (*cryptomeria japonica*) the most popular species for CLT in Japan. The CLT test specimens had five layers and the thickness of each layer was 30mm. The GLT test specimens had 12 layers and thickness of each layer was 30mm. The test specimens were put in a conditioned chamber and conditioned for 10 days followed by 3 days' humidification, 7 days' drying, 10 days' humidification, 17 days' drying and 3 days' humidification. The relative humidity of chamber during the humidification process was 100% and that of the drying process was approximately 40%.



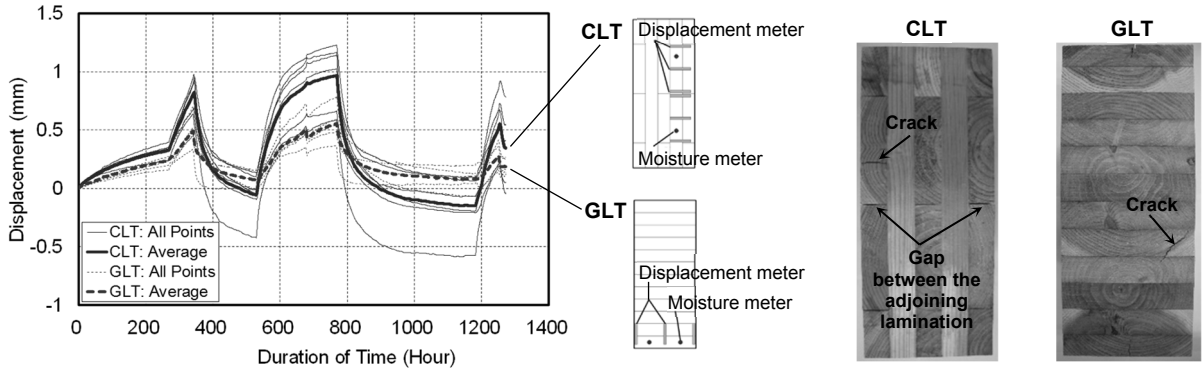
(a) CLT (b) GLT

Figure 6. Shape and size of the test specimens and configuration of the measuring points.

Note: The displacement of CLT was measured at 13 points (the gray bar) and moisture content was measured at 4 points (the gray circle). The local displacement of GLT was measured at 6 points and moisture content was measured at 4 points.

3.3 Results and Discussion

The measured deformation of the cross section of CLT and GLT under humid and dry cyclic climate was measured as shown in Figure 7(a). The narrow lines give the displacement of each measuring point and the thick lines give the average displacement of the measuring points. The deformation of CLT (solid line) is approximately 2 times larger than that of the GLT (broken line). CLT seem to have larger shrinkage and swelling than GLT. The damages of the cross section of CLT and GLT are given in Figure 7(b). Where GLT had only one standing out crack CLT had few cracks on its lamination and gaps between the adjoining laminations.



(a) Deformation under humid and dry cyclic climate (b) Damages of cross section

4 Effect of Weather Resistant Paint Against Distortion Prevention

4.1 Testing to Verify the Effect of Weather Resistant Paintings

To evaluate how the weather resistant paint can reduce the distortion of CLT under humid and dry cyclic climate test specimens painted by weather resistance paints were put in chamber under humid and dry cyclic climate. Four CLT test specimens were tested and three of them were painted by different types of weather resistance paint as shown in Table 1. The species of the test specimens was Japanese Cedar and the size of the test specimens was 1000mm in length, 1000mm in width and 150mm in depth. The density and initial moisture content of the test specimens are given in Table 1.

Table 1. Type of weather resistant paints and density and initial moisture content of CLT test specimens.

Name of test specimens	Type of paint	Density (kg/m3)	Moisture content (%)
Control	No painting	423.5	9.3
Painted-1	Penetrating type 1	415.2	10.6
Painted-2	Penetrating type 2	418.9	13.2
Painted-3	Film forming type	417.4	11.8

The displacement of the test specimens was measured for 8 points for each test specimen. The in-plane displacement and the out-plane displacement of the laminations were measured as

illustrated in Figure 8. The measuring points no.1, 2, 5 and 6 are to measure the out-plane deformation of the laminations and the measuring points no.3, 4, 7 and 8 are to measure the in-plane deformation of the laminations. And the measuring points no.1, 2, 3 and 4 are measuring the deformation of the laminations that have their sap-side on the surface side of CLT and the measuring points no.5, 6, 7 and 8 are measuring the deformation of the laminations that have their heart-side on the surface side of CLT.

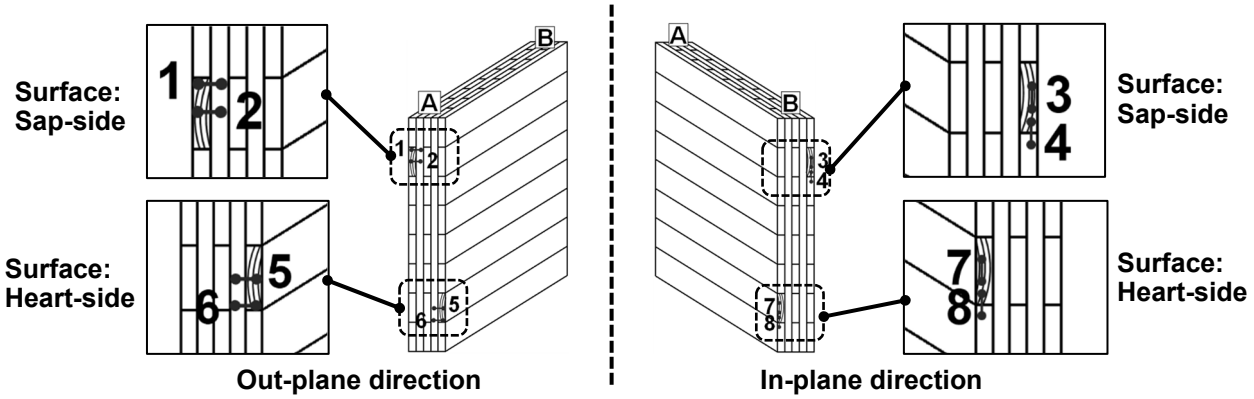

Figure 8. Location of the displacement meters set to measure the displacement of the laminations.

4.2 Results and Discussion

The movement of the laminations measured by the displacement meters no.1, 2, 5 and 6 are given in Figure 9. Figure 9 gives the maximum movement of the four measuring points. The movement of the CLT with no painting (control) was the largest and the movement of CLT painted with film forming type paint was the smallest. The movement of CLT painted with penetrating type paint was almost same to that of CLT with no painting.

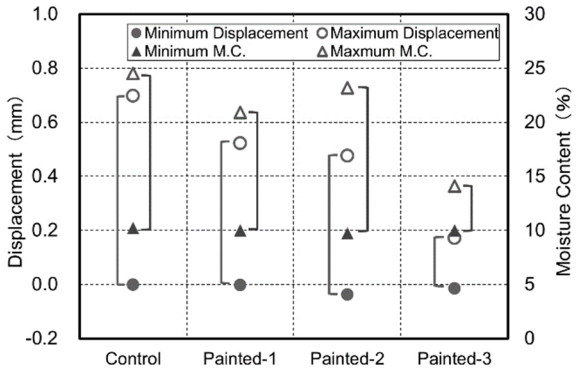

Figure 9. Movement of displacement and movement of moisture content.

Note: ○ gives maximum displacement measured by the displacement meters no.1, 2, 5 and 6 and ● gives minimum displacement. △ gives maximum moisture content of the CLTs and ▲ gives minimum moisture content.

The tendency of the moisture content was almost similar to that of the displacement. The moisture content of CLT with no painting had the largest variation and that of CLT painted with

film forming type paint had the smallest variation. The film forming type paint seems to work well as to reduce the deformation of CLT under humid and dry climate. And the penetrating type paint seem to not work well as to reduce the deformation of CLT.

5 Effect of the Surface Direction (Sap-Side or Heart-Side)

5.1 Testing to Verify the Effect of the Surface Direction

To verify the effect of the surface direction of the out most layer on the distortion of the laminations CLT composed of sap-side on its surface and CLT composed of heart-side on its surface were tested for their distortion. Figure 10 gives the size and shape of the test specimens and the location of the measuring points for deformation and moisture content. The test specimens were 800mm in length, 800mm in width and 90mm in thickness. And the species of the laminations were Larch (*larix kaempferi*) or Sakhalin fir (*abies sachalinensis*). These two species are the northern species in Japan and known as to have relatively high response for moisture content movement. The test specimens were set in a climate that was controlled as to have relative humidity 100% for 6 days followed by relative humidity 40% for 12 days and again relative humidity 100% for another 6 days. The response of the CLT under humid and dry cyclic climate was measured for two directions the out-plane direction and the in-plane direction as shown in Figure 10.

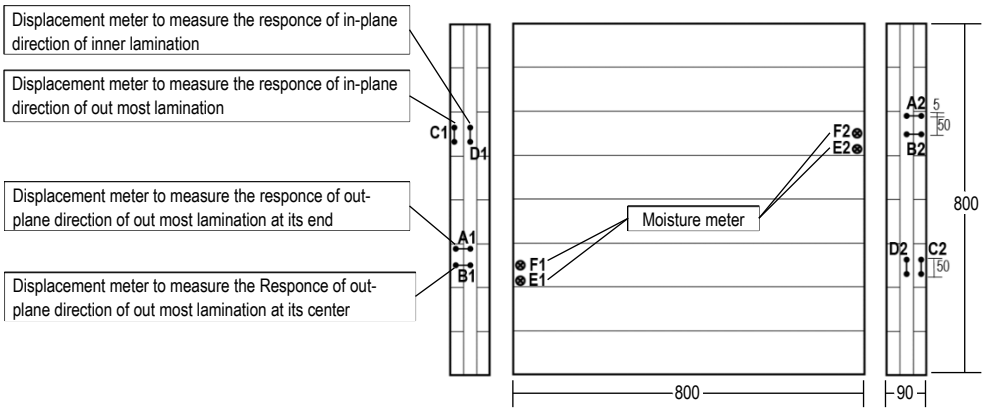

Figure 10. Size and shape of the test specimens, the location of displacement meters and moisture meter.

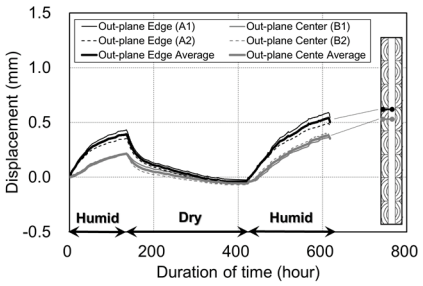
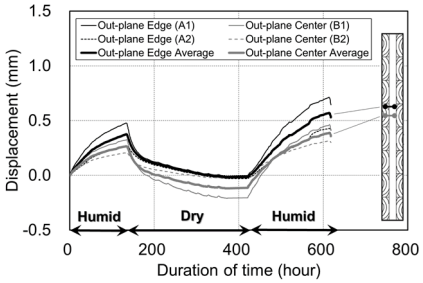
5.2 Test Results and Discussion

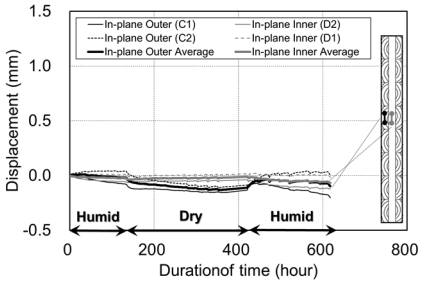
The out-plane movement of the out most laminations of Larch CLT under the humid and dry cyclic climate is given in Figure 11(a) and (b). And the in-plane movement of the out most laminations of Larch CLT under the humid and dry cyclic climate is given in Figure 11(c) and (d). The out-plane deformation of the out most laminations was larger than the in-plane deformation. And in general, CLT composed of laminations with heart wood side on the surface side had relatively larger deformation than CLT composed of laminations with sap wood side on the surface side. The test result for Sakhalin fir CLT was almost same to that of Larch CLT. These test results indicate that one solution to reduce the moisture related deformation of CLT is to arrange the out most laminations so as to cover the surface of CLT with the sap wood side of the laminations.



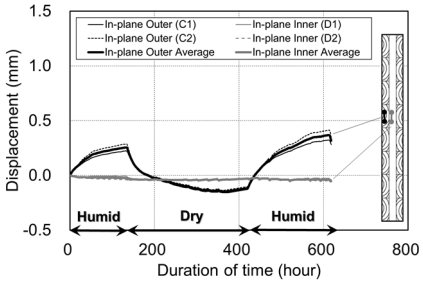
(a) Out-plane direction, Surface sap wood.



(b) Out-plane direction, Surface heart wood.



(c) In-plane direction, Surface sap wood.



(d) In-plane direction, Surface heart wood.

Figure 11. Response of the CLT under humid and dry cyclic climate (Larch).

6 Conclusion

A series of tests were carried out to estimate the mechanism of distortion of the CLT and to evaluate the capability of surface coating or surface painting against the distortion prevention. The results are summarized as follows;

- The deformation of CLT was approximately two times larger than that of the GLT. CLT showed larger shrinkage and swelling than GLT. The arrangement of the lamination si supposed to cause this difference.
- The film forming type paint seems to work well as to reduce the deformation of CLT under humid and dry climate. And the penetrating type paint seem to not work well as for reducing the deformation of CLT.
- One solution to reduce the moisture related deformation of CLT is to arrange the out most laminations of CLT so as to cover the surface of CLT with the sap wood side of the laminations.

Determination of the Deterioration Characteristics of Facade Materials: A Case Study

Nil Kokulu

Antalya Bilim University, Faculty of Fine Arts and Architecture, Çıplaklı Mh. Akdeniz Blv. Pk:07190 Döşemealtı, Antalya, nil.kokulu@antalya.edu.tr

Abstract. *Deterioration of the facade materials of a building and its importance are topics that are not getting the attention that they deserve and need. If a material can't meet its accepted performance criterion during its service life then deterioration may occur on the surface, inside, under or at the structure of the material. Environmental, construction related, and human related agents collaborate with the mechanisms and make an effect which concerns the durability. Therefore, detecting the deteriorations of the materials play an important role for the maintenance planning. This study aims to detect the agents, mechanisms and effects of the deteriorations of a case building. A systematic approach was developed by making literature review. Hostile environmental analysis and building facade inspection have been made by the visual observations on a specific day. Deteriorations occurred at granite, wood composite, aluminum, glass and ceramic materials have been discussed.*

Keywords: *Environmental Deterioration, Facade Inspection, Agents, Mechanisms, Durability.*

1 Introduction

Building components are expected to maintain their required performance levels over their service life. In order to succeed in this process, identifying the environment and the future cause of the deteriorations are a precondition. During the literature reviews, it is seen that facade materials such as granite, wood composite, aluminium, glass and ceramic are exposed to deteriorations as time progresses.

According to Grelk *et al.* (2007), bowed granite cladding is a problem caused by the temperature differences and the moisture. Also, Marie (2013), in her article, states that natural stone facades perform differently over time and the colour of the facade may change according to cracking, dirt, corrosion, carbonation and biological colonization. This change causes visual aesthetic problems and the problems may differ according to person's characteristics.

Morrel *et al.* (2010), state that as a biological agent, white rot fungi and brown rot fungi can easily deteriorate wood in wood plastic composites (WPC) and may cause loss of weight depending on the climate. The most important factor was determined as moisture for fungal decay. They also argue that WPC's bending properties change when exposed to fungi. The authors go on to say that physical agents are also important when deterioration of WPC's is the subject. Although the damage seems like it is on the surface, chemical discoloration occurs beneath the surface and it is very difficult to remove. Also, UV degradation changes the characteristics such as colour, surface composition and mechanical changes of WPC's.

According to Honfi *et al.* (2014), in their article about the glass structure failures, they described two kinds of exposures which are faults and errors. Faults are the physical reason for the failures such as excessive loading, surface damage and moisture, while errors are the logical reason of the exposures such as modelling and calculation errors, poor manufacturing and detailing errors.

Corrosion is most common in metals and observed to some extent in ceramics. Khanam *et al.* (2015), state that corrosion on aluminium has seen because of the saline environment. They state that chloride ions attack to aluminium film and made pits on the top. This causes structural failure of the material.

Besides the obvious problems of breakage, ceramics deteriorate during their service life according to temperature, external loads, vibrations and environment. They may contain soluble salts which can crystallize at or near the surface and destroy the material. Also, unstable glazes of the ceramics may cause crumbs on the surface (Museum Management Programme, 2018).

In this study, the deteriorations formed in granite, wood composite, ceramic, aluminum and glass and their causes have been explained systematically. Agents, mechanisms and effects of the deteriorations were identified. Results and expected damage are explained at the end.

2 The Case Study

2.1 Preparing the Data Analysis

In this section, specific data, information and analysis of the front facade of the building are intended to provide a proper method for conducting the deteriorations. The first part of this section provides a draft of the proposed systematic approach to study that reflects on an individual understanding and perception of the research process. The second part consists the inspections of the hostile environment and the facade of the building. For the hostile environmental analysis, site selection, building information and the climate data were studied. For the facade of the building, facade materials and their structure system were investigated.

2.2 Systematic Approach to Study

A systematic approach is an outline of the researcher for determining the steps of the case study (Figure 1).

Macro environment analysis focuses on the continental observations consisting of location, orientation of the building, surrounding buildings, traffic and pedestrian roads and vegetation at the site. Meso environment analysis consist of climate type, dominant wind direction, temperature, precipitation, air content, pollution and soluble salts which influence the building. Micro environment analysis consist of age, height, architectural form, function, facade materials, material types, their characteristics and material structure system.

Data collected after the macro, meso and micro analysis and was used as a component while making the visual observations. Visual observations consist of the sunny and rainy-day conditions of the east facade. According to this conditions, agents of the deterioration have been analyzed by taking the feedback from the literature review. According to Kuş (2018), agents in the built environment very rarely act alone but neither work together. The effect of the agent occurs when a mechanism reveals its appearance.

Performance deteriorates at a rate depending on the environment, the design of the building, building materials, maintenance and usage (Song and Lim, 2016). In this case, since the building is at a very young age, it is not possible to visually observe the deteriorations but estimate them with the help of site analysis and visual observations.

Although all the visual information and the literature review provided, it is not possible to be certain about the future deteriorations.

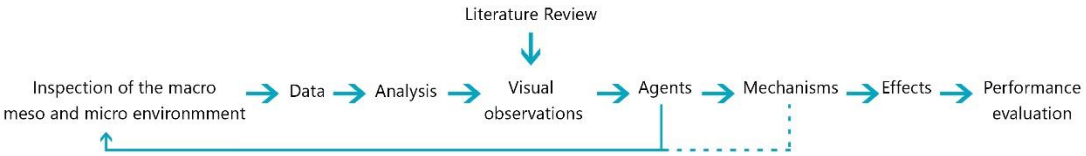

Figure 1. A systematic approach.

2.3 Macro Environment

The building is located on the intersected corner of Portakal Çiçeği street and 1460 street in Antalya, Turkey. It is a seven storey-high residential building on the right with a distance of 8.40 meters, ten storey-high residential building on the back with a distance of 14 meters and front with a distance of 40 meters and two storey-car parking on the southwest with a distance of 21.5 meters. The main entrance faces to east (Figure 2). This facade always takes the sun directly without having any shading areas. The temperature and the light play a crucial role on materials. 1460 street and Portakal Çiçeği street have intense traffic. This causes air pollution which may create deterioration. The distance from the sea is 1 km and the height of the building from the sea is 22.5 m. The pedestrian roads and the vegetation around the building can be seen in Figure 3. There is an open area in front of the main facade. There are also car parking areas on the east and the west facade.

Figure 2. East facade of the building.

2.4 Meso Environment

Antalya has a hot humid climate with rainy winters. The dominant wind direction is from northeast to southwest (Figure 3). The temperature changes 10°C to 35°C through the year. October, November and December are the months that take most of the rainfall (Holiday-weather, 2018).

The air contaminates soluble salts because of the distance within the sea. This may cause material deteriorations by collaborating with the mechanism. According to SİM Project, Sulphur dioxide and particulate matter has been diagnosed in the air (Sürekli Eğitim Merkezi, 2019). Sulfur dioxide and its acid derivations are known to cause considerable damage to materials. The east and north facade is open whereas the south and west facade are in the shade caused by surrounding buildings. There isn't so many people around the building except the Wednesdays because of the local bazaar. The building welcomes the animals.

Figure 3. The site plan, the section of the site (on the left) and dominant wind direction and the movement around the building (on the right).

2.4 Micro Environment

The six-storey office building is three years old. It has a rectangular form with the dimensions of 42.50 meters to 18.95 meters. The height of the building is 18.60 meters. The facade materials of the modern designed building are ceramic, aluminum, glass, granite and wood composite (Figure 4). The properties of the materials can be seen on Table 1.

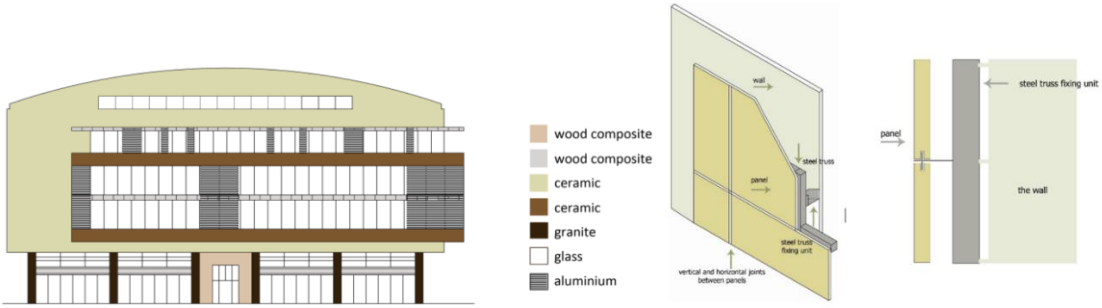

Figure 4. Facade materials of the building and the structure system of the materials.

Table 1. Properties of the facade materials.

Materials	Color	Surface finish
Ceramic	beige	unglazed
Ceramic	brown	unglazed
Granite	black	polished
Aluminium	white	polished
Wood composite	white	flat
Wood composite	light brown	flat
Glass	blue	flat

Steel truss metal panel curtain wall system has been used for the facade system. A cross or vertical steel truss is installed on the structure first. Then, a panel is fixed to the steel truss. Finally, the vertical and horizontal joints between the panels are filled with back-up materials and then finished with sealant. No anchorage system and no joints can be seen from the external (Figure 4) (Song and Lim, 2016). The corner adjoining parts of the granites are unpolished. This part may take water and air to the inside and different types of deteriorations may occur.

3 Analysis

3.1 Visual Observation Information

For the case study, visual observations are made. The observations took two hours from 12.00 to 14.00. The materials on the east facade have been examined according to their instant conditions in a sunny day and in a rainy day (Table 2). Also, future deterioration problems are discussed.

Table 2. Visual observation conditions.

	Sunny day conditions	**Rainy day conditions**
Observation day	10.11.2018	17.11.2018
Climate type	Winter	Winter
Temperature	17°C	14°C
Humidty	43%	86%
Wind direction	NE to SW	NW to SE
Wind speed	3 km/h	21 km/h
Rain ration	0%	70%

According to sunny-day and rainy-day conditions shading areas of the building have been examined. The facade of the building takes most of the sun except upper part of the facade of the ground floor in a sunny day, while it is totally in shade in a rainy day.

3.2 Agents, Mechanisms and Effects

Agents of deteriorations have been analyzed while making environmental analyses. 5 types of agents have been observed. These agents are grouped as; physical agents (temperature, moisture, light and wind), chemical agents (water, air, salts), biological agents (plants, birds, mold), design decisions, vandalism.

There exist 4 major typical mechanisms of deterioration, which lead to failure. These are grouped as; mechanisms caused by material properties, mechanisms caused by material structure properties, environmental mechanisms, construction related mechanisms.

A review of the causes of failure identified twelve of the most frequent sources of deterioration in facade materials are; dirt and dust accumulation, spalling, biological colonization, staining, corrosion, efflorescence, gypsum crust, cracks and breakage, discoloration, UV degradation, chipping, scratches. Agents, mechanisms and effects of the deterioration for each facade material can be seen in Table 3.

4 Results and Discussions

In this study, visual observations have been made to determine the future deteriorations. Since the building is only three years old, only the dirt deposition and the discoloration on the surface of the granites and discoloration on the WPC's caused by the rain have been observed. Expected deteriorations of the materials are discussed below.

Dirt and dust deposition occur on the cracks and on the surfaces of the panel with the help of the wind. High traffic areas cause great accumulation of dirt (Museum Management Program, 2018). The east facade is located on one of the most intense traffic areas. Dirt and dust deposition would be seen on the granite columns in the future. Wind can bring salts in the

air to the panel surface which can cause spalling (Museum Management Program, 2018). Spalling couldn't be seen on the front side of the columns. But it is seen on the north side of the columns. The reason is, the east side takes the sun more than the north side and can easily dry whereas the north side is always on shade. Biological agents such as bacteria, algae, fungi, and moss grow on stone surfaces and cracks with the help of humidity (Museum Management Program, 2018). The lower side of the columns can easily deteriorate because they are exposed to water more than the higher parts. Color changes on the panel surfaces may be caused by the design decisions. The sun plays an important role for this type of deterioration. This may also effect visual aesthetics (Mauko *et al.*, 2006).

Bowing and expansion due to temperature changes (Grelk *et al.*, 2007) may occur on the front side of the columns with the help of the temperature. Staining from water absorbtion or vapour condensation may occur on granite (ICOMOS, 2019). The corners of the granite are capable of water intake. Corrosion occurs when the chemical reactions happen (Shaw and Kelly, 2006). The corners of the granite have started to corrode and may cause structural problems in the future. Ceramics may contain soluble salts that can crystallize at or near the surface and destroy the panel (Museum Management Program, 2018). The adjoining parts of the ceramics are capable of salt intake. So, the efflorescence is possible.

Because of the location of the facade, air pollution may cause wet deposition where there is no rain-wash. This may cause gypsum crust (Agnes *et al.* 2012). Observations after the rain showed that, some part of the ceramics dry longer than the other parts. Condensation can lead to mold growth, noxious odors and deterioration of building finishes of the panels (Campante and Paschoal, 2002). Biological activity would be seen on the cracks of the ceramics (Agnes *et al.* 2012). Cracking occurs when thermal movement isn't provided (Goldberg, 2002).

Figure 5. Facade of the building (on the left), facade of the building in 30 years (on the right).

The panels would be affected by the temperature. It is clearly seen that no expansion joint was used, either vertical or horizontal. This may cause cracks and/or breakage even falling of the panels. Corrosion may occur on the metal structural supports and anchors of ceramic tiles (Campante and Paschoal, 2002). The panel joints may easily take water and air inside of the structure. Color changes create visually unproper aesthetic that can be seen on the ceramic tiles (Song and Lim, 2016). The reason of this can be dirt deposition which comes with the wind. Biological agents may use wood as a food source or for living with the help of water intake from the cracks or joints. This may cause weight loss of the panel (Morrell *et al.*, 2010). The WPC's on the east facade can easily take water from the rain. It is clearly seen that air pollution

came with the rain and created a color change at the surface. Because of the absorption characteristics of the WPC's moisture may cause damage of the material especially on the shading areas (Morrell *et al.*, 2010). The lower parts of the wood composite look better than the upper parts. It is probable that the upper parts would have a mechanical degredation in the future. Especially in the summer, the sun plays an important role. Wood absobs the UV lights. This causes loss of surface quality and change in the mechanical properties. UV degradation would be seen at the WPC's especially on the unshaded areas in the future.

Table 3. Agents, mechanisms and effects of the deteriorations.

GRANITE	**Agents**	**Mechanisms**	**Effects**
	Wind	Pollution caused by traffic	Dirt and dust accumulation
	Moisture + wind	Salts on the surface	Spalling
	Mositure + wind	Cracks	Biological colonization
	Design decisions	Sun	Color changes
	Temperature	No gaps between the panels	Bowing and expansion
	Moisture	Panel joints	Staining
	Air + water	Panel joints	Corrosion
CERAMIC	**Agents**	**Mechanisms**	**Effects**
	Soluble salts	Adjoining parts of the ceramic	Efflorescence
	Design decisions	Air pollution	Gypsum crust
	Moisture	Shading areas	Mold growth, Noxious odors
	Temperature	No gaps between the panels	Cracks, Breakage
	Air + water	Panel joints	Corrosion
	Wind	Air pollution	Discoloration
WOOD COMP.	**Agents**	**Mechanisms**	**Effects**
	Biological agents	Water intake from the cracks	Weight loss of the material
	Wind	Air pollution	Discoloration
	Moisture	Absorption characteristics of wood	Damage
	Light	The color of the panels	UV degradation
ALU MINI UM	**Agents**	**Mechanisms**	**Effects**
	Air + water	Profile properties	Corrosion
	Design decisions	Sun	Color changes
GLASS	**Agents**	**Mechanisms**	**Effects**
	Wind	Design decisions	Breakage
	Birds	Structural problems	Chipping
	Human related	-	Scratches
	Moisture	Application failures	Discoloration

Because of the design decisions, wind cause breakage of the glass panels which are not in a proper location of the facade (Honfi *et al.,* 2014). This may occur on the northeast side of the building because of the dominant wind direction. Birds cause chipping on the edges of the panels arised from the structural problems (Honfi *et al.,* 2014) This may occur on the upper parts of the façade. Vandalism may occur on the lower parts of the building on glass. Cleaning the panels with inappropriate materials may lead to deterioration. Moisture may ruin the mechanical and physical properties of stone and this causes discoloration. Since most of the building gets rain-washed, the glass panels can easily lose their visual aesthetics.

The method presented in this paper was developed as a tool for the prediction of the service life of building components. Deteriorations have been anaylzed by a systematic approach using environmental analysis, visual observations and literature review. It is clearly seen that, deteriorations on the facade of the building will occur in the future (Figure 5).

Abstract. *There is a continued process to implement innovative materials to enhance the sustainability and durability of the built infrastructure. Technologies developed over the last two decades have facilitated the use of glass fiber reinforced polymer (GFRP) composites as internal reinforcement bars (rebars) for concrete structures, which have proven to be an alternative to traditional steel reinforcement due to significant advantages, such as magnetic transparency and, most importantly, corrosion resistance, equating to durability and structural life extension. This study evaluates the durability of three different available and most commonly used GFRP rebar types, based on exposure to aggressive environments, such as those experienced in coastal areas. For that, the specimens were expose to high pH seawater solution (that simulates the alkalinity of the concrete exposed to seawater), at 60 ºC for different periods of time: 45, 90, and 180 days. The durability of these GFRP rebars was assessed by testing four different physio-mechanical properties, including: tensile strength, elastic modulus, and transverse and horizontal shear strength. Preliminary results show that the resilience of the GFRP rebars after being exposed to high pH seawater at high temperature, varies considerably among the three different types. The tensile strength was the most affected physio-mechanical property.*

Keywords: *Composites, Durability, GFRP Rebars, Resilience.*

1 Introduction

The use of GFRP bars (Glass Fiber Reinforced Polymer) is gaining importance as internal reinforcement for reinforced concrete (RC) structures, primarily due to the corrosion-resistant properties. One of the most important applications for this alternative reinforcement is its use in coastal RC structures where corrosion of traditional steel rebars is critical (Nolan, Rossini and Nanni, 2018) and poses significant issues for the longevity and cost of the infrastructure. This is especially important in marine environments due to: i) salt water in direct contact with concrete structures, through foundations or by air and ii) the need to increase the infrastructure's future resilience and sustainability to sustain the numerous effects related to climate change, such as the sea level rise. These critical needs may no longer be of concern with the use of

GFRP bars; which are composite reinforcing bars made of glass fibers embedded in a resin matrix and are non-corrosive. Because the driving force for such alternative reinforcement bars is the lifespan extension of RC structures, the durability of GFRP rebars must be carefully evaluated, as these aspects are fundamental for the expansion and extended application of this technology.

Concrete is considered a highly alkaline material, with typical pH values for freshly placed concrete above 12.5 to 13.9 for concrete made with high alkaline cement (Grubb, Jennifer A., *et al.,* 2007). When using steel reinforcement, the high alkalinity of the concrete provides corrosion protection to the steel by providing a passive layer of iron oxide (Fe_2O_3). Throughout the service life of the reinforced concrete structures, different phenomena such as carbonation, ingress of corrosive agents through voids and cracks, etc. lead to the breakdown of this passive layer, favouring the corrosion of steel. With GFRP rebars, however, the high alkalinity of concrete does not have a protective effect as for the steel, but it appears to affects the durability of the rebars in a negative way instead.

In the literature, different studies exist that have proven the deterioration of the tensile properties of GFRP rebars embedded in concrete or subjected to high pH solutions which simulate the alkalinity of the concrete, through accelerated aging protocols (Dejke and Tepfers, 2001; Chen, Davalos and Ray, 2006; Robert, Cousin and Benmokrane, 2009; Robert and Benmokrane, 2013; Wang, X.-L. Zhao, *et al.*, 2017). In addition, Wang *et al.* (2017) evaluated the effect of the simulated seawater and sea sand concrete on the horizontal shear properties of GFRP rebars, while Ruiz Emparanza *et al.* (2018) Yan *et al.* (2017) and Dong *et al.* (2016) assessed the resilience of bond properties of GFRP rebars embedded in concrete and exposed to seawater. Each of these studies are focused on the resilience of a single mechanical property, and to the best knowledge of the author, no research exists that integrates a combined durability assessment of different mechanical characteristics, which would help to have a better understanding of the degradation mechanism affecting GFR bars.

Therefore, this study is comprised by the evaluation of the durability of three different commercially available GFRP rebars exposed to a combination of high pH and seawater, simulating coastal reinforced concrete structures. The rebars were aged for up to 180 days at 60°C to accelerate the degradation process. High temperature is used since it is expected that the rate of reaction will double every 10°C (Pauling 1988). A temperature of 60°C was chosen based on the practices found in the literature (Dejke and Tepfers, 2001; Chen, Davalos and Ray, 2006; Robert, Cousin and Benmokrane, 2009; Robert and Benmokrane, 2013; Wang, X.-L. Zhao, *et al.*, 2017). Four different mechanical properties were tested: tensile strength, modulus of elasticity, transverse shear strength and horizontal shear strength.

2 Experimental Program

Three types of GFRP bars, denoted as A, B and C, were tested for comparison purposes due to diversity of the products in the GFRP rebar market (Ruiz Emparanza, Kampmann and De Caso Y Basalo, 2017). All tested bars in this study had a nominal diameter of 10-mm and were made of continuous EC-R glass fiber and impregnated with a vinyl ester resin. However, the manufacturing process and surface enhancements varied among them: Type-A bars were sand-coated, Type-B were helically wrapped, while Type-C were ribbed (see Figure 1).

Figure 1. GFRP rebars Type A, B and C (from left to right).

The focus of this study was to assess the mechanical performance of three GFRP bar types before and after being aged in simulated seawater concrete pore solution. Four different mechanical properties such as tensile strength, modulus of elasticity and transverse and horizontal shear strength were evaluated. For every property and exposure condition, a minimum of three specimens were tested. Table 1 summarizes the test matrix with the corresponding standardized test method used in this study.

Table 1. Test Matrix for durability assessment.

Rebar type	Temp. °C	Duration Days	Mechanical Property	Test Method
A B C	60	45 90 180	Tensile Strength Modulus of Elasticity	ASTM D7205
			Transverse Shear Strength	ASTM D7617
			Horizontal Shear Strength	ASTM D4475

In addition to the tests run on specimens that were aged at 60 °C for 45, 90 and 180 days as seen in Table 1, three repetitions per mechanical property were tested on non-exposed specimens. These results were used as benchmark to assess the resilience of the mechanical properties after the accelerated aging protocol.

2.1 Simulated Environmental Exposure Condition

The accelerated aging of the GFRP bars specimens was achieved by completely immersing the bars into a to high pH seawater solution at 60 ºC and different exposure times (45, 90 and 180 days). The seawater used was directly taken from Key Biscayne (Florida, USA). The solution was made by dissolving calcium hydroxide, sodium hydroxide and potassium hydroxide in seawater (2 g of $Ca(OH)_2$ + 2.4 g of NaOH + 19.6 g of KOH per liter of seawater). The mass concentrations of the solution were chosen according to Chen et. al 2006 (Chen, Davalos and Ray, 2006). The high alkalinity solution simulates the pore solution of normal concrete with a pH value of about 13.6.

2.3 Specimen Preparation

After each exposure condition, the GFRP rebars were extracted from the solution and prepared for testing according to the corresponding ASTM standards. The preparation of the specimens used to test the transverse shear strength consisted of cutting the rebars to 230 mm specimens while the samples for horizontal shear were cut to a length of 6 times the diameter (60 mm). The preparation of the tensile samples to assess the ultimate tensile strength and modulus of elasticity, was more extensive: after the rebars were cut to length of 1000 mm, protective anchors were installed at both ends of the samples to protect the rebar when being gripped by the loading machine. The anchorage system was accomplished by a 300 mm long steel pipe filled with expansive grout which will reduce lateral stresses during griping, since GFRP rebars are weak in the transverse direction compared to the longitudinal one.

2.3 Testing Procedure

Each of the tests were conducted in accordance with the corresponding ASTM: the test setups are shown in Figure 2.

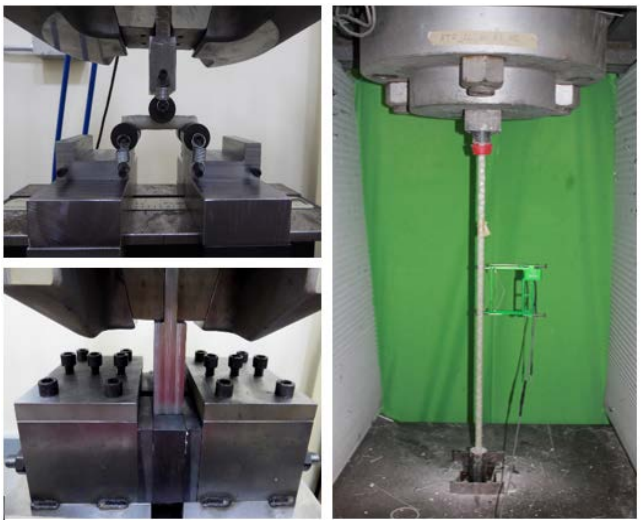

Figure 2. Test setup: horizontal shear test (top left), transverse shear test (bottom left), and tensile test (right).

In this study, all tests were performed by applying displacement-controlled loading using a Baldwin machine with a capacity of 890-kN for the tensile test, and a 133-kN Instron test frame

for transverse and horizontal shear tests. The test rate for the tensile test was 2 mm/min, while for transverse and horizontal shear test specimens were tested at a rate of 1.3 mm/min. As per the corresponding ASTMs (see Table 1), for transverse and horizontal shear tests, the crosshead displacement and the load were recorded. For the tensile tests, in addition to the load, each of the specimens were instrumented with a 100 mm long extensometer to record the strain, which was then used to determine the modulus of elasticity.

3 Results and Discussion

For the three different types of rebars within the scope of this research project, four mechanical properties of unaged and aged specimens were evaluated.

3.2 Unaged Samples

The mechanical properties for 'as-received' GFRP bars used in this study are summarized in Table 2. Mechanical characterization of pristine GFRP bars provided unconditioned values as a reference for residual strength after exposure.

Table 2. Nominal mechanical properties of 10mm diameter reference GFRP bars.

Rebar type	Tensile Strength		E-Modulus		Transverse Shear Strength		Horizontal Shear Strength	
	Avg.	CoV	Avg.	CoV	Avg.	CoV	Avg.	CoV.
	MPa	%	MPa	%	MPa	%	MPa	%
A	953.8	5.5	51570	5.1	212.4	4.8	42.9	7.7
B	834.0	5.5	55340	2.0	194.5	3.3	45.3	5.4
C	982.5	4.3	54570	6.0	211.2	2.6	50.3	5.6

3.2 Aged samples

After being exposed to high pH seawater solution for 45, 90 and 180 days, the aged samples were tested, and the results obtained for each of the four mechanical properties were compared to the benchmark values obtained from the unaged specimens, to obtain the retention over time, as shown in Figure 3 ,4 and 5.

For all the rebar types, the tensile strength was the most affected property with a reduction of up to 41% for Type-A, while the tensile capacity for Type B and C decreased 29% and 20% respectively. Compared to the literature, Chen *et al.* (2006) saw higher degradation (about 70% of degradation after 180 days) when exposing GFRP rebars to the same solution (except they used tab water instead of seawater to mixed with the same proportions of hydroxides).

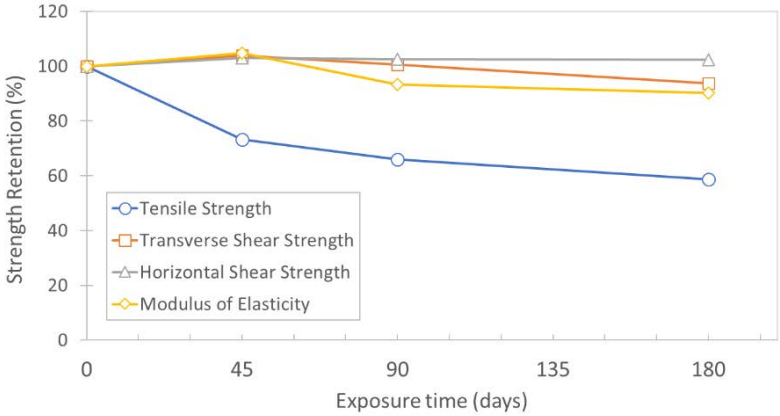

Figure 3. Retention of the tested mechanical properties for Type-A rebars.

This could be due to the lesser development of the GFRP products back in 2006. More recent research conducted by Robert *et al.* (2013) showed a lower reduction (about 10%), but the simulated seawater pore solution had a lower pH (12.15 compared to 13.5 of the current study) and the aging temperature was of 50 °C instead of 60°C.

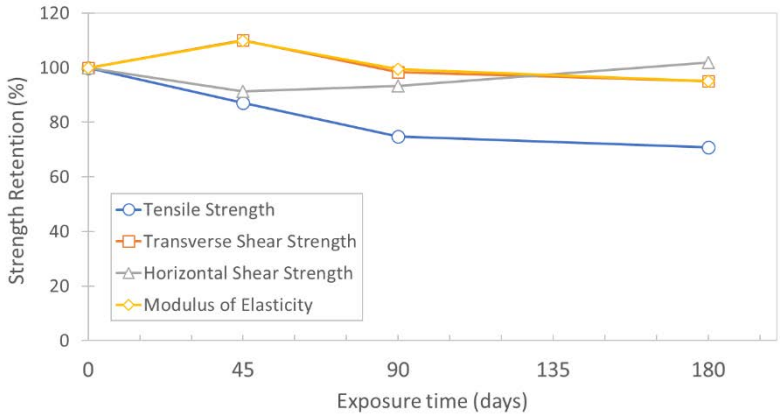

Figure 4. Retention of the tested mechanical properties for Type-B rebars.

The second most affected property was the modulus of elasticity, even if the reduction was relatively low: between 5% and 13%. These values are aligned with the data found in the literature (Robert, Cousin and Benmokrane, 2009; Robert and Benmokrane, 2013), where it was seen that that degradation of the modulus was insignificant compared to the reduction of the maximum tensile capacity. It is believed by the authors that a degradation of the fiber and resin interface takes place with the time, which affects the stress transfer between fibers. This reduction is more noticeable at a critical strain (related to the maximum tensile strength) where the decrease in the stress transfer capacity may lead to the inability to activate all the fibers of the cross section of the rebar which will result in higher strains in those fibers that are being engaged. This will then cause failure of individual fibers at an earlier stage, leading to a premature failure of the rebar. However, since the elastic modulus is not related to individual

or incremental fiber failures but rather to the sum of the elastic strain all along the coupon or rebar gage length, is not that heavily affected.

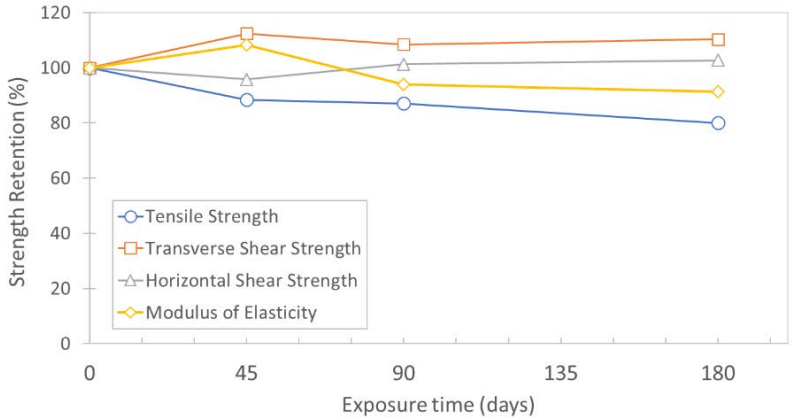

Figure 5. Retention of the tested mechanical properties for Type-C rebars.

Finally, for all the rebar types, the deterioration in terms of transverse and horizontal shear capacity was insignificant. Similar behavior has been reported by Benmokrane *et al.* (2015), in which GFRP bars (vinyl ester resin matrix with E-glass fibers) where exposed to alkaline solution (pH 12.6 – 13.0) and resulted in horizontal and transverse shear strength reduction of 5% and 10%, respectively, after 5,000 h at 60°C. This was also seen by Dejke *et al.* (2001), even though Wang *et al.* (2017) saw a decrease in the horizontal shear capacity after the rebars being aged in a high pH solution. This decrease can be related to the use of different types of rebars, specially to the type of fiber the rebars tested by Wang *et al.* (2017): E-Glass was used instead of E-CR Glass, being this last one the upgraded version of E-Glass, with corrosion resistance features.

4 Conclusions

In this study, the durability of three different GFRP rebar types was assessed after being exposed to a high pH seawater solution at 60 ºC and different exposure times (45, 90 and 180 days). Four different mechanical properties were tested: tensile strength, modulus of elasticity, transverse shear strength and horizontal shear strength. It was seen that the resilience after the accelerated exposure depended on the type of rebar. However, for all of them, the tensile strength was the most affected mechanical property, with a reduction of 20 and 41%, followed by the elastic modulus, which decreased between 5% and 13%. Finally, the horizontal and transverse shear strength capacities were almost unaltered after the aging process. These preliminary results were aligned with the findings reported by other researchers in the literature.

Regarding the significant difference in the reduction between the tensile strength compared to the modulus of elasticity, authors believe that it could be related to the degradation of the fiber and resin interface, which affects the stress transfer between fibers. This reduction is more noticeable at a critical strain (related to the maximum tensile strength) where the decrease in the stress transfer capacity may lead to the inability to activate all the fibers of the cross section of the rebar which will result in higher strains and, therefore, premature failure in those fibers

that are being engaged. But, since the elastic modulus is not related to individual or incremental fiber failures but rather to the sum of the elastic strain all along the coupon or rebar gage length, is not that heavily affected.

However, the authors of the article acknowledge that more data is needed to confirm these preliminary conclusions. Future research activities include the extension of the aging time and addition of extra exposure temperatures. This data will be then used to model the durability and predict the service life. Finally, it needs to be noted that the durability prediction values should be compared to results obtained from existing structures, to calibrate the durability model.

Abstract: *Gypsum boards with glass mat reinforcement are used in light weight facade systems. These boards were recently brought to the Brazilian market. Therefore, there are few studies and little practical knowledge of their performance over time, mainly concerning to durability. The gypsum boards manufacturers set that these boards always need to be coated, however they can be exposed to natural conditions during the construction site period. A study is necessary to evaluate the feasibility of using these boards in Brazil, since the exposure conditions relating to humidity, temperature and solar radiation are different from Europe and North America. The aim of this paper is to show the approach used to evaluate the durability of the gypsum board with glass mat reinforcement, and also show the test results. In order to establish the durability approach, standards were adopted, as well as the functional performance concept. In addition, the tests considered that such boards would be used on the facade and should behave similarly to other boards used in facades in Brazil, such as fiber cement boards. Thus, mechanical tests were done in steady state, saturated and after aging in cycles of immersion, drying and heating. Other evaluations were made on gypsum boards applied on exposed walls. The results showed that even the board strength decreases after the accelerated aging cycles, the final value remains in an acceptable level. In addition, boards applied on exposed walls for 12 months have been presenting a good performance; meaning no cracks neither detachments, even though the follow-up still needs to be maintained longer.*

Keywords: *Gypsum Boards with Glass Mat Reinforcement, Durability, Performance, Aging.*

1 Introduction

Gypsum boards with glass mat reinforcement[1] were recently brought to the Brazilian market and it has been used in light weight facade systems[2]. There are no Brazilian standards concerning these boards, however, there are American and also European standards (ASTM C1177, 2017 and EN 15283-1, 2009) and some publications relating to moisture resistance

[1] Gypsum boards with mat reinforcement are composed of set gypsum plaster core reinforced with inorganic fibers which are arranged in a woven or non-woven mat to form flat rectangular boards. Admixtures, fillers and fibers dispersed in the core may also be present (definition of EN 15283-1, 2009).

[2] Site of construction products in Brazil, available in<https://www.aecweb.com.br/emp/p/usg-brasil_34433_1>

(CMHC, 2007; Randall *et al*., 2016). Although, these standards and publications, there are few studies and little practical knowledge of the performance of these boards over time in Brazil, mainly concerning to durability requirements. Singh and Garg (1992) have defined the durability of glass reinforced gypsum composite by assessing its behavior in water, in natural weathering exposition and after wetting and drying aging cycles.

The use of glass mat gypsum boards in external facades is recommended only as a substrate to a coating system – whether a Direct Applied Finish System (DAFS) or an External Insulated Finish System (EIFS). Glass mat board manufacturers set that these boards cannot stay apparent, meaning no coating, during their entire service life. However, they may be exposed to natural conditions during the construction site period during one year at most.
The boards are used as a component of a facade system. Once assembled in facades, they must contribute to ensure the design life (DL) of the complete system. This is an actual discussion in Brazil, mostly because of the residential building performance standard, ABNT NBR 15.575-1 (2013), set a minimum DL of 40 years for façade systems of residential buildings.

A study is necessary to evaluate the feasibility of using these boards in Brazil, because of the design life requirement set on NBR 15575 and because of the exposure conditions relating to relative humidity, temperature and solar radiation are different among Europe, North America and Brazil. For example the average temperature in South East Brazil is around 23°C and 76% of relative humidity, with an average solar radiation of 18 MJ/(m2.dia) (Tiba, 2000, Inmet site – available in < http://www.inmet.gov.br/portal/>.

In this context, the aim of this paper is to show the approach settled to evaluate the durability of the gypsum board with glass mat reinforcement for use in facades of multi-story building in Brazil, and also show the tests results. Therefore, this study is related to the durability assessment of the glass mat product (board), does not considering the whole facade system.

2 Research Method

The durability approach settled here is according to ISO 15686-2 (2012) concepts: a) definition of user needs, material requirements and characterization; b) preparation – identifications of aging agents, mechanisms and effects, choice of performance characteristics and evaluation techniques; c) exposure and evaluation – short-term exposure (accelerated exposure) and long-term exposure (field exposure); and analyzing and interpretation. The table 1 shows the durability approach developed to this study based on the authors experience and knowledge.

Table 1. Durability approach developed to this study, based on ISO 15686-2 (2001) concepts.

Stage	Descriptions/ Definitions	Reference
Definitions		
User needs	The intention is to use this gypsum board in facades of multi-story building in Brazil façades in Brazil	Principles set to this work
Performance requirements relating to gypsum board durability	Strength reversability Moisture resistance	CMHC (2007); Randall *et al*. (2016) and Singh and Garg (1992)
Material characterization	Density, water absorption, dimensional changes due to moisture and bending strength	Characteristic from ASTM C1177 (2017), EN 15283-1(2009) and NBR 15498
Preparations		
Identification of aging agents	Water, solar radiation, hot temperature	Adapted of ISO 19208 (2016)
Mechanisms and effects	Water is the main agent of plaster degradation due to the solubility of the gypsum. By the action of wet-dry cycles of the environment, the gypsum dissolves and precipitates continuously, but the attached crystals are deposited on the surface and do not have the same imbrication of the first formation.	John, V.; Cincotto, M.A. (2017)
c) exposure and evaluation – short-term exposure (accelerated exposure) and long-term exposure (field exposure);	All characteristics were evaluated before and after stress by immersion in water associated to differents temperatures (Figure1)	Proposal of this paper. The most tests were carried out considering the NBR 15498

The tests (characteristics evaluation before and after short term exposure) were designed considering that gypsum boards with glass mat reinforcement will be used on the facade and should behave similarly to other boards applied in facades in Brazil, such as fiber cement boards, even they will be coated after at maximum one year (Figure 1)**.** Then, mechanical tests were done in steady state, saturated and after aging (cycles of immersion in water and drying), since the water is the most important aging agent for these boards (Figure 1).

In additional, a field exposure is carrying on since four gypsum boards were assembled on exposed walls it has been twelve months. These walls are in São Paulo city, West region, placed directed to North.

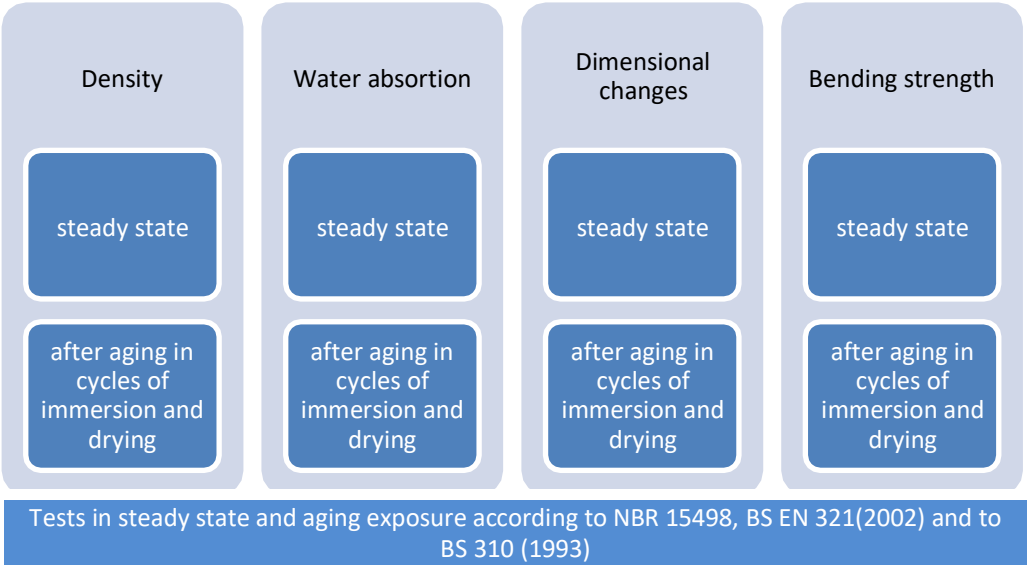

Figure 1. Tests of gypsum boards under stress condition.

The test in normal condition, steady state, means keeping the samples for three days to (20±2) º C and (50±5) % of relative humidity. Two kinds of short aging exposure were carried on: one adopting the fiber cement standard (ABNT NBR 15498, 2016) and the other adopting the OSB board standard (BS EN 321, 2001).

The aging test specified by ABNT NBR 15498 (2016) consists of subjecting the samples to 50 aging cycles. Each cycle consists of the following steps: immersion in water at 20°C for 18 hours and exposure at 60°C for 6 hours. The aging test specified by BS EN 321 (2002) consists of subjecting the samples to 3 aging cycles. Each cycle consists of the following steps: immersion in water at 20°C for 72 hours, then exposure at -12°C for 24 hours and finally exposure at 70°C for 72 hours. At the end of the aging cycles, the samples were conditioned at 20°C and 65% relative humidity until they reached constant mass (equilibrium condition). In the state condition, it determined the flexural tensile strength and the modulus of elasticity of aged and non-aged samples according to BS EN 310 (1993).

3 Results and Discussion

3.1 Density

According to NBR 15498 (2016) samples of gypsum boards were measured and weighed; the average results can be seen in Table .

Table 2. Gypsum boards with glass mat reinforcement densities.

Steady state	After aging in cycles of immersion and drying [(1)]	Difference between normal and aging conditions
798,6 ± 6,30 g	784,13 ± 19,45 g	14,47g (1,81%)
[(1)] aging exposure according to NBR 15498		

3.2 Water Absorption

Moisture content was calculated, according to NBR 15498, using 250x100 mm samples for gypsum board, which are the same sizes of the bending test samples. The results shown in Table 3 are the average of 10 samples at 21ºC and 65% RH.

Table 3. Moisture content of Gypsum boards with glass mat reinforcement (average result).

Steady state	After aging in cycles of immersion and drying (1)	Difference between normal and aging conditions
(36,6 ± 0,95) %	(55,5 ± 3,4)%	18,9%
(1) aging exposure according to NBR 15498		

In additional, the moisture content tested according to EN 15283-1 (standard for Gypsum boards with fibrous reinforcement), is around 4%, which means these boards is Type H1, with reduced water absorption rate.

3.3 Dimensional Changes

The dimensional changes relating to width and length were tested using 250x100 mm samples for gypsum board, which are the same sizes of the bending test samples. The results shown in Table are the average of 10 samples.

Table 4. Dimensional change in width and length.

	Steady state	After aging in cycles of immersion and drying (1)	Difference between steady and aging conditions
width	1,15 %	1,23%	0,08%
length	0,26%	0,18%	0,08%
(1) aging exposure according to NBR 15498			

3.4 Bending Strength after Immersion and Dry

The bending strength according to NBR 15498 (2016) was tested using 250x100 mm samples for gypsum board. The results shown in Table 5 are the average of 10 samples.

3.5 Bending Strength and Modulus after Immersion, Freezing and Heating

The bending strength and modulus of gypsum board was tested using 250mmx50 mm according to BS EN 310 (1993), in steady conditions and after short aging exposure, that was based on BS EN 321 (wood board) as showed in Table 6.

Table 5. Bending strength results before and after short term exposure.

Requirements	Steady state	Saturated condition – immersion in water for 24hours	Steady state, after aging in cycles of immersion and drying**	Satured condition, after aging in cycles of immersion and drying
Bending strength Longitudinal direction (MPa)*	7,9 ± 0,5	4,7 ± 0,4	5,9 ± 0,2	2,6 ± 0,2
Bending strength Transversal direction (MPa)*	6,0 ± 0,8	4,3± 0,5	4,5 ± 0,6	2,2 ± 0,2

* the samples were removed from the gypsum board considering longitudinal and transversal direction

** at the end of the aging cycles, the samples were conditioned at 20°C and 65% relative humidity until they reached constant mass (equilibrium condition).

Table 6. Average results obtained from the characterization of gypsum board according to BS EN 321.

Requirements*	Steady state	Steady state, after aging in cycles of immersion freezing and heating **	Variation (%)
Bending strength (MPa)	7,11 ± 1,26	6,03 ± 0,9	-18%
Modulus of elasticity (GPa)	2,65 ± 0,3	2,02 ± 0,4	-19%
* the samples were removed from the gypsum board only considering the longitudinal direction			
** at the end of the aging cycles, the samples were conditioned at 20°C and 65% relative humidity until they reached constant mass (equilibrium condition).			

The variation between the results of the physical characteristics of gypsum board mat reinforcement in steady state and after aging exposure were under 20%; density was almost zero, water absorption was around 18% and dimensional changes were around 0,08%. Relating to bending strength, the results in the saturated state were greater than 50% of the results in the steady state. The ratio of bending strength in the transversal by the longitudinal direction was greater than 70%, both in the steady and saturated state. These bending strength results meet the NBR 15498 specifications. Once considering a severe condition, the bending strength in saturated state after aging was 50% of the bending strength of the saturated boards in steady state. Relating to the exposure to wetting / freezing / heating cycles by BS EN 321, it can be seen from the analysis of Table 4 that both the bending strength and the modulus of elasticity after the aging cycles presented values above 80% of the initial values.

3.6 Long-Term Exposure (Field Exposure)

Gypsum boards mat reinforcement were installed in two walls structured by steel frame, forming a wall of 2400 mm wide x 2400 mm length. After 12 months of exposure, no significant occurrences (no cracks neither detachments or wraps) were found on the boards.

4 Conclusions

This paper shows an approach to evaluate the durability of gypsum boards mat reinforcement used in the facade, considering water as the main aging agent, since the board may have contact with rainwater and solubilize the plaster. Then, tests were made to evaluate the physical and mechanical characteristics of these boards under normal condition (steady state) and after aging, cycles of immersion in water and drying. It was assumed that glass mat gypsum boards should behave similarly to other facade sheets, such as fiber cement and wood boards. For this reason, it was adopted the aging exposure methods indicated in both standards.

Concluding, the tests results show that the difference between physical characteristics before and after aging is less than 20%. Regarding to the mechanical characteristics, the bending strength losses after aging were on average less than 50%. However, after conditioning under normal conditions there is a resistance return, the strength after aging, at steady state, is similar to the resistance in the initial saturated state (table 5). Concerning the natural exposure, the boards have been providing good results, even though the follow-up still needs to be maintained longer.

Abstract. *Fibre Reinforced Polymers (FRP) have been widely used to strengthened construction structural elements in the last years because of their mechanical pros. However, the durability of these materials is always controversial. In particular, the effect of long-term contact with water on the mechanical properties of FRPs is studied in this research throughout the implementation of accelerated degradation tests. Samples of Carbon FRP and Glass FRP were immersed into supply water, water with salts and surfactants and highly chlorinated water. In all cases, electrical current passing through the samples was also imposed. Tensile tests on pristine and degraded samples were carried out to determine the influence of these aggressive environments on the tensile strength and the Young's modulus of the specimens. Finally, superficial (ATR) FT-IR analyses were conducted to assess possible chemical changes in the samples surfaces. Results indicated that the chemical composition of used resins was not modified due to the water exposure. No hydrolysis process took place during testing time on the surface. However, mechanical properties were reduced, especially when samples were exposed to plain supply water, which may be related to the physical degradation caused by moisture intake by diffusion.*

Keywords: *Composites, Hydrolysis, Mechanical Properties, Accelerated Degradation, Waste Water.*

1 Introduction

Fibre Reinforced Polymers have been commonly used to strengthen existing building structures in the last years. Their significant stiffness, outstanding strength and low weight make FRP an interesting building material for retrofitting, rehabilitation or strengthening concrete or masonry structures. In addition, one of the main advantages pointed out by FRP suppliers is its corrosion resistance in wet environments, although this statement is not always proved.

In fact, FRP durability have been a controversial topic from the very beginning because of the organic nature of the matrix where fibers are embedded into. In this line, several researches may be found in the literature.

Some researchers investigated the durability of FRP components. In this line, carbon fiber has been proved to be resistant to acid and alkali environments and it can only be oxidized by strong oxidants (Zhu and Hu, 2017). In contrast, glass fiber is known to degrade in presence of water, especially in alkaline environments (Bank, Gentry, and Barkatt, 1995), where greater alkalinity is directly correlated with faster rate of glass fiber erosion. The strength of glass fiber

is permanently reduced after soaking in water because of the chemical reaction of glass fiber and water (Zhu and Hu, 2017). This fact is increased by alkalinity. Regarding corrosion, glass fiber can be affected by hydrofluoric acid but it shows a good corrosion resistance.

According to (Department of Defense USA, 2002) epoxy shows good chemical resistance but its mechanical properties are clearly reduced in the presence of moisture because it is composed by a large number of polar OH groups that facilitate attractive interaction with polar molecules like water (Panda and Mamta, 2010). Polyester durability mostly depend on their typology. Hence, orthophthalic polyester is far more affected by water presence than isophthalic polyester. According to Shaoru Zhu *et al.* (Zhu and Hu, 2017), the chemical medium can penetrate into the polymer, react with it and cause the polymer to swell. This process can produce salts, hydrolysis, saponification, sulfonation, oxidation or nitrification, which causes the breaking of the main valence bond. In general, resins have a significant cross-linking degree that brings resistance to medium corrosion. Hence, controlling curing degree is essential and it is mainly related to the hydrolytic activation energy of its hydrolyzed groups in the corresponding acid-base medium. Thus, corrosion resistance of the matrix highly depends on the curing/hardening agent.

Regarding the durability of the FRP composite material, it is stated (Cromwell, Harries, and Shahrooz, 2011; Karbhari *et al*., 2003) that hydrothermal effects are dominant. Water or moisture absorbed by the FRP matrix can result in physical changes to the matrix (including plasticization and a reduction in glass transition temperature) which result in a breakdown of the resin matrix that makes it possible further affectation of fiber and matrix-fiber interface. According with (Karbhari *et al.*, 2003), moisture diffuses into all organic polymers, leading to changes in thermophysical, mechanical, and chemical characteristics. Additionally, the primary effect of the absorption is on the resin itself through hydrolysis, plasticization, saponification, and other mechanisms, which cause both reversible and irreversible changes in the polymer structure.

Several absorption studies, like (Sun and Li, 2011) proved that the diffusive and capillary processes were the main ways composites absorb moisture. The existence of water molecules in the FRP can weak the performance of interface between the fiber and matrix. This effect can reduce the shear performance of the FRP and cause the progression of delamination between layers.

Beside moisture, chemical attack (*e.g.* acid and alkali solutions) also contributes to degradation of FRP by accelerating the hydrolysis process (Karbhari *et al.*, 2003; Liu, He, and Xiong, 2017). It is demonstrated that the tensile strength of FRP composites immersed in acid and alkali solutions decreases faster than those immersed in distilled water (Liu *et al*., 2017). Additionally, scanning electron microscope (SEM) analysis shows that immersion in alkali solution causes degradation of the fiber-matrix interface and that degradation leads to significant reduction in the tensile properties of basalt and glass FRP composites. Moreover, ingress of alkaline media into fiber can cause surface pitting, hydroxylation, hydrolysis and leaching that not only affect the integrity of fiber but also expose fiber to further degradation. This was especially observed for glass fiber composites because the reaction between glass fibers and alkali substances led to increase water uptake (Sun and Li, 2011). Similar response was observed for acidic media (Liu *et al.*, 2017). According to the wet-dry cycles test results, degradation of aramid and basalt FRP sheets in sulfate and chloride solutions were more significant than in alkali and acid solutions because sulfate and chloride solution promoted

crystallization, which accelerated the degradation. Carbon and aramid FRPs were more stable although. In contrast, glass FRPs were susceptible to moisture extracting ions from glass fiber showing lower chemical resistance.

Two processes are observed when a FRP is exposed into an aggressive media: physical adsorption of the medium caused by swelling and resulting in the destruction of the resin structure; and chemical effect on the bonds of resin molecules resulting in a performance decrease (Zhu and Hu, 2017). It is also stated that the chemical attack involves specific chemical reaction of the polymer with the fluid in the case of polyesters. In this case, the most common failure mode is the hydrolysis by water, acids and alkalis. Esters, and carbonate groups are particularly susceptible to this hydrolysis process (Bagherpour, 2012).

Hydrolysis is a reaction that involves the breaking of a bond in a molecule using water. Molecule polarity promotes moisture sensitivity. Therefore, using hardening or catalytic systems which provide a less polar molecular structure are preferred to avoid water absorption and reduce hydrolysis problems (Ellis, 1993).

Regarding the effect of saline environment, it was proved (Bank *et al.*, 1995) that the rate of strength degradation of aramid/epoxy composites in saline solution was less than that in distilled water. This behavior was justified because the presence of "massive" salt molecules slowed down the absorption rate of water, resulting in a slower rate of hydrolysis process. This fact was also proved by (d'Almeida, 1991).

Regarding the effect of chlorinated environment, it is known that chlorinated water is normally more corrosive than distilled water because of the higher conductivity and the penetrating power of the chloride ion through surface films on metals. The rate of corrosion is controlled by the chloride content, oxygen availability, and the temperature. However, the effect of the presence of chlorides is not specifically investigated for FRPs.

Regarding the effect of degradation of the mechanical properties, tensile strength of FRPs is more affected than elastic modulus because of environmental exposure, as stated by (Cromwell *et al.*, 2011).

As a conclusion of the literature review, it is stated that chemical and physical affectations are possible on FRPs exposed to aggressive media, mostly involving resin matrix. Studying the particular effects of salts and surfactants rich water and highly chlorinated water is necessary for the application of these materials on water treatment plants.

2 Materials and Methods

Two types of FRPs were produced and tested: glass fiber and polyester resin FRP (GFRP) and carbon fiber and epoxy resin FRP (CFRP). Tensile tests were performed on unaltered samples, samples immersed in supply water, samples immersed in water with salts and surfactants representing increased aggressivity of waste water and water highly chlorinated to represent a long term effect of chloride in supply water.

2.1 Materials

The used glass fiber was E-Glass Chopped Strand Mat with no orientation and a density of 225g/m^2. Filaments of the fibers were covered by silane to enhance chemical compatibility with polyester resins. The used carbon fiber was unidirectional 300g/m^2 0.165mm thickness fiber.

The polyester was an unsaturated resin of orthophthalic type and standard glycols, dissolved

in styrene (acts as hardener). The catalyst was methylethylketone peroxide. Epoxy resin was a combination of formaldehyde (polymer with 2-(chloromethyl)oxirane and phenol) and bisphenol A epichlorohydrin polymer. As hardener for the epoxy resin, a mixture of Isophoronediamine and Trimethylolpropane was used.

2.2 Sample Production

FRPs were manually laminated on a glass plate previously prepared with unmolding agents. Four layers of carbon fiber and seven layers of glass fiber were respectively used. Over each fiber layer the corresponding resin was manually applied with a brush (see Figure 1 (a)) at a ratio of 50% fiber and 50% resin. Finally, perforated release film and non-woven breather felt were placed below weight application tools to absorb excessive resin during curing process.

Resulting CFRP plate was 1mm thickness whereas GFRP plate was 4mm thickness. These plates were manually cut to the desired dimensions of 12.5mm x 200mm in the case of CFRP and 25.0mm x 200mm in the case of GFRP. Twelve specimens of each FRP type were obtained. These were divided in four groups of three samples. Each group was subjected to a different media type (unaltered specimens, supply water, waste water and chlorinated water) before tensile testing.

2.3 Degradation Method

Artificial concentrated wastewater containing 100g of urea, 50g of detergent powder (25% of sodium carbonate, 10% of sodium percarbonate, 10% of benzensulfonic acid, 3% of no ionic surfactant, 3% of silicic acid), 35g of NaCl per 1L of supply water was produced according with typical compounds found in wastewater as by (Garcia, 1985). Artificially highly chlorinated water was produced by adding 35g of NaCl per liter of supply water. Additionally, three samples of each FRP were also immersed into supply water for comparison with artificial concentrated wastewater and highly chlorinated water.

All immersed samples were subjected to an imposed electrical current according with (International Standardisation Organisation, 2017) which corresponded to 2.4mA for CFRP samples and 20mA for GFRP samples. Immersion lasted two weeks. Surface of GFRP specimens showed different coloring depending on the treatment as presented in Figure 1(b).

(a) (b)

Figure 1. (a) CFRP production and (b) GFRP specimens state before tensile tests; from left to right supply water, wastewater, chlorinated water and untreated.

2.4 Tensile Testing

Before performing tensile tests samples were prepared to avoid local stress concentration failure mode. This was achieved by covering the endings of the samples by two thin aluminum sheets bonded to both sides of the sample with epoxy resin. These sheets avoided clamp indentation on the sample during tensile test.

Tensile tests were performed with an electromechanical press at a constant displacement rate of 2mm/min, acquiring force and displacement at 50Hz until tensile failure.

2.5 ATR FTIR Testing

Samples were subjected to Fourier-transform infrared spectroscopy analysis (FTIR) after tensile test. This test was conducted to observe if there were changes of chemical bonds on the specimens after being treated by supply water, waste water or chlorinated water. Attenuated total reflection (ATR) technique was used because it is able to examine directly the sample without further preparation but obtaining only the chemical characteristics of the surface of the sample. The FTIR spectrometer used in this study was FTIR-8300.

3 Results

Quantitative results from the tensile tests and qualitative observations of the FTIR analysis are summarized in this section.

3.1 Tensile Strength

The tensile strength (f_t) of each sample was calculated assuming a uniform stress distribution on the cross section, so dividing the maximum applied force by the cross area of the specimen. All specimens broke by material tensile failure so no sliding respect clamps neither local stress effects were observed. Tensile strength results are summarized in Table 1.

Table 1. Results of the tensile tests.

	Supply water		***Wastewater***		***Chlorinated water***		***Untreated***	
	f_t (MPa)	*E (MPa)*	*f_t (MPa)*	*E (MPa)*	*f_t (MPa)*	*E (MPa)*	*f_t (MPa)*	*E (MPa)*
CFRP	1108	34364	1294	30556	1331	26912	1311	25967
	921	31561	1246	34375	1020	24359	1495	30351
	1049	28378	1413	28399	1246	27616	1033	26257
GFRP	139.3	3333	143.0	3590	150.1	4043	164.2	3613
	149.1	3784	115.7	2881	138.7	2765	159.9	3711
	157.4	3824	160.0	3243	155.8	3522	147.4	3120

3.2 Elastic Modulus

Elastic modulus (E) was calculated as the slope of the linear part of the stress-strain curve, which was set between 20MPa and 100MPa for GFRP and between 100MPa and 600MPa for CFRP. Strain was calculated as the measured axial displacement divided by the total length of the sample. Results are summarized in Table 1.

3.3 FTIR Analysis

Representative FTIR analysis results are showed Figure 2. The analyses have to be performed by qualitative comparison of the presence/absence of particular peaks in the specific ranges of the corresponding compounds. Hydroxyl groups, which are related with hydrolysis processes, are supposed to appear around 3500 cm^{1} (red line in Figure 2).

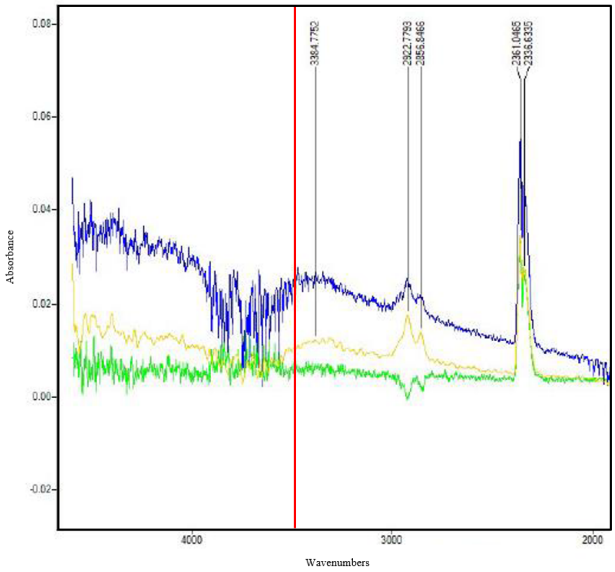

Figure 2. Effect of waste water and supply water on CFRP (left). Yellow for untreated, blue for waste water and green for supply water treated specimens.

4 Discussion

Regarding quantitative results about tensile strength and elastic modulus it is observed that immersing GFRP with an electrical current causes the decrease of the tensile strength in all cases. This strength reduction is equivalent for specimens immersed into supply water and into chlorinated water (-5.5% and -5.7% respectively), so adding NaCl makes no apparent effect on the tensile strength reduction of GFRP. Immersing GFRP in wastewater brought the higher tensile strength reduction (-11.2%). It is also associated with the most significant reduction of the elastic modulus (-7.0%) whereas immersion of GFRP in chlorinated water has no effect (-1.1%) on this parameter and immersion in supply water showed an increase (+4.8%).

In relation with CFRP specimens, the greater reduction of the tensile strength (-19.8%) is observed for specimens immersed in supply water. Treatment in chlorinated water also causes a decrease of this parameter (-6.3%) whereas immersion into wastewater showed an apparent increase (+3.0%) of the tensile strength. Elastic modulus of CFRP is increased when immersing it into supply water (+14.2%) or wastewater (+13%) with no significant difference among them. However, it is reduced when immersed in chlorinated water (-4.5%).

Looking at the results on the whole, it may be stated that chlorinated water caused the reduction of tensile strength and elastic modulus for both FRPs. Wastewater causes the reduction of mechanical properties of GFRP but increases the ones of CFRP. Finally, exposure to supply water reduces the tensile strength but increase the elastic modulus.

Incorporating the results of the ATR-FTIR analysis, it is noted that no hydrolysis happened because hypothetically resulting hydroxyl group was not detected in any case. The corresponding peak (3500cm^{-1}, red line in plot of Figure 2 as example) were not qualitatively observed in any case. Results of CFRP may indicate the physical resin adsorption of the medium, which caused the swelling of polymer, also induced by the electrical field. This adsorption is restrained by the presence of massive ions like salts and surfactants at the sample surface. In this line, surfactants are really likely to move on to the exposed sample surface. In addition, the imposed electrical current would have polarized the specimen surface, changing the properties of the solid-liquid interface and making it easier for the salt ions to adhere on to this surface. The combination of electrical polarization, so promoting ions adhesion to the surface, and superficial attachment of surfactants explained the lower water adsorption, so the lower reduction or even increase of the tensile strength for CFRP immersed in chlorinated and wastewater, respectively. The same tendency should be valid for glass fiber. In fact, surfactants were detected in resin surface of GFRP specimens. However, in the case of GFRP another process plays an important role in the opposite direction: glass fiber is sensitive to alkaline environments and higher alkalinity of wastewater may explain the greater degradation of the specimens immersed in this media because of fiber degradation. Supply water and chlorinated water showed similar tensile strength reduction because of the sensitivity of glass fiber to the moisture, which had greater effect than water adsorption restrain for chlorinated water.

Finally, inclusion of water molecules into resin structure of the matrix may explain the apparent increase of the elastic modulus, which is more evident for the cases in which water molecules adsorption was not limited, so for specimens immersed in supply water. Similar effect was observed for CFRP into wastewater but, in contrast, glass fibers really degraded in this alkaline media so a reduction of elastic modulus of GFRP was observed. Finally, variation of the elastic modulus of specimens immersed in chlorinated medium was not significant, reaching a balance between stiffening because of hypothetic adsorption of water molecules and degradation of material for both FRPs.

5 Conclusions

Combining mechanical analysis and chemical ATR FTIR analysis makes it possible to understand the underlying causes of the observed changes in the mechanical properties of FRPs immersed in aggressive water environments. The following conclusions are obtained:

- Exposure to supply water reduces the tensile strength and increases the elastic modulus of GFRP and CFRP. In contrast, exposure to chlorinated water causes the reduction of both parameters, whereas wastewater causes the reduction of mechanical properties of GFRP but increases the ones of CFRP.
- Water adsorption causes the swelling of the polymer, which is accelerated by the polarization induced by the electrical field, reducing the tensile strength.
- Media with massive ions or surfactants that tend to adhere resin surface, even more under an imposed electrical field, showed lower water adsorption by the matrix, so less degradation of the tensile strength results.
- Inclusion of water molecules into resin structure may result in a stiffer response of FRPs although further research is required to confirm this point.

As practical conclusion, plain water is showed to be the most aggressive media for the matrix

resin and a real problem to be faced for improving FRPs durability.

Durability Studies of Polyurethane-Based Structural Adhesives Used in Engineered Wood Products in New Zealand

Catherine L. Nicholson

BRANZ Ltd, 1222 Moonshine Road, RD1, Porirua, 5381, New Zealand,
catherine.nicholson@branz.co.nz

Abstract. *The New Zealand Building Code is unique in the world in requiring evidence of a minimum durability of 50 years for all structural building elements. This prescriptive durability requirement equally applies to the adhesives used in structural applications such as engineered wood products (EWPs), including glulam, CLT and LVL. Conventional resorcinol-based structural adhesives have a long history of use in New Zealand, providing evidence of their ability to meet stringent durability requirements. Structural adhesives based on polyurethanes (PURs) are used extensively in other parts of the world and are rapidly gaining increasing interest in New Zealand due to their perceived environmental and production advantages. However, without a sufficiently long history of use, and a lack of data around their performance in the preservative treated pine EWPs typically manufactured in New Zealand, it is difficult to provide evidence of long-term durability for PURs in our domestic building industry. In this work, attenuated total reflectance Fourier transform infrared (ATR FTIR) spectroscopy in conjunction with multi-component analysis (chemometrics) was used to understand the changes that accelerated ageing cause in the chemistry of five PUR-based adhesives. The effect of hygrothermal stress was investigated through exposure of samples to accelerated ageing cycles of varying temperatures and humidities for up to 3 years' duration. Different samples were affected to different extents by each cycle. Spectroscopic data were also used to build predictive models which have the potential to be used in long-term durability assessment. Spectroscopic investigation in conjunction with mechanical testing offers the opportunity to provide a robust, fit-for-purpose test methodology for assessing the long-term durability of PUR-based structural adhesives.*

Keywords: *Adhesives, Durability, Degradation, Spectroscopy, Chemometrics.*

1 Introduction

The inclusion of a materials durability clause within New Zealand's performance-based Building Code (NZBC) is unique in the world. This clause requires all building elements to demonstrate durability for a minimum specified time (NZ Government, 2014). In the case of structural building elements, the durability requirement is 50 years.

Structural adhesives are a critical component of engineered wood products (EWPs) including glulam, laminated veneer lumber (LVL) and cross-laminated timber (CLT). EWPs manufactured in New Zealand are predominantly produced using pine (*Pinus radiata*) that has been preservative treated. Chromated copper arsenate (CCA) is widely used as a timber treatment, with micronised copper azole (MCA) being a newer alternative on the market.

Traditional formaldehyde, phenolic or resorcinol-based adhesives have a long history of use in New Zealand and are known to perform well over many decades. Polyurethane (PUR) adhesives, widely used throughout Europe and North America (Lehringer *et al.*, 2014), are attracting increasing interest from EWP manufacturers in New Zealand. However, without a

sufficiently long history of use or long-term durability data available for its performance to be evaluated in products manufactured using preservative treated pine, it is difficult to demonstrate that structural building elements containing PUR adhesives will meet the minimum 50-year durability clause. There is, therefore, a continuing need for the development of standard test methods for the service life prediction of materials for specific applications such as these (Lee *et al.*, 2008; Marston *et al*., 2011). Accelerated ageing is commonly used in these tests.

This paper describes results from a research study investigating the long-term durability of PUR-based structural adhesives. The ultimate aim of this work is to develop standard test methods which can be used for the long-term durability evaluation of products containing PUR adhesives. To achieve this, two concurrent workstreams are being undertaken. The first aims to enhance our fundamental understanding of PUR materials chemistry by subjecting adhesive films to various environmental conditions and monitoring structural changes over time. The second aims to investigate the performance of the adhesive bondline in laboratory-fabricated EWP samples through conventional mechanical testing. This dual aproach has been successfully employed by other researchers (Ren *et al*., 2013), who found that the complementary advantages of both methods enhanced an overall understanding of structure – durability relationships in polyurethane adhesives used for timber bonding.

The focus of this paper is on the work that has been carried out on the PUR adhesive films. The effects of three accelerated weathering cycles of varying temperatures and humidities for up to 3 years' duration are reported for five commercially available PUR adhesives. The results are an extension of the preliminary work carried out on the same adhesives described by Nicholson *et al*. (2017) using attenuated total reflectance Fourier transform infrared (ATR FTIR) spectroscopy and chemometrics.

FTIR spectroscopy has been widely used in the analysis of construction materials (Shaw *et al*., 2016; Pellizzi *et al*., 2014; Zhang *et al*., 2013; Mitchell *et al.*, 2013; Jelle *et al.*, 2012) and polyurethanes (Bockel *et al*., 2018; Clerc, *et al*., 2017; Ren *et al*., 2013; Sterley *et al*., 2012). It is a rapid, non-destructive analytical technique which can also be used for *in situ* testing. Chemical changes in the structure of the PUR adhesive due to ageing and accelerated weathering can be monitored to predict likely degradation mechanisms, durability characteristics and expected service life.

The accelerated ageing cycles were chosen based on the likelihood that PURs would be subjected to hygrothermal stress under in-service conditions. It is known that under conditions of elevated temperature and moisture, the constituent polyol and urethane chemical entities may be hydrolysed (Dubelley *et al.*, 2018). The susceptibility to and extent of degradation of individual PURs is highly dependant on composition. Photolysis induced by UV exposure is also an important factor to consider. Photolysis results are not presented here because the adhesive films used in this study were not formulated to withstand UV exposure and were severely degraded within only days or weeks of accelerated and outdoor ageing respectively.

In the preceeding work (Nicholson *et al*., 2017), structural changes in the adhesives exposed to accelerated ageing had been monitored over a very limited timeframe. A main conclusion was that much longer ageing times were required to build a better picture of degradation mechanisms and structural changes in order to understand the durability implications of these changes. The results reported here describe the effects of longer exposure times on the samples. The additional data now provide better insight into degradation mechanisms and have also enabled predictive models to be developed for durability evaluation.

2 Materials and Methods

2.1 PUR Adhesive Samples

Five commercially available PUR-based adhesives were selected to undergo accelerated ageing tests. Adhesives were cast onto wooden sticks and pressed flat to minimise the effect of foaming during curing. All samples were allowed to cure for at least the minimum time recommended by the manufacturer under normal laboratory conditions (approximately 22°C, 55% RH) before undergoing testing. Control samples were stored in a constant climate laboratory at 20°C and 50% RH.

2.2 ATR FTIR Spectroscopy and Chemometrics

ATR FTIR spectroscopy was performed with an Agilent Technologies 4300 instrument. Spectra were collected using MicroLab PC software and a diamond ATR sampling interface over the spectral range 650-4000 cm^{-1}. A background of 16 scans was recorded before each spectrum of 64 scans with a resolution of 4 cm^{-1} was acquired. Spectra were analysed and predictive models developed using GRAMS IQ (version 9.1) software. Table 1 shows the spectral regions of interest relevant to the PUR structure. Partial least squares calibration and cross-validation was used to assess the validity of the predictive models.

Table 1. Spectral band assignments for regions relevant to PUR structure in FTIR spectra (modified from Delpech *et al*., 2012).

Wavenumber (cm^{-1})	Band assignment	Vibrational mode
800-400	N-H	Bend
1075	C-O (urethane & ether)	Stretch
1250-1240	C-O-C (ether) N-H C-N	Assymetric stretch Bend Stretch
1374	C-H (methyl)	Symmetrical bend
1450	C-N-H (urea)	C-N stretch N-H symmetrical bend
1560-1530	C-N-H (urethane)	C-N stretch N-H symmetrical bend
1715-1630	C=O (urethane & urea)	Stretch
2250-2275	O=C=N (free isocyanate)	Stretch
2970-2850	C-H (methyl & methylene)	Stretch
3335-3320	N-H (urethane & urea)	Stretch

2.3 Exposure Cycles for Accelerated Ageing Tests

The adhesive samples were exposed to a range of temperature and humidity conditions (Table 2). A complete Cycle A was 1 day in length, a complete Cycle B was 1 week in length and Cycle C represented constant exposure to elevated temperature and humidity. Controls were sampled at the same time intervals as the exposed samples.

Table 2. Description of exposure cycle conditions for accelerated ageing tests.

Cycle A	Cycle B	Cycle C
6 hours @ 30°C, 95% RH 6 hours @ 60°C, 75% RH 6 hours @ 10°C, 50% RH 6 hours @ -10°C	5 days @ 70°C, 90% RH 1 day @ -20°C 1 day @ 80°C, < 15% RH	Constant 65°C, 100% RH

3 Results

All five adhesives had broadly similar composition as determined by ATR FTIR (Fig. 1).

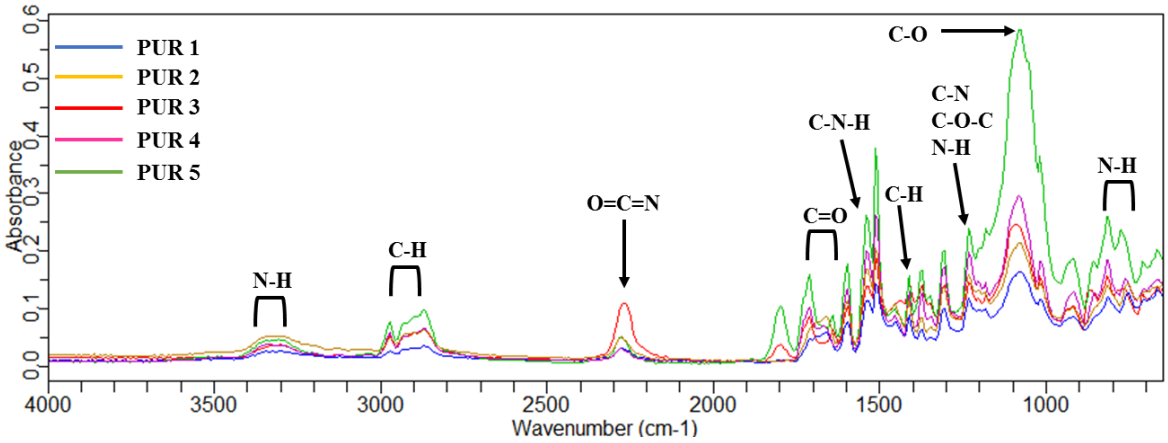

Figure 1. ATR FTIR spectra of freshly cured adhesive samples.

The adhesives were affected by the three exposure cycles in different ways. In general, PUR 1 and PUR 2 exhibited little discernible difference between the control and aged specimens. This is illustrated in Fig. 2 which shows sample PUR 1 after exposure to Cycle C for 3 years. Considerable colour changes were observed for both PUR 1 and PUR 2. Originally both cream, they turned light yellow during Cycle A, orange / brown during Cycle B and dark brown during Cycle C. Control samples did not change colour.

Structural changes were clearly evident in the FTIR spectra of PUR 3 during Cycles B and C but minimal changes were apparent during Cycle A when compared with controls. These differences were observed throughout multiple regions of interest. Fig. 3 shows sample PUR 3 after exposure to Cycle C for 3 years. Colour changes were also observed for these specimens. Originally beige, as ageing progressed they remained beige during Cycle A, turned white and powdery during Cycle B and became chocolate brown during Cycle C. Control samples did not change colour.

PUR 4 and PUR 5 behaved in a similar manner to each other. Some differences were observed in spectra when compared with the controls during all three exposure cycles. This is illustrated in Fig. 4 which shows PUR 5 after exposure to Cycle A for 18 months. Both PUR 4 and PUR 5 darkened significantly in colour during ageing in Cycles B and C but not Cycle A.

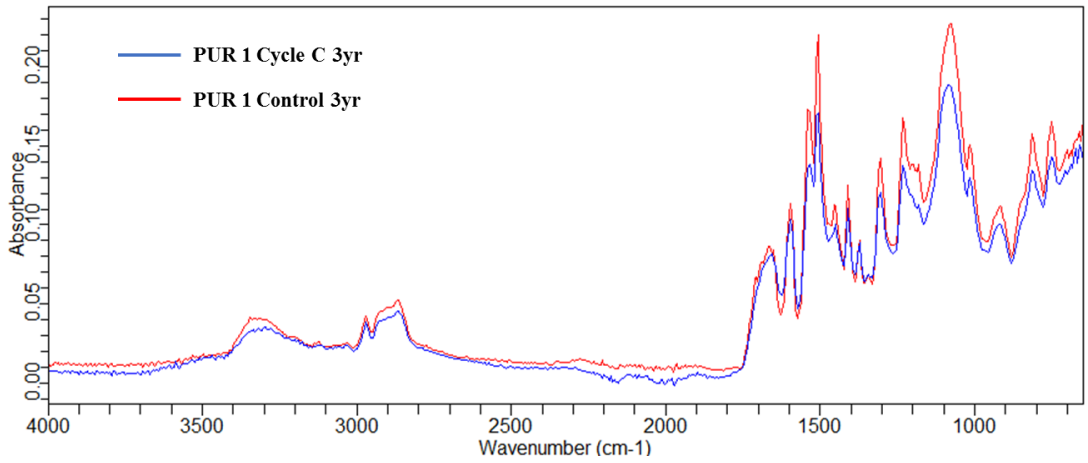

Figure 2. ATR FTIR spectra of sample PUR 1 and control after 3 years of exposure to Cycle C.

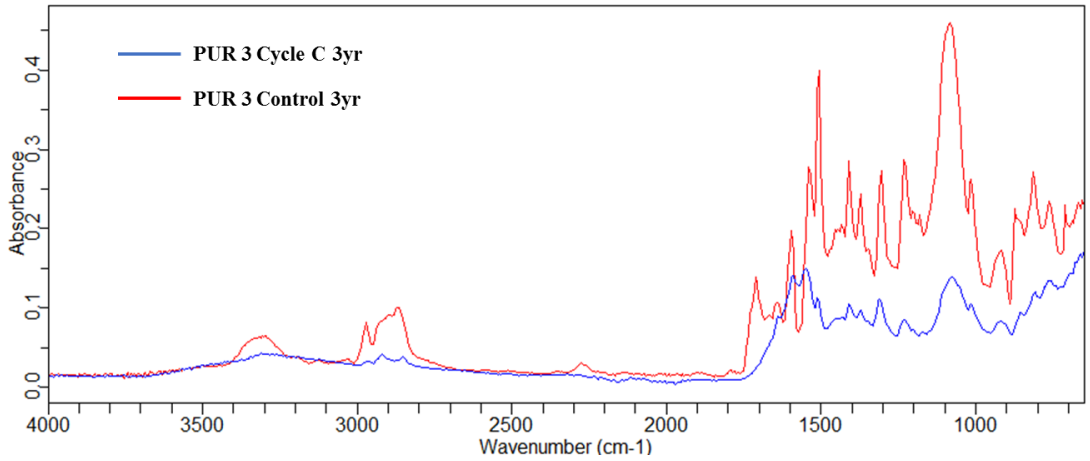

Figure 3. ATR FTIR spectra of sample PUR 3 and control after 3 years of exposure to Cycle C.

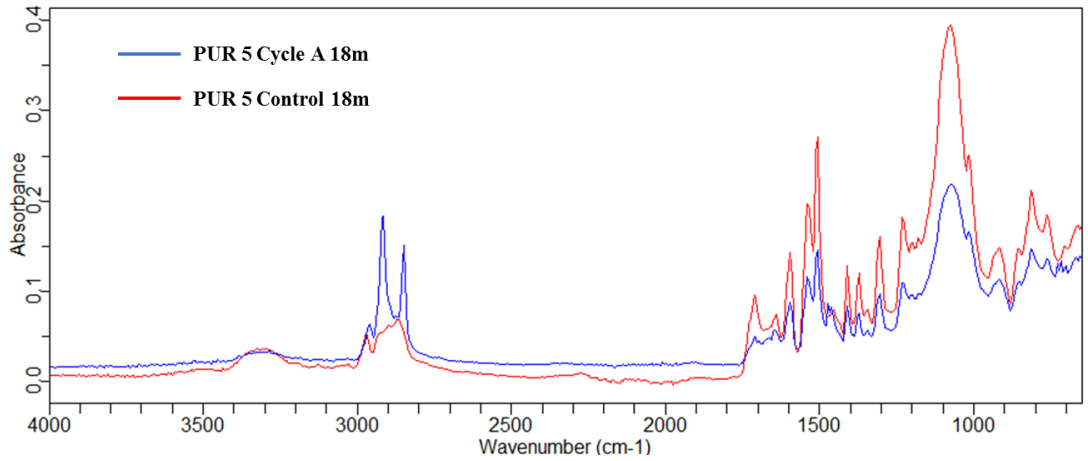

Figure 4. ATR FTIR spectra of sample PUR 5 and control after 18 months of exposure to Cycle A.

Validation results for predictive models of each adhesive sample and accelerated ageing condition were variable. Fig. 5 shows the cross-validation plot for the predictive model using PUR 1 subjected to Cycle C for up to 3 years. This had a coefficient of determination (R^2) of 0.91.

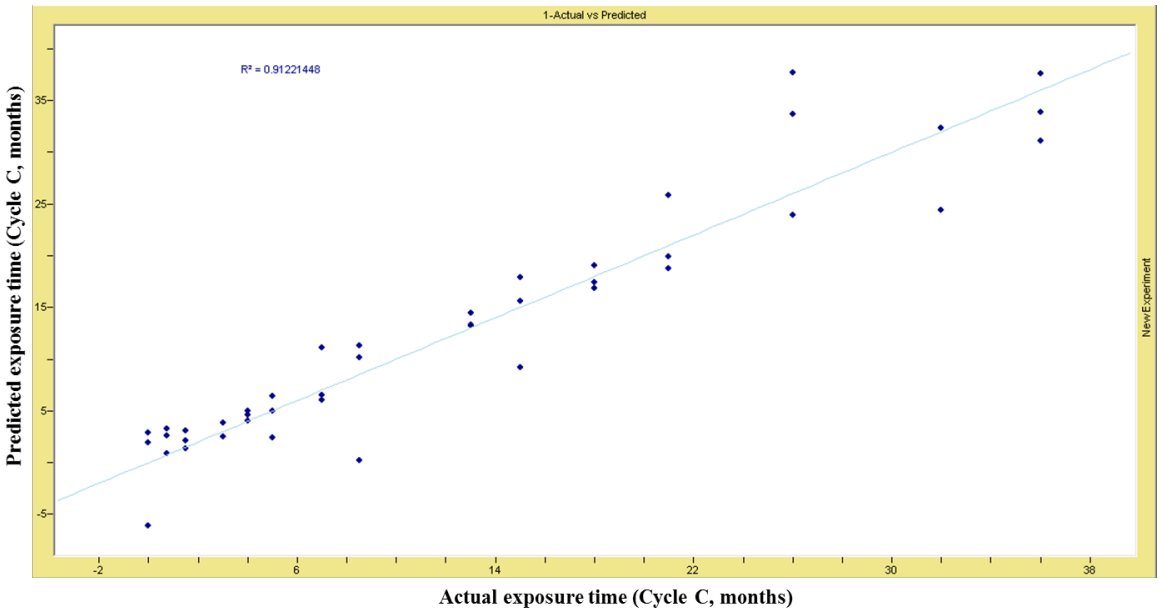

Figure 5. Cross-validation plot for the predictive model based on PUR 1 subjected to Cycle C (R^2 = 0.91).

4 Discussion

Although the five PUR adhesive samples had similar compositions, differences in spectra between control and aged samples were observed during accelerated ageing. These differences ranged from subtle to pronounced but indicate that structural changes have occurred.

PUR 1 and PUR 2 exhibited no obvious structural changes during any of the three ageing cycles (Fig. 2). The only difference noted was the reduction in intensity and eventual disappearance of the peak at around 2275 cm^{-1} (Fig. 1). This is associated with free isocyanate and its disappearance would be expected as the adhesive cured. This is confirmed by the control sample which exhibited identical behaviour. On the basis of the spectroscopy data, these samples both appear to be highly resistant to hydrolysis. However, colour changes were noted, suggesting some structural changes that were not immediately apparent by spectroscopy.

In contrast, PUR 3 showed evidence of significant hydrolytic degradation during cycles B and C (Fig. 3). There was an overall reduction in peak intensity compared with the control, and complete loss of structure in the region 1000 – 650 cm^{-1} associated with N-H bonds and over 3400 – 1800 cm^{-1}, also associated with N-H as well as C-H bonds (Table 1). Pronounced reduction in the peak at 1538 cm^{-1} asociated with C-N-H bonding is indicative of loss of the urethane structure and accounts for the observed discolouration of the samples. The disappearance of the peaks between 1750 - 1650 cm^{-1} further supports degradation of the urethane structure, being associated with the C=O bonds in urethane.

PUR 4 and PUR 5 showed evidence of some subtle structural changes around 1700 cm^{-1} associated with the C=O and C-N-H bonds in urethane and more obvious changes between 3000 – 2800 cm^{-1} associated with C-H bonding.

While the three exposure cycles were designed to be severe, they are not extreme relative to the New Zealand climate. Conditions experienced by building materials may well reach or even exceed 70ºC and 80% humidity in the north of the North Island in summer and drop to -20ºC in the south and central South Island in winter. However, it is the continuous nature of exposure under these conditions which would not be expected in-service.

It is clear that PURs cannot be treated as a generic class of adhesives that will behave identically. The wide range of PUR adhesive formulations available, and the apparent differences in resistance to hygrothermal degradation highlighted in this work, likely precludes development of a single generic test to predict the long-term durability of a given adhesive. It is more likely that new PUR adhesives will need to be tested individually to assess performance. However, the results from this work suggest that a relatively simple accelerated ageing test based on Cycle C, i.e. performed at elevated temperature and humidity over a period of several months, would give an indication of the durability of a PUR adhesive to hygrothermal stress.

The cross-validation plot for the predictive model based on PUR 1 subjected to Cycle C (Fig. 5) suggests that it may be possible to incorporate such a model into an assessment methodology for long-term adhesive durability prediction. This model will be tested using laboratory-fabricated EWP samples which are undergoing natural outdoor ageing. This will provide a measure of the reliability of the correlation that can be expected between natural weathering and accelerated ageing. Successful development of predictive models and correlation of PUR film data with mechanical testing of wood-PUR composites would assist with building a more complete picture of long-term durability.

5 Conclusions

The properties of a PUR-based adhesive, including its likely durability, are strongly related to its composition and structure. Even apparently similar PURs can exhibit pronounced differences in behaviour when subjected to hygrothermal stress. In addition, the same adhesive did not always exhibit the same structural changes when subjected to different ageing cycles. This suggests that a generic durability test for all PUR-based structural adhesives is unlikely to be feasible.

Spectral changes indicative of structural degradation had a relatively early onset within weeks or a few months of exposure to the test cycle. A simple set up consisting of sustained high temperature and humidity could be considered as a rapid screening test for new or unknown PUR adhesives.

While spectroscopy alone cannot determine long-term durability, this technique can contribute important chemical information and complement other more conventional mechanical testing methodologies. Development of predictive models may further enhance its value. A combined spectroscopic and mechanical testing approach offers the opportunity to develop a robust, fit-for-purpose test methodology for assessing the durability and expected service life of PUR-based structural adhesives used in New Zealand-manufactured EWPs.

Effect of Carbonation in Mortars with Different Types of Metakaolin and Curing Procedures

Helena Carasek, Mônica E. Jungblut, Paulo M. Passos and Oswaldo Cascudo

PPG-GECON, Universidade Federal de Goiás-UFG, Av. Universitária, nº 1488, 74605-220-Goiânia, Brazil, hcarasek@ufg.br; monicaengel.j@hotmail.com; paulompengc@gmail.com and ocascudo@ufg.br

Abstract. *This study aimed to evaluate the influence of different types of metakaolin and curing conditions on mortars depth of carbonation. To do so, prismatic mortar specimens were produced by using three different 1:2 mix proportions (binder: sand): a reference mix proportion (without mineral addition) and two mixes with partial replacement of the cement by metakaolin, in the content of 10% by mass of cement. Two types of metakaolin with different characteristics were used in order to verify their capacity of changing the mortar microstructure and the pore solution, modifying this way the carbonation behavior of these materials. Three curing conditions for the test specimens were defined: no wet curing and wet curing (by immersion in water) for 3, 9 and 28 days. After the accelerated carbonation procedure in a CO_2 chamber (in an atmosphere of 10% of CO_2), with a relative humidity of 70% and a temperature of 20°C, for a period of 7 days, the carbonation depth was measured by using pH-indicators based on phenolphthalein and thymolphthalein. The results indicated influence of the type of curing in the carbonated depth and the significant interaction between curing and the type of metakaolin. When wet curing was not performed, the carbonation was more intense in the reference mortar. The effect of curing in the mortars with metakaolin was much less significant compared to that in the reference mortar. A global discussion about carbonation behavior of metakaolin modified mortars will be performed, based on the characteristics of the metakaolins.*

Keywords: *Carbonation, Durability, Metakaolin, Curing Procedures, Mortar.*

1 Introduction

The durability of structures fits into an important context for building performance, as well as sustainability and economy.

Among the phenomena responsible for the deterioration of reinforced concrete, there is the reinforcement steel corrosion due to carbonation or chloride attack. This pathological manifestation causes the most damage due to the technical difficulty of long-term recovery and to the cost involved (Castro *et al.*, 2008). Carbonation is a natural phenomenon that occurs by the chemical reaction between carbon dioxide, presents in the atmosphere, with cement hydration products, thus reducing the concrete pH. As a result of the phenomenon, the depassivation of reinforcement steel occurs, facilitating the onset of corrosion.

In this context, mineral additions play an important role in the improvement of concrete and mortars properties, regarding mechanical resistance and durability, since its use in concrete improves the interfacial transition zone, densifies the cement paste, refining pores and reducing their interconnectivity. On the other hand, when considering carbonation, additions can lead to a negative effect, namely: a reduction in the carbonation resistance of the concrete, due to the reduction of the "alkaline reserve" of the cementitious system. This effect is influenced by the type and content of mineral addition used, as well as by the water/binder ratio and curing

conditions (Cascudo; Carasek, 2011).

Several authors have studied the effect of mineral additions on durability parameters, such as porosity, permeability, carbonation, chloride attack and others (Hossain *et al.*, 2016; Papadakis, 2000; Lim; Mondal, 2015). Some authors report that the replacement of cement by metakaolin increases the carbonation depth (Meddah *et al*., 2018; Fikhailenko *et al.*, 2018), whereas other researchers have observed smaller depths (Duan *et al.*, 2012, 2013; Rossignolo; Oliveira, 2006). So, there are still divergences in relation to the behavior of concrete or mortar modified with metakaolin, with regard to its performance against carbonation.

Thus, this work aims to analyze the influence of different metakaolins and curing conditions in the accelerated carbonation of mortars, trying to understand this behavior from the point of view of the characteristics of metakaolin. In addition, it was sought to analyze the relationship between the measurements of carbonated depth using two pH indicators: phenolphthalein and thymolphthalein based solutions.

2 Experimental

2.1 Materials

The mortars were produced with a washed riverbed quartz sand, with a fineness module of 1.65 and a maximum size of particles of 1.18 mm. The cement used was a Brazilian-type CP II F-40 portland cement, with a specific surface area of 4120 cm²/g and chemical characteristics according to Table 1. A polycarboxylic ether based superplasticizer admixture (density of 1.09 g/cm³ and solids content of 30%), water from public supply network, and two metakaolins derived from different deposits (Table 2) completed the constituent materials of the produced mortars. Brazilian-type CP II F – 40 is a portland cement similar to European CEM II/A-L 42,5 R (NF EN 197-1: 2012), being composed of 75-89% of clinker and calcium sulfate, and 11-25% in mass of limestone filler, according to the Brazilian standard NBR 16697: 2018.

Table 1. Chemical characterization of cement (C) and metakaolins (J1 and J2).

	Chemical (%)									
	Al_2O_3	SiO_2	Fe_2O_3	CaO	MgO	SO_3	Loss Ignit.	Free CaO	Insoluble Residues	Alkali Content
C	4.24	18.48	2.63	61.02	4.33	2.76	4.99	0.78	1.10	0.66
J1	37.1	52.7	2.3	0.1	1.0	---	2.7	---	---	1.5
J2	39.5	47.6	5.3	0.1	0.3	---	4.7	---	---	0.5

The two metakaolins showed different chemical compositions. J1 has higher SiO_2 content and the reddish coloration of metakaolin J2 is explained by the higher iron oxide content in this material. Regarding fineness, J2 is 30% finer than J1. Despite these differences, the two metakaolins studied showed very similar pozzolanic activity (modified Chapèlle - NF P18-513: 2012).

Table 2. Metakaolins' complementary characterization.

Metakaolin	Aspect/Colour	Specific gravity (g/cm^3)	BET Fineness (m^2/g)	Chapèlle (mg $CaOH_2$/ g)
J1		2.58	22.13	1037
J2		2.60	28.71	1075

2.2 Preparation of Specimens and Test Methods

Three different mortars were produced, one as reference and the other two with 10% replacement of cement by metakaolin J1 or J2, in mass. The mortars were produced with a 1:2 mixture (binder:sand, in mass), since this is a mix proportion commonly used in the mortar fraction of various concrete mix designs (1:2:3-binder:sand:gravel). The consistency index was maintained in 320±20 mm (according to ASTM C230: 2014). After mixing, two mortar specimens were cast, under controlled conditions, in prismatic dimensions of 40x40x160 mm (ASTM C349: 2018). The mortars' composition and identification are shown in Table 3.

Table 3. Mortars' identification and composition (kg/kg).

Identification	Cement	Metakaolin	Sand	Water/Binder	Superplasticizer Admixture
A – R	1.0	0,0	2	0.55	0
A - J1	0.9	0.1 (J1)			0.022
A - J2		0.1 (J2)			0.037

After 24 hours of molding, the specimens were demolded and subjected to four different curing conditions: no wet curing and curing by immersion in lime saturated water for 3, 9 and 28 days. For the specimens without wet curing, they were packed in PVC plastic after demolding and stored in a laboratory until the tests performing. For those specimens cured for 3 and 9 days, they were air-dried for about two hours (after the curing period) and then packed by means of PVC plastic until they reached the testing age of 28 days, in order to prevent natural carbonation.

At 28 days of age, the accelerated carbonation test (7 days) was started. Before the start of carbonation, the specimens were preconditioned with humidity (70±5%) and temperature (20±1°C) controlled (no CO_2), according to standard ISO 1920-12 (2015). It was used one CO_2 incubator, model 6034-1, Caron brand, with temperature of (20±1)°C, relative humidity of (70±5)% and CO_2 content of 10%. The carbonation depth was measured by spraying the pH indicators (thymolphthalein and phenolphthalein-based solutions) and using a digital calliper with an accuracy of 0.01 mm, as shown in Figure 1. Each specimen was sliced two times, resulting in a four-sided measurement of 40 x 40 mm, a specimen. In 2 faces the phenolphthalein was applied, and in the other two it was the thymolphthalein. On each side 4

measures were taken (in the central region on each side), which implies that the mean results of carbonation depth were obtained using 16 individual measures.

The compressive strength test (ASTM C349:2018) was performed with the mortars subjected to wet curing for 28 days.

a)  b) 

Figure 1. Measurement of carbonated depth using a) phenolphthalein and b) thymolphthalein.

For result analysis, the data was treated with Dixon statistic test (ASTM E178: 2016) in order to remove spurious values, and then analyzed using variances analysis (ANOVA) to identify the study's significant variables. In addition, multiple comparisons of means were performed by the Duncan test.

3 Results and Discussion

3.1 Compressive Strength

Table 4 presents the results of mortars' compressive strength. It can be noted that the metakaolin mortars achieved higher strengths compared to the reference mortar; in addition, there was no significant difference in strength between A-J1 and A-J2.

Table 4. Compressive Strength at 28 days of age.

Mortar	A - R	A – J1	A – J2
Compressive Strength - mean (MPa)	34	43	42
Standard Deviation (MPa)	10.4	5.0	2.7

3.2 Carbonation

The results of mortars' carbonation depth, for different curing situations, are presented in Figure 2. The carbonation depth is reduced with wet curing, showing the importance of performing curing in order to increase the durability of reinforced concrete. Comparing carbonation depths of mortars submitted to wet curing for 28 days and mortars not submitted to wet curing, it is possible to observe a reduction in carbonation up to 70% for A-R, and 45 % for A-J1 and A-J2.

The increase of wet curing time from 3 to 28 days reflected in a less pronounced depth reduction, about 50%, 25% and 30% for mortars A-R, A-J1 and A-J2, respectively. It is interesting to note that the type of curing exerts a greater influence on the reference mortar than on the metakaolin mortars (A-J1 and A-J2). It was found that concretes modified with metakaolin without the application of any curing procedure show superior carbonation resistance compared to reference concretes. From the literature, it is known that mineral additions such as blast furnace slag and fly ash require wet curing for a long time to consolidate

the pozzolanic reactions (Sulapha *et al.*, 2003), and that superpozzolans such as silica fume, nanosilica and metakaolin are generally not sensitive to wet curing (Couto *et al.*, 2003). This was verified in the present work for metakaolin and the main argument on the issue is based on the physical transformation capacity of the cement paste by the action of pozzolan, which reduces porosity and refines pores, thus increasing the volume of micropores capable of retaining water in its capillary structure (Duan *et al.*, 2013). In these cases, it can be said that self-healing occurs due to changes in the material's microstructure.

The analysis of variance - ANOVA (Table 4) confirms the statement that the type of curing exerts a strong influence on the carbonation depth, while type of mortar did not present significant effect on the results of this research.

Table 4. Carbonation depth ANOVA.

Efect	**SQ**	**GL**	**MQ**	$\mathbf{F_{calc}}$	$\mathbf{F_{tab}}$	**Result** (5% significance)
Model	652.73	11	59.34	78.5	1.8	Significant
Residual Error	278.02	368	0.76			
Total	930.75	379				
Type of curing	574.50	3	191.5	253.5	2.6	Significant
Mix design	2.80	2	1.40	1.9	3.0	Not Significant
Type of curing x Mix design	64.14	6	10.69	14.2	2.1	Significant
Residual Error	278.02	368	0.755			
Coefficient of Determination (R^2) = 0.70				**Coefficient of Correlation (R)** = 0.84		

The multiple comparison of means (Figure 2), where dashed lines indicate separation into different groups, shows that the mortars with metakaolin present a tendency to be similar regarding the carbonation for all the curing conditions. The behavior similarity of mortars A-J1 and A-J2 can be explained by the fact that the metakaolins presented similar reactivity (Chapèlle - Tab. 2), confirmed by the compressive strength results (Tab. 4), despite the chemical, coloring and fineness differences of the two pozzolans. When comparing the metakaolin mortars with the reference mortar (A-R), a distinct behavior is observed. In intermediate curing, the three mortars show same pattern from the statistical point of view.

However, when no wet curing is performed, the reference mortar presents a higher carbonation depth than the mortars with metakaolin. When wet curing is performed for 28 days, this behavior is reversed; this explains the significant interaction between Type of curing x Mix design found in ANOVA (Tab. 4). The approximately 50% increase in carbonation depth for A-J1 and A-J2 regarding A-R, in the wet curing for 28 days situation, can be explained by the hydration process and the pozzolanic reactions, in which the increased time of wet curing allowed better conditions for the hydration and pozzolanic reactions to occur, improving mortars' microstructure, but with pozzolanic reactions there is also reduction in alkaline reserve of mortars with mineral additions (Thomas; Matthews, 1992; Cascudo; Carasek, 2011). In contrast, the shorter depth for A-J1 and A-J2 without wet curing, regarding A-R, can be explained by the greater influence of curing on reference mortar, in addition to the filler and pozzolanic effects of mineral additions, which refined the mortars' porosity and microstructure (Duan *et al.*, 2013), as previously discussed.

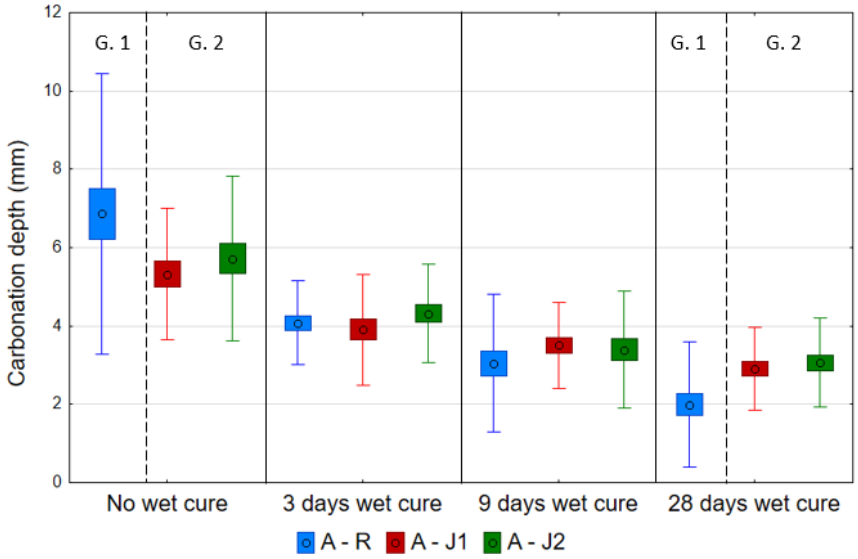

Figure 2. Carbonation depth results analyzed with multiple comparison of means.

3.3 Relationship Between pH Indicators

Figure 3 shows the relationship between the carbonated depth measurements made with thymolphthalein and phenolphthalein, and the strong correlation between these two variables ($R^2 = 0.89$). It is noted that, in general, the thymolphthalein indicated greater depths than the phenolphthalein, which can be attributed to the difference between the indicators' pH turning ranges (phenolphthalein from 8.0 to 9.8 and thymolphthalein from 9.3 to 10.5). Other authors (such as: Kazmierczak; Lindenmeyer, 1996; Yu; Lee; Chung, 2010, Reis; Camões; Ribeiro, 2016; Revert *et al*., 2016, Thiel; Gehlen, 2019) have worked with indicators and discussed the relationships between the measurements obtained.

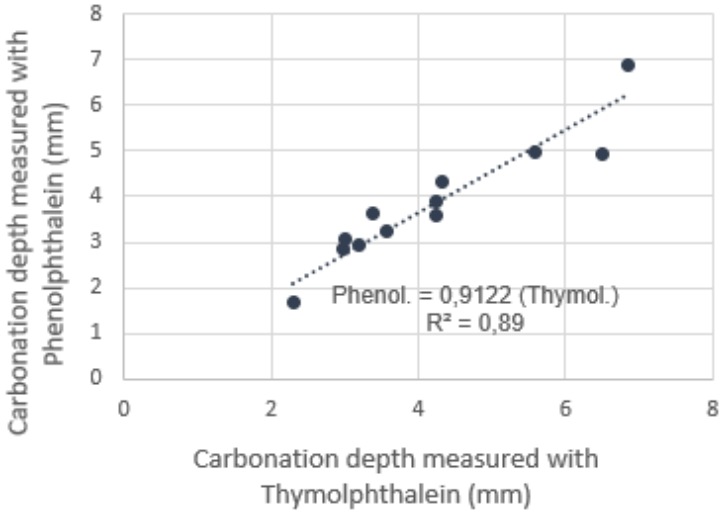

Figure 3. Relationship between carbonated depths with different pH indicators.

The equation obtained for this correlation can be highlighted; the carbonated depth readings with phenolphthalein are equivalent to 0.9 times the readings taken with thymolphthalein. An interesting aspect, and perhaps new, was noticed: this relationship between the variables matches the relationship between the two extremes of the pH ranges nominated by the different pH indicators (9.3 / 10.5 = 0.9; where 9.3 is the maximum pH indicated by phenolphthalein and 10.5 is maximum by thymolphthalein).

4 Conclusions

Based on the research presented, the following conclusions can be drawn:

Despite of the chemical, coloring and fineness differences of both metakaolins studied, there were no statistically significant differences regarding the carbonated depths of the mortars prepared with them. These metakaolins had similar pozzolanic activity (measured by the Chapèlle method), showing that this characteristic is very relevant to explain the carbonation of mortars with metakaolin.

The curing condition had a strong influence on carbonated depths of mortars. This depth is reduced with wet curing and with the increased time of immersion in water, showing the importance of wet curing for increasing the durability of reinforced concrete. However, metakaolin mortars are less affected by wet curing when compared to the non-pozzolan mortars (reference cementitious mortars). This is certainly due to a self-healing action exerted by a microstructure with refined pores, referring to systems with metakaolin, with greater water retention capacity.

As for the carbonate depth measurements performed with phenolphthalein and thymolphthalein based indicators, a strong linear correlation was observed between the two variables ($R^2 = 0.89$). The carbonated depth readings with phenolphthalein are equivalent to 0.9 times the measured readings with thymolphthalein. This relationship between the variables is exactly the relationship between the two extremes of the indicators' pH turning ranges (phenolphthalein = 9.8 and thymolphthalein = 10.5).

Abstract. *Chloride-induced corrosion of reinforcing steel rebar is one of the major durability issues affecting reinforced concrete structures (RC). Various models have been developed to assess the durability design with regard to corrosion prevention in chloride-bearing environments, which refer mainly to uncracked concrete. Cracks, however, are frequently present in real RC structures and accelerate corrosion initiation of steel reinforcement, resulting in a shortened service life. This paper presents preliminary results concerning chloride-penetration resistance of different types of uncracked and cracked concrete, made with Ordinary Portland (OPC), Portland-Limestone (PLC) and Pozzolanic cement (PC) and a water/cement ratio of 0.45. Load-induced micro-cracks were obtained with a specifically developed technique. Cracked and uncracked concrete specimens were immersed in a sodium chloride solution for 32 and 90 days. The chloride penetration front was detected on split surfaces, perpendicular to the exposed surface, with a colorimetric technique to evaluate the combined effect of cracks and cement type on the chloride-penetration resistance of different concretes. Results showed that in uncracked conditions cement type strongly affected chloride penetration depth in concrete. A mathematical model was applied to evaluate chloride diffusion coefficient (D) from chloride penetration depth measurements and exposure time. The lowest value of D was found for PC concrete, that can be attributed to a higher pore refinement in the cement paste, five times higher for OPC and nine times higher for PLC. In cracked conditions, an additional penetration of chlorides occurred in correspondence of crack, even for micro-cracks 10-50 μm wide and 8-30 mm deep, leading to a decrease in chloride penetration resistance. The model however did not provide for an estimation of D in correspondence of the crack.*

Keywords: *Reinforced Concrete Durability, Cracked Concrete, Chloride Penetration Resistance.*

1 Introduction

Reinforced Concrete (RC) is one of the most widely used construction materials for the realization of modern structures and architectures. The considerable efforts made in the recent past to understand the degradation processes affecting RC constructions led to the development of useful tools and design models aimed at preventing corrosion of steel reinforcement rebar, which is the main cause of premature failure of RC structures (Bertolini *et al.*, 2004). These tools and models require several durability-related design parameters, among which the chloride penetration resistance of concrete is of particular relevance for the evaluation of the service life of a RC structure in chloride-contaminated environment.

Several studies have been carried out to investigate the main influencing factors of chloride penetration resistance of concrete, such as, for instance, the cement type. However, these studies - as well as current durability design models - often refer to uncracked concrete, a condition that is rarely met in real RC structures. Cracks in the concrete cover represent a privileged path for chlorides and it is therefore of fundamental importance to evaluate the effects of cracks on chloride penetration resistance of concrete (ACI 201.2R-16, 2016).

In recent years, an ever increasing number of studies has been addressed to this topic (Gu *et al.*, 2015) and, as a general result, it seems that even micro-cracks (crack opening smaller than 100 μm) can locally affect chloride penetration in concrete (Yoon and Schlangen, 2014). In some tests the chloride penetration resistance is evaluated by means the so called colorimetric method. One of the advantages in applying this method to cracked concrete is that it provides a visual detection of chloride penetration in correspondence and in the vicinity of crack. In literature, this method has often been applied to concrete specimens with wide artificial cracks (notches) subject to accelerated exposure test (Audenaert *et al.*, 2007, Marsavina *et al.*, 2009, Li *et al.*, 2016). Few studies, however, have been addressed to the application of colorimetric technique on cracked specimens subject to natural exposure conditions.

In this study, preliminary results are presented within a wider research project concerning the effects of cracks on RC durability. The chloride penetration resistance of three different types of concrete, obtained with water/cement ratio of 0.45 and different cements, was evaluated in uncracked and load-induced micro-cracked configurations. After the immersion of the concrete specimens in NaCl solution for 32 and 90 days, the chloride penetration was evaluated via colorimetric technique, and was correlated with crack geometrical parameters.

2 Experimental Procedure

2.1 Materials and Specimens

Concrete specimens were realized with three different mixes, considering three different types of cement. Details on concrete mixing proportions, and properties at fresh and hardened state are reported in Table 1.

Table 1. Concrete mixing proportions and properties.

	OPC	PLC	PC
Cement, kg/m^3	422	422	422
Water, kg/m^3	190	190	190
Aggregate, kg/m^3	1731	1731	1731
w/c	0.45	0.45	0.45
Superplasticizer, mL	15.5	10	12
Slump, mm	130	170	165
Density, kg/m^3	2496	2526	2477
$f_{c,cube,7days}$, MPa	54.0	56.9	54.6
$f_{c,cube,28days}$, MPa	76.9	60.8	67.4
$f_{c,cube,120days}$, MPa	86.9	76.8	81.4

It was considered an Ordinary Portland Cement (OPC) type CEM I 42,5R as reference, a Portland-Limestone Cement (PLC) type CEM II/A-LL 42,5R, which is one of the most widely used in Italy, and a cement with pozzolanic additions, Pozzolanic Cement (PC) type CEM IV/A(V) 42,5R-SR. The concrete mixes were obtained with 422 kg/m^3 of cement and 190 kg/m^3 of water (w/c ratio equal to 0.45), and 1731 kg/m^3 of limestone aggregates with maximum diameter of 9 mm. To improve workability at fresh state, an acrylic-based superplasticizer was added to each mix. For each concrete type, six cubic specimens 100 mm side were cast for compressive strength, which was executed after 7, 28 and 120 days of moist curing on two specimens per time. For chloride penetration resistance six prismatic specimens of dimensions 120×90×50 mm were manufactured for each concrete type. To promote the formation of the crack during the cracking procedure, four prismatic specimens were provided with a central V-shaped notch, about 5 mm deep, along the longitudinal direction on the casting surface. After casting, all concrete specimens were covered with a plastic film. The subsequent day were demoulded and placed in the curing chamber (four of them after the cracking procedure), where they were kept at 20°C and RH>90% for 28 days. Table 1 shows the average concrete properties at hardened state. An increase of compressive strength in time was observed, with compressive strengths of 77, 61 and 68 MPa reached respectively by OPC, PLC and PC concretes after 28 days of moist curing.

2.2 Cracking Procedure

A mechanical loading procedure was developed in order to induce cracks on the casting surface of specimens. A universal testing machine was used to reproduce a sort of tree-point bending test, as shown in Figure 1. The procedure was executed 24 hours after casting, on specimens presenting the longitudinal notch, for details see (Russo *et al.*, 2019). At the end of the cracking procedure the specimens were placed in the curing chamber.

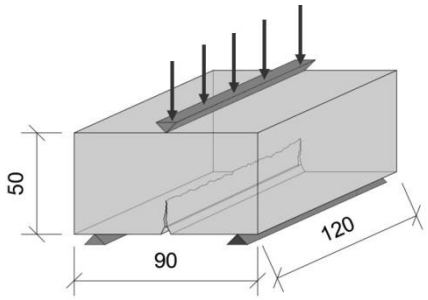

Figure 1. Specimen geometry (dimensions in mm) and cracking procedure.

2.3 Chloride Penetration Resistance

Uncracked and cracked concrete specimens were exposed to chlorides by immersion (EN 12390-11:2005). After 28 days of curing the specimens were vacuum saturated with demineralized water. At the end of the saturation procedure they were left immersed in water and within 24 hours removed from water in order to seal with epoxy resin all the surfaces, except for the casting surface. After 24 hours the specimens were immersed in a saturated solution of calcium hydroxide for 18 hours. Finally, all the specimens were immersed in a 3%

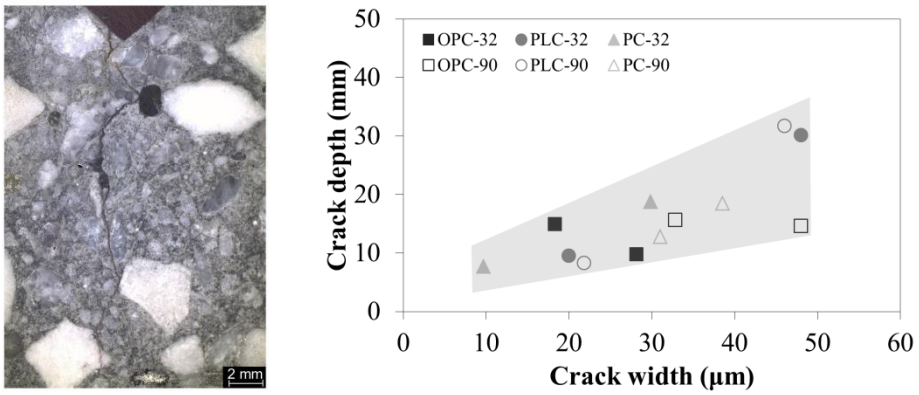
by mass sodium chloride solution, for 32 and 90 days (concrete will be henceforth identified with a code indicating the cement type and the days of exposure, *e.g.* OPC-90 for specimens obtained with Ordinary Portland Cement and exposed to chlorides for 90 days). At the end of the exposure time, the specimens were split with a hydraulic press in one point along the longitudinal direction, and therefore perpendicular to the crack plane for cracked specimens.

On the freshly split surfaces a silver nitrate solution (0.1 M) was sprayed, in order to evaluate the chloride penetration profile. The chloride penetration depth was measured in seven different positions, i.e. in the central point and at a distance of 10 mm, 20 mm and 30 mm on each side. For cracked specimens, the central measure was done starting from the tip of the notch, in order to exclude its influence on the penetration profile. A further measure was also done for cracked specimens, corresponding to the maximum penetration depth starting from the tip of the notch. For each concrete type, two cracked specimens were provided for each exposure time, while the same two uncracked specimens were used for both the exposure times. The fracture surfaces of the uncracked specimens analyzed after 32 days of exposure were sealed with epoxy resin, and the day after were exposed again to chlorides, in order to be analyzed also after 90 days of exposure. After chloride penetration measurements the split surface was impregnated with a colored superfluid two-component epoxy resin. The following day, a thin concrete slice, parallel to the split surface where chloride penetration depth was evaluated, was cut with a water cooled cutting saw. The concrete thin slice was then polished and observed at the stereoscopic microscope in order to detect the two main crack geometrical parameters, crack width and crack depth.

3 Results and Discussion

3.1 Crack Geometrical Parameters

Figure 2a reports, as an example, a wide field image of a cracked PC-90 specimen, obtained combining three different images at 6× of magnification. Wide field observation was done in order to detect the main path of the crack and to identify crack tip. The parameter crack depth was then measured with a caliper, as the distance between the notch tip and the crack tip.



(a) (b)

Figure 2. (a) Microscopic image of cracked PC-90 specimen; (b) Crack width as a function of crack depth.

The parameter crack width is intended as the crack opening at the exposed surface, in correspondence of the tip of the notch. Five measurements were done at 50× of magnification, in a range of about one millimeter from notch tip, and then averaged. Figure 2b reports the results obtained for the two replicated samples of the three concrete types after the two exposure times. Crack widths resulted to be included in the range 10-50 μm, while crack depth included in the range 8-30 mm. Despite data were characterized by a quite high dispersion, increasing crack width an increase also in crack depth was observed, which was independent from the cement type and the exposure time.

3.2 Chloride Penetration Resistance

A colorimetric technique was used to evaluate the chloride penetration profiles on the split surfaces of different cracked and uncracked concretes. Figure 3a and 3c show, as an example, the chloride penetration profile in PLC uncracked and cracked specimens respectively, after 32 days of exposure. The penetration depths in different points after 32 days of exposure for the three cement types are reported in Figure 3b for sound and 3d for cracked configuration.

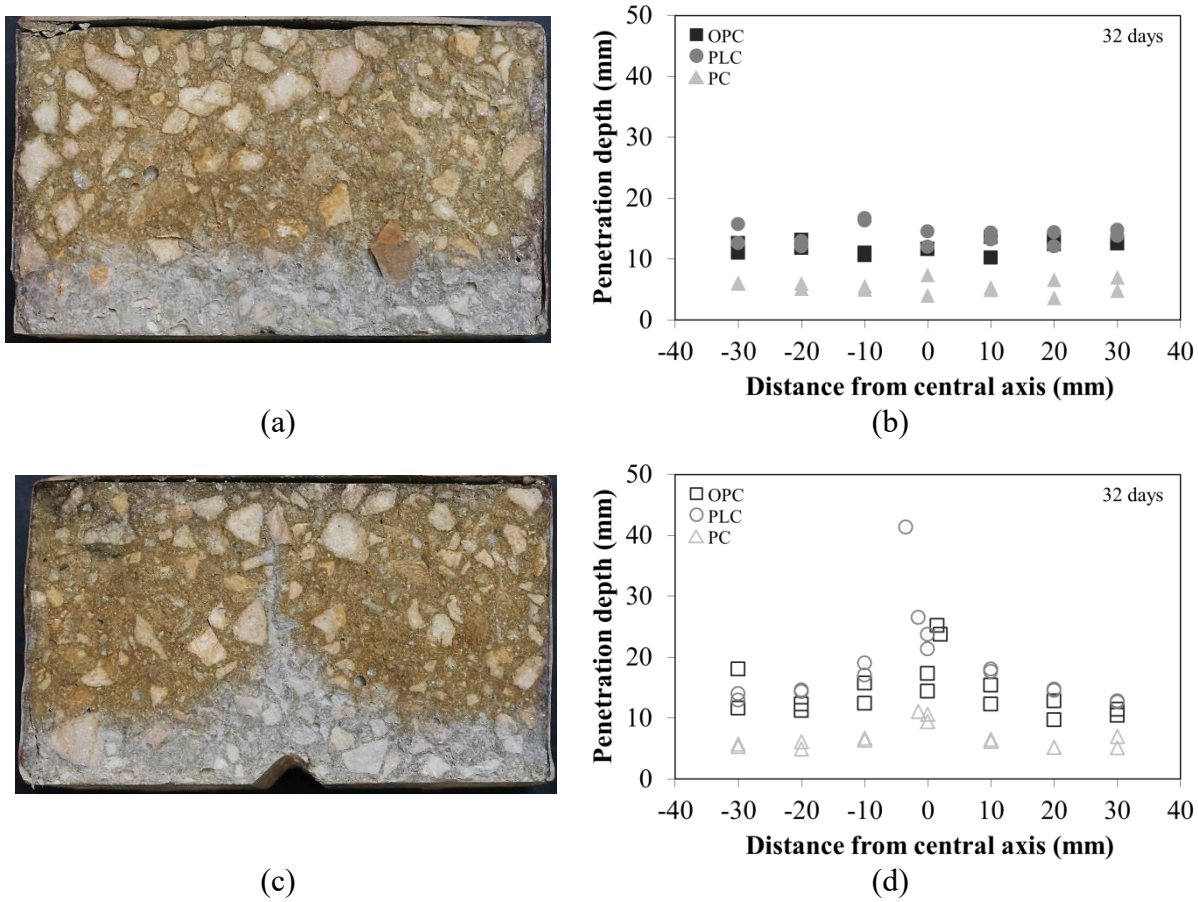


Figure 3. Chloride penetration in PLC-32 (a) uncracked and (c) cracked specimen; Chloride penetration depth measured in different points at different distances from the central axis of the specimen for different concrete types in (b) uncracked and (d) cracked specimens after 32 days of exposure.

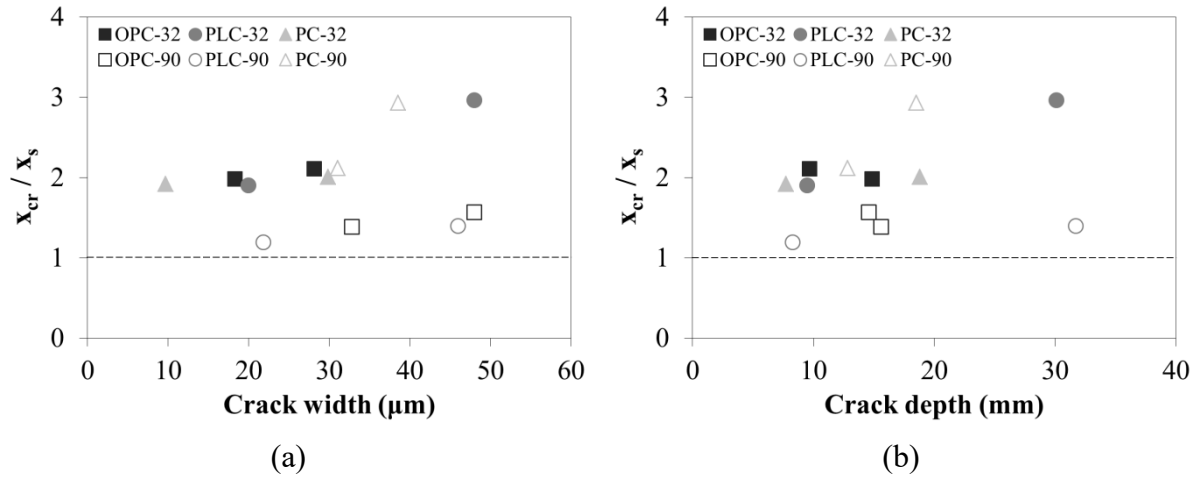

Figure 4. Local increase of chloride penetration depth in correspondence of the crack with respect to sound conditions, as a function of (a) crack width and (b) crack depth.

In Figure 3b it can be observed that, in sound conditions and for each type of concrete, the penetration depth was almost constant along the specimen and comparable between the two replicate specimens. As expected the lowest chloride penetration profiles were referred to the PC cement type, showing a chloride penetration depth of about 5 mm after 32 days of exposure. This can be attributed to a higher pore refinement in the cement paste, and therefore a higher chloride penetration resistance of this concrete type. On the other hand, despite the results of compressive strength, OPC and PLC resulted to have similar chloride penetration depths, of about 10 to 15 mm after 32 days of exposure. The same trend of penetration profile was detected on cracked specimens, except for the measurements carried out in the vicinity of the central axis, where penetration profiles were clearly altered by the presence of the crack (in this point the measurements were done starting from the tip of the notch).

In order to account for the influence of crack geometrical parameters, in Figure 4 is shown the local increase in chloride penetration depth in correspondence of the crack with respect to sound conditions (x_{cr}/x_s) as a function of crack width and crack depth for both the exposure time. x_{cr}/x_s represents the ratio between the chloride penetration depth in the crack and the average penetration depth in sound specimens. It can be observed that chloride penetration in the crack resulted always higher with respect to uncracked conditions, until a maximum of 3 times higher. The local increase of penetration depth in the crack after 32 days of exposure resulted always doubled for crack widths included in the range 10-30 μm and crack depth about 10-20 mm, independently from the concrete type, indicating that micro-cracks could lead to a significant increase of the chloride penetration. After 90 days of exposure, for PC concrete the local increment in correspondence of crack was still similar, while for OPC and PLC a lower local increment was detected, included in the range 1.2-1.5, although crack parameters were comparable to those at 32 days of exposure. This effect will be further investigated to understand if it is due to some self-healing effects, or simply to data scattering.

From the measurements of penetration depths, an attempt was made in order to evaluate chloride penetration resistance of the different concretes in terms of chloride diffusion coefficient. The diffusion coefficient was calculated considering a linear correlation between

the chloride penetration depth and the square root of time, according to the relationship proposed by Collepardi *et al.*, 1970:

$$x = 4\sqrt{Dt} \tag{1}$$

where x is the chloride penetration depth, t is time and D is the chloride diffusion coefficient of concrete.

Figure 5 shows the relationship between the chloride penetration depths for different concretes and the square root of time. It seems that for all cement types in uncracked conditions there is a general decrease in the chloride penetration rate over time (i.e. ageing effect), which has already been detected (Collepardi and Biagini, 1989), although for longer exposure times with respect to those considered in this study. Anyway, a single linear interpolation was done for each type of concrete, and the values of the diffusion coefficient are reported in the chart legend. The highest chloride penetration resistance was detected for the PC concrete, whose chloride diffusion coefficient resulted equal to 0.34×10^{-12} m^2/s, while D was more than 5 times higher for OPC concrete (1.79×10^{-12} m^2/s) and nine times higher for PLC (3.06×10^{-12} m^2/s), consistent with literature data (Collepardi and Biagini, 1989). The determination of the diffusion coefficient from the correlation (1) in the case of cracked configurations resulted to have some limitations, not only because of the ageing effect but also because of crack geometrical parameters, which were different in correspondence of different measurement surfaces. For PC the linear correlation was still able to fit results, and the value of the diffusion coefficient in the crack resulted to be equal to 1.82×10^{-12} m^2/s, more than five times higher than the value measured in uncracked conditions. Conversely, for OPC and PLC cement types, a linear correlation, in correspondence to the crack, could not be detected. This is a direct consequence of the effect previously detected, *i.e.* OPC and PLC showed lower local increase in chloride penetration depths independently from crack parameters at 90 days of exposure.

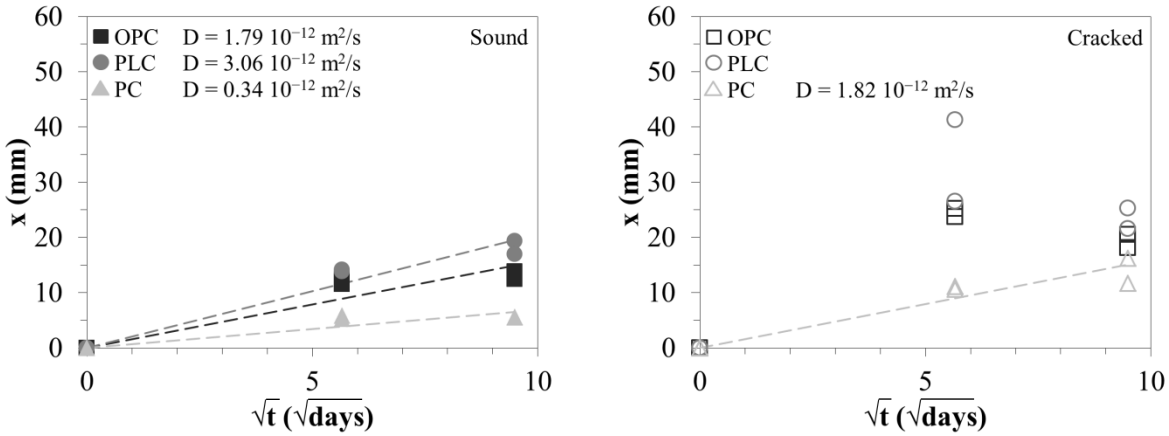

Figure 5. Chloride penetration depths as a function of the square root of time for the different concretes in (a) sound and (b) cracked conditions.

4 Conclusions

Chloride penetration in concretes made with Ordinary Portland (OPC), Portland-Limestone (PLC) and Pozzolanic (PC) cement was investigated through a colorimetric technique in uncracked and cracked configurations. Cracked specimens were obtained with a sort of three-point bending procedure able to generate V-shaped micro-cracks, with crack opening included in the range 10-50 μm and crack depth included in the range 8-30 mm. In uncracked configuration, PC was the concrete type showing lowest chloride penetration depths, due to a higher pore refinement. In cracked configuration the chloride additional penetration in the crack (x_{cr}/x_s) was evaluated as a function of two main geometrical parameters, crack width and crack depth. Independently from the concrete type, x_{cr}/x_s was always included in the range 1.2-3. Chloride penetration resistance of different uncracked and cracked concretes was investigated also in terms of chloride diffusion coefficient (D). In uncracked conditions D resulted to be equal to 1.79×10^{-12} m^2/s for OPC, 3.06×10^{-12} m^2/s for PLC and 0.34×10^{-12} m^2/s for PC concrete. The application of the same mathematical model to cracked concrete resulted limited by the fact that crack geometrical parameters were not considered.

Effect of Coexisting Materials on Secondary Ettringite Formation

Kennosuke Sato[1], Tsuyoshi Saito[2] and Tatsuhiko Saeki[2]

[1] Department of Civil & Environmental Engineering, University of Yamanashi, 4-3-11, Takeda, Kofu, Yamanashi, 400-8511, Japan, satok@yamanashi.ac.jp

[2] Department of Civil Engineering, Niigata University, 8050, Ikarashi Ninocho, Nishiku, Niigata, 950-2181, Japan, tsaito@eng.niigata-u.ac.jp

Abstract. *The expansion of cement paste can occur as a result of secondary ettringite formation due to attack by sulfates. It has been proposed that this expansion is affected by coexisting hydration products such as calcium-silicate-hydrates (C-S-H), although the mechanism has not yet been clarified. The present study experimentally examined the effects of coexisting materials on secondary ettringite formation. Synthesized monosulfate and coexisting materials such as C-S-H were mixed with a sodium sulfate solution. The secondary ettringite proportion was markedly increased by the presence of C-S-H, and calcium-aluminate-silicate-hydrates (C-A-S-H) containing four-coordinate Al were formed in these samples. It is evident that ettringite is likely to form from four-coordinate Al, and that C-S-H promotes secondary ettringite formation because it transitions six-coordinate Al derived from the monosulfate to four-coordinate Al by substituting Al in the Si chains.*

Keywords: *Sulfate Attack, DEF, Secondary Ettringite Formation, Coexisting Materials, C-S-H.*

1 Introduction

Expansion due to sulfates is typically referred to as either external or internal sulfate attack, depending on the sulfate source. Internal sulfate attack after high temperature curing is also referred to as delayed ettringite formation (DEF) (Collepardi, 2003). Both external and internal sulfate attack are attributed to secondary ettringite formation in the cement paste.

Ettringite has the composition $C_6A\bar{S}_3H_{32}$ and is formed from tricalcium aluminate (C_3A) in Portland cement or from aluminum in supplementary cementitious materials during the early stages of hydration. Ettringite is subsequently converted to a monosulfate (Ms) form having the formula $C_4A\bar{S}H_{12}$ as the sulfate ion concentration in the liquid phase decreases. When sulfate ions are supplied to the hardened cement paste they react with the Ms to reform so-called secondary ettringite. However, the mechanisms which can explain all expansions due to secondary ettringite formation in a unified manner has not yet been proposed.

It has been suggested that the expansion due to secondary ettringite formation is affected by the properties of hydration products coexisting with the ettringite, such as calcium-silicate-hydrates (C-S-H). Taylor *et al.* (2001) proposed the DEF expansion mechanism in a mortar. According to this mechanism, ettringite may have a greater degree of expandability when it is formed in the outer C-S-H near the boundary between two C-S-H phases (outer C-S-H and inner C-S-H) than when it is formed in the outer C-S-H far from the boundary.

The goal of the present study was to experimentally examine the effects of coexisting materials on secondary ettringite formation. This was accomplished using a synthesized Ms sample in conjunction with coexisting materials such as C-S-H. The Ms and other materials were mixed and hydrated using a sodium sulfate solution, followed by analysis.

doi:10.23967/dbmc.2020.153

2 Methods and Materials

2.1 Preparation of Materials

The Ms was prepared from a suspension of a 1:1 molar mixture of C_3A, which was prepared by calcining of $CaCO_3$ and Al_2O_3, and $CaSO_4$ in deionized water, at a water to solid mass ratio of 10:1. The solid and aqueous phases were separated after curing at 20 °C for 14 d.

C-S-H, calcium hydroxide (CH) and hydrogarnet (HG) were used as the coexisting materials in this work. Because silica stone does not react at ambient temperature and pressure, silica stone powder (SSP) was also used for the purposes of comparison with other coexisting materials. In addition, amorphous silica (AS) and Al-substituted C-S-H (C-A-S-H) were used in verification experiments. Three C-S-H samples having different CaO to SiO_2 molar ratios (C/S ratio) (of 0.80, 1.00 and 1.50) were synthesized by reacting mixtures of CH, ethyl silicate and deionized water for 2 d at 40 °C, after which the solid and aqueous phases were separated by vacuum filtration. HG was synthesized via the reaction of C_3A with deionized water at a water to solid mass ratio of 1:1. Samples were cured for 28 d at 40 °C, after which the solid phase was separated by vacuum filtration. C-A-S-H was synthesized based on the method of Pardal *et al.* (2009). The CH, AS and SSP (purity > 96%) used in this work were all commercially-available products.

These materials were dried under 110 °C in a drying oven (defined as 0% RH), and subsequently crushed into particles smaller than 90 μm. The H_2O to SiO_2 molar ratios of C-S-H having the C/S ratios of 0.8, 1.0 and 1.5 dried at 110 °C were 0.63, 0.67, 0.82, respectively.

2.2 Mixing with a Sodium Sulfate Solution

The mixing proportions of the Ms and the coexisting materials are summarized in Table 1. Herein, the C-S-H and C-A-S-H specimens are termed CSH0.8, CSH1.0, CSH1.5, CASH0.8, CASH1.0 and CASH1.4, where the numerical portion of the name gives the C/S ratio. The effects of the chemical composition of the mixture were assessed by simultaneously

Table 1. Specimen proportions.

Sample name	Powder composition (mass%)										
	Ms	CSH 0.8	CSH 1.0	CSH 1.5	CH	HG	SSP	AS	CASH 0.8	CASH 1.0	CASH 1.4
Ms+CSH 0.8	50	50	–	–	–	–	–	–	–	–	–
Ms+CSH 1.0	50	–	50	–	–	–	–	–	–	–	–
Ms+CSH 1.5	50	–	–	50	–	–	–	–	–	–	–
Ms+CH	50	–	–	–	50	–	–	–	–	–	–
Ms+HG	50	–	–	–	–	50	–	–	–	–	–
Ms+SSP	50	–	–	–	–	–	50	–	–	–	–
Ms+AS	50	–	–	–	–	–	–	50	–	–	–
Ms+(CH+AS)1.0	50	–	–	–	27.61	–	–	22.39	–	–	–
Ms+(CH+AS)1.5	50	–	–	–	32.46	–	–	17.54	–	–	–
Ms+CASH 0.8	50	–	–	–	–	–	–	–	50	–	–
Ms+CASH 1.0	50	–	–	–	–	–	–	–	–	50	–
Ms+CASH 1.4	50	–	–	–	–	–	–	–	–	–	50

combining CH and AS with the Ms. In these trials, the CH and AS were mixed so that the C/S ratio was either 1.00 or 1.50 and the mixture was combined with the Ms at a mass ratio of 1:1.

Each mixture of the Ms and the coexisting materials were mixed with a 0.5 M sodium sulfate solution at a liquid to powder mass ratio of 2:1. They were manually mixed for 3 m and transferred into a plastic bottle and cured at 20 °C for 1 d.

After the curing, the samples were broken into small pieces and immersed in acetone for 2 d to prevent further hydration. These specimens were subsequently placed under vacuum to remove the acetone and stored in a vacuum desiccator in the presence of silica gel for 2 d. The samples were crushed into particles smaller than 90 μm and dried at 20 °C and 11% RH using a saturated LiCl solution in a vacuum desiccator until the sample mass no longer changed.

2.3 Analysis

Powder XRD was used for the identification and quantification of hydration products after mixing with the sodium sulfate solution.

For the measurement of the pH and ionic composition of the liquid phase, a Ms specimen together with coexisting materials were mixed with a 0.5 M sodium sulfate solution at a liquid to powder mass ratio of 3:1. After mixing, each sample was placed in a plastic bottle and then cured at 20 °C for 1 d, after which the solid and liquid phases were separated by centrifugation. The pH of the liquid phase was measured using a glass electrode pH meter and the concentrations of Na^+, Ca^{2+} and SO_4^{2-} ions in the liquid phase were analyzed.

Solid state ^{27}Al nuclear magnetic resonance (NMR) was employed to determine the chemical state of Al in each sample after mixing with the sodium sulfate solution. The ^{27}Al magic angle spinning (MAS) NMR experiments were performed with a ECA800 operating at 18.79 T with a 3.2 mm probe and a spinning frequency of 20 kHz. ^{27}Al spectra were recorded with a 0.6 μs pulse width and a recycle delay of 1 s between scans.

3 Results

3.1 Formation Characteristics of Secondary Ettringite

Figure 1 shows the XRD patterns of Ms samples with each coexisting material after mixing with the sodium sulfate solution. SSP does not react at ambient temperature and pressure, and so does not contribute to secondary ettringite formation. The ettringite peaks of the Ms+CH and Ms+HG were not increased in intensity as compared with Ms+SSP. Thus, when CH and HG coexist (that is, even when the Ca and Al necessary for the formation of the secondary ettringite are supplied), there was almost no secondary ettringite formation. In contrast, the diffraction peaks due to Ms almost disappeared while those resulting from ettringite increased when C-S-H was added to the Ms.

3.2 Effects of pH and Calcium Leaching

The pH values and ionic compositions of the liquid phases after mixing with the sodium sulfate solution are provided in Table 2. In all cases, the pH was in the range of 11.57 to 13.39, which is associated with the stable formation of ettringite (Stark and Wicht, 2003; Shimada et al., 2005). The Ms+CSH1.5 had the highest Ca^{2+} concentration, and the values for the Ms+CSH0.8 and Ms+CH were especially close. The pH of the Ms+CH was higher than that

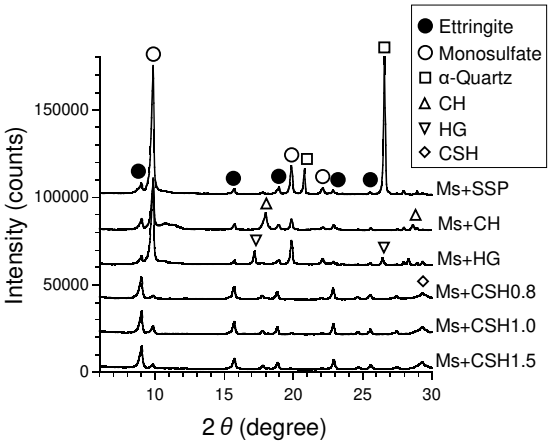

Figure 1. XRD patterns of monosulfate specimens with coexisting materials after mixing with a sodium sulfate solution.

Table 2. pH values and ionic compositions of the liquid phases.

	pH	Na^+ (mol/L)	Ca^{2+} (mol/L)	SO_4^{2-} (mol/L)
Ms	12.38	1.81	0.01	0.35
Ms+SSP	12.54	1.13	0.02	0.38
Ms+HG	12.43	1.11	-	0.34
Ms+CH	13.39	1.09	0.04	0.05
Ms+CSH0.8	11.68	0.78	0.04	0.24
Ms+CSH1.0	12.60	0.88	0.06	0.28
Ms+CSH1.5	11.57	0.86	0.12	0.13

of the Ms+CSH0.8, although the amount of secondary ettringite in the latter material was significantly greater than that in the former. Kunther *et al.* (2015) reported that of the extent of Ca^{2+} leaching decreases with decreases in the C/S ratio of the C-S-H, such that the supersaturation of ettringite in the pore solution decreases and expansion of the mortar is suppressed. This suggests that a higher Ca^{2+} concentration in the liquid phase will promote secondary ettringite formation. However, the results of this study show large differences in the extent of secondary ettringite formation, even when the Ca^{2+} concentration in the liquid phase is constant. Moreover, although the Ca^{2+} concentration of the liquid phase was slightly higher in the case of the Ms+CSH1.0 compared with the Ms+CSH0.8, and both pH values were in the range required for ettringite to be stable, the amount of secondary ettringite in the latter material was greater. Thus, the promotion of secondary ettringite formation due to the presence of C-S-H is not completely explained by conventional theories regarding the effects of the pH and Ca^{2+} concentration of the liquid phase.

3.3 Effects of Ca and Si-Based Materials

Si in the C-S-H is thought to have played an important role in secondary ettringite formation in the present work. Figure 2 shows the XRD patterns of Ms specimens with added Ca and Si-based materials after mixing with the sodium sulfate solution. For comparison, the XRD patterns generated by the Ms+SSP, Ms+CH, Ms+CSH1.0 and Ms+CSH1.5 are also provided

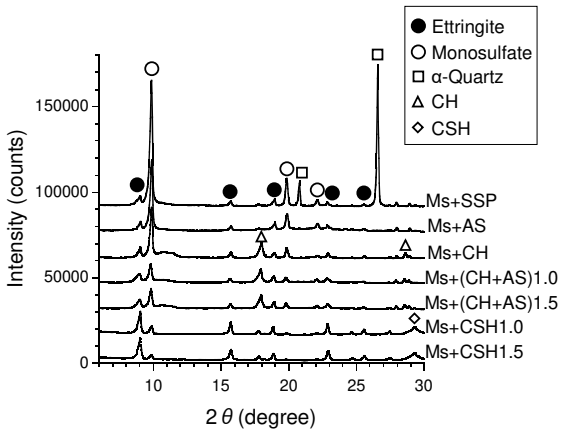

Figure 2. XRD patterns of monosulfate specimens with added Ca and Si after mixing with a sodium sulfate solution.

in the figure. These patterns demonstrate that the Ms diffraction peaks produced by the Ms+AS were slightly less intense than those in the Ms+SSP pattern. When both CH and AS were present, the Ms peaks were further decreased. Therefore, it appears that the simultaneous addition of both Ca and Si promoted the dissolution of the Ms. Conversely, the ettringite peaks did not increase significantly even when both CH and AS coexisted. Thus, even when the chemical composition in the sample is the same as that of C-S-H, the amount of secondary ettringite is greatly increased only when C-S-H is present.

3.4 Evaluation of the Chemical State of Al

The chemical state of Al, which is an important constituent element of both Ms and ettringite, was investigated using ^{27}Al NMR. Figure 3 shows the ^{27}Al NMR spectra of Ms specimens with each coexisting material after mixing with the sodium sulfate solution. For all coexisting materials, two peaks corresponding to six-coordinate Al appeared. These two peaks are attributed to Ms and ettringite (Skibsted *et al.*, 1999; Andersen *et al.*, 2004). The Ms+HG also generated a HG peak close to the ettringite peak (Cuesta *et al.*, 2017). In the case of the sample without C-S-H, a six-coordinate Al peak produced by the Ms is clearly present. In contrast, the spectra obtained from the samples with C-S-H contain a significantly reduced Ms peak along with a much more intense ettringite peak. Thus, these ^{27}Al NMR data also demonstrate that the coexistence of C-S-H promoted secondary ettringite formation.

Moreover, each of the three samples containing C-S-H generated a broad peak corresponding to four-coordinate Al. This peak is also generated by C-A-S-H, in which Al is substituted for Si in the silicate chains of C-S-H at pairing and bridging sites (Richardson, 2004). Because the bridging sites in the silicate chains are increased as the C/S ratio decreases, Al is more readily substituted for Si at these sites (Pardal *et al.*, 2012; Renaudin *et al.*, 2009). It is therefore apparent that, in samples containing C-S-H, the Si in the silicate chains were substituted with Al released by dissolution of the Ms to generate C-A-S-H.

3.5 Effect of the Presence of C-A-S-H

Figure 4 presents the XRD patterns of Ms specimens with added C-A-S-H after mixing with the sodium sulfate solution, along with the patterns of the C-S-H samples for comparison

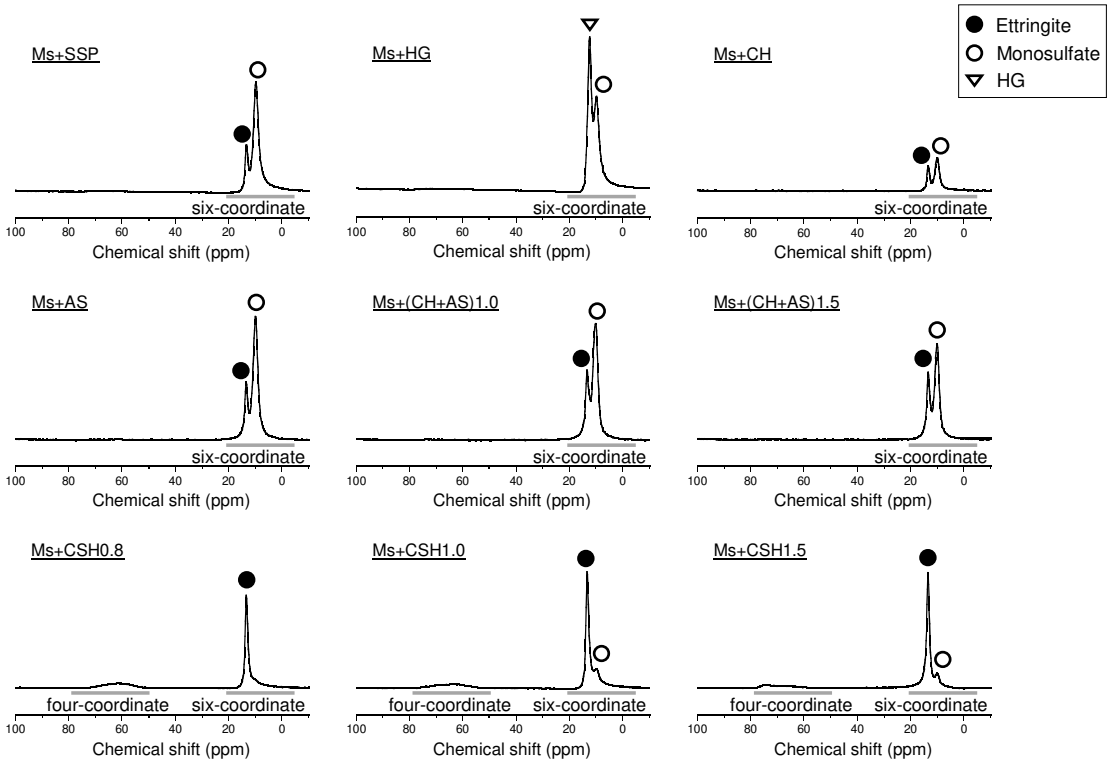

Figure 3. ^{27}Al NMR spectra of monosulfate specimens with coexisting materials after mixing with a sodium sulfate solution.

purposes. The Al/Si ratio in the C-A-S-H was 0.05. These data confirm that the Ms+CASH generated more intense Ms peaks than the Ms+CSH at equivalent C/S ratios. In addition, although the ettringite peaks were less intense than those generated by the samples containing C-S-H, these peaks were more intense compared with those generated by samples with other coexisting materials. Therefore, in the case of the Ms+CASH, the reaction of the Ms did not proceed as readily, although the ettringite peak was relatively high. These results suggest that C-A-S-H contributed to the formation of secondary ettringite by supplying Al.

Figure 5 provides the ^{27}Al NMR spectra of Ms samples with C-A-S-H after mixing with the sodium sulfate solution. These spectra confirm that the peak ascribed to six-coordinate Al in the Ms was more intense than those generated by specimens made with C-S-H. The samples with C-A-S-H as the coexisting material also produced six-coordinate Al peaks corresponding to ettringite that were comparable to those obtained from the C-S-H samples.

The combined XRD and NMR data suggest that the presence of C-A-S-H promoted secondary ettringite formation primarily by consuming four-coordinate Al in the C-A-S-H.

4 Discussion

This work demonstrates that only the presence of C-S-H markedly increased the amount of secondary ettringite in the samples. The ^{27}Al NMR spectra show that four-coordinate Al appeared only in samples in which C-S-H coexisted with the Ms, and this Al is attributed to the C-A-S-H (Richardson, 2004). Samples containing C-A-S-H were mixed with the sodium sulfate solution and examined by XRD and ^{27}Al NMR. The level of ettringite was found to be

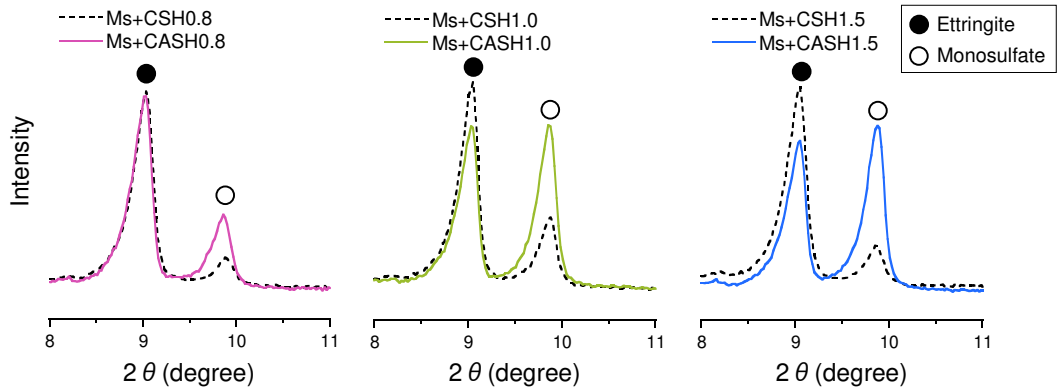

Figure 4. XRD patterns of monosulfate specimens with C-S-H or C-A-S-H after mixing with a sodium sulfate solution.

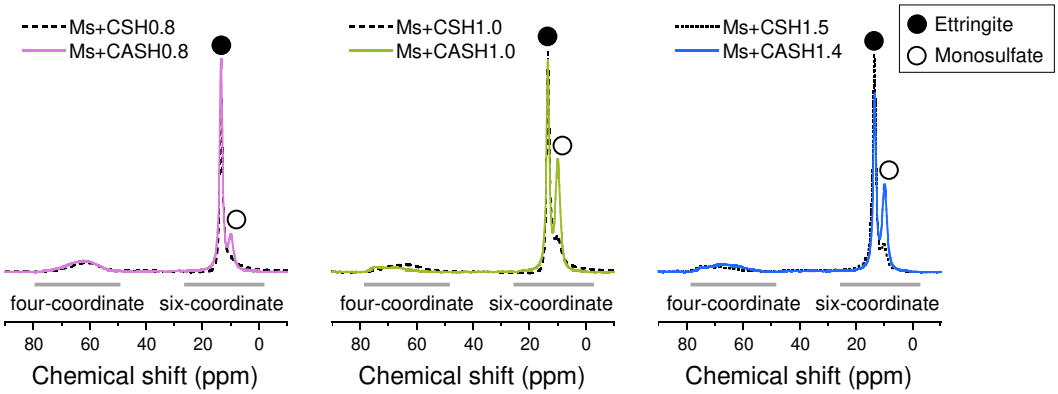

Figure 5. ^{27}Al NMR spectra of monosulfate specimens with C-S-H or C-A-S-H after mixing with a sodium sulfate solution.

equal to that in samples containing C-S-H, although the Ms peaks were not deceased.

These results suggest that the presence of four-coordinate Al is closely related to se condary ettringite formation, hence we assessed the Al coordination numbers in the samples. In the absence of coexisting materials, or when materials other than C-(A)-S-H coexist with the Ms (that is, when four-coordinate Al is not present), ettringite having six-coordinate Al is directly formed from Ms having the same six-coordinate Al. Under such conditions, the formation of secondary ettringite does not readily proceed.

In the case that C-S-H is present, Al released from the Ms is substituted into the silicate chains in the C-S-H. As a result, C-A-S-H is formed with four-coordinate Al. If a sufficient concentration of sulfate ions is available, ettringite is more likely to be formed from four-coordinate Al than from the six-coordinate Al in the Ms. That is, the presence of C-S-H promotes secondary ettringite formation by changing the Al coordination number.

As such, ettringite is likely to be formed from four-coordinate Al, and C-S-H promotes secondary ettringite formation by substituting Al into the silicate chains and converting six-coordinate Al to four-coordinate. On the other hand, using SCMs is beneficial to decrease sulfate attack, while the production of C-A-S-H is increased with the amount of added SCMs. Based on the results of the present study, ettringite is likely to be formed when SCMs are used,

however; the expansion is actually suppressed. Because of that, the expansion due to secondary ettringite formation may be related not only to the amount of ettringite but also to the location of ettringite formation.

5 Conclusions

The purpose of this study was to investigate experimentally the effects of coexisting materials on secondary ettringite formation. The conclusions can be summarized as follows.

- When monosulfate and C-S-H are mixed with a sodium sulfate solution, the amount of secondary ettringite is increased in comparison with other coexisting materials.
- The ^{27}Al NMR results confirm that C-A-S-H containing four-coordinate Al is formed in samples made with C-S-H. In addition, when C-A-S-H is added to the monosulfate, secondary ettringite is generated at a comparable level to that found in the C-S-H samples, although the monosulfate remains intact. It appears that ettringite is likely generated from four-coordinate Al, and that C-S-H promotes secondary ettringite formation as a result of transitioning six-coordinate Al to four-coordinate Al by substituting Al in the Si chains.

Abstract. *This study examined crack repair methods using alginate gel films (1.5 wt.%) mixed with healing agents under wet and dry actions. The healing agents consist of Bacillus subtilis (natto) as an aerobic microorganism and glucose as an organic carbon source, thereby producing insoluble calcium carbonate in the gel films in the presence of calcium ions. In this study, repaired surface in cracked mortar specimens (ϕ50×100mm) was observed by microscope. In addition, water absorption test was carried out in assessing the effectiveness of crack repair for the cases of alginate gel films with or without calcium carbonate precipitation induced by the microbial activities. Based on the observations made by microscope, precipitates in white color were clearly observed after 8 weeks on the cracked surface of specimens especially under wet conditions. In the case of the specimens with higher sealing rate of crack repair, the alginate gel films were remained intact under dry and wet actions, which is advantageous to keep moisture by swelling. Water absorption test was carried out using repaired mortar specimens with average crack size of 0.5 mm. Based on the results obtained, water absorption rate is substantially decreased in the specimens with increasing sealing rate of crack repair. The results suggest that higher crack sealing rate associated with calcium carbonate precipitation leads to higher resistance against water absorption tested in accordance with ASTM C 1585.*

Keywords: *Self-Healing, Aerobic Microorganisms, Bio-Composite, Water Absorption.*

1 Introduction

Recently, repair materials associated with microbial induced calcium carbonate precipitation (MICCP) have been intensively studied in the field of self-healing concrete *e.g.* (Jonkers *et al.*, 2010). We proposed a liquid based repair system comprising dry yeast, organic carbon sources, calcium sources mixed with Tris alkali buffering solution (Kawaai *et al.*, 2016; Putri *at el.*, 2016). The grout used for repairing cracks in concrete is supposed to seep into deeper zones in cracks, joints and gaps spatially distributed in larger areas. Then, calcium carbonate precipitation mainly contributing to the sealing effect can be formed in the cracks well before 24 hours (Kawaai *et al.*, 2016). It has been reported that the precipitation rate was largely dependent on the concentration of constituents, pH levels, and ambient environment such as temperature. The effect of temperature is significant in facilitating the precipitation process (Putri *et al.*, 2016), thus leading to a larger amount of precipitates formed compared to those tested in normal room conditions.

Apart from the grout system, the activity of Bacteria added to mixing water was observed to be limited owing to the pore solution with highly alkaline environment (Jonkers, 2011). In order

to protect them from corrosive agents and the severe environment, much research has been carried out in the development of encapsulation techniques including expanded clay particles, glass tubes, superabsorbent polymer, more recently alginate-based systems (Jonkers, 2011; Tittleboom *et al.*, 2011; Wang *et al.*, 2014; Palin *et al.*, 2016).

According to past research reported by Kawaai *et al.*, (2017), precipitation of calcium carbonate in alkaline environment has been confirmed by precipitation tests using aerobic Bacillus subtilis (natto) encapsulated in calcium alginate capsules. Sodium alginate extracted from brown seaweed could provide viscosity in aqueous solution, which varies depending on the concentrations. When sodium alginate dissolved in a liquid is used for repairing cracks in concrete, there is a strong possibility that the alginate reacts with calcium ions available on the cracked surface, thus forming a polymer comprising calcium alginate via ion-link on the cracked surface. This could result in in-situ encapsulation for the microorganism and nutrients in the cracks. Generally, there are two types of microorganisms, anaerobic and aerobic microorganisms. The former can metabolize an organic carbon sources in an oxygen-free environment. On the other hand, the latter requires oxygen for the metabolic activity. In this study, we selected Bacillus subtilis (natto) as an aerobic microorganism. The liquid-based mixture is supposed to be applied to concrete structures in tidal zones under marine environment. Dissolved oxygen is expected to be available during the wet and dry cycles. Based on the above background, this study examines the effect of crack repair using the viscosity modified mixture containing the Bacillus subtilis (natto) and nutrients via liquid-based approach under wet and dry conditions

2 Experimental Programs

2.1 Materials

First, culture solution of Bacillus subtilis (natto) containing sodium alginate is stirred using a stirrer for 30 minutes until the sodium alginate dissolves. Subsequently, Tris buffer solution or glucose is added. The concentrations of each constituent of the mixtures are shown in Table 1.

The experimental parameters include the presence (N1 mixtures) and absence (W mixture) of Bacillus subtilis (natto), the concentration of sodium alginate is specified as 1.5 wt.% for all the mixtures tested. The use of Tris buffer solution with concentrations of 0.1 mol/L is also considered as a testing parameter. In this study, three mixtures were totally prepared.

Table 1. Concentrations of each constituent of mixtures.

Mixtures		Sodium Alginate (%)	Glucose (mol/L)	Tris buffering solution (mol/L)
N1	N1-G1-T0	1.5	0.4	-
	N1-G1-T1	1.5	0.4	0.10
W	W -G0-T0	1.5	-	-

2.2 Cultivation of Bacillus Subtilis (natto)

In this study, Bacillus subtilis (natto) was cultivated using culture media mainly comprising NH_4Cl, NH_4NO_3, Na_2SO_4, $MgSO_4$, $CaCl_2$, K_2HPO_4, KH_2PO_4 in this study. The round rod shape of Bacillus subtilis (natto) forms a spore per a bacterial cell in the bacterial body. Spores are formed when it becomes an environment not suitable for growth such as oxygen, water and nutrient sources. And then, they become dormant and inactive. However, if the environment is set, the spore dormancy state ends, and germination begins. And then it becomes vegetative cell and the activity starts. Therefore, the Bacillus subtilis (natto) has higher resistance to environmental fluctuation compared to other microorganisms. In this study, the culture solution of the Bacillus subtilis (natto) after 24 hours was used as repair mixtures. Before preparing the mixtures, the dissolved oxygen concentration in the culture solution was measured to confirm the metabolic activity of Bacillus subtilis (natto) without an aeration apparatus.

2.3 Specimen Preparation and Exposure Tests

In this study, a mortar specimen with a water cement ratio of 0.5 and unit water content of 316 kg/m^3 and unit weight of crushed sand 1264 kg/m^3 was prepared using a cylindrical mold of ϕ 50×100 mm. Specimens were demolded after 24 hours and sealed curing was carried out until the age of 28 days. In order to simulate the cracks generated in the concrete member, split cracks were induced using a loading machine. The experimental set-up is similar to tensile strength test. The crack width was targeted around 0.5 mm. And then, the repair mixtures were poured into the cracks. After 1 week, exposure tests were carried out either through wet conditions (12 hours) and dry conditions (12 hours) or only wet conditions (24 hours). Wet cycles were executed using distilled water containing NaCl (3%) for both cases.

2.4 Measurement of Crack Width and Sealing Rate

The crack width and sealing rate by MICCP are measured using microscope (Dino-Lite Edge AM7915, ANMO) as shown in Figure 1. The five points highlighted in the figure are consistently measured using two specimens subjected to each exposure condition. The sealing rate is calculated based on the ratio of widths occupied with the precipitates over crack widths at each measurement point.

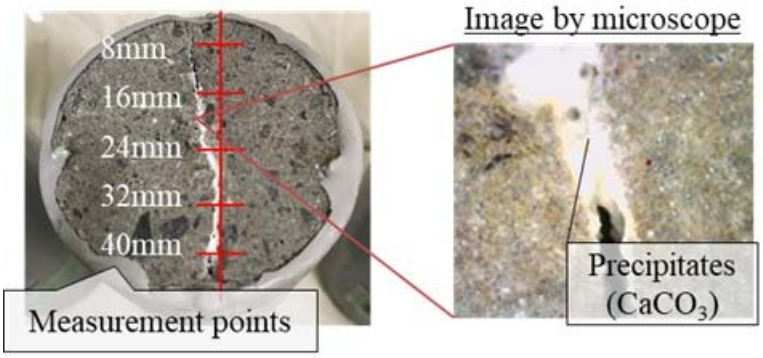

Figure 1. Measurement of crack width and sealing rate by microscope.

2.5 Measurements of Rate of Absorption of Water

The rate of absorption of water was measured in accordance with ASTM C 1585-13 using the specimens subjected to wet and dry cycles or wet condition. The test is carried out in such a way that the repaired surface was exposed to the distilled water and the water is basically absorbed through the capillary suction as shown in Figure 2. The measurements were carried out up to 7 days at predetermined intervals. Based on the changes of weight of the specimens, the rate of absorption of water is calculated using Eq. (1).

$$I = \frac{m_t}{ad} \tag{1}$$

where I: rate of absorption of water, m_t: changes of weight of the specimen, a: area of the immersed surface, d: density of water.

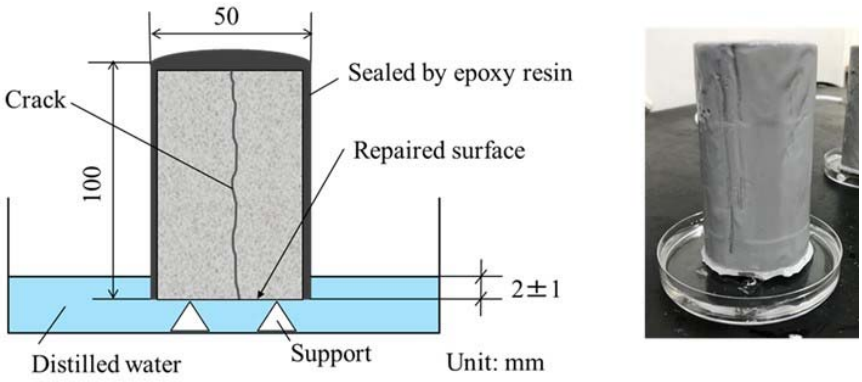

Figure 2. Testing set-up of absorption of water.

3 Experimental Results and Discussion

3.1 Exposure Tests Under Wet and Dry Cycles

For the mortar specimens repaired with each mixture, the materials formed on the cracked surface were firstly observed by microscope. The observations were made before repaired, 7 days later before the specimens were exposed to the dry and wet cycles and 56 days after the exposure. It should be noted that the average crack width was about 0.57 mm for the specimens tested. As can be seen in Figure 3, precipitates in white colour were not observed by microscope on the specimens for all the mixtures tested after the specimens were exposed to the room conditions controlled at 20°C for a week. Subsequently, precipitates were clearly observed on the specimens repaired with each mixture. However, the distribution of precipitates was largely varied, thus resulting in differences in the sealing rate. The sealing rates were 25.8% (N1-G1-T1), 40.0% (N1-G1-T0), 10.0% (W-G0-T0), and 13.8% (No repair). As observed by microscope, the sealing rate is clearly higher in the cases of specimens repaired with the N1 mixtures. It should be noted that the self-healing could naturally take place in the absence of

the microorganism owing to the unhydrated cement and carbon dioxide dissolved in the distilled water. The difference observed in the sealing rate could be also affected by the gel films formed on the cracked surface. It is partly because the moisture kept in the gel films can be released to the crack even under dry conditions in the exposure conditions. Thus, the sealing effect could be obtained even under the dry conditions in such a case. As observed on the repaired surface after the exposure tests, the higher sealing rate obtained in the case of N1-G1-T0 mixture can be explained by the fact that the gel films were present and remained intact through the dry and wet actions.

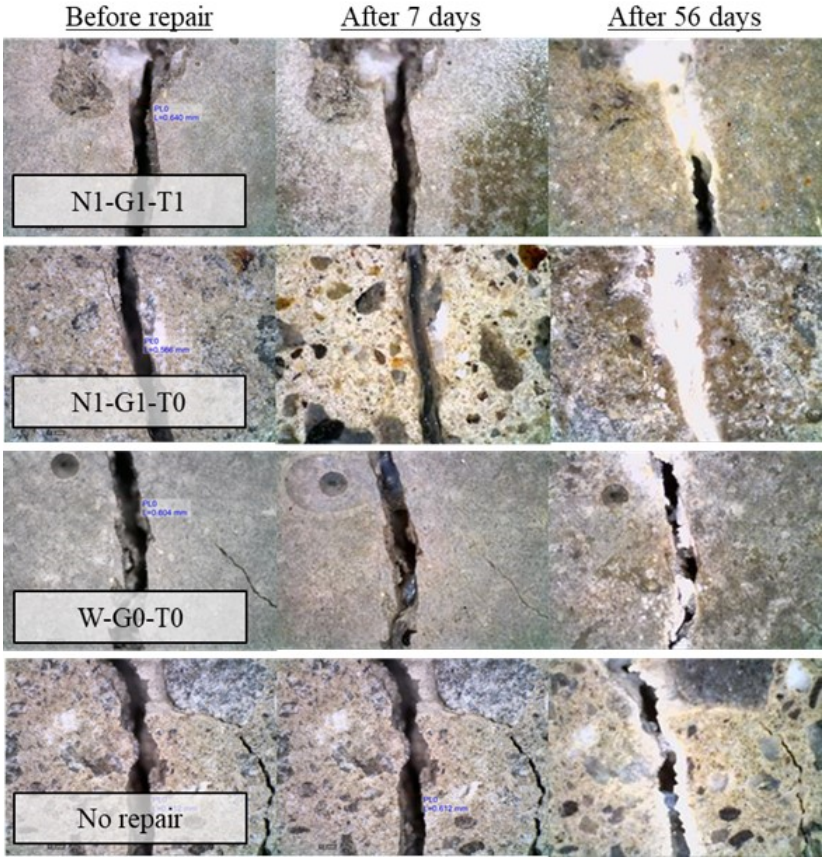

Figure 3. Observations by microscope on the repaired surface (wet and dry condition).

3.2 Exposure Tests Under Wet Condition

For the specimens exposed to the wet condition, the average crack width ranged from 0.48 to 0.51 mm. As shown in Figure 4, similar to those observed in the specimens subjected to the wet and dry conditions, precipitates in white color were clearly observed by microscope on the specimens especially repaired with the N1 mixtures after 56 days exposure. The sealing rates were 53.0% (N1-G1-T1), 74.4% (N1-G1-T0), 35.4% (W-G0-T0), and 37.9% (No repair). The effect of repair with respect to the sealing rate was found to be higher in the case of the wet conditions compared to those observed in the specimens exposed to the wet and dry environment. This could be attributed to the higher availability of moisture and dissolved oxygen for the MICCP processes in the N1 specimens. It should be noted that the gel films were

remained intact especially in those specimens. This contributed to the bio-composite formation accompanied by the calcium carbonate precipitations inside the gel films. The specimens repaired with each mixture and exposed to the exposure tests were further tested by the water absorption tests, which is discussed in Section 3.3.

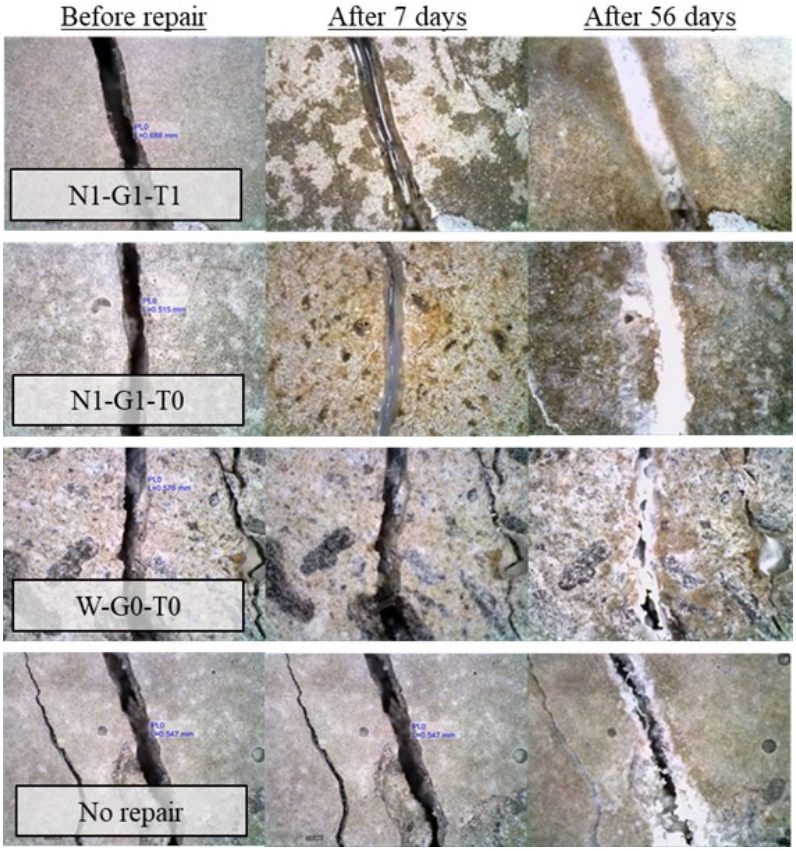

Figure 4. Observations by microscope on the repaired surface (wet condition).

3.3 Rate of Absorption of Water

Water absorption test was carried out based on modified procedure in accordance with ASTM C 1585. According to the standard, the primary gradient is obtained based on the changes of weight up to 24 hours, and the subsequent changes of weight are classified into secondary gradient. Figure 5 shows the primary gradients calculated based on the testing results for the all the mixtures including specimens without repair. As can be seen in the figure, the primary gradients are decreased with increasing rate of sealing effect of crack repair. In particular, the smallest gradient was obtained in the case of N1-G1-T0 mixture. This is consistently observed in each exposure condition, thus suggesting that the crack repair using the N1-G1-T0 mixture contributed to higher resistance against the ingress of water through the cracks. Although the sealing rate is slightly lower in the case of specimens exposed to wet and dry environment as reported in Section 3.1, the resistance against the water absorption could be enhanced using the crack repair though the MICCP. As discussed in Section 3.1 and 3.2, the presence of gel films are significant factors contributing to higher sealing effect in both exposure cases, which led to

the formation of bio-composite through the calcium carbonate precipitation. The results suggest that higher sealing rate of crack repair associated with calcium carbonate precipitation leads to higher resistance against water absorption tested in accordance with ASTM C 1585 in this study.

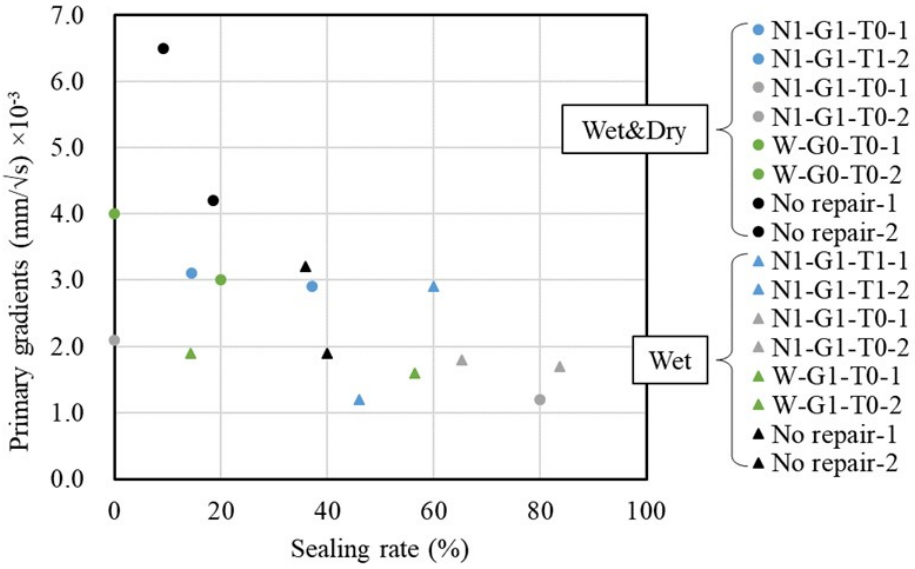

Figure 5. Primary gradient of water absorption test and sealing rate of crack repair.

4 Conclusions

- Based on the observations made on the sealing rate of crack repair, the presence of gel films remained intact on the cracked surface under exposure conditions could contribute to higher sealing effect in the cases of the N1 mixtures.
- The results suggest that higher sealing rate of crack repair associated with calcium carbonate precipitation leads to higher resistance against water absorption especially in the case of the N1-G1-T0 mixture under both exposure conditions (wet&dry and wet) tested in this study.

Abstract. *Water is one of the main factors affecting the durability of porous materials and it is one of the most common causes of their degradation. Physical phenomena such as freezing or salt crystallization, as well as the development of fungi and moulds, are caused by the presence of moisture. In wet material thermal conductivity coefficient increases and the heat loss begins to rise. Hydrophobization is one of the protecting methods of porous materials against water. Two different type of water-repellent agents were used for the internal hydrophobization. The first of them is an aqueous emulsion of silane: triethoxy(octyl)silane (OTES) and the second one is also an aqueous emulsion but the matrix is poly(dimethylsiloxane) (PDMS). The paper focuses on the use of organosilicon water repellents. The main purpose of this paper is to determinate the possibility of use organosilicon agents as admixtures to internal hydrophobization. We compared results obtained for two different silicon-based admixtures. We investigated influence of both water-repellents on basic characteristics such as: absorbability, capillary water absorption and mechanical properties of cement mortar as well as heat of hydration of cement paste.*

Keywords: *Internal Hydrophobization, Cement Mortar, Silane, Siloxane.*

1 Introduction

In 2018, in Poland, cement sales amounted to 18 million tons (Polish Central Statistical Office, 2019). And it is growing every year. Cement-based building materials are one of the most commonly used one. But, as all we know, they are porous, which means that their resistance to water is insufficient. Water is one of the main factors affecting the durability of porous materials and it is one of the most common causes of their degradation. Physical phenomena such as freezing or salt crystallization, as well as the development of fungi and moulds, are caused by the presence of moisture. In wet material thermal conductivity coefficient increases and the heat loss begins to rise. Not to mention aesthetic features (*e.g.* stains) and deterioration of the microclimate. The appropriate design and composition of building material may already be a part of protection against water. The hydrophobization process might complement to these actions. Hydrophobization can be carried out in two ways from the technological point of view. The material may become hydrophobic by applying water-repellent coatings on the surface or by using suitable admixtures as one of the components. Internal hydrophobization carried out with the hydrophobic admixtures causes, contrary to surface treatment, the hydrophobization of the surface and internal surface (Barnat-Hunek, 2016).

There are very limited number of regular studies or they are insufficient in determining the effectiveness of internal hydrophobization of cement-based building materials with

organosilicon compounds. In this paper we investigate the influence of two different silicon-based admixtures on fundamental properties of cement mortar/paste. The addition of hydrophobic admixtures to the batch water was intended to create a hydrophobic material in its whole volume.

2 Hydrophobizing Agents

Considering the chemical nature of porous building materials, it can be seen, that silicon compounds (silicon dioxide, silicates, aluminosilicates etc.) are part of natural and manufactured building materials. Therefore, organosilicon compounds have found practical use in the hydrophobization of building objects. They are mainly based on and silicon-oxygen (Si-O) and silicon-carbon (Si-C) bonds. The basic structure of organosilicon compounds is a polysiloxane chain (O-Si-O-Si-O) and the type of substituents affects the diversity of spatial arrangements that can be created from the basic chains (Barnat-Hunek, 2016).

Science the 1950's silicon-based compounds have been used in industrial applications. Hydrophobic agents based on organosilicon compounds are the youngest, and the most promising, group of hydrophobic agents for internal treatment. The main groups of these compounds are alkylsilanes, arylsilanes, halosilanes, silanols, siloxanes, silylamines and silyl esters. Among all different kind of hydrophobic products developed for the building industry, silicone resins, silanes, oligomeric and polymeric siloxanes have proved to perform best in surface hydrophobization. Until recently stearates and oleates were used as waterproofing admixtures. Effective surface hydrophobization with organosilicon agents caused attempts to use them as admixtures. It turned out that organosilicon compounds used as water-repellent admixtures are the most efficient in protecting from water penetration (Barnat-Hunek, 2016; Grabowska *et al.,* 2019; Roos *et al*., 2008).

2.1 Triethoxy(octyl)silane

Silanes are monomeric molecules (have one atom of silicon) with low molecular weight of 178. They are a silicon analogue of methane. Silane derivatives of the general formula: R_nSiX_{4-n} have the most important practical significance (R can be a hydrogen atom, an alkyl or aryl group, X can be a halogen atom or an alkoxy group). Longer alkyl chain-length provides desired water resistance of the modified material and steric protection to the silicon-oxygen bond. Initially silanes undergo hydrolysis and polycondensation reactions. Subsequently they cross-link under elimination of alcohol and as a result of which polymers, with polysiloxane chain, are formed. (Ciabach, 2001; Roos *et al*., 2008). Triethoxy(octyl)silane is an alkyl alkoxy silane with three ethoxy groups and one octyl group in its structure (Fig 1).

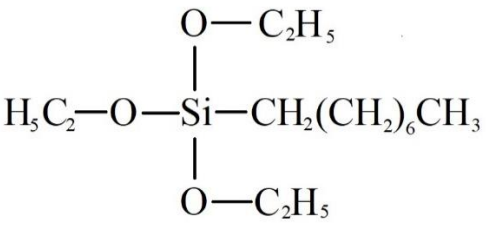

Figure 1. Structure of triethoxy(octyl)silane.

2.2 Poly(dimethylsiloxane)

Siloxanes are oligomeric molecules with a molecular weight about 400-600. The basic structure of siloxanes is a polysiloxane chain (O-Si-O-Si-O). Polysiloxanes are versatile materials. They have an excellent chemical, physical, and electrical properties. Poly(dimethylsiloxane) (PDMS) is an important example and the most common polysiloxane of this class of polymers. The chains of polysiloxanes consist alternately connected silicon and oxygen atoms. Inorganic chain and the presence of strong bonds (Si-O and Si-C) provide significant thermal and oxidative resistance as well as resistance to UV radiation of polysiloxanes. Despite of the polar character of siloxane bonds (Si-O bonds have ionic character in 50%) organosilicon compounds show similarity to paraffins in terms of low critical surface tension. Siloxanes have very low surface energy and exceptional hydrophobicity. PDMS chains are arranged in helixes and present of the methyl groups ($-CH_3$) give hydrophobic character of modified materials. Weak intermolecular interactions, characterizing PDMS, provide a significant gas diffusion coefficient. Organosilicon compounds, compared to other polymers, are characterized by very high oxygen, nitrogen and water vapor permeability (Chruściel *et al.*, 2008, Cypryk *et al.,*2007; Grabowska *et al.,* 2019;).

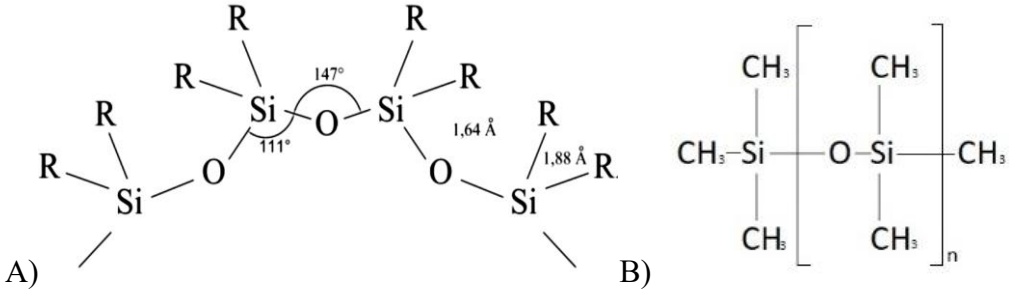

Figure 2. A) Polysiloxane chain (Cypryk *et al.,*2007), B) Structure of PDMS.

3 Materials

The Ordinary Portland Cement 42.5 R was used. Table 1 shows composition of investigated cement mortars. They were prepared according to Polish standard PN-EN 196-1 with a water-cement ratio (w/c) equal to 0.5. Prismatic samples of mortar, with dimensions160x40x40 mm, were prepared for mechanical, absorbability and capillary water absorption tests. Isothermal calorimeter was used to determine the influence of organosilicon admixtures on the heat of hydration of cement paste.

Two different type of water-repellent agents were used for the internal hydrophobization. The first of them is an aqueous emulsion of silane: triethoxy(octyl)silane (OTES). The second admixture is also an aqueous emulsion but the matrix is poly(dimethylsiloxane) (PDMS). The amount of the hydrophobic admixture in cement mortar or paste was 0%, 1%, 2% or 3% (refer to cement mass). They were added to the batched water. Both admixtures are recommended for volume hydrophobization.

Table 1. Composition of cement mortar.

	Water repellent agent		
	OTES/ PDMS		
	1%	***2%***	***3%***
W/C	0.5		
Cement [g]	450		
Sand [g]	1350		
Water [g]	225		
Admixture [g]	4.5	9.0	13.5

4 Results

4.1 Mechanical Test

Table 2 shows the results of mechanical test received after 1, 2, 7 and 28 days of curing for hydrophobized cement mortars. Results shown in Table 2 represent the average value taken over six samples. The compressive strength test was carried out on halved, prismatic samples left after flexural strength test. Results of each test of cement mortar admixed PDMS show substantial decrease in mechanical strength. After 28 days of ageing addition of poly(dimethylsiloxane) (PDMS) based admixture decreases the mechanical properties by almost a factor of two. The addition of 1% silane admixture does not decreases significantly compressive strength after 1, 2, or 7 days of curing. Noticeable loss of the strength is observed for 2% and 3% addition of silane after 1, 2, 7 and 28 days and for 1% of OTES after 28 days.

Table 2. Compressive strengths after 1, 2, 7 and 28 days of curing.

Water repellent agent	**Amount**	**Compressive strength [MPa]**			
		1 day	2 days	7 days	28 days
Reference	0%	14.40	23.04	31.16	45.25
OTES	1%	13.17	22.34	32.71	38.35
	2%	8.27	18.22	28.72	38.19
	3%	7.05	17.18	27.59	36.36
PDMS	1%	5.03	8.76	10.47	25.84
	2%	3.83	8.31	9.02	23.53
	3%	3.65	9.07	11.91	22.16

4.2 Absorbability

Absorbability of hydrophobized cement mortar is shown in Table 3. The test was carried out on three specimens for each composition. After 28 days of curing prismatic samples were dried and, after that, progressively flooded with water. Subsequently mortar samples were weighed

every 24 hours until constant weight was received. The addition of silane admixture and 2% of PDMS admixture decrease significantly absorbability. Lower values was observed for silane.

Table 3. Results of absorbabilty test of hydrophobized cement mortar.

Water repellent agent	Amount	Absorbability
Reference	0%	7.6%
OTES	1%	3.9%
	2%	2.3%
	3%	2.2%
PDMS	1%	6.3%
	2%	3.7%
	3%	6.5%

4.3 Capillary Water Absorption Test

One of the most common tests to show hydrophobic effect is capillary water absorption test. Table 4 presents the results taken over three halved, prismatic samples (six in total). Test was carried out according to PN-EN 1015-18. After 28 days of curing mortar samples were dried at 80ºC. Thereafter sealing material was applied on the side surfaces of mortar specimens (40 x 80 mm). Mortar prisms were vertically immersed in water to a depth of 1 cm and weighed after 10 min, 30 min, 60 min, 90 min, 2h, 3h, 4h and 24h. Both used admixtures decrease capillary water absorption coefficient. Lower values were observed for silane.

Table 4. Results of capillary water absorption test of hydrophobized cement mortar.

Water repellent agent	Amount	Capillary water absorption coefficient, $\frac{kg}{m^2 * min^{0,5}}$
Reference	0%	0.206
OTES	1%	0.042
	2%	0.023
	3%	0.020
PDMS	1%	0.115
	2%	0.106
	3%	0.098

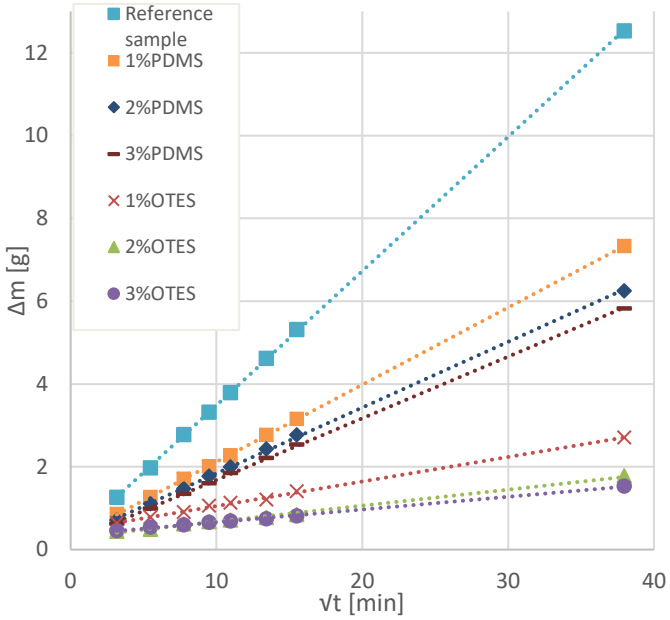

Figure 3. Mass changes of cement mortar samples during capillary water absorption test.

4.4 Heat of Hydration

The heat of hydration of cement paste with organosilicon admixtures was measured. The w/c ratio was 0.5 and the Portland Cement 42.5 R was used. Test was carried out in an isothermal calorimeter TAM Air, at temperature T=20°C. The heat was measured during 7 days for each sample. Two samples were analyzed for each composition of cement paste. 1%, 2% or 3% of organosilicon admixture was added per cement mass. The heat of hydration after 41 hours is shown in Table 5.

Table 5. Influence of organosilicon admixtures on heat of hydration.

Water repellent agent	Amount of admixture	Average hydration heat after 41 h [J/g]
Reference	0%	217.25
OTES	1%	180.00
	2%	157.78
	3%	149.12
PDMS	1%	187.10
	2%	199.70
	3%	182.05

5 Discussion

The presented test results unequivocally demonstrate the interaction between used admixtures and the cement matrix. Both admixtures gave a visible hydrophobic effect. The addition of admixture based on PDMS successfully reduces capillary water absorption. For reference sample capillary water absorption coefficient was 0.21 kg/(m^2*$min^{0.5}$) and 0.098 kg/(m^2*$min^{0.5}$) for cement mortar containing 3% of PDMS admixture. Absorbability of hydrophobized cement mortar decrease to 3.7% from 7.6%. As it was shown in Table 5 poly(dimethylsiloxane) also interacts with Portland cement. The heat of hydration of Portland cement decrease from 217,25 J/g to 182,05 J/g. Even better hydrophobic results in reducing capillary water absorption and absorbability were obtained for the second admixture based on triethoxy(octyl)silane. This water-repellent agent decreases capillary water absorption by almost 90% (from 0.21 kg/(m^2*$min^{0.5}$) to 0.02 kg/(m^2*$min^{0.5}$)) and reduce absorbability by 70% (from 7.6% to 2.2%) at the maximum amount of admixture. Also, in case of silane admixtures heat of hydration was reduced. The lowest value was obtained for 3% of OTES (149.12 J/g). Unfortunately, both admixtures decrease compressive strength of cement mortar. The largest decreases in compressive strength were observed for the content of 3% of silicon-based admixtures. PDMS admixture reduce mechanical strength of cement mortar by an average of 50% and OTES one only by 15%.

The present of non-polar such as methyl groups (-CH_3) and octyl groups (-C_8H_{17}) attached to the silicon atom provide desirable effect of internal hydrophobization of cement mortar. For the same reason the compressive strength of cement mortar might have been decreased. Changes in the heat release, during hydration process**,** indicate that the admixtures can bind to the cement phases (alite, belite or tricalcium aluminate) making water-cement reaction more difficult. This may cause incomplete hydration of the cement and thus a subsequent decrease in strength.

6 Conclusions

From the obtained results obtained the following conclusions can be drawn:

- Internal hydrophobization by using organosilicon admixtures is possible, but it has its own limitations. The hydrophobic effect depends on type of used organosilicon compound.
- Both admixtures were recommended for internal hydrophobization of cementitious materials by the producers. But treatment with triethoxy(octyl)silane gives better hydrophobic effect than poly(dimethylsiloxane) by reducing the capillary water coefficient by 90%.
- Both admixtures decrease in compressive strength, but OTES based admixture reduce it by 15% and PDMS one by up to 50%.

As a conclusion, it can be said that triethoxy(octyl)silane is an efficient water-repellent agent for cementitious materials. However, the first results are very promising, but this issue still requires more studies. Especially when it comes to mechanical properties.

Abstract. *The environment in which the concrete structure is inserted has a great influence on its durability and its service life. Thus, the present work aims to study of the performance of 5 types of concretes of same compressive strength (35 MPa at the age of 28 days) and considers kinetic and thermodynamic aspects of the corrosion induced by chlorides. The 5 types of concretes studied were produced with the use of mineral additions in partial replacement on cement mass (10% of silica fume, 30% of fly ash and 20% of metakaolin), besides the control situation (without mineral addition). The water-to-cementitious materials ratio was different for the concretes ranging from 0.30 to 0.55. Specifically, for the concrete with fly ash, two water/binder ratios were studied (0.30 and 0.40) with the goal of verifying if there are or not significant differences on properties of corrosion with little change of water quantity in the mix. The chloride attack consisted by 308 days (44 weekly cycles) in immersion in aggressive solution rich in chlorides and subsequent drying in a laboratory environment. During this period, the corrosion potentials (E_{corr}) and corrosion rate (i_{corr}) from polarization resistance (R_p) of steel bars were monitored. As a general result, it was possible to compare the performance of concretes at the same class of compressive strength to denote which systems have the longest durability in view of attack by chloride. The results have shown that the concretes produced with mineral additions did not show steel bar corrosion, thus configuring major service life for them. Control concrete presented depassivation of reinforcing steel, E_{corr} more electronegative and higher i_{corr} over time.*

1 Introduction

Brazilian energy matrix is composed of approximately 60.8% of hydroelectric power plants that have vulnerability in periods of drought (Gomes *et al.*, 2019). The energy policy covers tax incentives for the generation of energy from alternative sources, such as wind energy that shows its low environmental impact, low gas emissions and towers deployment.

The Brazilian northeast region was the first to house these wind farms in the country and a large number of towers are being deployed in these coastal. The wind potential of other regions of the country has been studied. In these wind farms, the base of the wind towers is made of reinforced concrete and both humidity and chloride ions may be present. This combination is extremely deleterious for concrete, since chloride ions, when in critical concentration level near the reinforcement, they can trigger the corrosion process.

For preventing corrosion at the base of wind towers, concrete of high performance can be designed. The concrete improved composition makes difficult for aggressive agents to enter from exterior to its internal structure, increasing the material's service life, safety and durability and reducing maintenance costs (Oliveira and Cascudo, 2018).

In this sense, concretes of the same strength class, with or without supplementary materials, can have different durability and service life, when exposed to harsh environments, especially containing chlorides. The use of supplementary materials, i.e. mineral additions in the composition of concretes and their benefits, has been extensively studied in recent years by literature (Ferreira, 2003; Ramezamianpour *et al*., 2012; Figueiredo *et al.*, 2014, Shi *et al.*, 2017; Rattanashotinunt *et al.*, 2018). These materials can increase concrete durability making the ingress of aggressive agents, such as chloride ions, more difficult. On the other hand, these materials can also change the pH´s pore solution, leading to a reduction of its alkalinity, which can make the steel bars in the concrete vulnerable to corrosion. However, among the mineral additions, some of them may present better performance and increase the service life of the structures, specially the so-called super pozzolans of high reactivity and fineness.

In Brazil, concretes are specified and purchased based on compressive strength, maximum water/binder ratio and environmental aggressiveness class (ABNT NBR 6118: 2014). Thus, the C35 compressive strength class is an intermediate class for most constructions and also meets the construction of wind tower concrete bases.

The aim of the present paper is to evaluate the protection ability of concretes against the steel bar corrosion. The compared concretes have the same compressive strength (C35 MPa) at the age of 28 days and the same exposure condition in harsh environment, containing chlorides. Concrete with fly ash (FA), silica fume (SF), metakaolin (Mk) and without mineral addition – Control (CR) were studied. Additionally, for the concrete with fly ash, the influence of a water/binder ratio also were measured (0.30 and 0.40). Thermodynamic (E_{corr}) and kinetic (i_{corr}) parameters of reinforcement corrosion were evaluated.

2 Experimental Program

2.1. Materials

The concrete mix proportions were based on previous studies from the durability´s study group of the Federal University of Goiás (Carasek and Cascudo, 2001; Ferreira, 2003). The composition was a combination of Portland Brazilian cement (composed by 6–10% in mass of limestone filler and by 90–94% of clinker – with a small amount of calcium sulfate), whose mechanical strength requirement is a minimum of 32 MPa of compressive strength of the age of 28 days – similar to European CEM II/A-L, mineral additions (silica fume, fly ash or metakaolin), fine sand aggregate (river sand) and coarse aggregate (stone from mica schist metamorphic rock), plasticizer, superplasticizer and tap water (potable water from the public distribution network). In the concrete mixtures, 10%, 30% and 20% of cement (by weight) were replaced by silica fume, fly ash and metakaolin, respectively. Furthermore, a control concrete (without mineral additions) was studied.

The water-to-cementitious materials ratio was different for the concretes ranging from 0.30 to 0.55. However, all concretes showed compressive strength at the age of 28 days of 35 MPa. Specifically, for the concrete with fly ash, two water/binder ratios were studied: 0.30 and 0.40.

Table 1 shows the compositions of the concretes and Table 2 shows the compressive strength of concretes at the age of 7, 28 and 91 days. The slump test was fixed in (80±10) mm. Steel bars with a nominal diameter of 10 mm (0.4 in.) were used to evaluate the corrosion.

Table 1. Composition of concretes used under this investigation.

Materials	Concretes*				
	Control	Silica Fume	Fly Ash		Metakaolin
Portland cement (kg/m^3)	552	331.2	525.0	487.5	294.4
Water/binder ratio	0.40	0.55	0.30	0.40	0.55
Mix Unit (kg) (cement: mineral addition: sand: stone)	1,0: 0.0:0.8:2.1	1.0:0.1:1.9:3.5	1:0.3:0.7:2.1	1:0.3:0.7:2.3	1:0.3:2.1:3.9

Superplasticizer (%)	0.00	0.15	0.08	0.01	0.00

*10%, 30% and 20% of cement (by weight) were replaced by silica fume, fly ash and metakaolin, respectively.

Table 2. Average of compressive strength of concretes studied at the ages of 7, 28 and 91 days.

Age (days)	Average compressive strength and water/binder ratio				
	Control	Silica Fume	Fly Ash		Metakaolin
	0.40	0.55	0.30	0.40	0.55
7	27 (0.8)	25 (0.4)	29 (1.0)	27 (0.1)	28 (1.3)
28	36 (1.4)	36 (0.4)	36 (1.9)	33 (1.4)	32 (1.3)
91	41 (0.3)	42 (0.6)	49 (0.9)	44 (1.8)	39 (1.7)

*Standard deviation is given in parentheses.

From Table 2, it was possible to observe that although all concretes have the same mechanical strength at 28 and 91 days (except fly ash concretes at the age of 91 days, in which their values of strength are slightly higher, in the order of 45 MPa to 50 MPa), they have different microstructure and porosity characteristics. As the water/binder ratios are different (among some of these concretes), the global porosity and the pore size distribution are, in fact, different among them. This interferes with important aspects related to durability, such as: interconnectivity and tortuosity of pores, in addition to the compactness characteristics of the paste - aggregate interfacial transition zone (Oliveira and Cascudo, 2018). Although the mechanical strengths are similar (premise of the present work), it is important to note that there are different cementitious systems being compared.

The steel bar used in the specimens was of a single type, having been used a Brazilian CA-50 carbon steel (for reinforced concrete structures). This steel meets the Brazilian standard of steel for reinforced concrete structures (ABNT NBR 7480: 2007) and it featured a yield strength higher than 500 MPa.

In order to standardize the surface conditions of the bars, they were initially chemical cleaned using a solution of (Hexamethylenetetramine) (Figure 1a). The general appearance of steel bars after chemical cleaning can be seen in Figure 1 (b). However, this procedure did not allow the complete removal of visible oxides from the bars. So, it was necessary to perform a mechanical cleaning performed with a circular brush attached to emery, as shown in Figure 1 (c). The

appearance of the bars before and after mechanical cleaning can be seen in the Figure 1 (d). Finally, the steel bars were identified (Figure 1 e). These bars had a total length of 15 cm (6 in.) and they were partially inserted into of concrete´ specimens, constituting 2.5 cm (1 in.) of cover thickness. Just a portion of steel, as showed Figure 1 (f) (5 cm = 2 in.) was exposed to corrosion induced by chloride ions (Figure 1 f). The surface area of rebar exposed to corrosion was 12.88 cm^2 (5.15 in^2) (Figure 1 g).

Cubic concrete specimens of 1500 mm side were produced and they were reinforced with four longitudinal rebars of 10 mm of nominal diameter. These test specimens were designed for the electrochemical tests, while for the electrical resistivity test, the same cubic specimens were used, but without steel bars. Oliveira and Cascudo (2018) used the same specimen shape. After manufacturing, the test specimens were under cure for 28 days in a controlled room (temperature of 22±2ºC and a minimum relative humidity of 95%). Thereafter, the specimens remained until the age of testing in the laboratory environment, which corresponded to the age greater than 91 days.

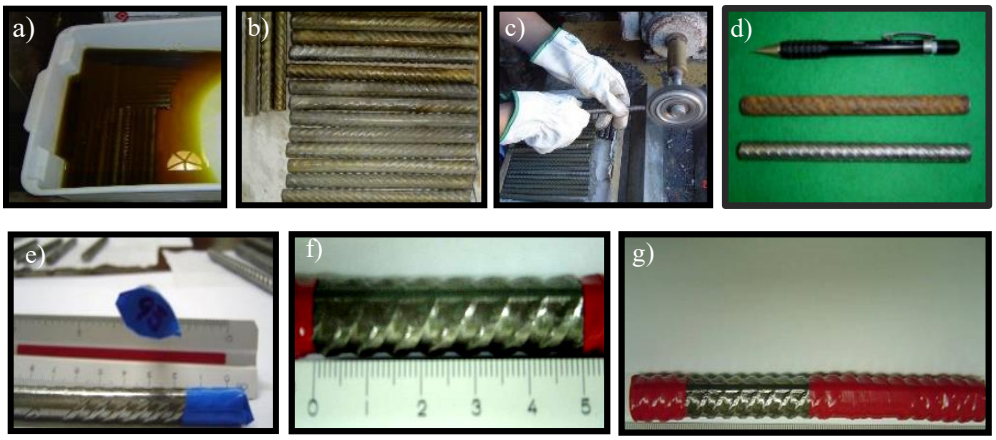

Figure 1. Preparation of steel bars: (a) chemical cleaning with (Hexamethylenetetramine), (b) final appearance of the bars after chemical cleaning, c) mechanical cleaning, (d) before and after mechanical cleaning, (e) bar identification, (f) bar ends wrapped with electrical tape and (g) bar center detail (5 cm) ready to be placed in the molds.

2.2. Methods

The corrosion was induced by wet–dry cycles in NaCl solution (NaCl diluted to 5% by mass or 0.855 M). The weekly cycles were 2 days of partial immersion of the specimen until 15 cm of its height in NaCl aggressive solution and subsequent drying during 5 days in a controlled environment (40ºC of temperature and 50 ± 5% of relative humidity).

The NaCl solution was replaced every four cycles (28 days) to facilitate aeration in a sufficient level so that the corrosion could develop. Specimens were subjected to total of 44 cycles or 308 days of attack in aggressive solution containing chlorides. The definition of the cycles was based on the studies of Cascudo (2000), considering the fact that concrete absorbs water much faster than it loses (during drying), reason why it was adopted 2 days of wetting and 5 days of drying. The importance of cycles to accelerate the phenomenon of corrosion was explained by Oliveira and Cascudo (2018).

The techniques of half-cell potential - E_{corr} (ASTM C 876: 2015) and polarization resistance (R_p) were used, the latter making it possible to estimate the instantaneous corrosion rate (i_{corr}).

These electrochemical measurements were performed by means of a three-electrode arrangement using a Voltalab 40 PGZ potentiostat, managed by Voltamaster software.

A working electrode (rebars embedded in concrete), a saturated calomel electrode – SCE (as the reference electrode) and a counter electrode of stainless steel (externally in contact with one of the faces of the concrete test specimen) were used connected to the potentiostat. In order to avoid interferences from external electric field, the measuring set up (i.e. the concrete test specimen with the 3 electrodes) were inserted inside a Faraday cage, where all the electrochemical measurements were taken. The criteria of ASTM C 876: 2015 were considered to evaluate the results of E_{corr} (mV). These criteria consider that if E_{corr} is more positive than -126 mV (SCE), the steel is passive and the probability of corrosion is smaller than 10%. Also, if E_{corr} is more negative than -276 mV (SCE), they consider that active corrosion is developing. Finally, there is a range of uncertainty with potentials between -126 mV and -276 mV (SCE).

From polarization resistance or linear polarization (R_p), it was possible to assess corrosion current density (i_{corr}). The Stern–Geary equation (Equation 1) and the proportionality factor (B Stern-Geary constant) were used.

$$i_{corr} = B/Rp \quad (1)$$

It was adopted a value of 26 mV for corroding steel and a value of 52 mV for passive steel, as established by Andrade and Alonso (2001). The criteria were adopted, which associate corrosion rates with the intensity of corrosion on corrosion levels.

3 Results and Discussion

Figure 2 (a and b) shows E_{corr} and i_{corr} against the number of cycles, respectively. The results are the average results of 4 rebars for each type of concrete. Table 3 shows the magnitude of the corrosion potentials for the studied concretes.

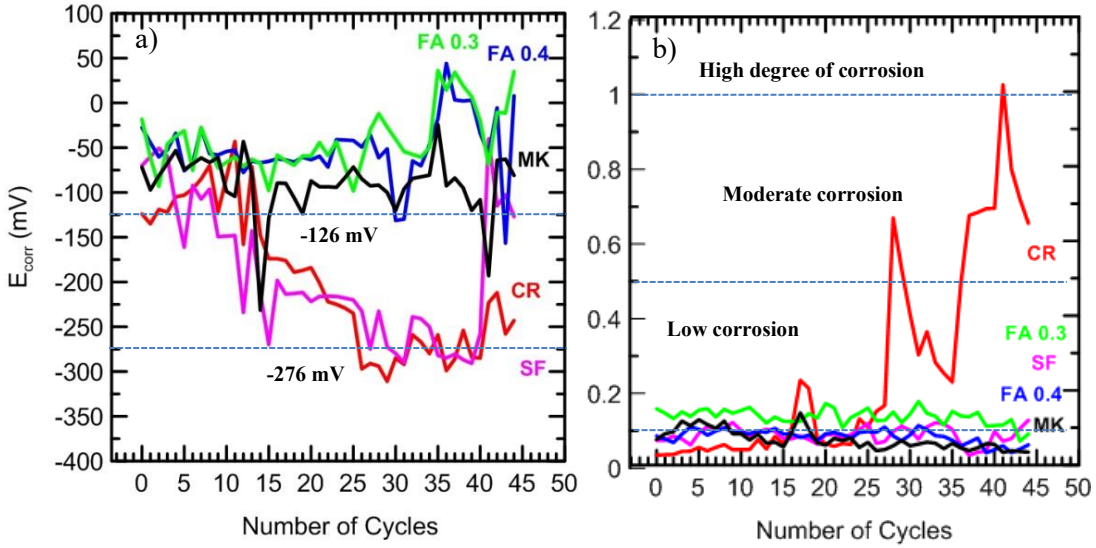

Figure 2. Influence of the type of concrete in terms of initiation and propagation of corrosion induced by chlorides on the concretes performance: representative curves of (a) E_{corr} (SCE) and (b) i_{corr} *versus* attack time by chlorides (number of wet-dry cycles in NaCl solution) according to ASTM (ASTM C 876: 2015) and Andrade

and Alonso (2001) criteria, respectively.

Table 3. Magnitude and average of E_{corr} during the 44 cycles of immersion in aggressive chloride-containing solution.

Concretes	Partial replacement of cement, by weight (%)	Water/binder ratio	E_{corr} – magnitude* (mV)	Probability of corrosion - Criteria of ASTM C 876 (ASTM, 2015)	E_{corr} - average (mV)	Time for depassivation of reinforcing steel (cycles)
CR	0	0.40	-311	> 90%	-199	28
SF	10	0.55	-291	> 90%	-192	No**
FA	30	0.30	-157	Uncertain	-51	No***
		0.40	-98	< 10%	-42	No***
MK	20	0.55	-231	Uncertain	-90	No***

* Magnitude in the table means the maximum individual value obtained. ** There were no signs of depassivation of reinforcement. *** This concrete meets the criterion adopted to define the depassivation of reinforcement and is in the uncertainty range regarding the probability of corrosion. The kinetic aspects can confirm if the reinforced is really depassivated.

From the Figure 2 and Table 3, for concretes with the same compressive strength (35 MPa), it is clear the beneficial effect that the supplementary cementitious materials – SCMs (mineral additions) provide to the concretes, regardless of the water/binder ratio, promoting significantly more electropositive corrosion potential values in relation to the reference concretes. Thus, it can be seen that the control concrete, compared to the concretes with SCMs, exhibit a greater tendency to the depassivation of reinforcement when inserted in environments containing chloride ions. Silica fume, contrary to expectations, did not achieve the best corrosion potential performance. These results are in accordance with the literature (Andrade and Buják, 2013; Jin *et al.,* 2017).

It is worth mentioning the good performance of fly ash concretes, with behaviors close to concrete with metakaolin. The silica fume concrete did not present a good performance regarding E_{corr}, and the lowest performance was presented by the control concrete. Thus, the effectiveness of SCMs in physically and chemically protecting the rebar keeping it passivated as long as possible became evident. This result is important because even though the corrosion induction method used in this work is accelerated, it reports the time until the depassivation of reinforcement, which means that, comparatively, there is a very significant response concerning the differences in performance of the various concretes analyzed (in terms of their actual expectations of durability). Only control concrete gave unequivocal evidence of reinforcement depassivation over the 44 attack cycles. With the exception of the silica fume concrete, the other concretes with mineral additions presented regions with low probability of corrosion or uncertain probability. The E_{corr} average values for metakaolin (water/binder ratio of 0.55) and fly ash (w/b = 0.3) concretes were similar. This evidences the overperformance of metakaolin as a mineral addition, since the difference in terms of w/b ratios for these two concretes is very high.

The silica fume concrete showed E_{corr} magnitude more negative and an indication of active corrosion after some few cycles. In spite of this behavior, the silica fume system did not evidence active corrosion in the period of test, based on i_{corr} results (corrosion rates obtained by

determining R_p). This can be seen in Figure 2b. This apparently different behavior for concrete with silica fume regarding the values of E_{corr} (compared to the concretes with metakaolin and fly ash) certainly reproduces some level of perturbation at the steel–concrete interface in terms of the passive layer (Oliveira and Cascudo, 2018). Probably due to local pH changes (because pore solution is different in silica fume modified systems), it is possible that thermodynamic changes occur at the interface, with changes in the state of electric charges on the electrode (reinforcement), perceived by drops in potential values (to more electronegative values).

Finally, the control concrete showed increase of values of i_{corr} (corrosion rates) in the beginning of dry-wet cycles. This denotes reduction of service life and durability. For the silica fume concrete, in terms of the corrosion rates, there was no increase in i_{corr} values over time, as well as there was no indication of depassivation of steel or significant corrosion for these concretes, within the test period. Thus, despite the negative E_{corr} values, there seems to be no depassivation and active corrosion in concrete with silica fume.

4 Conclusions

The following conclusions can be drawn from the present paper:

- More than one technique is important to diagnose the condition of the reinforcement and to assess the protection capacity of concrete.
- Control´s concrete protected less the steel bar against corrosion induced by chlorides, indicating E_{corr} more negatives and higher corrosion rates (i_{corr}).
- According to E_{corr} values, the concretes with mineral additions have showed similar performance among them (the silica fume concrete initially showed doubt, but later it was confirmed that there was no corrosion) and significantly better behaviors compared to control concrete.
- All concretes with mineral additions have not presented significant corrosion induced by chlorides for the 44 cycles (or 308 days - analyzed period).
- The influence of the small change in water/binder ratio on fly ash concretes was not significant, both for E_{corr} and i_{corr}.
- Metakaolin showed high performance as a supplementary cementitious material, even in a higher water/binder ratio.
- Among the concretes studied, those with mineral additions had higher durability and thus major service life.

Abstract. *The performance decay of a building component is influenced by a huge variety of parameters, interacting between them and determining different results in terms of service life and performance over time. For this reason, evaluating and modeling the performance of a component requires the comprehension of the way and the measure the single factors affect it, and turning this into an analytical model is a very complex operation. Moreover, components of existing buildings are subjected to an additional incognita: the characteristics and the durability of the materials, which is hardly a certain information, and can vary between similar buildings, affecting the accuracy of the evaluation. This study, conducted according to the guidelines of ISO 15686:7 code, investigates on a common solution for interventions on existing buildings, the ETICS, surveying their current performance degree through thermographic camera tests. The aim is to appreciate the difference in the performance decay between different façades of the same building – a homogeneity that allows to estimate this parameter alone - in order to reach an analytical expression of the variation of performance decay according to the difference in the exposure. The sample is constituted by buildings of large dimensions and well-known original projects and details of successive interventions, located in the city of Naples. The data obtained with in-field measurements were subjected to statistical analysis, to allow the quantitative determination of the impact of this parameter.*

Keywords: *Durability, ETICS, in-field Measurement.*

1 Introduction and State of the Art

In the last decades, together with the acknowledgement of the necessity to plan the maintenance of a building in advance, an increasingly higher importance has been given to the role of the comprehension of the dynamics of performance decay of building materials and components. In fact, knowing the trends and the times of performance decay is a required item, in order to predict the performance levels that will be reached through time, according to which maintenance interventions can be chosen.

Since diseconomies in terms of maintenance choices evidently lead to a waste of resources, the consequences of a scarce knowledge about the performance decay of components rapidly produce effects on the aspects of sustainability and energy consumption, which is a critical topic in the current situation of the construction industry. Despite that, accomplishing a high level of detail in the understanding of the processes that determine the performance decay of building components is definitely not an easy task. On one hand there are the intrinsic

characteristics of the materials, which can also be determined through laboratory tests which simulate the passing of time (i.e. accelerated aging tests), but on the other hand the actual in-use condition of building components has several possible variations: the micro-context, and macro-context of the building, the compatibility with other components, and many more. This evidence is also embodied in the structure of the Factor Method, which attributes a separate weight for the external and internal environment.

It seemed interesting to refer to a specific component for which the environmental impact of the maintenance activity has been emphasized (Minarovičová, 2015), that is used to produce benefits in terms of durability of the system, and improvement of thermal – so, energy – performance: the ETICS or External Thermal Insulation Composite Systems.

They consist in an insulation board bonded onto a new or existing masonry or concrete wall, and mechanically fixed with anchors. The insulation board is then protected by a base coat, usually 3-4 mm thick, made of the cement mortar with resin used as adhesive, but reinforced with a glass fibre mesh. Onto the base coat a 'key coat', or primer, is applied, and then the finishing, which is usually a thick (1.5-2 mm) top coat. This technology is very common all over Europe, thanks to its low cost and the possibility it offers to accomplish a very good improvement of the thermal properties of the building envelope.

The research investigates the variation of the trend of its performance decay according to the environmental exposure, and in particular the cardinal exposure: considering that very often it is applied on the whole surface of buildings, then the differences in the behavior of the ETICS on the single façades are an interesting item.

This kind of solution is defined in UNI/TR 11715 code, “Thermal insulation products for buildings - Design and in-situ installation of External thermal insulation composite systems with renders (ETICS)”, and its aspects related to durability have attracted a strong interest, in the field of research. The most part of the experimentations has focused on laboratory tests, making use of climatic chambers by simulating the aging process through specific cycles, among which the first attempts were performed by Daniotti and Paolini (2005), who realized qualitative comparisons between the durability of different solutions of ETICS, without developing re-scaling factors to relate it to natural time. In the same year, Bochen *et al.,* (2005) performed other climatic chamber tests, also determining the equivalence to natural aging. Years later, Griciuté *et al.,* (2013) made more experimentations involving the accelerated ageing of ETICS.

Other researchers investigated specific aspects of the durability of ETICS, among which Topcu and Merkel (2008), who focused on the moisture absorption, Künzel and Zirkelbach (2008), who studied the influence of rain water leakage on the hygrothermal performance of ETICS. There has been, in general, a much higher number of laboratory experimentations than field tests, including computational and theoretical modelling of the durability of this solution, such as the computational analysis performed by Koči *et al.,* (2012) and the multi-physics modelling by Daniotti *et al.,* (2014). On the other hand, there has been a much lower, and more recent, number of field researches on the durability of ETICS, realized by De Freitas (2016) and Kvande (2018). In these and other cases, little use of the thermographic camera has been noticed.

2 Materials and Methods

The investigated solution of ETICS has the following structure:
- skim “Klebocem”, width 0.5 cm;
- SK insulating panel “Stiferite”, width 4 cm;
- mechanical anchors in PVC, 2 per m^2;
- primer “Klebocem”;
- glass fiber mesh, width 0.3 cm;
- primer “Klebocem”;
- colored top coat “Rivaton”, width 0.2-0.3 cm.

The research has been carried out as a thermographic and photographic analysis on ten buildings in Naples, Italy – in Via Attila Sallustro - which have been built in 2012-2013. They are all buildings in reinforced concrete, consisting of seven floors and a total lateral surface, constituted by hollow bricks and ETICS, of 25000 m^2. The device used for the thermographic survey was a thermographic camera IR FLIR 250T, and the output consisted in a total of sixty thermographic pictures, taken from the ground level, which show several relative differences in the superficial temperature, highlighting phenomena of detachment which could not, in most of the cases, be noticed by simple visual inspection. The individuation of the performance level of the various parts of the building followed the procedure suggested in ISO 15686-7 code.

Also, in accordance with the recommendations from UNI EN ISO 4628-1 code, it is necessary to define performance degrees as numbers from 1 to 5, detailed in Table 1, in order to attribute quantitative scores to each of the thermographic and photographic frames, which represent the in-use condition that they display.

Table 1. Performance degrees for the in-use conditions of the ETICS.

Degree	Type of symptoms	In-use condition of the ETICS
1	No symptoms	No performance decay
2	Slight symptoms	Cracking and blistering phenomena on the surface (millimetrical size)
3	Medium symptoms	Macro-cracking and macro-blistering phenomena on the surface (centimetrical size)
4	Strong symptoms	Slight detachment of the panels
5	Totally unacceptable	Partial/total detachment of the panels

The definition of the performance degrees displays two typologies of anomalies: the “slight symptoms” and the “medium symptoms” refer to the finishing layers, which have a basically protective performance and effect on the panels, while the “strong symptoms” and the “totally unacceptable” state are related to the panels themselves, and therefore have a much stronger significance in terms of performance decay of the ETICS.

In several cases, the thermographic frames show thermal gradients – caused by detachments - also in locations where no performance decay is visible by sight and by photographic frames, nor is related to an anomaly in the superficial layers, as acknowledged through tactile contact: this means that their origin has to be linked to an anomaly in the inner layers, presumably the panels themselves.

Figure 1 shows the distribution of the optical cones of the thermographic and photographic frames, numbered from 1 to 17; for each of them, 3-5 shots have been taken.

Figure 1. Distribution of the optical cones of the thermographic and photographic frames.

The photographic survey shows that the main typology of anomalies consist in cross-shaped cracks in correspondence of some mechanical anchors, and in the form of horizontal lines, in correspondence of the contact between two adjacent panels, as shown in Figure 2.

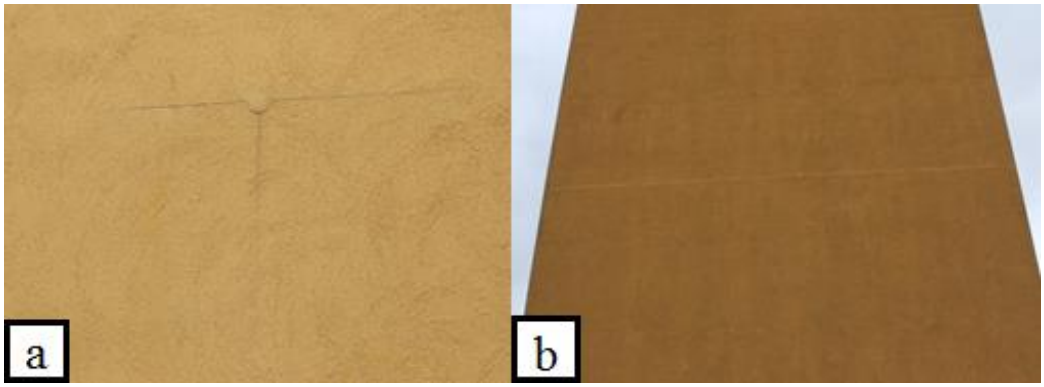

Figure 2. Photographic frames: a) cross-shaped crack in correspondence of a mechanical anchor; b) line-shaped crack in correspondence of the contact between two adjacent panels.

Thermographic frames show color – corresponding to temperature – variations both in the shape of lines, which confirm the detachment revealed by the photographic information, and in the form of diffuse areas, as in Figure 3.

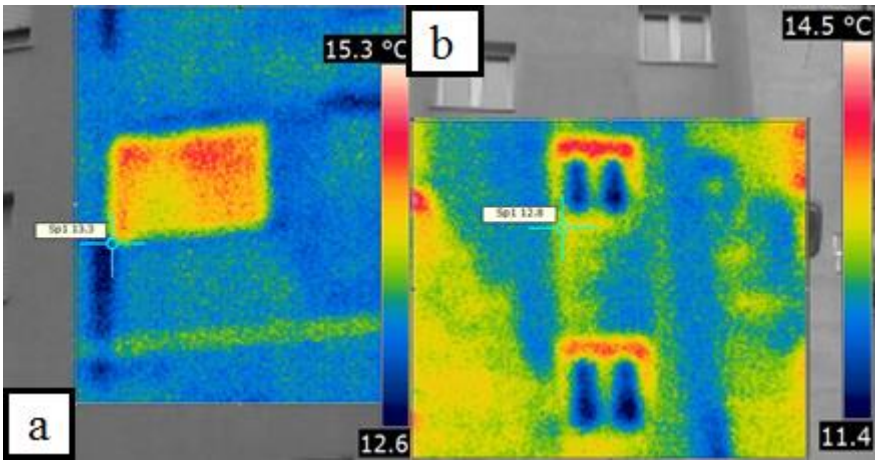

Figure 3. Thermographic frames: a) horizontal line at different temperature; b) diffuse thermal gradient on the surface.

3 Results and Discussion

A score between 1 and 5 was attributed to each of the photographic and thermographic frames, according to the typology and distribution of decay; the score of 5, corresponding to an unacceptable performance, was never attributed. Then, statistical analysis were performed on the sample, leading to the Gauss distribution shown in Figure 4.

Figure 4. Gauss distribution of the state of decay of the ETICS in the experimentation, measured in the performance degrees of Table 1.

The mean value of the performance decay is equal to 1.74, while the standard deviation is 1.28. The result seems coherent with the age of the sample buildings, and is strongly dependent on the output of the thermographic survey. In fact, as it was partially pointed out in the previous paragraphs, several areas did not present any visible – nor sensible - decay in the external layers, but the thermographic frames showed a thermal gradient, which had to be related to a detachment of the panels, signalling a more consistent state of decay.

In order to break down the obtained data, it was chosen to perform also separate analyses by dividing the output according to the cardinal direction of the façades. This led to four

different gauss distributions, respectively for the main cardinal directions of the building: E-NE, N-NW, W-SW and S-SE, reported in Figure 5.

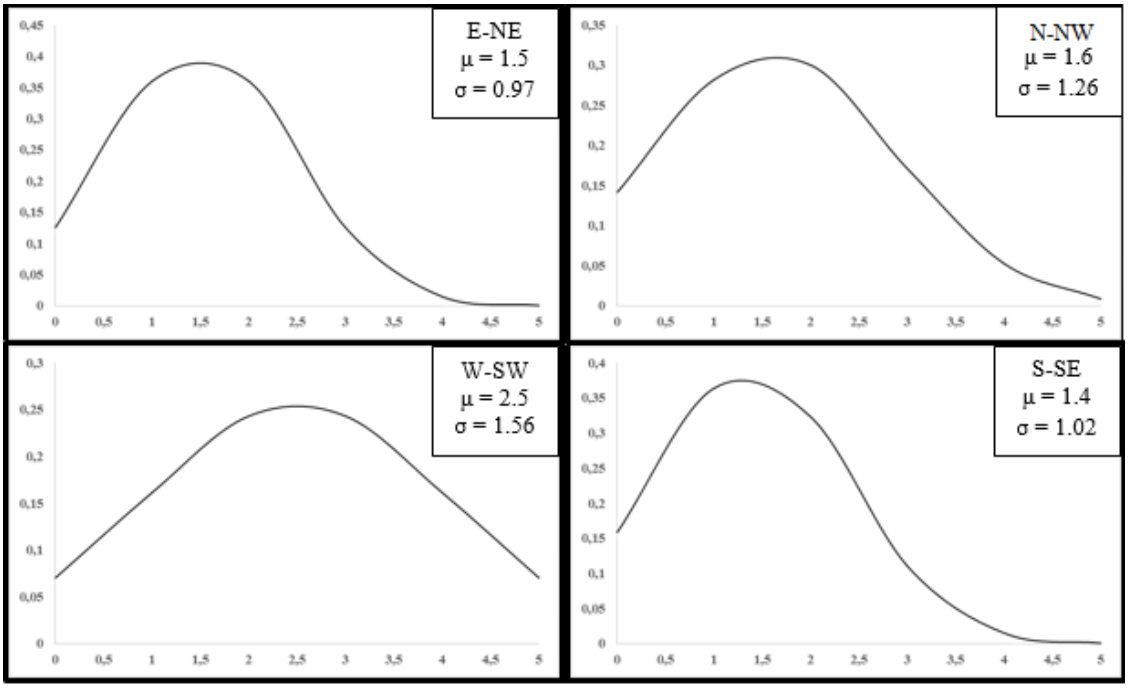

Figure 5. Gauss distribution of the state of decay of the ETICS in the experimentation for each cardinal exposure, with the detail of mean value (μ) and standard deviation (σ).

It can be noticed that, differentiating the analysis on the single façades, the results generally become more accurate: in 3 cases out of 4, the deviation is lower than in the analysis on the whole surface. Moreover, it emerges that values of higher decay correspond to the W-SW façade, while the other cardinal exposures have better performances. Since there is a higher frequency of detachment of panels, associated with higher performance degrees, this is also probably the reason behind the higher deviation.

The more negative value of performance decay in the W-SW direction seems particularly strong, reaching a ratio of 1.5-1.8 with the values in the other directions. Qualitatively, this phenomenon could be explained in relation to the less favorable conditions that insist on this façade, in particular solar exposure.

4 Conclusions

As for many materials in the sector of building constructions, the large use of ETICS in the current building industry does not find its counterpart in a sufficient quantity of field experimentations, compared to the notable number of theoretical models and laboratory tests; considering the complexity of the factors that influence this aspect in relation to the context, it is certainly necessary to encourage a more frequent use of field experimentations to enrich the database concerning the states of decay.

The aim of the experimentation carried out in this work was not to try to produce a relation

between time and decay, as the collected data only refer to a single year, then it is not realistic to hypothesize a trend on its base, but rather the focus was on two significant aspects:
- the opportunities to make use of different tools and instruments for the monitoring activity, questioning their utility and the typology and level of information that they can provide;
- the qualitative differences that may exist in the decay of the same component, as a consequence of the variation of micro-contextual aspects.

The first point clearly refers to the use of the thermographic camera, and surely this case has provided a good proof of its peculiarities: incipient detachments between the panels could be noticed only thanks to the use of this instrument, allowing a much clearer picture of the state of decay; looking forward to the availability of quantitative data about the evolution of this anomaly, this is certainly an interesting information in the field of predictive maintenance.

At the same time, it has to be noticed that thermographic surveys do not show the dimension of the detachment, but only its existence; then, it is not possible to deduce the entity of the reduction of the thermal performance that the ETICS have to provide. So, an interesting development can be individuated in the possibility to link thermographic surveys to partially destructive tests, aimed to ascertain the dimension of the detachment, associate it to the output of the thermographic survey, and quantitatively determine its influence on the thermal performance of the ETICS.

Concerning the second aspect, the strong difference between the higher performance decay observed on one of the façades (W-SW) and the one on the others (E-NE, N-NW and S-SE) is certainly an interesting result, which is probably better not to refer yet to a single parameter, as the solar exposure might be, but rather to consider as an item of future interest, in the perspective of more detailed assessments of the weight of the micro-climatic factors that influence the durability of the single components. On this side, for future experimentations, it will be interesting to gather data from thermographic surveys on similar buildings in different geographic locations, in order to evaluate the entity of the differential performance degree with other climates. In this way, more light can be shed on the mechanism of the environmental influence on the performance of ETICS, and of buildings components in general.

Abstract. *Existing RC Buildings have some cracks and the repairing service might last the buildings for long life. The durability of the RC component is evaluated by several ways as like as carbonation resistance test, permeability test, water penetration test, and so on. Therefore, it need to be measured how much advantage the concrete crack with repair have for the durability. The aim of this paper is to study on advantage of repairing a crack of concrete to the carbonation resistance and the water-absorbing property by the experimental way. The specimens were prepared in the following point. The finishing (direct finishing and mortal tile finishing), crack width (0, 0.05, 0.5, and 2mm), and choice repairing or not. All concrete specimens were formed 10 x 10 x 20cm and those W/C were 0.55. Then, the specimens were tested by the accelerated carbonation. After 4, 8 and 26weeks accelerated carbonation, the carbonation depth and the carbonation shape of the concretes were measured by 1% phenolphthalein reaction. Also, the amount of absorbed water from the bottom were measured at 1, 3, 6, 24, 48, 72 and 168h. From the results, the carbonation went rapidly located in 2cm around the crack in the case of the no-repair specimens, regardless of any finishing. But in the case of the specimens repaired, it went evenly from the exposure side. And water absorbing test results show a trend that water amount of the concrete with a crack more increase than one of the no-crack concrete.*

Keywords: *Concrete, Crack with Repair, Carbonation Resistance, Water Absorption.*

1 Introduction

Existing RC buildings ordinary have some cracks. These expand air permeation and water penetration (D. Breysee *et al.*,), which cause irregular carbonation (Xiao-Hui *et al.*, 2018), and rebar corrosions rapidly.

On the other hand, cracks of the reinforced concrete components sometimes have been repaired, and that might last the buildings for long life.

And now, the durability of the reinforced concrete components is evaluated by several way as like as the carbonation resistance test, the permeability test, the water penetration test, and so on. Therefore, it need to be measured how much advantage the concrete crack with repair have for the durability. The aim of this paper is to study on advantage of repairing a crack of the concrete to the carbonation resistance and the water-absorbing property by the experimental way.

doi:10.23967/dbmc.2020.066

2 Specimens

2.1 Specimens Type

Table. 1 shows specimen type. 2piece of each type specimens were prepared. 10 x 10 x 20 cm rectangular column concretes were made. Many have a man-made crack at the center of oneself, and half of those were repaired.

Table 1. Specimen type.

No.	Finishing	crack (mm)	Repair material
1	Direct finishing	-	-
2	Direct finishing	0.5	-
3	Direct finishing	0.5	Soft epoxy resin grouting
4	Direct finishing	2	-
5	Direct finishing	2	U cut and filling with sealing agent
6	Direct finishing	0.05	-
7	Direct finishing	0.05	Coating with flexible synthetic resin emulsion
8	Mortal tile	0.5	-
9	Mortal tile	0.5	Soft epoxy resin grouting
10	Mortal tile	0.5*1	-
11	Mortal tile	2	-
12	Mortal tile	2	U cut and filling with sealing agent
13	Mortal tile	-	-

*1 Motal tile have no crack but concrete 0.5mm crack

2.2 Mix Proportion of Concrete

Table 2. shows the mix proportion of the concrete. Portland cement was used, and form off 3days after cast. Then, 20℃ RH 60 % air curing for not less than 28 days.

Table 2. Mix proportion.

SL	W/C	s/a	BVg	W	C	S	G
(mm)	(%)	(%)	(m^3/m^3)	(kg/m^3)			
18	55.0	45.8	0.59	180	327	793	961

2.3 Concrete Crack Width

The crack width of concrete were 0mm (no-crack), 0.05mm, 0.5mm, and 2mm. After air curing of the concrete, bending the concrete and put ones together carefully so as to being each crack wide. So, a man-made crack which pass through to another side was at the center of the specimens. Mortal tile also have a crack in response to each concrete crack, except No.10 in Table 1, which mortal tile have no-crack but concrete has a 0.5mm-wide-crack .

2.4 Finishing

Finishing type were direct finishing and mortal tile finishing. Making the mortal tile finishing, 2cm mortal were plastered after making concrete crack and cured for not less than 28days by oneself. Except some specimens, mortal tile finishing also have a crack. The crack of mortar bed were made by the way of putting a rubber in and remove it while mortar set. And, the tile were cut ahead and put on mortar bed adjusting a crack.

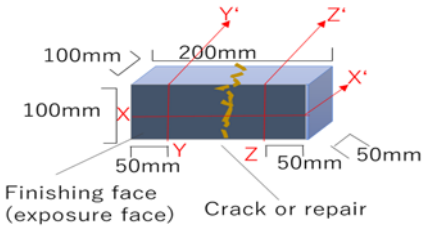

Figure 1. Cut directions after accelerated carbonation test.

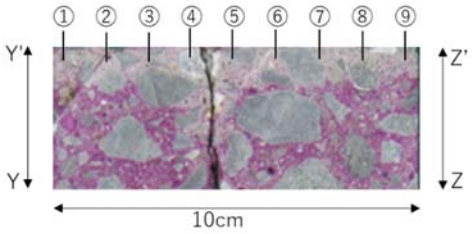

Figure 2. Measurement spots on x-x'cut side.

2.5 Repair Materials and Methods

Used repair materials and methods were shown in table 1. These repair material and method were select corresponding with the crack width. The soft epoxy resin grouting applied for 0.5mm crack, U cut and filling with the sealing agent applied for 2mm crack of either finishing. Also, coating with the flexible synthetic resin emulsion were applied for 0.05mm crack of direct finishing specimens.

3 Experiment

3.1 Accelerated Carbonation Test

The specimens were sealed with aluminium tape so that only the finishing face were exposure in 20℃, RH60%, and CO_2 5% room. And, the term of accelerated carbonation were 4, 8 and 26 weeks.

3.2 Measurement Carbonation Depth

After the accelerated carbonation, specimens were cut along x-x', y-y' and z-z' directions as Figure 1. by diamond cutter, and then solution of 1% phenolphthalein in water were sprayed. Carbonation depths were measured at 5spots on y-y' and z-z' cut side. In case of x-x' cut side, 9spots located in 10cm around the crack were measured as shown in Figure 2.

3.3 Water Absorption Test

After the curing and sealing, specimens were set on the water and measured the amount of the absorbed water at 1, 3, 6h and 1, 2, 3, 7 days. Water were absorbed from the bottom of the specimens.

4 Results and Discussion

4.1 Carbonation Depth on y-y' and z-z' Cut Side

This paragraph shows the results of the carbonation depth from exposure side on y-y' and z-z' cut side. Averaged value of y-y' and z-z' are shown.

4.1.1 The results of the no-repair case

Figure 3. shows the carbonation depth on y-y' and z-z' cut side of the no-repair case. In case

(a) Direct finishing (b) Mortal tile finishing

Figure 3. The carbonation depth on y-y' and z-z' cut side of the no-repair case.

(a) Direct finishing (b) Mortal tile finishing

Figure 4. The carbonation depth on y-y' and z-z' cut side of the repair case.

of the direct finishing, the carbonation depth at 4, 8 and 26 weeks were 7～13mm, about 12mm, and 16 ～24mm respectively. Also, it were under 3mm, 4mm and 6mm respectively in case of the mortal tile finishing.

4.1.2 The results of the repair case

Figure 4. shows the carbonation depth on y-y' and z-z' cut side of the repair case. Except No.7, the carbonation depth at 4, 8 and 26 weeks were 10～12mm, 12～14mm and 18～23mm respectively in case of the direct finishing, that was close to the results of the no-repair case. Also, it were under 2mm, 3mm and 5mm respectively in case of the mortal tile finishing, that was also close to the results of the no-repair case. Note, No.7 were coated at all face with the flexible synthetic resin emulsion, so carbonation did not go.

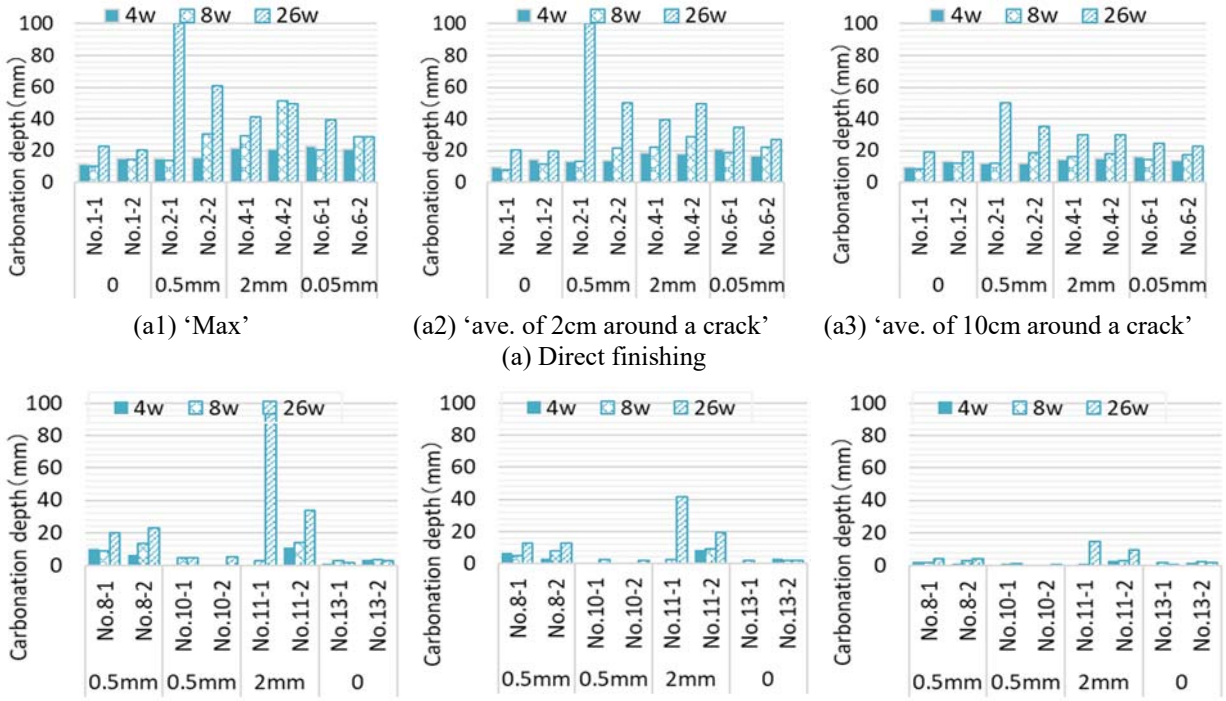
4.1.3 Discussion

From the results in Figure 3. and Figure 4., the carbonation depth at each term were same, regardless of repair or not. That shows the process of carbonation located on 5cm away from a crack were not relate with a crack or repair.

Add to that, the mortal tile finishing have larger resistance for carbonation than the direct finishing have, as well as the previous studies on preventive effect of finishing materials against carbonation (Kono *et al.*, 2008).

4.2 Carbonation Depth on x-x' Cut Side

This paragraph shows the results of the carbonation depth from the exposure side on x-x' cut side. In the following figures, the symbol 'Max' means the maximum value in the 9 spots results on x-x' cut side as shown in Figure 2., the symbol 'ave. of 2cm around crack' means average of the results of the spots of ④, ⑤, ⑥ in Figure 2., and the symbol 'ave. of 10cm around crack' means average of 9 spots results.



(a1) 'Max' (a2) 'ave. of 2cm around a crack' (a3) 'ave. of 10cm around a crack'

(a) Direct finishing

(b1) 'Max' (b2) 'ave. of 2cm around a crack' (b3) 'ave. of 10cm around a crack'

(b) Mortal tile finishing

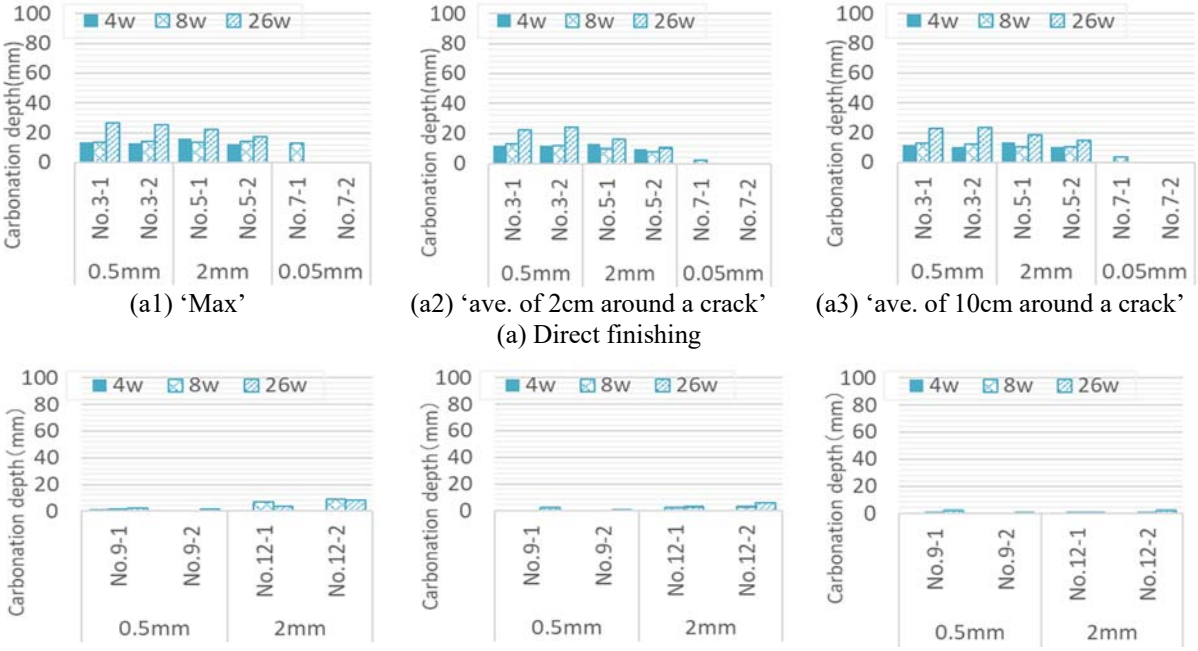
Figure 5. The carbonation depth on x-x' cut side of the no-repair case.

4.2.1 The results of the no-repair case

Figure 5. shows the carbonation depth on x-x' cut side of the no-repair case. From the results of 'max' of No.4 and No.6, the carbonation depth were about 20mm at 4weeks, that was twice of the result of y-y' and z-z' cut side at Figure 3 (a). And the results at 8 and 26weeks were so large as 30mm and 50mm. Also, the results of 'ave. of 2cm around a crack' of No.2, No.4, and No.6 were about 15～20mm at 4weeks, that was about half time of the result of y-y' and z-z' cut side. And No.2 at 26weeks were 100mm. Meanwhile, the result of No.1, which don't have cracks, at 4, 8 and 26weeks were about 10mm, 10mm and 20mm each, regardless of 'Max', 'ave. of 2cm around crack', and 'ave. of 10cm around crack', that was close to the results of y-y' and z-z' cut side.

And then, focused on the mortal tile finishing specimens, the carbonation depth of No.8 'Max' at 4, 8 and 26 weeks were about 9mm, 12mm and 20mm, also that of No.8 'ave. of 2cm around a crack' were 5mm, 7mm and 13mm, and also that of No.8 'ave. of 10cm around a crack' were 3mm, 3mm and 4mm respectively. Likewise, that of No.11-2 'Max' at 4, 8 and 26 weeks were about 11mm, 14mm and 34mm, also that of No.11-2 'ave. of 2cm around a crack' were 9mm, 9mm and 20mm, and also that of No.11-2 'ave. of 10cm around a crack' were 3mm, 3mm and 10mm respectively.

Both 'Max' and 'ave. of 2cm around a crack' results were more than double for that of y-y' and z-z' cut side as showed in Figure 3. So, these 'Max' and 'ave. of 2cm around a crack' results of x-x' cut side were so larger than that of y-y' and z-z' cut side.



(a1) 'Max' (a2) 'ave. of 2cm around a crack' (a3) 'ave. of 10cm around a crack'

(a) Direct finishing

(b1) 'Max' (b2) 'ave. of 2cm around a crack' (b3) 'ave. of 10cm around a crack'

(b) Mortal tile finishing

Figure 6. The carbonation depth on x-x' cut side of the repair case.

And, results of 'ave. of 10cm around a crack' of x-x' cut side were not differ greatly from that of No.13 which have no crack as showed in Figure 3 (b). By the way, No.10 results show that carbonation didn't go at all as 0mm at 8weeks and 5mm at 26weeks, because this specimen have a concrete crack but no crack of tile.

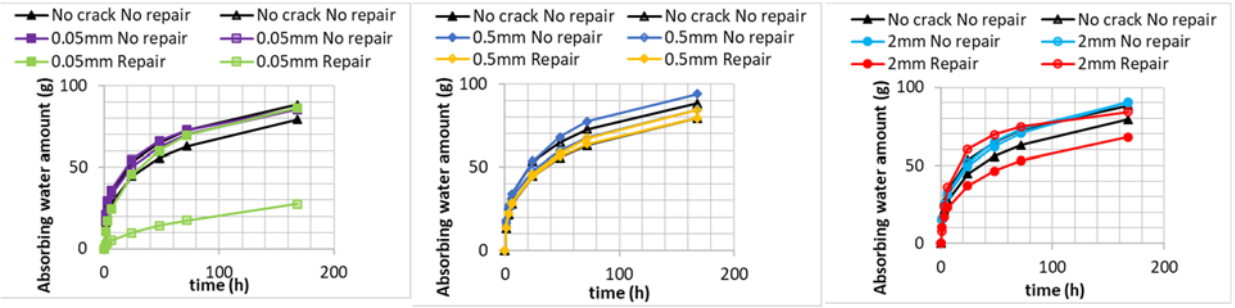
4.2.2 The results of the repair case

Figure 6. shows the carbonation depth on x-x' cut side of the repair case. The 'Max' of No.3 and No.5 at 4, 8 and 26 weeks were about 13mm, 13mm and 23mm, also that of 'ave. of 2cm around a crack' were about 11mm, 11mm and 18mm, and also that of 'ave. of 10cm around a crack' were 11mm, 11mm and 20mm respectively. So, these have no difference in measurement field. Add to that, these results were close to the results of No.1 (no-crack case) as well as y-y' and z-z' cut side showed at Figure 4.

And, No.7 were coated at all face with the flexible synthetic resin emulsion, so carbonation have not gone.

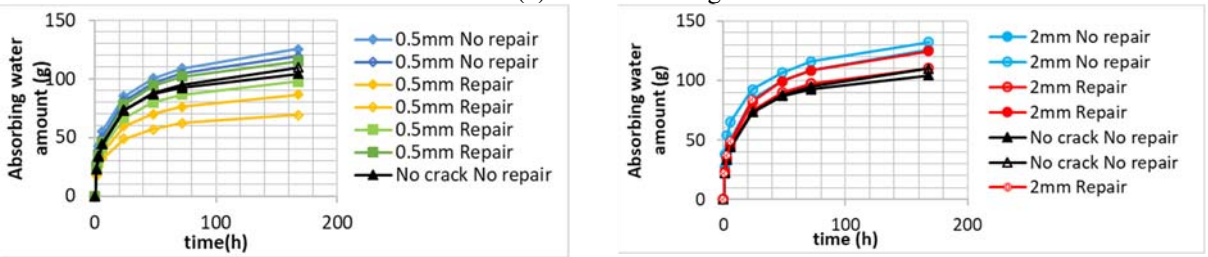
As an exception case, the results of No.11 which have 2mm-wide crack shows the carbonation depth were small until 8weeks but it were large at 26weeks. Because of the repair method that block up by buried only surface layer but the filling didn't reach to deep part, the carbonation went rapid where the filling didn't reach.

And then, focused on the mortal tile finishing, the 'Max' of No.12 at 4, 8 and 26 weeks were about 0mm, 8mm and 6mm, also that of 'ave. of 2cm around a crack' were 0mm, 3mm and 4mm, and also, that of 'ave. of 10cm around a crack' were 0mm, 1mm and 2mm respectively. And the carbonation depth of No.9 at 4, 8 and 26 weeks were under 2mm regardless of the symbol. These were close to the results of the no-crack case as well as the results of y-y' and z-z' cut side.



(a1) 0.05mm-crack-wide (a2) 0.5mm-crack-wide (a3) 2mm-crack-wide

(a) Direct finishing



(b1) 0.5mm-crack-wide (b2) 2mm-crack-wide

(b) Mortal tile finishing

Figure 7. The amount of absorbed water

4.2.3 Discussions

In the case of the no-repair, the carbonation went rapidly located in 2cm around the crack but not rapidly at 10cm far from a crack, regardless of any finishing.

On the other side, the carbonation of the specimens repaired went evenly from the exposure side and that were similarly to the no-crack case, although there is an exception.

From these, the repairing service have advantage of the carbonation resistance compared to crack left case, though it is not confirmed durability of the repair materials in itself.

On a side note, the carbonation depth averaged located at 10cm around the crack of the no-repair specimens were close to that of the area far from a crack, and close to the no-crack case. It indicate that the influence of a crack appear little in large mass.

4.3 The Amount of Water by Absorption Test

Figure.7 shows the results of the amount of absorbed water from the bottom side. From the results, the amount of absorbed water of the specimens having a crack were bigger than the no-crack specimens. Also, those of the specimens repaired were smaller than that of the no-repair, however there were exceptions.

5 Conclusions

- The aim of this paper is to study on advantage of the repairing a crack of concrete for the carbonation resistance and water absorption resistance by the experimental way. Then, this paper shows the results of the accelerated carbonation test and water absorption test. Prepared concrete specimens were distinguished as the finishing type,

the crack width, taking repair or not, and the repair materials. The results in this study indicate as following.

- The mortal tile finishing have larger resistance to the carbonation than the direct finishing have.
- The carbonation went rapidly located in 2cm around the crack in the case of the no-repair specimens, regardless of any finishing.
- From the results of the repair case, the carbonation went evenly from the exposure side. It was the same process as the no-crack case.
- The amount of the absorbed water of the specimens having a crack were bigger than the no-crack specimens, and some specimens repaired a crack were smaller than that of the no-repair case.
- Many repairing service have advantage of the carbonation resistance as well as water absorption resistance compared to a crack left, though it is not confirmed durability of the repair materials in itself.

Gold Leaf Murano Glass *Piastras*' Performance in the *Trencadís* Catalan Modernism Mosaic: Recognition of Primary Alteration Patterns

Héctor Y. Orozco Camargo[1] **and Joan Ll. Zamora i Mestre**[2]

[1]Master's Degree in Advanced Studies in Architecture-Barcelona (MBArch), Universitat Politècnica de Catalunya-BarcelonaTECH, ETSAB, Av. Diagonal, 649, 08028-Barcelona, Spain, Arq-HO@hotmail.com

[2] Laboratori d'Innovació i Tecnologia de l'Arquitectura (LiTA), Universitat Politècnica de Catalunya (UPC) - BarcelonaTECH, Pere Serra, 1-15, 08173-Sant Cugat del Vallès, Catalunya, Spain, joan.lluis.zamora@upc.edu

Abstract. *Gold leaf Murano glass is a unique product that over the centuries, especially during Byzantine period, has been used as facing forming big flat or curved mosaics that result in an architecture full of light and symbolism. This product is presented in a format of squared piastras with the same approximate dimensions that the gold leaves ones have (8x8 cm). Piastras are cut in smaller squares (1-1,5cm) in order to obtain the tiles that form mosaic's cladding. This cladding technique was incorporated during Catalan Modernism. Through this technique, beautiful pieces of tesseras of gold leaf Murano glass combined with others of opaline glass. In order to overcome the artistic challenges from this architectural movement, new mosaics were placed outdoors in order to shine by the incident sun beams and the square tiles were replaced by irregular tiles that form polygonal meshes capable of coating double curvature surfaces with great elegance. This location and prolonged exposure to the weather cause, over time, a deteriorated appearance, despite being composed of great resistant materials such as gold and glass. Studies oriented to know the phenomenology of this deterioration are being carried out and its impact on the expected durability of this coating. Being a handmade product and completely manual execution, the first studies have aimed to identify the primary anomalies that are originally generated in the different layers of this product at the time of manufacture, transport and handling. Knowing these primary anomalies must allow to prevent their occurrence and reduce their incidence in the manifestation of so-called secondary anomalies. All this in order to prolong the useful life of this appreciated architectural cladding.*

Keywords: *Brightness, Mosaic, Modernism, Trencadís, Gold leaf Murano Glass, Alteration Patterns.*

1 Introduction

Gold Leaf Murano glass consists of two external layers of different thickness and different glasses and a thin inner layer of gold leaf inserted between both. The main purpose of this product is to provide a glazed surface with the maximum brightness, colouring and texture. These features are given by the gold leaf itself. The two layers of glass provide to the gold leaf protection and transparency.

Gold is a ductile and soft material that does not corrode when it contacts with air. Gold it is not reactive not toxic. In contrast, it is an excellent reflector of infrared radiation. It is also a good heat absorber and it has a great capacity to reflect light. Within its chemical peculiarities, it should be mentioned that gold is easily lacklustre by sulphur (lost of brightness), attacked by

chlorin and for cyanide solutions in the presence of oxygen and insoluble in acids. Since gold leaves are a handmade material, occasionally, their alloys are made with other metals to reduce its cost and to obtain nuance variations in its colour appearance. Currently, there are different active gold leaf Murano glass producers. This research has been carried out on *piastras* with dimensions of 8x8cm, and with an approximate thickness of 6mm, without any treatment or alteration, as delivered by the distributor. Samples of gold leaf Murano glass consist of a first layer of transparent common glass of 6mm of thickness approximately (face A) + a gold leaf layer with a thickness of between 0,1 and 0,001µm approximately + a transparent blown glass with a thickness between 0,2mm and 0,5mm (face B), which is shown in the image 1.

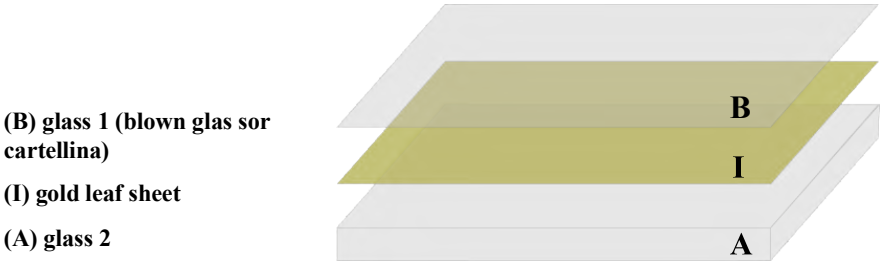

Figure 1. Composition of a gold leaf Murano Glass *piastra*.
(source: authors).

2 Interpretation of the Manufacturing Process of Gold Leaf Murano Glass

Gold leaf Murano glass is made overlapping the different layers in succession and applying final treatments to ensure the unity of the group.

2.1 Manufacturing Process of Gold Leaf Sheets

Although there are some small variations specific to each company at some point in the production process, the following basic steps are followed in order to obtain the gold leaf:

1. Heavy: gold from other remains is weighed.
2. Melting: by melting, a ingot of approximately 1cm thick is obtained.
3. Laminate I: it is the first forming that is done by inserting the ingot between two horizontal rollers. This process is done very slowly so as not to lose gold's malleability.
4. Measurement and cut: a measure is made with a compass in order to know where to cut the tapes that have already left the laminate. After this, the various plates are put together to continue with the next step.
5. Laminate II: through this second lamination by other rollers flat pieces of 4x4 cm are obtained.
6. Counterbalancing and cut: previously laminated the gold leaf sheets are counterbalanced one on the other, in the middle of it, is bent perpendicularly with a wooden dowel and cut in half. They are then counterbalanced and cut again, resulting in pieces of 2cm x 2cm.

From these pieces obtained from 2 cm x 2cm, hammering processes are applied with different levels of force to progressively reduce the thickness of the sheets.

7. Step for devastate: The first step in achieving this part of the process is to reduce as much as possible the humidity of the devastating device that will receive the gold, a process called

the "preparing". Followed by this, the gold is loaded into the devastating and then the smoothing process, which consists of constantly hitting the sheets while they are spinning. They are then cut again into 4cm x 4cm sheets.

8. Movement of the brazed: the same steps of the previous process are performed again with the aim of further reducing the thickness.

9. Movement of the mould: it is the final stage of hammering, in which it is sought that the centre of the surface of the bread and the rest perimeter have the same thickness and not present differential defects.

10. Transfer into books: it is the last step and consists of passing gold leaf sheets to white silk paper books to preserve it from humidity. The usual final measurement of the surface of the sheets is 8cm x 8cm.

During the manufacturing process of the gold leaf, the gold leaf may turn sour. This can happen repeatedly. In that case, the gold loses malleability, so it has to be cooked again and a resurrected is generated in which a greater molecular cohesion is created by which the gold increases its density.

2.2 Manufacturing Process for Murano Gold Leaf Glass

The primary anomalies can occur in any of the different processes that are carried out for the manufacture, transport and handling of the product so it is important to know the development of each of the phases.

1. The production process of Murano gold leaf glass begins with the manufacture of transparent blown glass balloons in order to obtain the minimum possible thickness, which are then cut into square segments slightly larger than those of gold leaf and left to cool.

2. The gold leaf is then manually extracted from the books and also applied manually to these glass segments.

3. The next step is the application of the thicker melting layer of transparent glass: the melted glass is poured onto the exposed face of the gold leaf and reheated to the gold leaf and the fine transparent base glass.

4. While the assembly is malleable, it is passed successively through several rollers to reduce the thickness to the desired thickness (approximately 5.95 mm) and the flat shape.

5. The *piastras* thus formed are raised with pliers and rotated to allow the best integration of the different layers.

6. Once the sheets of gold leaf are fully protected by both glasses, the whole is taken to the oven with the aim of sealing and definitively joining the different layers.

7. The parts removed from the furnace are again passed through the rollers because, having been subjected again to high temperatures, their thickness may have varied.

8. During the slow cooling, but even if the set is malleable, the pieces are cut again with the measurements of the format of the gold leaf (8cm x 8cm).

The product is stored until transport, the truck being the most common means of transport. For this purpose, the pieces are grouped and packed in honeycomb plastic film to avoid any possible external friction and are deposited inside boxes

3 Research Methodology

Since manufacturing is done by hand, this results in visually noticeable variations within the same batch of product; is why this study has been carried out using a comparative methodology of different samples in order to identify the most frequent anomalies. Similarly, this product is not covered by any regularity and its characteristics must be assessed by assimilation with other standards.

3.1 Scanning by Flat Scanner

Firstly, a cursory inspection of the parts was carried out, the parts were carefully washed and numbered. The parts have subsequently been digitized on both sides by the use of the flat scanner, obtaining digital images in .jpg. The use of the flat scanner model EPSON GT-15000 has proved to be the most efficient way of keeping a record and a detailed survey of all the pieces studied. The stored digital images have not had any kind of digital processing or subsequent manipulation.

The observation of this survey has confirmed that Murano gold leaf glass is a translucent and heterogeneous product, characterized by the light and shadow contrasts generated by the variation of the surface density between the different areas of the same sheet of gold leaf.

3.2 Visual-Instrumental Analysis Under Optical Microscope

Once those areas with unique features have been identified, these areas are inspected in greater detail using the Dino-Lite AM41115T model digital optical microscope, a portable instrument that allows in a very simple way to make a more detailed enlargement of the structure of these singularities or anomalies. A first discrimination, thanks to the focusing capacity of this device, is to identify in which of the different layers of the piece the alteration is manifested. Indirectly, the position of the anomaly may indicate when the production process occurred.

For the development of this study, three types of zoom have been carried out, depending on the face and the approach, in order to determine in which layer of the sample the anomaly is located; if they are on the inside face of the glass (a)on the sheet of gold leaf (b) or on the outer faces of protective glass (c):

- First, a 19X zoom was performed on side B (the smallest glass thickness) in order to observe the anomalies between layers.
- The same procedure is carried out on side A, but this time a 20X zoom is used as a thicker glass is being analysed and, Therefore, the focus for observing the golden material is at a greater distance from the surface.
- The last increase is made to 160X on both sides since with this increase it is interesting to analyse what is happening on the surface of the glasses.

Finally, these identified anomalies have been compiled in different groups, according to the layers in which they manifest:

- Group 1, anomalies located on the inside face of the glass (a) or on the sheet of gold leaf (b) and
- Group 2, anomalies located on the outer faces of the protective glass (c).

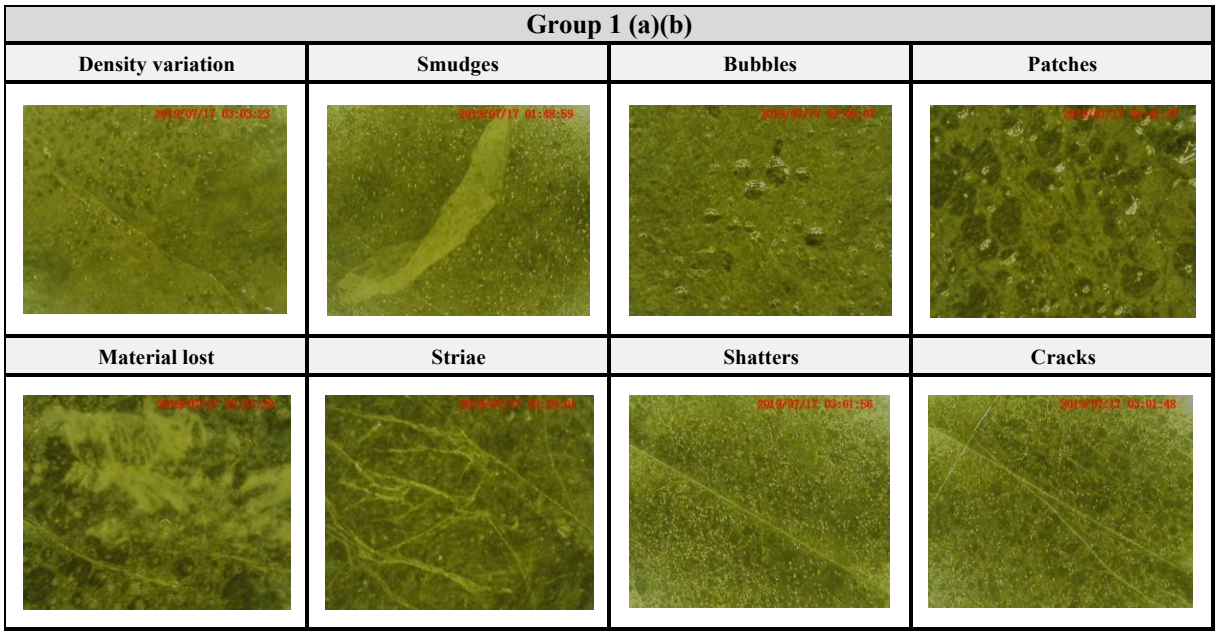

Figure 2. Alteration patterns in Group 1: On the inside face of the glass (a) or on the sheet of gold leaf (b). (source: authors).

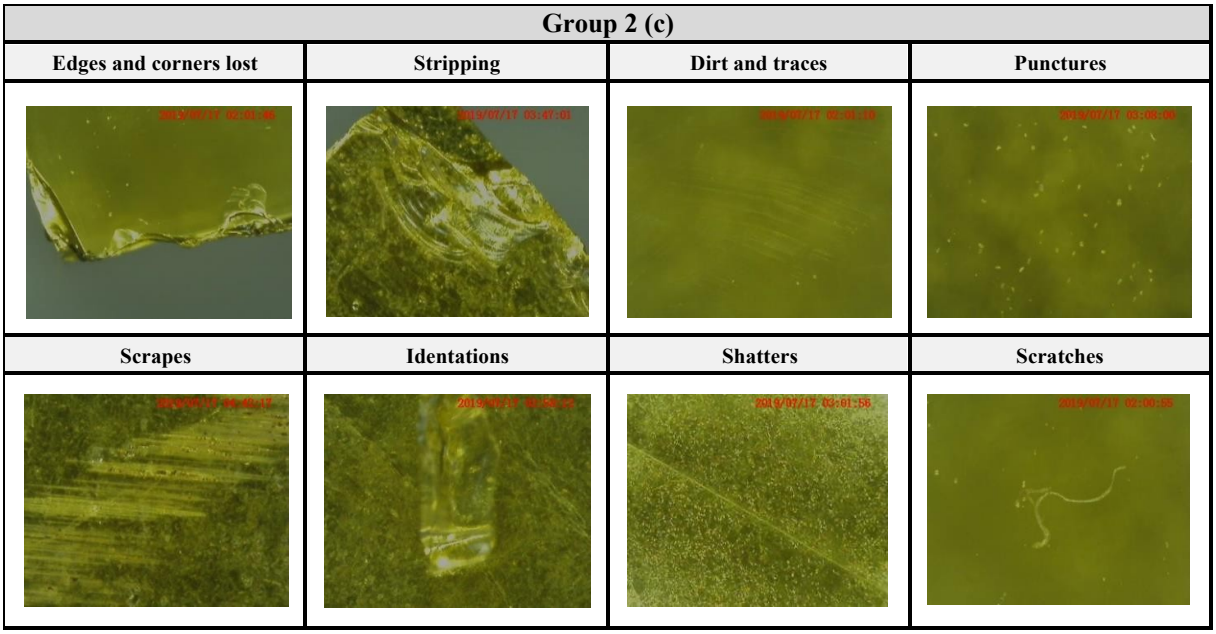

Figure 3. Alteration patterns in Group 2: On the outer faces of the protective glass (c). (source: authors).

3.3 Properties of Murano Glass Gold Leaf in Laboratory

In order to assess the durability of this product in a standardised way, a series of laboratory tests have been carried out following the UNE-EN ISO 10545 regulation for ceramic tiles; This decision was taken on the grounds that ceramic tiles are the alternative material most commonly used in the Catalan Modernism *trencadís* exterior cladding.

The tests that have been carried out are: determination of water absorption, open porosity, relative density and bulk density; determination of resistance to bending and breaking load; determination of chemical resistance; Determination of stain resistance; Determination of thermal shock resistance; Determination of surface abrasion resistance of enamelled tiles; Determination of scratch hardness; Determination of linear thermal expansion and Determination of freezing resistance. The 9 tests were carried out by a company specialising in this field.

- After the test on five *piastras* for the determination of water absorption, open porosity, relative and apparent density was obtained as a result of the mean values that the absorption of water from gold leaf Murano glass is 0.01%, the apparent porosity of 0.02% and both the relative and apparent density of 2,51 g/cm3, the common density of a glass.
- In order to determine the bending strength and the breaking load, seven samples were submitted with an average breaking strength of 2262 N, a resistance similar to that of rustic sandstone. While the maximum bending strength is 84.5 N/mm2, a value very close to the strength of a tempered glass.
- The test for chemical resistance showed that Murano gold leaf glass did not leave visible effects and therefore belongs to the first class: A, for resistance to cleaning products and pool salts. Similarly, resistance to strong and weak concentrations of acids and bases gives it the first class: HA and LA respectively.
- Three groups of 5 *piastras* have been subjected to different types of stains where it is found that the resistance of the product to stains is the maximum as they are easily removed by hot water.
- To determine the resistance to thermal coke, 5 *piastras* are subjected to 10 cycles of temperature variation between 15ºC and 145ºC by immersion. From the second cycle the product begins to crack and already in the third, pieces begin to fall off. The Murano glass of gold leaf having a metallic element between its layers, possesses a cohesion that helps to keep the whole together.
- The surface abrasion resistance test is evaluated by the PEI method (wet abrasion method) which measures the surface wear resistance of tiles and is classified in 5 degrees, where class 5 corresponds to the highest resistance. After the tests carried out on the samples, a result is given where the product corresponds to class 2 where the visible effects start to appear from 600 revolutions.

- For the determination of scratch resistance, the Mohs scale is used which, although already out of print, is not yet available for the determination of this type of test. After testing according to the Mohs scale, gold leaf Murano glass belongs to hardness 4, that is to the mineral: fluorite. A result far below the classification of glass strength.

- The results of the test to determine the resistance to linear thermal expansion, conclude with a variation of the expansion of the material with respect to the origin of 7,4x10-6/ºC in longitudinal direction and 7,6x10-6/ºC in a transverse direction, a result that is not significant.

- Finally. The test carried out to determine the resistance to frost results in 0% absorption and no defects.

4 Conclusions

- From the moment of its production, gold leaf Murano glass already presents substantial anomalies that can alter its future behaviour and durability.
- The manufacture and treatment of this product in its early stages should be more careful to reduce the risk of the occurrence of primary abnormalities which may be a risk factor for accelerating the occurrence of secondary abnormalities.
- The control of primary anomalies should not be to the detriment of the visual markings of this product.
- The first tests carried out in the laboratory indicate the appropriate quality of the glass and confirm some initial forecasts such as its weakness in the face of thermal shock or its low surface hardness.
- The durability of the product therefore falls heavily on the gold leaf itself; this stability will depend strongly on the perimeter sealing of the edges and the polluting products that can be introduced between the two glasses, during the manufacturing process (dust, gases, moisture, etc.), and on the rough surface of the gold leaf.
- There is not an adequate regulation for testing resistance to gold leaf Murano glass as the tests currently applied are governed by the characteristics of a very different product (ceramic tile) and, a more suitable element such as the case of a mirror, it lacks tests in the regulation that applies to it.

  The evaluation of the durability of this product according to the standard product of the flat glass industry, which is the mirror, has been pending for future research. The standard UNE-EN 1036 Silver-coated glass mirrors for internal use, even if it is confined to indoor situations, includes some environmental actions such as humidity and temperature in bathrooms. The conventional mirrors are flat, transparent, colourless, sodochalcium silicate glasses with parallel and polished faces, the rear face of which is covered with a sheltered silver reflecting reservoir, all this with a thickness between 2 and 10 mm allowed.
- It has been pending for future studies to evaluate the integrity of the whole when mechanical fractionation of the *piastras* is carried out by shear to obtain the irregular polygonal tesserae typical of the *trencadís*: in the case of glass of different composition and thickness, the mechanical fracture may give rise to weaknesses which leave the gold leaf unprotected from the external environment.

How to Determine when a New Building Product is Suitable – Certifications and Experience

Ernst J. de Place Hansen[1], Jørgen Nielsen[1], Eva B. Møller[2] and Ruut H. Peuhkuri[1]

Abstract. *Previously, only solutions with long-term experience were used in the building sector and it was sufficient to describe, e.g. in the building regulations, how they should be constructed. However, the innovation rate has gradually increased, encouraged by industrialization and by building regulations becoming more functional based. As a result, the required performance is often described for the whole building or for a building component, but not at product level. Furthermore, CE marking makes it possible to market and sell a product in any country within the European Union if only one or a few properties are declared, and these may even not be the most relevant ones for a specific application in a technical solution. A CE mark is therefore neither a quality mark nor an approval of the product for a specific application, although clients and consultants often believe this is the case. It is therefore a major challenge for the building sector to determine if a new building product is suitable in a specific technical solution (wall, roof, etc.). The paper identifies a gap between performance-based requirements for a technical solution and specific requirements to properties of building products. Two cases (flat roofs with no slope, MgO-containing boards used as wind barriers) show the possible economic consequences of not closing this gap; the technical solution failed, as one of the products was not suitable for Danish weather conditions. The first case initiated the formation of the Danish Building Defects Fund in 1986, the second one from 2015 shows that the gap still exits, 30 years later. The cases show how difficult it can be even for professionals to understand different certifications, especially when a product seems to be well suited for a specific use. Based on the cases, the paper presents a systematic approach that guides users through important issues relating to requirements for a moisture-safe building envelope.*

Keywords: *CE Marking, Building Products, Performance-Based Requirements, Documentation of Properties, Decision Chart.*

1 Introduction

Previously, only solutions with long-term experience were used in the building sector and it was sufficient to describe how the solutions should be constructed; consequently the innovation rate was low. In Denmark, this was more or less the case until construction of buildings became gradually industrialized in the late 1950s and early 1960s, to accommodate the increased demand of dwellings after the Second World War. Industrialization is characterized by innovation and construction of a large number of buildings with almost the same technical solutions, reducing the construction time and/or the manpower. However, this means that a mistake can be reproduced many times before a lack of performance is discovered, and by then the economic consequences may be large. The innovation rate has gradually increased,

encouraged by building regulations becoming more functional based. As a result, technical solutions used in building projects are often only described by the required performance.

The challenge of how to handle a high innovation rate has been recognized for many years, both nationally, *e.g.* (Blach & Christensen, 1974) and internationally *e.g.* (CIB, 1982). Normally, the way to evaluate a new product is to compare it with an existing product with a known performance, although this presupposes that the properties of the existing product are relevant and sufficient. A technical solution (a wall, a roof, etc.) is normally composed by several products (bricks, insulating materials, membranes, wood panels, etc.), for which specifications may be available. The challenge is to close the gap between performance-based requirements (durability, thermal insulation, etc.) specified for a technical solution, and specific requirements to properties of products included in the solution. This is especially important when new or not fully tested products are introduced, or when well-known products are used in new combinations.

The cases presented in Section 2 illustrate how expensive it may be if the gap of documentation has not been closed. Therefore, the building sector needs guidance to evaluate if technical specifications of products lead to the fulfilment of performance-based requirements for a complete technical solution. A method for systematic review of products is described and discussed in Section 3 and 4.

2 Expensive Experiences

In several cases, new products have been used in many buildings before it was discovered that the product was unsuitable for the used purpose. Two Danish cases are described; the second showed that the problem still exists despite lessons learned from *e.g.* the first case.

2.1 Case 1: Flat Roofs

Flat roofs became popular in Denmark in the late 1950s and early 1960s. At that time the building process became more industrialized using roofing felt and building elements made of concrete, replacing labor-intensive construction work using bricklayers and brick masonry. Until 1972, the building regulations required that roofs had a slope towards drain, but in a ten-year period until 1981, when many large industrialized housing projects were constructed, there was no minimum requirement for roof slope. Unfortunately, complete flat roofs were difficult to execute with sufficient quality and the roofing materials were not durable for this solution. Therefore, many roofs leaked and resulted in expensive renovation projects and claims corresponding to 4 % of the contract sum for dwellings with flat roofs (Bunch-Nielsen, 2019).

This experience and similar cases initiated the formation in 1986 of the Danish Building Defects Fund (www.bsf.dk), a mandatory insurance-based system for social housing projects, combined with a guidance on quality assurance in construction that counts for governmental and publicly subsidized building projects (National Building Agency, 1986). This was based on the expectation that preventing damage and defects is less expensive than doing repairs, for the society as a whole as well as for the building sector. Today, claims on flat roofs are down to 0.1-0.2 % and the service life of this type of roof construction has increased from 10-15 years to 30-40 years (Bunch-Nielsen, 2019).

2.2 Case 2: Magnesium Oxide Containing Boards as Wind Barrier

Around 2007, a new type of building boards was introduced in Denmark as an alternative to traditional products used as wind barrier on the cold side of the insulation layer in a lightweight facade construction. The boards were strong, fire resistant, light, cheap and good for the working environment. The boards were quickly taken up by the market as a new, interesting product. However, in 2015 it was realized that these new boards were not at all suited as wind barrier under normal Danish weather conditions.

The boards contain MgO, which is a salt with a relatively low equilibrium moisture content, taking up moisture from the surrounding air when the relative humidity is high. Once saturated, the boards release salty liquid (Figure 1) that make screws, fittings and staples corrode and eventually initiate wood rot in surrounding wooden elements. In the longer run, the boards may disintegrate and lose their fire resisting, wind protecting and stabilizing properties. The Danish Building Defects Fund (2015a) declared promptly that they would not cover new claims related to building projects using MgO containing boards. They had by then been used in almost 20.000 social housing homes in Denmark and in an unknown number of single-family homes, private housing, schools, day care centers, hospitals, and industrial and commercial buildings. The cost of replacing boards alone in social housing dwellings has been estimated to around 1 billion DKK (Danish Building Defects Fund, 2015b).

Figure 1. Wetting of a concrete foundation revealing that salty liquid has been released from MgO boards in the above lightweight external wall. Photo: Tommy Bunch-Nielsen.

A legal sequel is on-going; In one case, the architect/consultant was judged as being responsible for not having presented clearly enough to the client, that the product was not thoroughly tested. In another case, the contractor was acquitted as he had followed recommendation from BYG-ERFA published in 2013 (BYG-ERFA, 2013) stating that MgO-containing boards were used as wind barriers, indicating that it had become a well-known product for this use. Since 2015, BYG-ERFA warns against this use of the boards (BYG-ERFA, 2015).

The binder in MgO board is formed by a chemical reaction between MgO and $MgCl_2$. Boards containing $MgSO_4$ were later introduced to the market because of the less hygroscopic behavior of $MgSO_4$ compared to $MgCl_2$ but they showed not to be a feasible alternative in Denmark and countries with a similar humid climate (Wøhler Nielsen *et al.*, 2019).

3 Systematic Review of New Products

To reduce the risk of using unsuitable products in technical solutions, decision makers need a way to review products. A method for a systematic review presented in this section is based on (Peuhkuri, Nielsen, and Møller, 2020) and (BYG-ERFA, 2017). It is a guideline to buyers of building products and other partners in a building project, who are supposed to demand documentation of relevant properties for new products or products used in a new way. Determination of requirements for products used in lightweight external walls is used as an example. The client should expect the consulting architect/engineer to:

- Identify new solutions in the building design
- Make sure that all relevant requirements for documentation of each product in each new solution is detailed and highlighted in the project documents (further detailed below)
- Ensure that suppliers' information about the product and documentation for critical parameters is present and critically evaluated.

Function of a product in a given solution. The function of a product must be identified before it is possible to identify the relevant properties. Opposed to a solid masonry wall, the functions of a lightweight exterior wall often are highly divided between products, so that one product acts as a vapor barrier, another as load bearing structure, etc. This makes it easier to develop new solutions where one product can be replaced by another disregarding all the other functions that the wall has to fulfil, provided that the products do not harm each other. In addition, there is a general requirement for durability. Further, not only the performance of the wall itself but also the joints with adjacent building elements is important.

Loads. The product may be exposed to a number of different loads in a construction. For a lightweight exterior wall, the position of the product in the wall determines the degree of the moisture load. Every load, including fire, freezing point passages, UV-exposure etc., must be quantified if relevant, including loads during the construction phase.

Relevant properties. The intended function of a specific product as part of a planned solution (*e.g.* that it contributes to the thermal insulation) and the loads it will be exposed to in the actual position in the solution, including loads during the construction phase, must be defined. This forms the basis for deciding which technical properties the product must be in possession of to function as expected in the solution.

Specification of requirements. A list of the specific requirements for a product to be used as intended in the technical solution can be based on a relevant harmonized European standard or a European Technical Assessment (ETA) in case the product is not covered by a standard. However, standards covering specific types of products, *e.g.* plasterboard or insulation, normally relate to product properties only and not to properties related to the technical solution, *e.g.* strength, fire resistance and sound insulation. In case a standard covers a technical solution, for example a lightweight wall, it usually focuses on statics and fire safety issues.

This means that where moisture loads are important, it is necessary (and legal) to supplement with requirements for moisture related properties, assuming these properties cannot be declared based on harmonized standards. This may be requirements related to moisture content at a specified relative humidity in the surrounding air, free water uptake, drying rate after water uptake, mechanical and chemical stability associated with moisture absorption, and durability in relation to moisture content. In addition, requirements for buildability must be included. In case it is decided to replace a product by another, the alternative product have to meet all the requirements, and not only one of them.

Documentation of product properties. For each of the listed requirements reference to a test standard shall be made. If a relevant harmonized European standard exists, it must be used.

4 Discussion

The cases in Section 2 illustrates, as previously stated in (de Place Hansen, 2013), that the buildings regulations' increasing use of performance-based requirements highlights the need for recommendations for levels of requirements for technical solutions and for communication about the experience with building products and solutions. Further, that building professionals should reflect more on the feasibility of a product or solution in a specific context, without having 40 years of experience from practice, as a lack of service life data not necessarily prevents new products and solutions to be promoted (de Place Hansen and Møller, 2015).

The introduction of CE marking makes it possible to market and sell a specific product in any country within the European Union (EU). However, a CE mark handled by EU, declaring specific properties of a building product, does not guarantee that the product complies with performance-based building requirements, being national based. Further, a CE mark is neither a quality mark nor an approval of the product for a specific application, although clients and consultants often believe this is the case. A product can get a CE mark simply by meeting a minimum requirement for a single property, *i.e.* CE marking does not ensure that the building product has all the relevant properties.

The producer might have had a specific use in mind, *e.g.* related to fire resistance or a specific climate, and not that it would be used in a climate where moisture related properties would be more relevant to document, but national authorities cannot force remaining properties to be declared. Further, a new product or a new use of a product is often not covered by a harmonized standard and an ETA is not necessarily issued, *i.e.* a CE mark is not required. It is therefore a major challenge for the building sector to determine if a new product is suitable in a specific technical solution, *e.g.* being able to withstand hygrothermal load during 40 years of use in a building envelope. Experience from the Danish Building Defects Fund has shown that requirements in relation to moisture are not sufficiently well formulated.

Further, by combining existing products with new products in a technical solution, it is necessary to expose how both new and existing products behave, to estimate how the combination will react, although this is not always sufficient (Ingeniøren, 2019). In general, the more products that are part of a technical solution, the harder it is to formulate product specifications for a solution adequate for a specific geographical location.

To close the gap between performance-based requirements and product specifications in an economical way, a simple, straightforward decision chart is suggested (Figure 2), combining the information presented in Section 3.

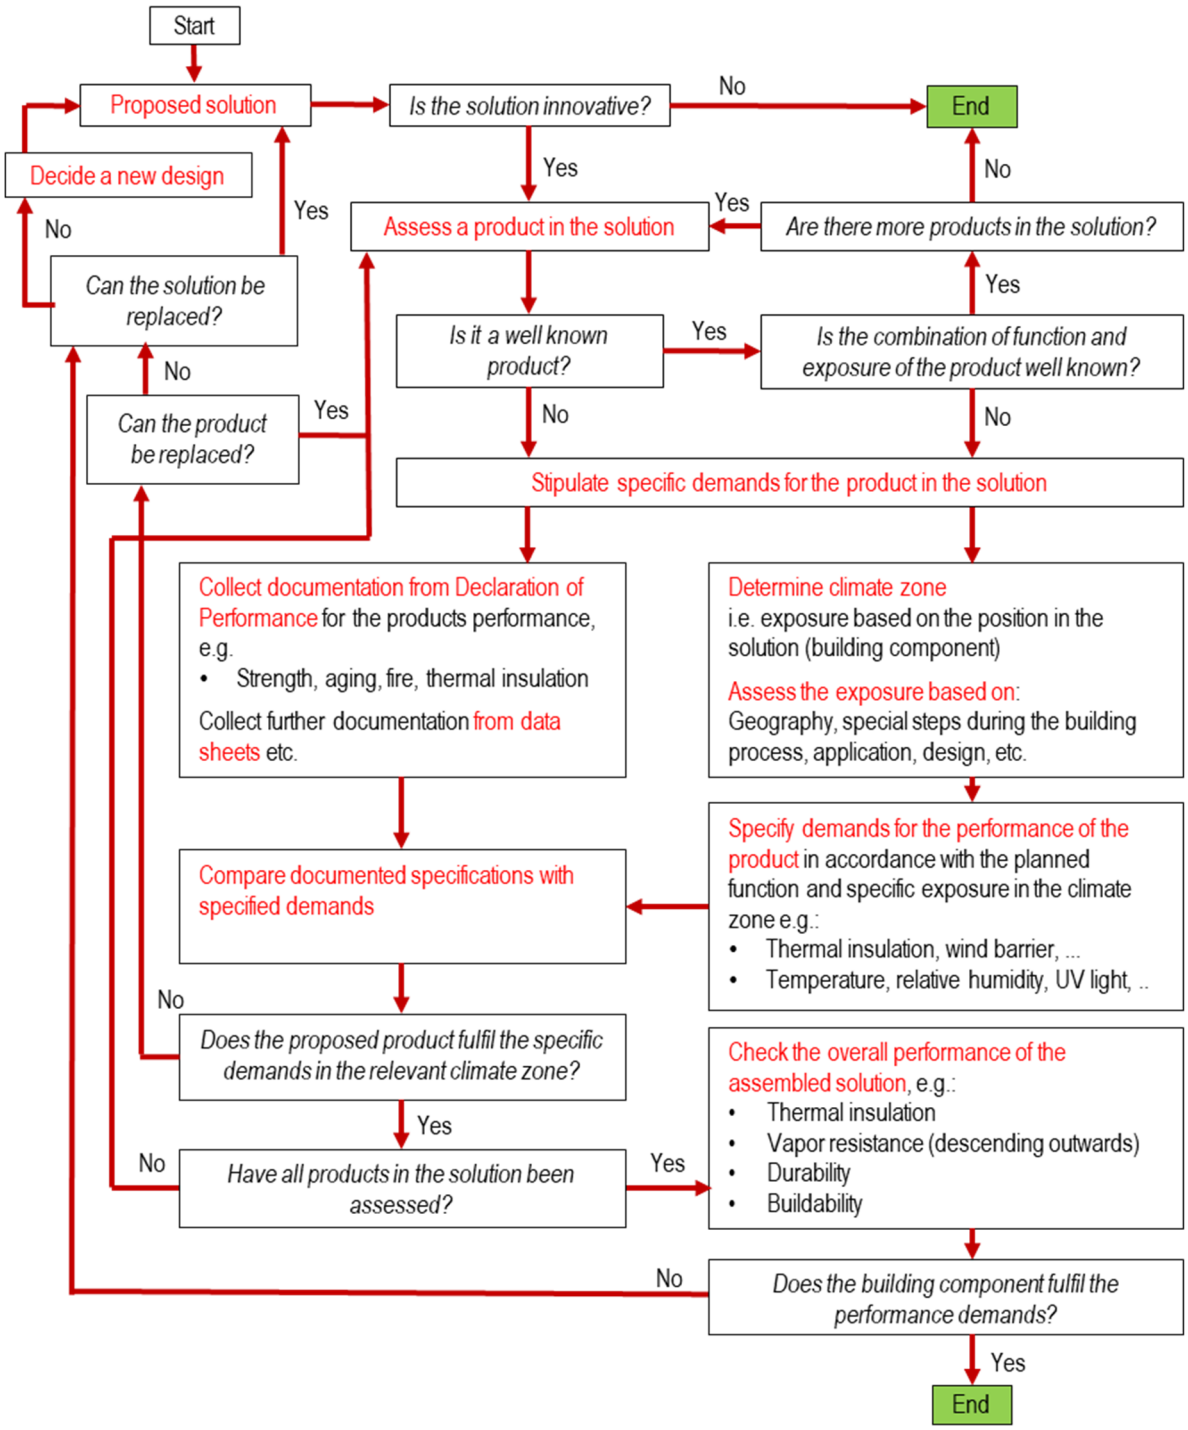

Figure 2. Decision chart guiding the user to ensure a suitable solution for an external lightweight wall, focusing on moisture related properties. Green boxes: A usable solution has been reached. Text in italic: Questions to be answered by the user. Boxes with text in red: Actions to be taken by the user. A guideline and eventually a checklist should expand each of these boxes.

The decision chart forces the user to consider different function-based requirements and guides the user through the most important issues to ensure a suitable solution for the building envelope, using a lightweight wall as an example. To use the chart for other types of external walls or other building elements, guidelines/checklists detailing the content of boxes with text in red should focus more on issues relating to statics, fire resistance, etc. The chart clarifies whether the risks the client takes are reasonable compared with the economic benefits. It can be used for both well-proven solutions with many years of good experience, as for new, innovative products or solutions. The more new products a technical solution includes, the harder the work to make it to the end of the decision chart.

The consultant must decide which requirements are needed for products used at a specific position in a specific technical solution for a building component. A documentation of this could be a part of a statement/declaration on risky conditions, including a description of how to minimize the risk. Together with an evaluation of the costs, the client has now a basis to decide whether he will accept the suggested innovative solution. For products used as roofing underlay this work has already been done in Denmark with the introduction of DUKO in 2004, an independent company that classifies roofing underlays and (since 2013) vapor barrier systems (https://duko.dk). Although this is a voluntary scheme, within a few years DUKO has increased the quality of roofs and reduced the amount of defects (Møller and Hansen, 2017).

In other wall types or in technical solutions used in other parts of the building envelope, the products involved may not have as specific functions as in lightweight walls. Nonetheless, it is still relevant to follow a systematic approach to ensure that all the relevant considerations are made when evaluating whether a suggested solution is suitable. As an example, a wall element that functions both as a load bearing structure, as thermal insulation and as a vapor barrier of course has to document all the properties relevant to comply with these functions when used at a specific geographical location.

For each new product, it can be costly to carry out tests to document whether it fulfils specific requirements, especially if the product can be used in many combinations with other products. Moreover, the producer may have a specific use in mind when putting it on the market, not considering other kinds of use. Consequently, producers may be reluctant to test for more properties than necessary for the intended use. Likewise, consultants and contractors neither have the time nor money to organize testing for more properties.

5 Conclusion

A gap between performance-based requirements specified for a technical solution and specific requirements to properties of products has been identified. Cases show that this gap still exists (second case) although problems with identification of relevant product requirements has been known for at least 30 years (first case). Further, cases show that it can be very expensive to use new products or technical solutions in a specific context if not all relevant properties are documented or if the products are not used as intended.

Closing the gap simply by asking for more documentation is not trivial as testing is expensive, and often the consultant lacks knowledge to identify what is relevant without a systematic approach. A decision chart was developed to guide the consultant into the needed systematic approach when deciding whether a specific product or solution is acceptable.

Acknowledgements

The development of the proposal for a systematic review of products and the decision chart presented in Section 3 and 4 was made possible by a grant from the Danish Building Defects Fund.

Impact of Portland Cement Content on Alkali Activated Bottom Ash

Luís Tambara Júnior, Malik Cheriaf and Janaíde C. Rocha

Laboratory of Waste Valorization and Sustainable Materials (ValoRes), Department of Civil Engineering, PPGEC, Federal University of Santa Catarina (USFC), Campus Trindade, 88040-900 Florianópolis, Brazil, luistambara@gmail.com, malik.cheriaf@gmail.com, janaide.rocha@ufsc.br

Abstract. *This study explores the behavior of blended mortars of low reactive bottom ashes (BA) and ordinary Portland cement (OPC) in an alkaline solution. Mortar mixtures incorporating OPC with different replacement levels (0% to 30% mass) were studied. Isothermal conduction calorimetric analysis was studied and 28-and 60-day mechanical strength values were found. SEM images was used to identifies porosity structures at 28-day. Water absorption was also investigated. The results revealed different behaviors to low (OPC 2.5 and OPC 5) and moderated (OPC 10 and OPC 30) OPC content. Increase in percentage of Portland accelerated hydration kinetics. There is a second peak formation for moderated OPC content, associated with C-A-S-H gel formation. The partial replacement of bottom ash by OPC tend to reduce the absorption. There is a slower initial water absorption to low OPC content. This behavior is due the higher unreacted BA content, that works as a filler. Otherwise, the increase of water absorption for OPC content is due to the coexistence of Portland cement hydrates and alkali activated reactions.*

Keywords: *Blended Mortars, Alkali Activation, Porosity, Bottom Ash.*

1 Introduction

Bottom ash (BA) represents 40% of ashes from the coal-fired thermoelectric power plants (Cheriaf *et al.*, 1999), it is estimated 4.5 million tons of BA per year in Brazil (IEA, 2016). Unlike fly ash, the disposal of bottom ashes goes to settling basin. Studies have shown the use of bottom ashes as an alternative aluminosilicate source for alkali activations (Topçu *et al.*, 2014, Tambara Júnior *et al*., 2018). However, its performance is worse than fly ash. This is due the less amorphous content, higher unburned coal and low reactive SiO_2 and Al_2O_3.

An alternative to improving alkali activation BA properties is to increase surface area (through grinding) and to reduce unburnt material, through calcination (Sathonsaowaphak *et al.*, 2009). Currently in the literature hybrid or blended cements are used to obtain better responses of the material (Garcia-Lodeiro *et al.,* 2016).

Durability remains a property requiring further studies on alkali activations. A problem reported about alkali activation materials is the higher sorptivity when compared with Portland cement. Some works (Collins and Sanjayan, 2000) affirm that this is due the large proportion of fine pores which results in micro-cracks in the matrix, increasing the water capillarity. To reduce the water sorptivity it is necessary add some material that densifies the sample (Rostami and Behgarnia, 2017).

In this article was investigate the influence of ordinary Portland cement (OPC) on the mechanical strength, kinetic of water absorption and pore structure (scanning electron microscope) of blended alkali activation mortar of BA/OPC. The reaction was monitored with isothermal conduction calorimetry to evaluate the heat flow variations in the pastes in the early time of reaction. The OPC was blended from 0%, 2.5%, 5%, 10% and 30%.

doi:10.23967/dbmc.2020.180

2 Experimental Procedure

2.1 Materials Characterization

A Mastersizer 2000 laser granulometer was used to obtain particle size distribution of OPC and BA (Figure 1) and the powder was dispersed in isopropanol. It is seen that the BA used in this study contained a finer particle size than BA. Where 86% of OPC and 99.9% of BA particle size measured under 45μm, in agreement with the size particle parameter used to improve ash reactivity (Fernández-Jiménez e Palomo 2003).

The BA and OPC oxide analysis and clinker phase compositions are presented in Table 1. To the cement the phase was estimated based on Bogue calculation method. To BA was performed a Rietveld refinement method (Rietveld, 1969) using X-ray diffraction test data. To determine the amorphous and crystalline content in the BA sample, the analytical reagent corundum (Al_2O_3) was added in a total of 10% by mass as an internal standard. The OPC is a type III and the BA is classified as ash type F (low calcium content).

The sand used in the mortar mixtures was a natural fine sand. It was obtained a relative specific density of 2600 kg/m³, water absorption of 1.6%, maximum grain size of 1.2 mm and minimum grain size of 0.15mm. The sand showed a fineness modulus of 1.83.

Table 1. Chemical composition.

Oxide analysys			Phase composition results

Others	2.17	7.32	free lime	1.25		
LOI[a]	3.80	6.67				

[a]Loss of ignation

A combination of sodium hydroxide (NaOH) pellets, water distilled and sodium silicate solution (Na_2SiO_3) was used as an alkaline activator (SiO_2 = 26.5%; Na_2O = 10.6%; H_2O = 62.9%; and density of 1.39 g/cm^3). Initially a 14M NaOH solution was prepared with distilled water, waiting up to room temperature. After that a ratio of 1:2 Na_2SiO_3 to NaOH solution were prepared. A superplasticizer additive based on polycarboxylate ether, with solids content of 0.22, was used to adjust the workability (flow value > 250 mm) required for self-leveling mortars.

To evaluate the effect of OPC content on the microstructure of blended alkali-activated mortars, it was prepared 5 mixtures. The sum of OPC and BA was considerate as binder. Hydrated mortars were prepared using the same liquid-to-binder (l/b) ratio of 0.55. The substitution in mass of BA for Portland cement was: 0% (*i.e.*, only bottom ash), 2.5%, 5%, 10% and 30%. The binder and sand ratio were kept constant from 1:2 (in mass). The molar ratios were between 2.6-3.1 to Si/Al, 0.27-0.30 to Na_2O/SiO_2 and equal to 12.3 to H_2O/Na_2O.

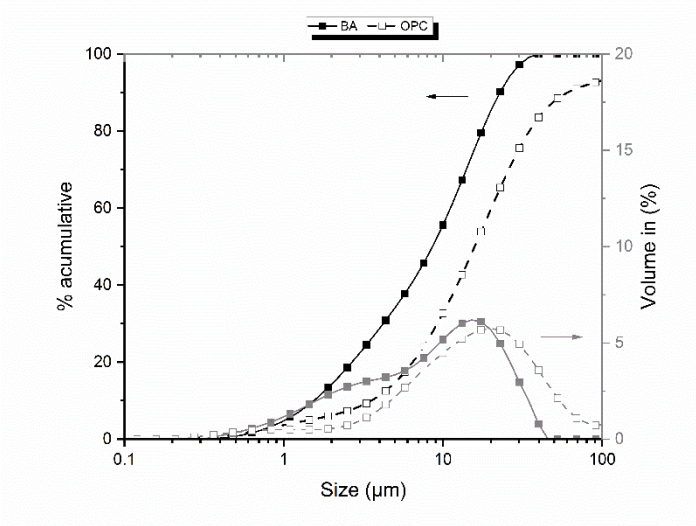

Figure 1. Particle size of OPC and BA.

2.2 Experimental Procedure

The mixing method consisted of an initial premix of the solutions (NaOH and Na_2SiO_3) until room temperature. After that, a dry mix powder of cement, bottom ash and sand of each proportion was executed. The solid/liquid mixing was performed in a planetary mixer, the first 2 minutes at 150 rpm and one last minute at 300 rpm. Then the mortars were added to the molds and cured for 24h at 80ºC.

Compressive strength was performed in cubic molds (4cm x 4cm), according to Brazilian Standard NBR 13279. To each mixture 6 samples were tested at 28 and 60 days of reaction. Calorimetric tests were performing to determine the heat evolution and the total heat through a conduction isotherm calorimeter TAM Air-Thermometric. The pastes were manually mixed for a period of 3 min with the same w/b ratio than mortars and then sealed. The samples were immediately placed in the calorimeter, under the same conditions as the mortars (80º ± 1ºC).

To stop the reaction at the test ages for microstructural analysis, the samples were kept in an oven at 40ºC until constancy of mass. Water absorption was evaluated over time for 24 hours through a method of Mariotte's bottle developed of laboratory ValoRes-UFSC. To analyze the microstructure images, the samples were carbon-coated and mounted on electron microscope slides for study under a JEOL JSM-6390SL (15.0kV) with energy-dispersive X-ray spectroscopy (EDS) performed at Central Laboratory of Electron Microscopy (LCME-UFSC).

3 Results and Discussion

3.1 Isothermal Calorimetry and Compressive Strength

The effect of OPC content on the rate of heat release and total heat release during alkali activation of the BA is shown in Figure 2. For all the samples is seen a faster reaction at 80ºC, due to this it was not possible to detect the first peak associated aluminosilicate dissolution, as observed in literature (Palomo *et al*., 1999; Garcia-Lodeiro *et al*., 2013). For the alkali

activation only with BA (OPC0) it is seen the lowest heat release and total heat. This is due its insufficient dissolution phases that start the formation of N-A-S-H gel.

Two different behaviors were observed according to the OPC content on the hybrid cements. Results are presented as low OPC content (OPC2.5 and OPC5) and moderate OPC content (OPC10 and OPC30). Even in small quantities, increasing OPC content accelerates the activation reaction. To low OPC content (Figure 2a) it is noticed the formation of a single peak in heat evolution. The increment of OPC content resulted in a higher heat release and total heat, this indicates an increase of reaction degree. OPC2.5 and OPC5 showed a total heat at 6 h of 59.79 J/g and 77.73 J/g, respectively.

Figure 2b shows heat flow curve and total heat for the alkali activation with moderate OPC content. It is observed a more intense and rapid first peak compared with low OPC content, followed by a short dormant period (occurs up to 15 minutes of activation). OPC10 and OPC30 presented a total heat at 6 h of 148.48 J/g and 126.76 J/g, respectively.

The quick first peak formation may be associated with an accelerated Si and Al dissolution and N-A-S-H formation. Also, a secondary peak starts after 15 minutes of activation. After the first gel formation the pH of pore solution decreases by which the calcium provided from OPC begins to react and form a (N,C)-A-S-H gel type (Garcia-Lodeiro *et al*., 2016).

OPC30 showed the highest total heat up to 1h of activation, however, OPC10 overcame the total heat in higher period. Martinez-Ramirez and Palomo (2001) showed that OPC hydration is retarded when alkali concentrations increases. This suggests that is greater amount of inner anhydrous cement to OPC30 than OPC10.

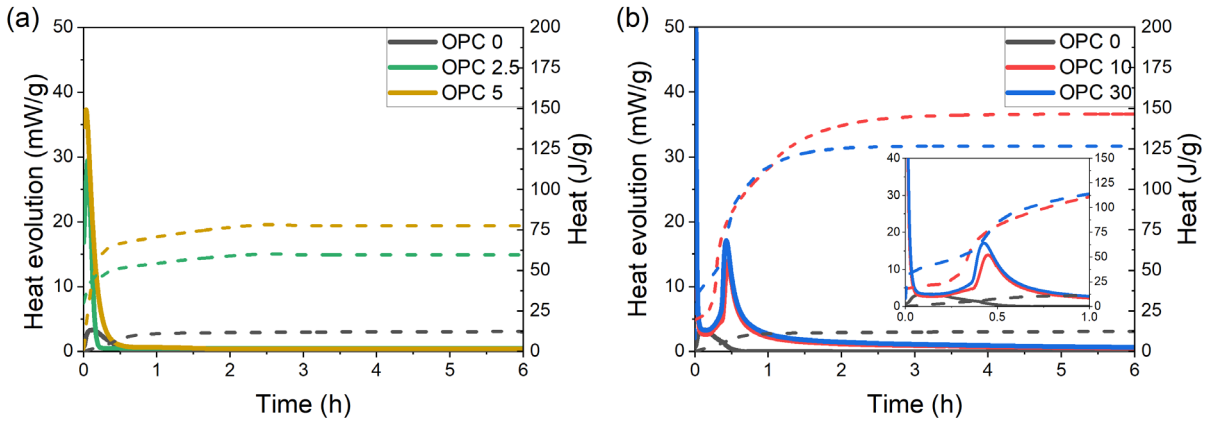

Figure 2. Heat flow and cumulative heat from the low OPC content (a) and moderate OPC content (b) alkali Activation.

Compressive strength was evaluated to later ages of 28 d and 60 days (Figure 3). OPC0 showed no strength development over the time of 60 days. This result shows that the exclusive alkali activation of BA results in a very slow evolution of reaction. The gain of compressive strength from 28 d to 60 d of OPC2.5, OPC5 correspond to 8.8%, 12.8% to low OPC content, a result in agreement with heat flow calorimetric analysis. To moderate OPC content the compressive strength for 28 d and 60 d increases 19.9% and 11.6% to OPC10 and OPC30, respectively. There is observed an optimum OPC content of 10% to blended mortar, increasing the bottom ash reaction.

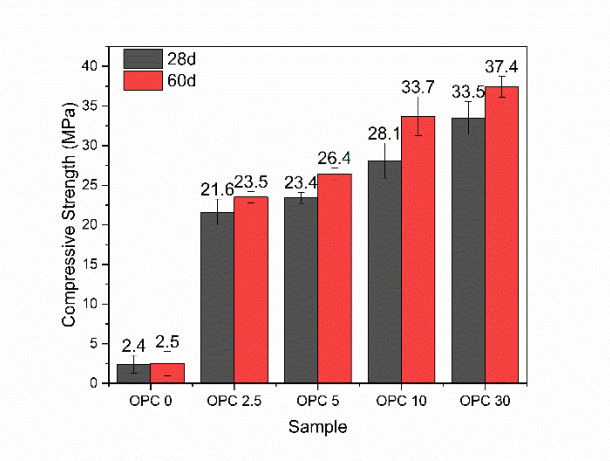

Figure 3. Compressive strength to 28 d and 60 d.

3.2 Water Absorption

Water transportation of mortars is an important property that mainly influences its durability. Figure 4 shows water absorption over a 24 h of experiment to low and moderate OPC mortars at 1 d and 28 d. The water absorption of the blended mortars reported in this work were obtained in the final rage of 2.27%-10.01% and 1.57%-4.30% for 1 d and 28 d, respectively. At 1 d of hydration, it is observed higher absorption of activation with increased OPC dosage.

At 28 d was observed to all samples a reduction of water absorption. Compared with 1d of hydration, OPC30, OPC10, OPC5 and OPC2.5 presented a water absorption reduction of 57.04%, 81.17%, 68.59% and 30.84%, respectively. Water absorption reduction is greater for moderate OPC mortars. It was observed that OPC10 showed the lowest water absorption to 28 days. The authors associate this behavior to the pore filling due best compatibility of last formation of (N,C)-A-S-H gels observed through microscopy analysis (Tambara Júnior *et al.*, 2018).

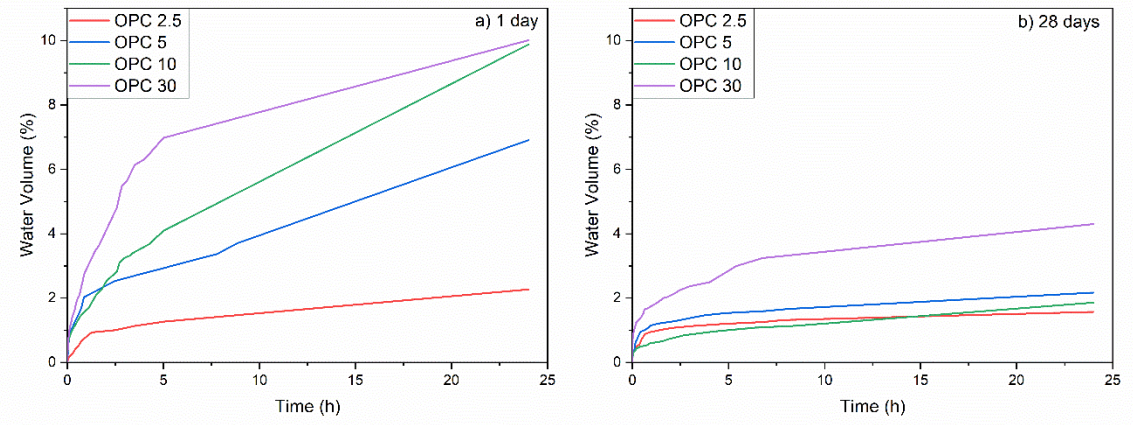

Figure 4. Water absorption of low OPC moderate OPC content at 1 day (a) and 28 days (b) of reaction.

3.3 SEM

As Figure 5a shows, the bottom ash after treatment presented predominance of irregular particles with few spherical particles, which difficult the activation. Figure 5b shows the OPC0 at 28 days of activation, where there is a larger presence of unreacted BA and insufficient gel formation, featuring in a higher porosity and low compressive strength (Figure 3).

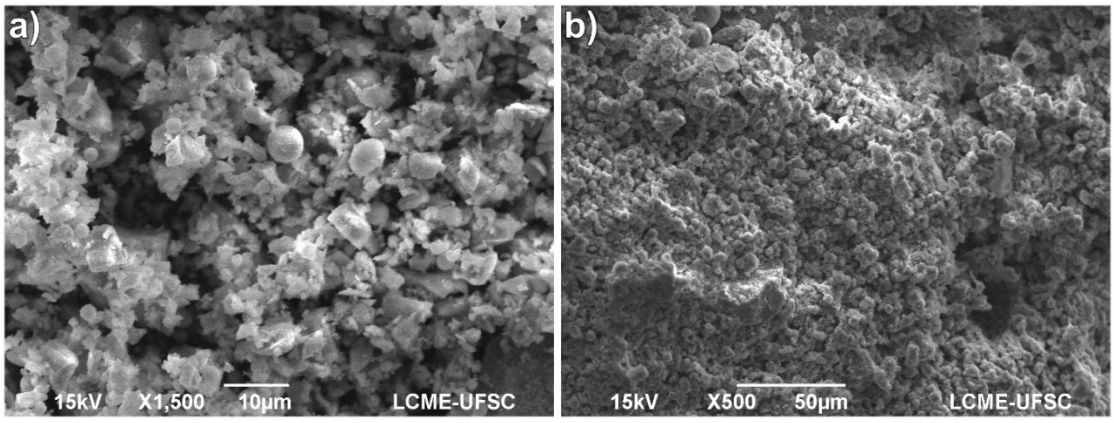

Figure 5. SEM images of a) BA and b) OPC0 hydrated at 28 days.

As visual criteria, analysis of pores size was evaluated through an image analysis software tool of SEM images. Figure 6 shows micrographs of low and moderated OPC samples at 28d. To OPC2.5 is the sample with the largest pore presence. It is observed a great presence of macropores 50 µm - 400 µm. To OPC5 was observed a reduction in the content of smaller macropores, with no significant difference to pores larger than 300 µm.

There is observed higher pore formation and unreacted bottom ash to low OPC content mortars. As calorimetry analysis shows, the improve of OPC content results in a higher energy release. This fact can be associated with the reduction of porous sizes, where this improves the silicon dissolution, resulting in a denser N-A-S-H/C-A-S-H gels.

Moderate OPC mortars resulted in a reduced presence of the larger porous size. OPC30 and OPC10 presented similar pore size range of 20 µm – 140 µm. Otherwise, it was observed the lower water absorption to the OPC10, that can be associated to a higher microporosity to OPC30 mortar.

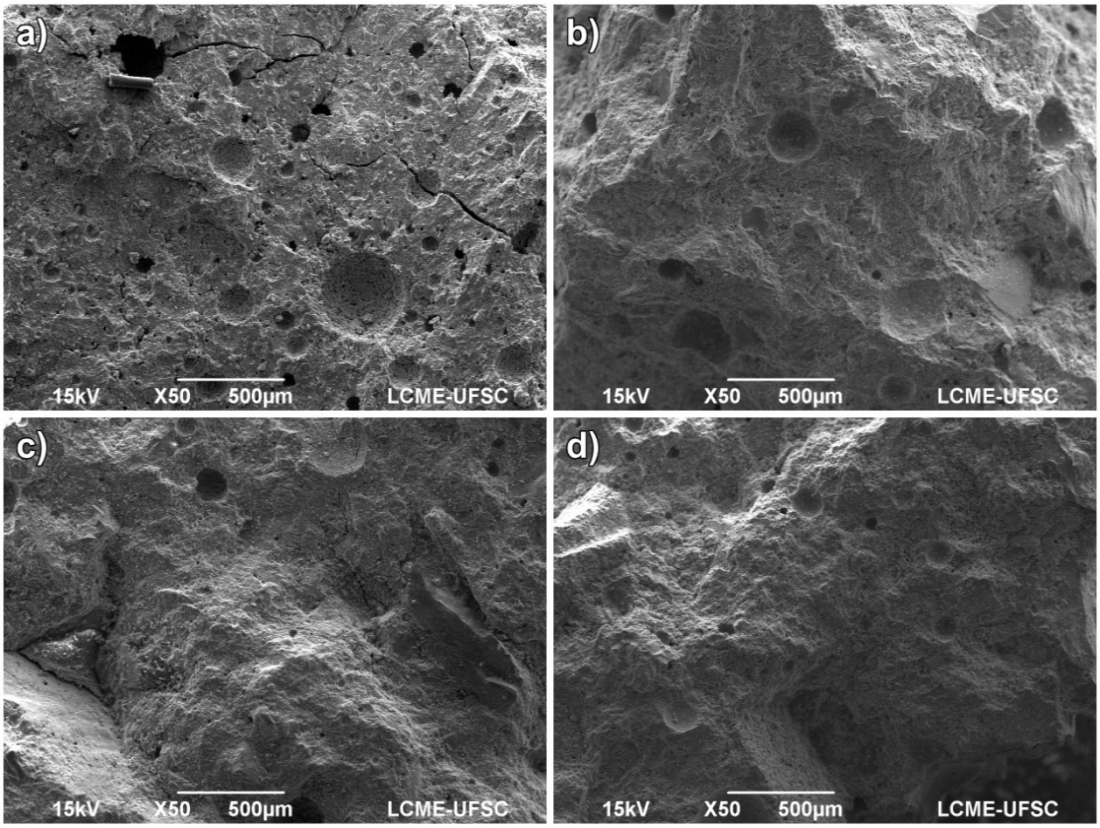

Figure 6. SEM images of 28 days a) OPC2.5, b) OPC5, c) OPC10, d) OPC30.

4 Conclusions

This study evaluated the OPC content on the blended mortars of bottom ash and Portland cement. It is concluded that there is different behavior between low to moderate OPC replacement, but even in low content (2.5% and 5%) there is a good contribution to activate bottom ashes with low reactivity.

To all the samples, as the OPC replacement increased the mechanical strength and the water absorption increases. This improved performance may be due to a denser microstructure generated to C-A-S-H gel formation observed through microstructural and calorimetry analysis that showed a secondary peak to moderate OPC content.

Furthermore, the 10% substitution of OPC significantly improved the parameters of durability, associated with the higher strength development at later ages and lower water absorption, due to its suitable Ca^{+} content provided by OPC. The increase of compressive strength and water absorption of OPC30 may be associated with a reduction of macroporosity but higher microporosity.

Abstract. *The use of mineral admixtures in concrete has grown in recent years, specially the high-performance ones, such as silica fume, nanosilica and metakaolin. Metakaolin has been extensively studied due to its high reactiveness. Thus, an experimental program was conducted to evaluate the behavior of compressive strength and non-steady state chloride migration due to differences of metakaolin characteristics. Three different metakaolins were characterized, then used in a 10% replacement ratio (of mass of cement), among two water/binder ratios (0.40 and 0.60) in concrete mixes. The results show that metakaolin increased compressive strength in every age tested. Moreover, durability properties were significantly enhanced due to the addition of metakaolin. Non-steady state chloride migration coefficient of metakaolin concretes were noticeably lower than plain concrete. In general, the addition of metakaolin in concrete caused pore refinement and reduction in total porosity, which lead to enhancements of mechanical e durability properties of concrete.*

Keywords: *Durability, Chloride Migration, Metakaolin, Compressive Strength.*

1 Introduction

Metakaolin (MK) is a relatively new supplementary cementing material (SCM), although there are studies and research in the past century, it was in the last two decades that MK was broadly studied. In Federal University of Goias (UFG), in Brazil, since 2000's several experiments were conducted with MK and other pozzolans (Cascudo, Mendes, Carasek, and Ferreira, 2014; Ferreira, Pereira, Lopes, Carasek, and Cascudo, 2004; Figueiredo *et al.*, 2014; Oliveira and Cascudo, 2018; Pereira, Lopes, Hasparyk, Carasek, and Cascudo, 2005). The results of these researches suggest that the overall good performance of highly reactivity metakaolin owes mainly to its fineness which leads to an enhancement of filler effect on concrete microstructure.

On the other hand, MK is obtained from the calcination of kaolinitic clay, mainly composed of kaolinite (hydrated aluminosilicate), which means that it's major composition is alumina (Khatib, Baalbaki, and ElKordi, 2018; Murat and Comel, 1983; Siddique and Khan, 2011). In this sense, some studies observed that MK can react with chloride ions in concrete resulting in a stable compound knows as Friedel's salt (Friedel, 1897). This means that the addition of metakaolin in concrete can improve the chloride resistance (Cascudo *et al.*, 2014; Talero, 2012), therefore improve the durability of concrete.

doi:10.23967/dbmc.2020.079

Thus, a research conducted to verify the influence of physical, chemical and mineralogical characteristics of highly reactivity metakaolins in mechanical and durability related properties of concrete. In the present paper the changes in compressive strength and chloride migration caused by MK properties were assessed.

2 Experimental Program

This paper is a part of a broader experimental program in which the influence of different types of highly reactivity metakaolins in the microstructure of concrete is evaluated.

2.1 Materials

Eight different types of concrete were mixed: with two water/binder ratios – 0,40 and 0,60 – as well as three different metakaolins – MK1, MK2 and MK3 – all from the same Brazilian manufacturer in a 10% content in substation of cement, in mass, and a plain concrete – with no MK - R. The complete composition of all eight mixes is presented in table 1.

Table 1. Compostion of concrete mixes.

Concrete mixes	Cement content (kg/m³)	Mix proportions, in mass (cement : metakaolin) : sand : crushed stone	w/b	Super-plasticizer (%)
40R	450	(1.00 : 0.00) : 1.68 : 2.37	0.40	0.36%
40MK1	405	(0.90 : 0.10) : 1.67 : 2.37	0.40	0.66%
40MK2	405	(0.90 : 0.10) : 1.67 : 2.37	0.40	0.64%
40MK3	405	(0.90 : 0.10) : 1.67 : 2.37	0.40	0.67%
60R	300	(1.00 : 0.00) : 2.98 : 3.53	0.60	0.33%
60MK1	270	(0.90 : 0.10) : 2.96 : 3.53	0.60	0.46%
60MK2	270	(0.90 : 0.10) : 2.96 : 3.53	0.60	0.38%
60MK3	270	(0.90 : 0.10) : 2.96 : 3.53	0.60	0.60%

Once the characteristics of the metakaolins are relevant to further understand the possible changes in concrete, some of their physical, chemical and mineralogical properties were analyzed: BET fineness, chemical composition by X-ray fluorescence, quantification of crystalline phases by X-ray diffractometry. Among of them, the pozzolanic index of metakaolin was measured by the Chapèlle's modified test (ABNT, 2010).

An ordinary Portland cement (OPC) (Brazilian type CP II F 40, similar to CEM II/A-L 42.5) was used in all concrete mixtures.

There were also used two different fine aggregates – both quartz sand, one with a fineness modulus of 2.09 and the other one with a MF = 3.54 – and two different coarse aggregates – both gneiss crushed stone, one with a MF equals to 5.71 and the other one with MF = 6.80. Also, a polycarboxylate-based superplasticizer was used in order to maintain the slump in a constant range, without changing the w/b ratio.

2.2 Methods

Concretes were tested in fresh state in which slump test was conducted to be kept in the range that was proposed (120 ± 20 mm). Then cylinder specimens were molded for tests in hardened state. Then they were cured immersed in water saturated of calcium hydroxide, at (23 ± 2)°C until the age of 28 days. Compressive strength tests were conducted with cylinder specimens (100 x 200 mm) of every concrete mix in four ages: 7, 28, 91 and 140 days.

The chloride resistance was measured by the Nordtest method, described in NT Build 492 (Nordtest, 1999). 100 mm × 50 mm cylindrical specimens were cut from the middle of 100 mm × 200 mm cylinders; subsequently, the apparatus, as described in the method, was assembled. This method, that was primarily proposed by Tang and Nilsson (1993), consists in forcing the chloride ions to migrate, with a direct electrical current applied in both cathodic and anodic solutions in which a specimen is immersed. This test, after some calculations based in some equations provided by the Nordtest standard, results in a coefficient of migration of chlorides in a non-steady state. This coefficient of migration is close to the coefficient of diffusion, which is the real mass transport of ions that occurs in concrete.

The results were also submitted the statiscal analysis of variance (ANOVA) and multiple mean comparison, from which some charts are presented herein.

3 Results and Discussion

Once the results of metakaolins characteristics are relevant to explain the changes in the properties of concrete, the results are presented in two section: first, the metakaolin results and then the concrete results.

3.1 Metakaolins Characterization

Although the metakaolins are produced by the same manufacturer, they are quite different, as can be seen in their chemical composition, presented in table 2.

Table 2. Chemical compostion of metakaolins.

Test Method	Content	MK1	MK2	MK3
X-ray Fluorescence Spectroscopy	SiO_2 (%)	56.46	52.58	51.43
	Al_2O_3 (%)	32.17	44.61	42.53
	Fe_2O_3 (%)	2.23	0.35	2.00
	CaO (%)	0.17	0.06	0.16
	MgO (%)	0.7	0.02	0.28
	K_2O (%)	2.16	0.09	0.95
	Na_2O (%)	0.04	0.04	0.02
	L.O.I. (%)	4.27	1.95	1.28
	Others (%)	1.65	0.11	1.14

It is known that MK1 and MK3 are obtained from the same raw material, while MK2 comes from another deposit. MK2 is white, so it is expected that it is the purest of all three, verified by chemical analysis, with around 97% of silica+alumina. The differences between MK1 and MK2 are also expressive, which may be due from the difference in the processing of raw material in the deposit (mainly a better refinement of the kaolin).

Table 3 shows other properties of metakaolins. The differences in their fineness are relevant. Although MK2 is the purest, it is the coarser metakaolin, which in theory may lead to lower reactivity. Also, it is interesting to observe the difference between the amorphous content, mainly between MK1 and MK3, which can be also explained by differences in the processing of material, especially in the calcination process.

Table 3. Physical and mineralogical properties of metakaolins.

Test Method	MK1	MK2	MK3
BET specific surface area (ASTM C 1069) (m^2/g)	19.75	8.13	30.99
XRD Quantification – Amorphous Content (%)	60.8	70.1	75.6
Chapèlle's Modified Method (ABNT NBR 15895:2010) - Pozzolanic index (mg $Ca(OH)_2/g$)	859	1027	1440

Finally, the pozzolanic index measured by the Chapèlle's modified method gives a overall understanding of the reactivity of the metakaolin, once it emulates the pozzolanic reaction (Quarcioni, Chotoli, Coelho, and Cincotto, 2015). According to this method, MK3 is the higher in reactivity, followed by MK2 and MK1.

3.2 Compressive Strength and Chloride Migration

Results of compressive strength along the age of concrete are presented in figure 1.

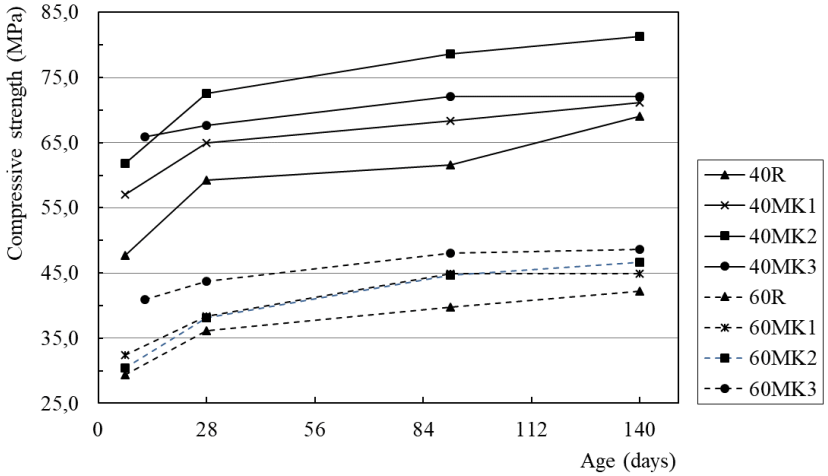

Figure 1. Results of compressive strength of concrete at ages of 7, 28, 91 and 140 days.

The difference between the w/b ratio is noticeable, as expected. It can be also seen that even in early ages MK concrete showed better results, which may be explained by the filler effect that is instantaneous. Also, at later ages MK concretes still showed better results. At 91 days a great part of the pozzolanic reactions have already occurred, it can be observed that mechanisms of action of MK in concrete changes depending on the w/b ratio. For the 0.60 concretes, MK3 presented the highest results, though for the 0.40 concretes, MK2 showed the higher value. This can be explained by the differences in the pore structure of the two groups of concrete, as the 0.40 concretes tends to be less porous, the filler effect is not that important compared to those of w/b of 0.60, so the coarser MK, although purer, showed better results, meaning that in this case the chemical reactivity took place.

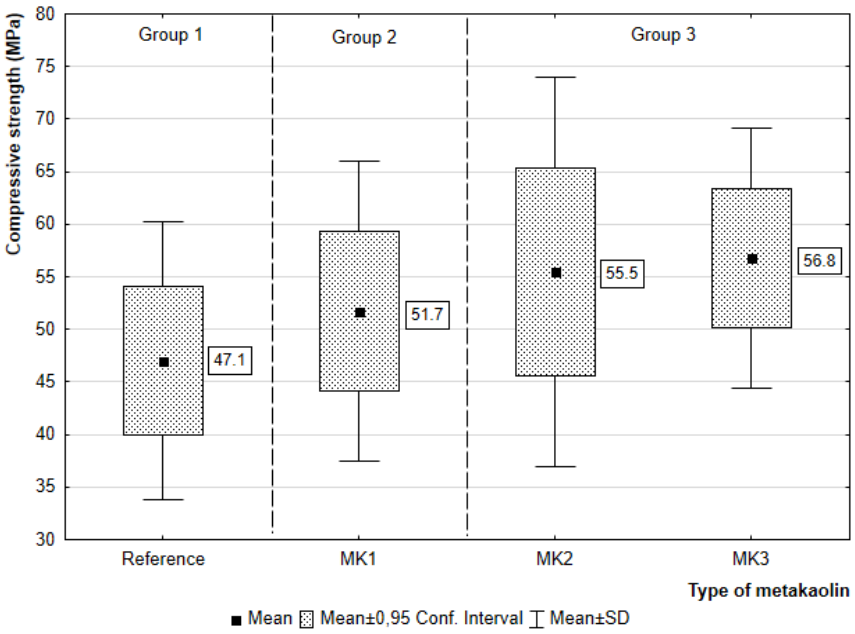

Figure 2. Multiple mean comparison of compressive strength and type of metakaolin.

Analyzing the ANOVA results, it showed that both variables (w/b and type of metakaolin) and their interaction were significant to explain the changes in compressive strength. The coefficient of determination of the model is 0.99. Figure 2 shows the multiple mean comparison segregation of the groups of statically equivalent concretes. It can be concluded that both MK2 and MK3 performed very well, in comparison to MK1 and plain concrete.

In chloride migration tests, MK concretes significantly outperformed plain concretes. Figure 3 shows the results of the non-steady state chloride migration coefficient. The w/b ratio was significant in the ANOVA model, as expected. So it was the type of metakaolin and their interaction, resulting in a R^2 equals to 0.98. Different that compressive strength, the Tukey's test from multiple mean comparison segregated the groups of statically equivalent results with some intersection. This means that it is possible to assure that the MK3 is superior than MK1 and plain concrete, but statically equivalent to MK2.

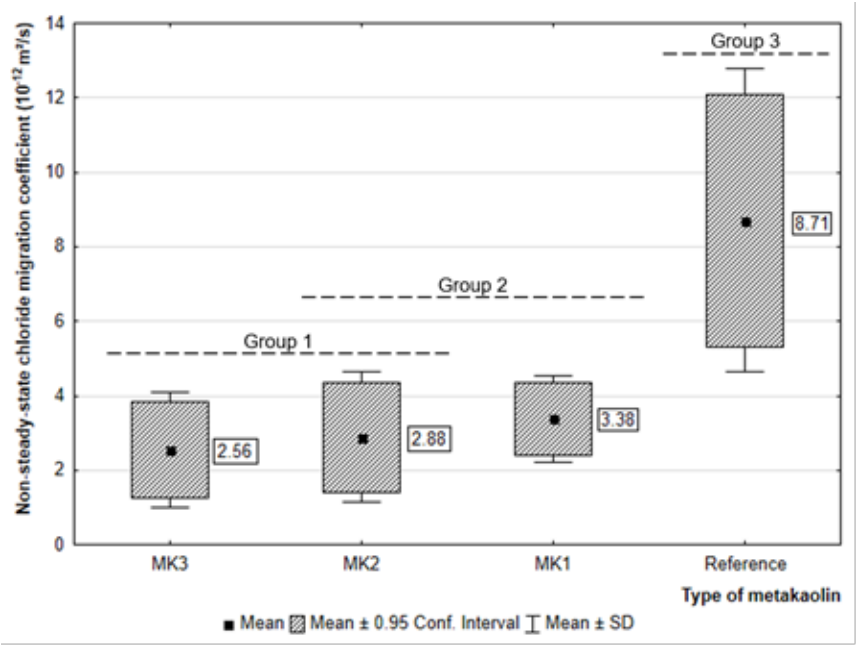

Figure 3. Multiple mean comparison of chloride migration coefficient and type of metakaolin.

It is noteworthy that even the worse result of MK concretes is way better than plain ones, as can be seen in figure 4. This means that MK can significantly improve the chloride resistance of concrete, and it is more efficient in doing it than a reduction of w/b ratio.

A possible explanation for this behavior can be due to the reaction of the chloride ions with the alumina present in metakaolins, thus forming the Friedel's salt (Talero, 2012). It can be also combined with the densification of the cement matrix that is assumed to occur with the addition of MK, once the compressive strength was also improved.

Besides that, with 0.40 w/b concretes, the differences of the three types of MK was more prominent. This may be due to the lower porosity of these concretes, and in this case, MK benefits are more evident, surpassing the effects of w/b ratio itself. Besides this, the correlation of these results and the results of Chapèlle's pozolanic index of the metakaolins are higher. This leads to the theory of chemical combination of aluminous phases with chloride ions.

Another interesting point is that every MK concrete is classified, according to Nilsson, Ngo and Gjørv (1998), as a very high or extremely high resistance to chloride attack. This means that MK concretes are significantly more durable than plain concrete. Plain concrete with w/b of 0.60, for example, is classified as a moderate chloride resistance.

It is clear that metakaolin concretes showed better results in comparison to plain concretes. The addition of MK in concrete seems to be more effective in improving the chloride resistance than the w/b ratio, evidenced by the fact that concrete with a higher w/b ratio and with the worser MK showed better results than a concrete with lower w/b ratio and without MK.

Also, for the compressive strength the enhancements caused by MK are noticeable, but in this case w/b ratio seems to be more relevant to determine.

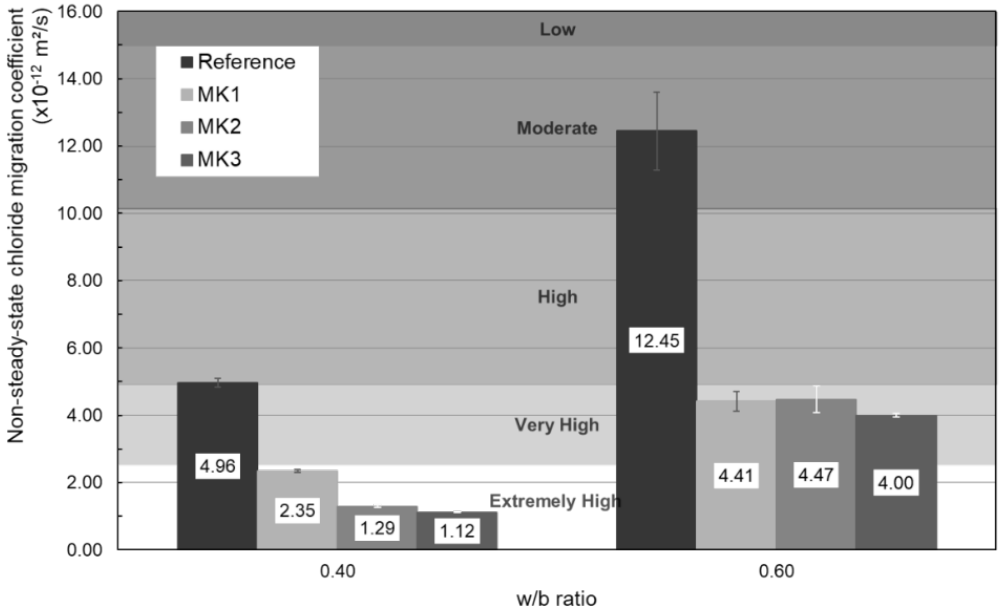

Figure 4. Mean values and standard deviation of non-steady-state chloride migration coefficient of all concrete mixtures, and the classification of chloride resistance from Nilsson, Ngo and Gjørv (1998).

5 Conclusions

- The pozzolanic activity index measured by the Chapèlle's modified method showed to be accurate to describe the overall behavior of the metakaolin, compiling the physical, chemical and mineralogical characteristics of the pozzolana in one result.
- Compressive strength was improved by the addition of metakaolin, and the interaction of the SCM was different depending on the w/b ratio.
- Metakaolin significantly enhanced the chloride attack resistance of concretes with both w/b ratio, even the worst MK with the 0.60 w/b presented better result than the 0.40 plain concrete, which demonstrate the effectiveness of MK to prevent chloride attack.

Acknowledgements

The authors acknowledge the contribution of Metacaulim do Brasil Company, which donated material, supported and financed this research. They also thank the company Eletrobras Furnas for all the support given in the experiments, as well as the following laboratories: LEDMa/UFBA for the XRD tests, LABMIC/UFG for the SEM analysis. Finally, the authors would like to thank CAPES and CNPq (Brazilian governmental institutions), which provided grants to researchers, as well as UFG and PPG-GECON.

Abstract. *The aim of this work is to better understand the influence of drying conditions and moisture content of concrete on the carbonation kinetics during accelerated tests. Cylindrical specimens of a typical concrete formulation for buildings were dried, after 28 days wet curing, under three different conditions: 80°C, 45°C and 20°C and 50% RH. The carbonation depth and the height of water absorption were measured during 70 days testing under 3% CO_2, 20°C and 65% RH. The results show that there is a significant difference in the drying behavior of cylindrical specimens between the lateral cast surface and their circular free surface. But, the drying cycle before accelerated carbonation tests has more influence on the carbonation rate than the type of exposed surface.*

Keywords: *Concrete, Drying, Accelerated Carbonation Test, Water Absorption.*

1 Introduction

Natural carbonation of concrete is one of the main reasons of steel reinforcement corrosion. The moisture conditions of concrete exposure have an important impact on carbonation kinetics. According to NF EN 206 (2014) standard, environments with medium relative humidity (between 50 and 70%) induce higher carbonation of concrete than drier or damper environments.

Accelerated tests are generally carried out to determine carbonation resistance of concrete and to assess the influence of various parameters of formulation, curing or ageing (Fattuhi, 1988; Alahmad *et al.*, 2009) Varying experimental conditions are used for the tests. In European level, there is not consensus for accelerated carbonation tests. For example, the Belgian standard recommends exposure of concrete specimens to 1% CO_2 while the French standard (NF XP P18-458, 2008) recommends 50% CO_2. The conditioning of specimens before CO_2 exposure varies even more strongly. For example, the European project of standard (prTS 12390-12, 2010) recommends 14 days drying in room conditions while the French standard recommends 14 days drying at 45°C. Different drying conditions before testing lead to different moisture content of concrete and consequently to varying carbonation kinetics (Parrott, .1996) (Galan, 2013).

The aim of the present work is to better understand the influence of drying conditions and moisture content of concrete on its carbonation kinetics during accelerated test.

2 Materials and Methods

A formulation of concrete with 275 kg/m^3 of CEM II/A-LL 42.5 R cement (according to EN 197.1 standard), 0.7 water-cement ratio and siliceous aggregates was used for the tests (Table

1). The compressive strength at 28 days was 26 ± 2 MPa and the density 2367 ± 10 kg/m^3. The formulation is representative of that used in France for building constructions in 50's and 60's presenting today many problems of reinforcement corrosion.

Table 1. Composition of concrete.

	kg/m^3
CEM II/A LL 42.5R	275
Sand 0/4	833
Coarse aggregate 4/16	1062
Water	193

Cylindrical Ø11x22 cm specimens were prepared and cured under water till 28 days. At 28 days, they were sawed into Ø11x7 cm specimens including the free surface of concrete of initial cylinders and into Ø11x11 cm specimens which excluded the bottom of the initial cylinders. The Ø11x7 cm specimens were covered with aluminum sheet in order to expose only the circular free surface of concrete of the initial cylinders. The Ø11x11 cm specimens were also covered with aluminum sheet in order to expose only the lateral cylindrical cast surface. With this setup, it could be expected that the free surface of specimens is representative of the free surface slabs and the cast surface of specimens is representative of cast surface of columns, beams or shells in buildings.

Both types of specimens were exposed to three different drying conditions before accelerated carbonation testing:

- 14 days at 80 ± 2°C plus 7 days at 20 ± 2°C and 65± 5% RH;
- 14 days at 45 ± 2°C plus 7 days at 20 ± 2°C and 65± 5% RH;
- 87 days at 20 ± 2°C and 50 ± 5% RH plus 7 days at 20 ± 2°C and 65 ± 5% RH.

The drying at 45°C for 14 days is recommended by the French standard NF XP P 18-458 (2008) for accelerated carbonation tests on concrete. The drying at 20°C and 50% RH for 87 days was chosen in order to reach almost the same loss of water per unit of exposed surface then that obtained in 14 days at 45°C. The drying at 80°C was applied to obtain strong and deep drying of the surface layer of concrete even if the concrete microstructure could be modified. A complementary drying for 7 days at 20°C and 65% RH was applied in all cases in order to stabilize moisture content of concrete in the same hydrothermal conditions than that used during accelerated carbonation tests. In fact, after drying, accelerated carbonation tests were carried out in 3% CO_2, 20 ± 2°C and 65 ± 5% RH for 70 days. According to Auroy et al. (2018), 3% CO2 is representative of natural carbonation. On the other hand, the hydrothermal conditions of accelerated tests are those of the French standard and close to those of the project of European standard prTS 12390-12 (2010): 20 ± 2°C and 55 ± 5% RH.

The carbonation depth was measured at 0, 28, 56 and 70 days testing by 0.2% alcoholic solution of phenolphthalein spayed to the fracture surface obtained by splitting of cylindrical specimens. In addition, on a second series of specimens exposed at the same conditions for the same periods, the height of water capillary absorption was measured after immersion in colored (by a small amount of fluorescein) water for one week. For this measure, the specimens were split and the thickness of saturated by colored water layer was determined on the fracture surface under ultraviolet light in the same way as the carbonation depth.

3 Results and Discussion

3.1 Drying

Figure 1 presents the loss of weight per unit of exposed surface of both types of cylindrical specimens during drying. The first observation is that the loss of weight, through the free (circular) surface of concrete, is between 2 and 2.5 times higher than that then that through the cast (cylindrical) surface for the different drying conditions. This happens because the surface layer of concrete has higher water content than the bulk material because of a small bleeding after casting.

The second observation is that drying at 80°C for 14 days eliminates an amount of water between 2 and 2.5 times higher than that at 45°C for 14 days or at 20°C and 50% RH for 87 days.

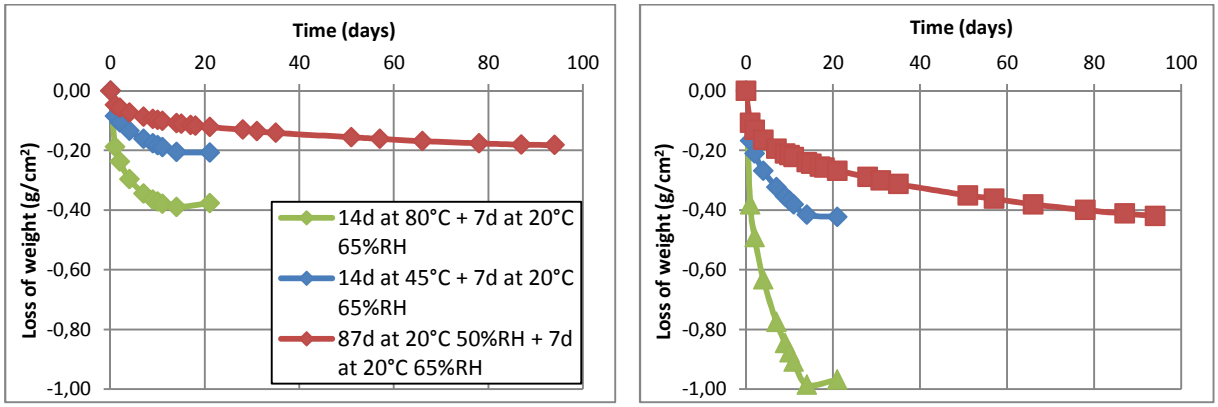

Figure 1. Loss of weight during drying. (a) Drying through the cast (cylindrical) surface of the Ø11x11 cm specimens. (b) Drying through the free (circular) surface of the Ø11x7 cm specimens.

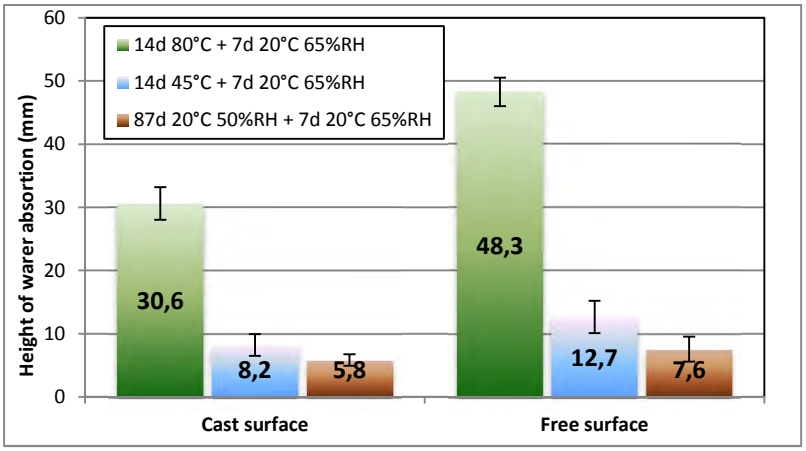

Figure 2. Height of water absorption at the end of drying.

The stronger or weaker elimination of water, according to the type of exposed surface (free or cast) and the drying condition, leads to higher or lower height of water capillary absorption

at the end of drying (Figure 2). However, the height of water absorption through the free surface is only between 1.3 and 1.5 times higher than that through the cast surface while the loss of water was between 2.0 and 2.5 times higher (Figure 1), leading to the conclusion that the surface layer of concrete presents differences in porosity and in porous size distribution comparatively to the bulk concrete. In fact, the breeding of concrete on the free surface leads to higher porosity and probably larger porous size distribution than in the bulk concrete.

The differences in porosity and in porous size distribution could be considered also to explain the significant difference of height of water absorption after 45°C drying for 14 days comparatively to that after 20°C and 50% RH drying for 87 days (Figure 2) even if in both cases the loss of weight per unit of exposed surface at the end of drying is almost the same (Figure 1). In fact, at the end of 20°C and 50% RH drying the concrete is more than 2 months older than that at the end of 45°C drying. During this time, the cement hydration progresses leading generally to lower porosity and to smaller porous size distribution.

3.2 Accelerated Carbonation

Figure 3 presents the carbonation depth during accelerated tests of both types of specimens for different drying conditions. It should be noted that the carbonation depth is negligible before carbonation test (0 mm for 80°C and 45°C drying and less than 0.5 mm for 20°C and 50% RH drying). It can be seen also that, in all cases, the carbonation depth progresses almost linearly with the square root of testing time, consequently a carbonation rate can be calculated for any case expressed in millimeter per square root of days (mm/days$^{1/2}$) presented in Figure 4.

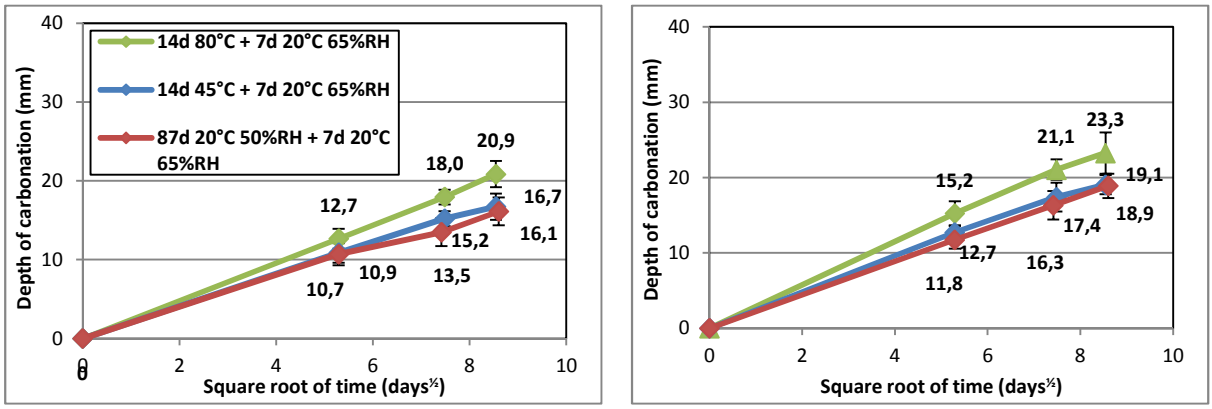

Figure 3. Carbonation depth as a function of square root of testing time (a) Carbonation through the cast (cylindrical) surface of Ø11x11 cm specimens. (b) Carbonation through the free (circular) surface of the Ø11x7 cm specimens.

The carbonation rate is higher through the free surface and after 80°C drying but is far from being proportional to the loss of water per unit of exposed surface during drying or to the height of water absorption at the end of drying. In fact, firstly the carbonation rate of specimens exposed du CO_2 through the free surface is only 13-19% higher than that through the cast surface for the different drying conditions. Secondly, the carbonation rate after 80°C

drying for 14 days is only 22-23% higher than that after 45°C drying for 14 days. Thirdly, the rate of carbonation obtained after 45°C drying is slightly higher (3 to 7%) to that obtained after 20°C and 50% RH drying for 87 days. These values allow to conclude that, firstly, a strong drying cycle (at 80°C) before accelerated carbonation tests has globally stronger influence on the carbonation rate than the type of the exposed surface (free or cast) and, secondly, the progress of hydration during the longer drying at 20°C and 50% RH does not have a very important influence on carbonation rate.

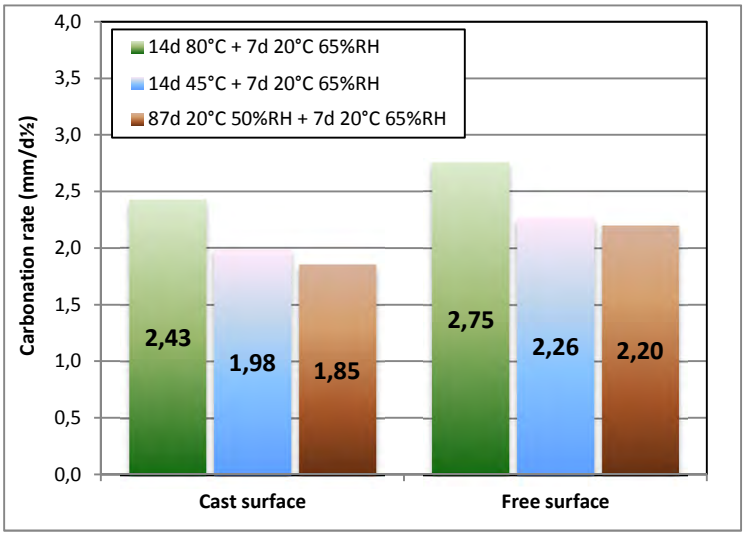

Figure 4. Carbonation rate during accelerated tests for different drying conditions and types of exposed surfaces.

3.3 Carbonation Depth and Height of Water Absorption

Figure 5 presents the comparison between the carbonation depth and the height of capillary absorption of colored water during the accelerated carbonation tests for all drying conditions and both types of specimens. It can be seen that, in all cases, the carbonation depth is systematically lower than the height of water absorption, leading to the conclusion that, for our tests, the carbonation occurs only into the unsaturated layer of concrete.

It can be seen also that the height of water absorption increases during accelerated tests. This means that the unsaturated layer of concrete becomes thicker during testing. This is particularly interesting in the light of the fact that carbonation reaction releases water (Verbeck, 1958; Parrot, 1991) and that the specimens didn't present any loss of weight during testing, rather a gain of weight. Taking into account that there is not any similar observation in literature, we can explain these results considering, firstly, the carbonation-induced changes in porosity and in porous size distribution (Galan, 2013; Auroy, 2018) leading to higher capillary absorption and, secondly, that moisture redistribution takes place in concrete during and because carbonation. In fact, Johannesson and Ulgenannt (Johannesson, 2001) based on sorption-desorption isotherms have concluded that well-carbonated cement mortar requires higher energy to absorb water molecules at its material surfaces accelerating the desorption isotherm and holding less water comparatively to noncarbonated cement mortar.

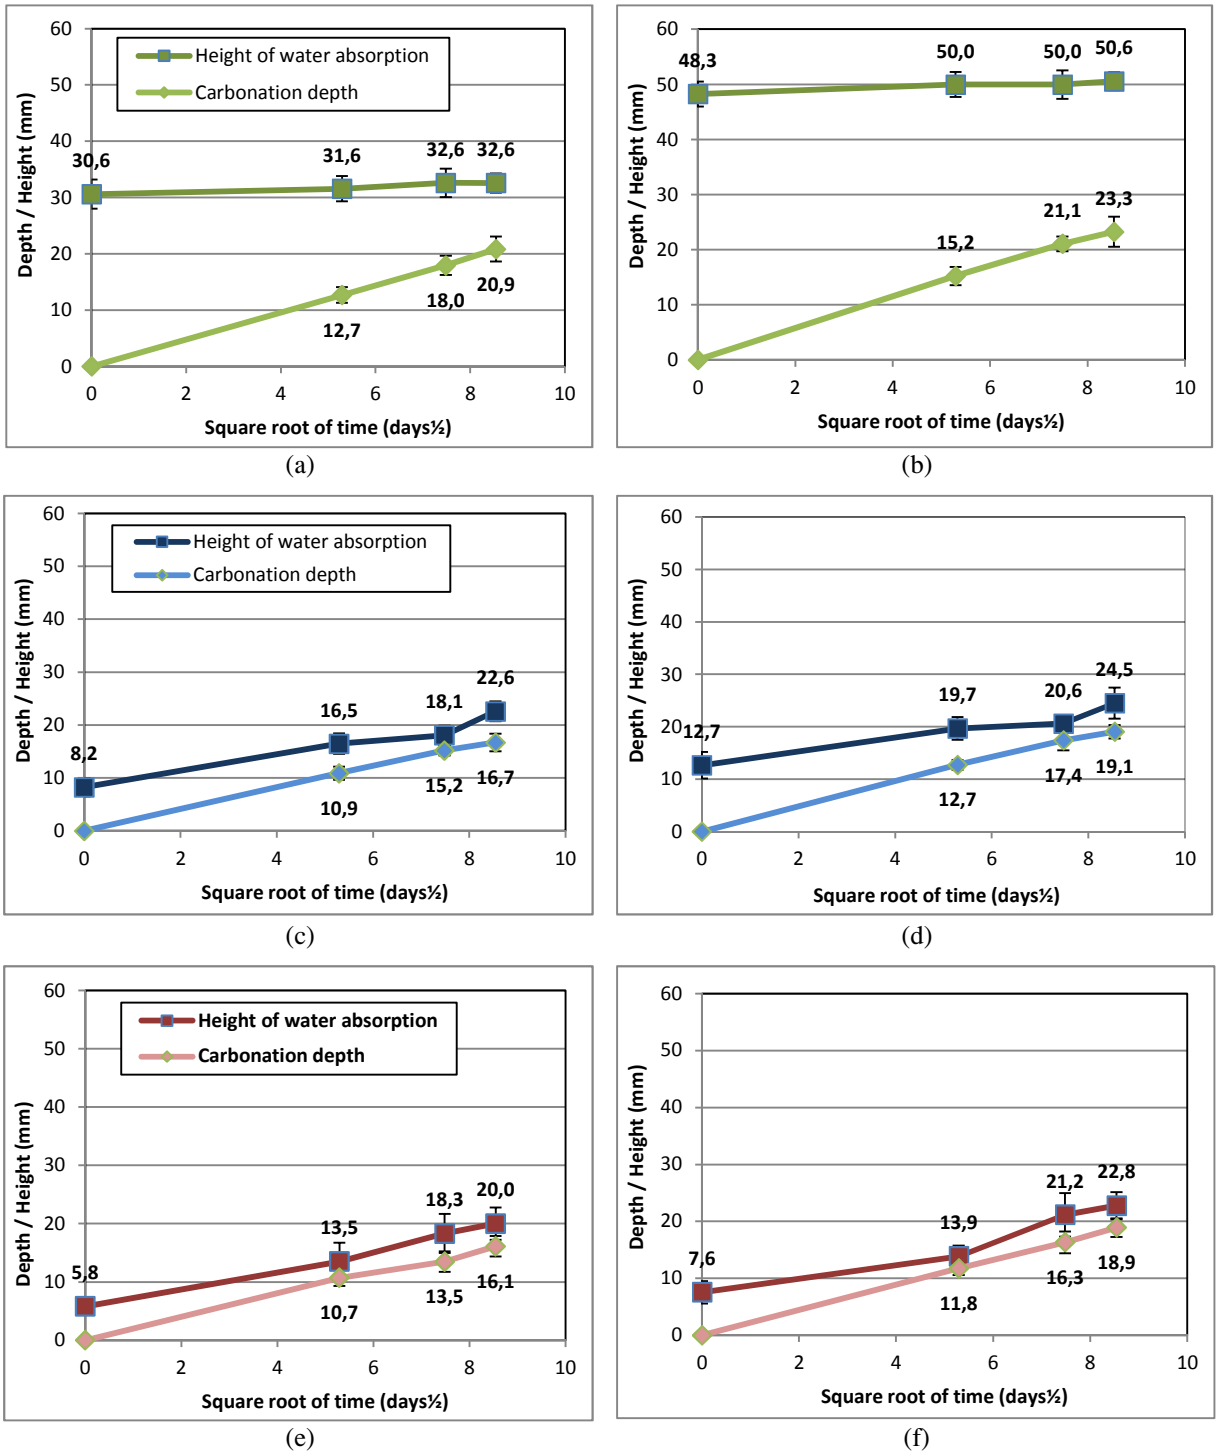

Figure 5. Carbonation depth and height of water absorption as a function of square root of testing time. (a) Through the cast surface after 80°C drying for 14 days. (b) Through the free after 80°C drying for 14 days. (c) Through the cast surface after 45°C drying for 14 days. (d) Through the free after 45°C drying for 14 days. (e) Through the cast surface after 20°C and 50% RH drying for 87 days. (f) Through the free after 20°C and 50% RH drying for 87 days.

The increasing of the height of water absorption follows mainly a proportional progression with the square root of testing time, allowing the determination of a rate of height increasing of water absorption during accelerated tests, expressed, just as the rate of carbonation depth, in millimeters per square root of days (mm/days^{½}) presented in Figure 6.

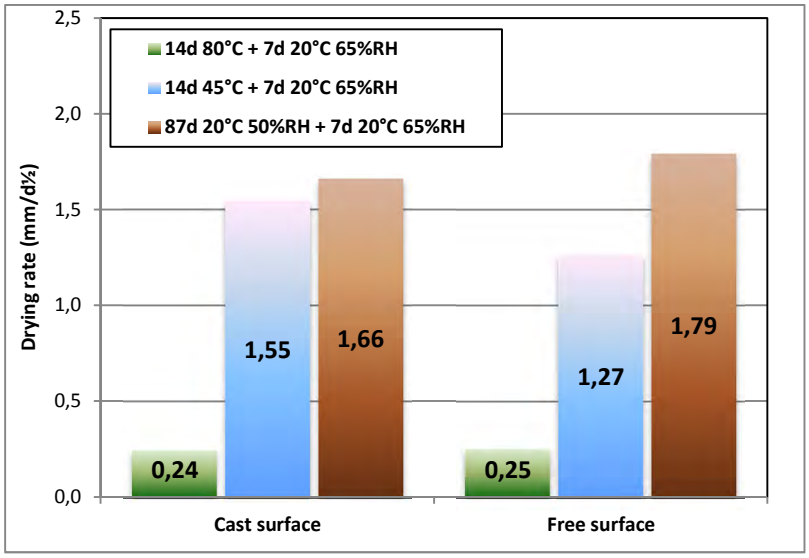

Figure 6. Rate of height increasing of water absorption during accelerated tests for different drying conditions and types of exposed surfaces.

The results of the Figures 5 and 6 show that the thickness increasing of the unsaturated concrete layer during accelerated testing is all the more important that the depth of carbonation is close. So, 20°C and 50% RH drying for 87 days leads to a relative low initial height of water absorption which progress quickly during accelerated tests with a rate close to the carbonation rate (1.66 and 1.85 mm/d^{½} respectively for exposure through the cast surface and 1.79 and 2.20 mm/d^{½} for exposure through the free surface). On the contrary, 80°C drying for 14 days leads to a relative high initial height of water absorption which progress slowly during accelerate tests staying away from the carbonated layer.

4 Conclusions

Accelerated carbonation tests were carried out after three different drying conditions through the cast and the free surface of specimens made with a typical concrete formulation for buildings construction in the 50's and the 60's. The height of water absorption was also measured at different stages of testing and compared to the carbonation depth.

The results show that there is a significant difference in the loss of weight per unit of exposed surface through the cast and the free surface of specimens. The height of water absorption through the cast and the free surface is also significantly different. But, the drying condition before accelerated carbonation tests has more influence on the carbonation rate of concrete than the type of the exposed surface. The carbonation rates through both types of surfaces and for 45°C and for 20°C and 65% RH drying are close, in accordance with literature. The carbonation rate for 80°C drying is significantly higher because of strong and

deep elimination of water modifying the concrete microstructure.

The comparison of carbonation depth and height of water absorption during accelerated tests show that the height of water absorption was systematically higher than the carbonation depth. Moreover, the height of water absorption increases during testing while the carbonation releases water and the specimens present globally a gain of weight. The hypothesis of moisture redistribution in concrete during accelerated carbonation tests was advanced to explain the increase of the unsaturated layer thickness in concrete. However, more tests are necessary to validate this hypothesis starting with the determination of the water quantity absorbed till saturation of concrete at each stage of accelerated tests in comparison with the loss of water at the end of drying. To the same end it would be also interesting to follow the carbonation rate and the height of water absorption beyond 70 days in order to identify what happens when the carbonation depth reaches the thickness of unsaturated concrete.

Abstract. *Experiments on the development of compressive strength and static and dynamic Young's moduli were performed by the following mix proportions of concrete: the first uses different types of Portland cement without fly ash (FA) with a water-cement ratio of 45%, keeping at different curing temperatures; the second partially use FA in place of the cement, with the other conditions same as above; the third uses only blast furnace cement B instead of Portland cement. With these specimens, we comparatively examined in terms of temperature adjusted concrete age, how the mechanical properties change with the use of cement only, FA replacement for cement and with variation in curing temperatures. As a result, it was confirmed that the replacement of cement by fly ash enhanced the long-term mechanical properties of concrete regardless of the curing temperature applied in this experiment.*

Keywords: *Fly Ash, Curing Temperature, Compressive Strength, Static Young's Modulus, Dynamic Young's Modulus.*

1 Introduction

Recently, in Japan, fly ash (FA) has been often used as a mineral admixture of concrete from the viewpoint of effective use of industrial waste and reduction of carbon dioxide (CO_2) emissions. (Takafumi, 2014) The use of FA as an admixture in concrete is said to be effective in improving concrete performance such as increasing workability of concrete, reducing thermal cracks, development of long-term strength, and suppressing salt damage and alkali-silica reaction. For this reason, in overseas countries, in particular in Asian countries, the trend of effective utilization of FA for concrete has become active due to the increasing number of coal power plants, because FA can be obtained at low cost as industrial waste. The pozzolanic reaction peculiar to FA is activated beneficially to develop the strength of concrete as the curing temperature increases. On the contrary, when the curing temperature is low, the strength enhancement due to the pozzolanic reaction does not progress and, in some cases, the expected effect may not be obtained.

Therefore, in order to understand the temperature dependency of the mechanical properties of the concretes using FA, three kinds of Portland cements which are partially replaced with FA were comparatively studied in terms of the impact by temperature on the development of

mechanical properties of concrete. Note that we obtained basic data on the mechanical properties of cement types and curing temperatures in order to make full use of the effect of fly ash used in place of cement.

2 Experiment Plan

2.1 Outline of the Experiment

Regarding the use of cements and FA, one case is that different mix proportions for concrete are prepared at curing temperatures of 5, 10, 20, and 30°C, using only normal Portland cement (N), moderate heat Portland cement (M), or low heat Portland cement (L) respectively with no FA, and another case is that the mix proportions are prepared in the same condition as above, except 30 % of the proportion of the cement was substituted by FA. The specimens of concrete prepared were tested to obtain the strength development (for the case of N, 15% substitution of FA was also applied). For comparison, a mix proportion using blast furnace cement B instead of cement was used in the experiment.

2.2 Materials and Mix Proportions

Table 1 shows the list of materials used, Table 2 the quality of FA, and Table 3 the mix proportions (blending). The FA used is JIS A 6201 FA II class product from Noshiro Thermal Power Plant, and water to binder ratio (W/B) is set to be constant at 45%. Limestone fine powder (LP) was used to stabilize the fresh properties of mix proportions (blending) with the FA replacement ratio of 30%.

Concrete mixing was carried out in an environment of 20 ± 3 ℃ using a horizontal biaxial forced mixing mixer with a nominal capacity of 100 liters. The target slump 60 minutes after the concrete is mixed up was 18.0 ± 2.5 cm, the target air content was 5.5 ± 1.5%, and the rates of air-entraining water reducing agent (AD) and air-entraining agent (AE) were determined by test kneading.

Table 1. List of materials used.

Material	Symbol	Name and quality
Binder	N	Normal Portland cement Density 3.16 g/cm^3
	M	Moderate heat Portland cement Density 3.21 g/cm^3
	L	Low heat Portland cement Density 3.22 g/cm^3
	BB	Blast furnace cement B Density 3.04 g/cm^3
Mineral admixture	FA	Fly ash Density 2.19 g/cm^3
	LP	Limestone fine powder Density 2.70 g/cm^3
Fine aggregate	S	Limestone crushed sand Surface dry condition density 2.67 g/cm^3
Coarse aggregate	G	Limestone crushed stone Surface dry condition density 2.70 g/cm^3
Chemical admixture	AD	AE water reducing agent
	AE	AE agent (the agent for FA is used for FA concrete.)

Table 2. Quality data of FA.

Test item		Test result
Silicon dioxide (%)		66.6
Moisture (%)		0.1
Ignition loss (%)		2.0
Density (g/cm^3)		2.19
Fineness	Specific surface area by Blaine method (cm^2/g)	3,880
Flow value ratio		104
Activity index (%)	Concrete age 28 days	86
	Concrete age 91 days	100

2.3 Test Items and Methods

Test items and test methods are shown in Table 4. Specimens were taken after confirming that the slump and air content satisfied the target values at a test of fresh concrete 60 minutes after the mixing. After curing 24 hours in an initial curing room at a temperature of 20 ± 2°C with a relative humidity of 95% or more, the specimens were removed from their forms to be cured in the water at specified temperature conditions until specified ages when the specimens were subjected to various tests.

3 Test Results and Discussions

3.1 Test Results of Fresh Concrete

Table 5 shows the test results of fresh concrete. At every mix proportion, the slump and air content after 60 minutes met the targets. Remarkably, the mix proportion with 30% FA replacement, despite the high use of AE agent, recorded a more than 0.5% decrease in air content presumably due to unburned carbon of FA. In particular, the mix of LF30 had an extremely high decrease of 2.4% in air content.

Table 3. Mix proportion of concrete.

Symbol	W/B (%)	s/a (%)	Slump (cm)	Air content (%)	Unit weight (kg/m^3)								Chemical admixture (%)

3.2 Relationship between Age and Compressive Strength

Figure 1 shows the relationship between age and compressive strength for each mix proportion. The strength at the age of 7 days of the mix proportions using only Portland cement without FA increased in the order of N> M> L, and the higher the curing temperature, the faster the development of strength. However, at a high curing temperature of 30°C, their increase of strength tended to slow down in an earlier stage: N peaked after age 28 days; M after 56 days; L after 91 days. On the other hand, it was observed that all the mix proportions with FA replacement for cement did not reach the peak and still continued to develop their strengths. The substitution of FA for cement demonstrates a high effect on strength increase.

The compressive strength of BB at the age of 7 days varied largely due to curing temperature, and at the temperature of 30°C, was equivalent to N, and at 5°C equivalent to M, with a large difference from the mix with Portland cement without FA. At the curing temperature of 30°C, the growth in strength of BB slowed down after 56 days of age.
On the other hand, the strength for mix proportions with FA developed in the order of NF15> NF30> MF30> LF30, and grew for a long period regardless of differences in binder type and curing temperature.

3.3 Relationship between Temperature Adjusted Concrete Age and Compressive Strength

The strength development of concrete is closely related with the maturity (time considering temperature ingredient) (Fuminori *et al.*, 1991), and this tendency is more pronounced for the case of a mix proportion using FA (pozzolan material). We studied on the relationship between temperature-adjusted concrete age （te） and compressive strength （f） (CEB, 1990) which are shown in Equation (1); maturity law.

$$t_e = \sum_{i=1}^{n} \Delta t_i \cdot \exp\left[13.65 - \frac{4000}{273 + T(\Delta t_i)}\right] \tag{1}$$

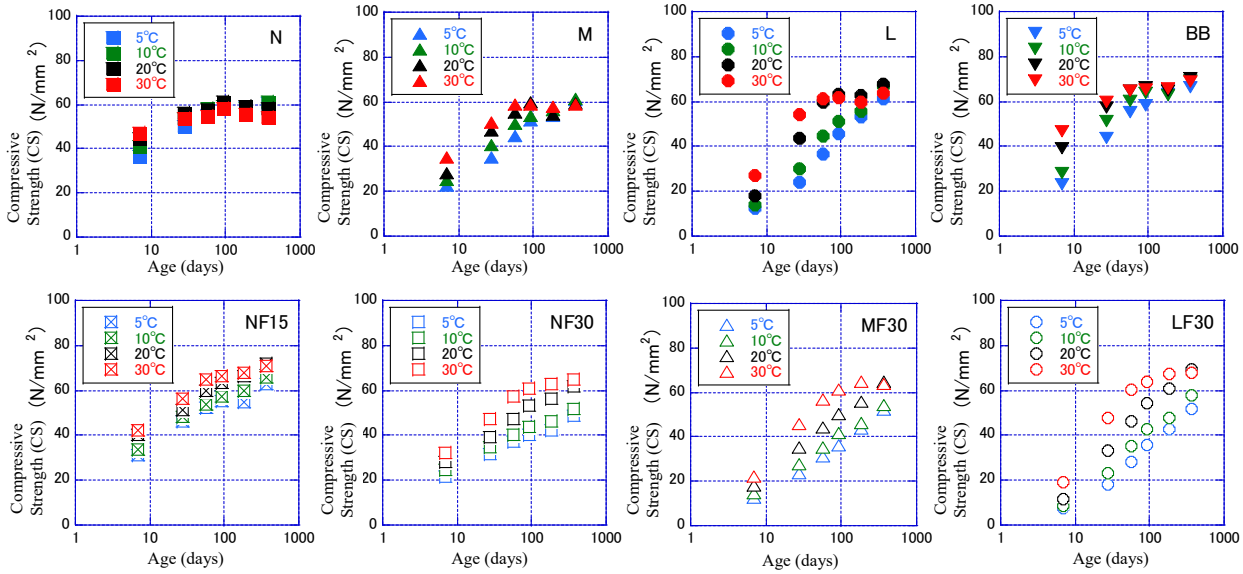

Figure 1. Relationship between concrete age and compressive strength in each mix.

Figure 2 shows the results of the relationship between temperature-adjusted concrete age and compressive strength for each mix proportion. The results of the regression analysis using Equation (2) are shown in Table 6 and Figure 2.

$$f(t_e) = a \cdot \log_{10} t_e + b \tag{2}$$

For N, M, L and BB, the data were regressed in the range with high linearity. “a” and “b” are regression coefficients obtained from experimental results.

Figure 2 indicates that the relationship between temperature adjusted concrete age and compressive strength for the mix proportions using FA keeps linearity for one year, while the relationship not using FA has limited linearity up to 91 days, from which we learn that strength development by FA continues for a long span of time. In the case of N without FA, the long term strength peaks at 60N/mm^2, while NF15 with 15% of cement replaced by FA still keeps increasing its strength even at about 80 N/mm^2, and NF15 with 30% replaced by FA does not peak even at 65N/mm^2. In the case of N, it was discovered that the effect of strength increase was greatly enhanced by about 15% replacement of cement by FA.

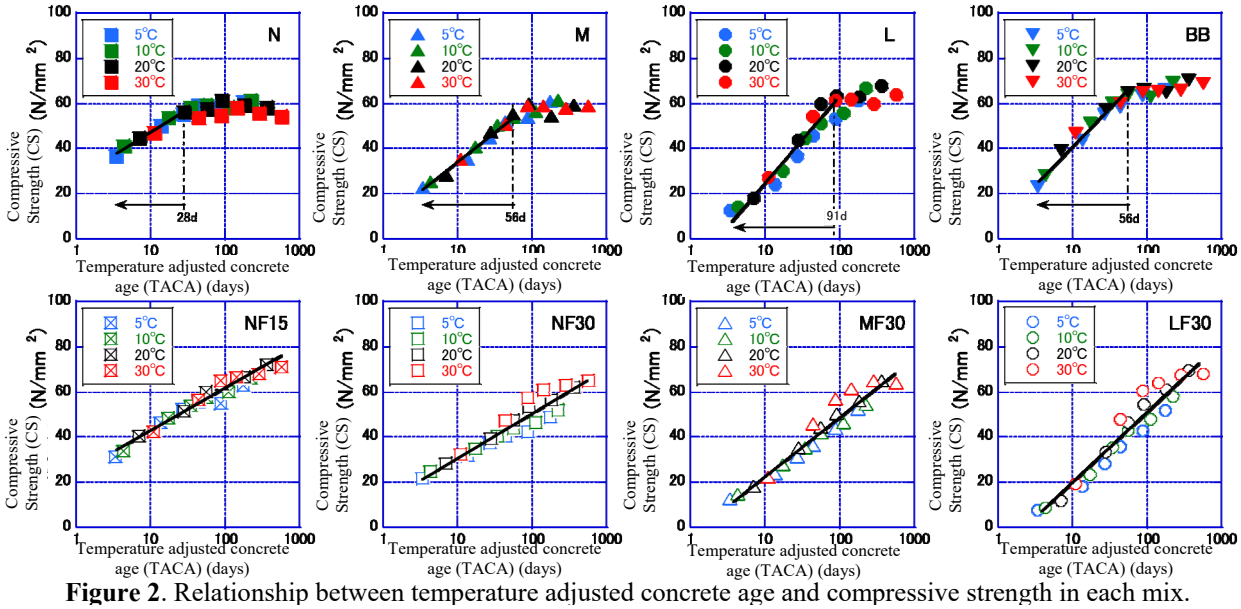

Figure 2. Relationship between temperature adjusted concrete age and compressive strength in each mix.

Table 6. Results of regression analysis for temperature adjusted concrete age and compression strength.

Symbol	Regression coefficient		Correlation coefficient	Regression interval
	a	b	R	
N	20.1	27.4	0.989	Up to Temperature Adjusted Concrete Age (TACA) 28 days
M	26.9	7.2	0.994	Up to TACA 56 days
L	36.3	-10.9	0.972	Up to TACA 91 days
BB	31.9	9.5	0.983	Up to TACA 56 days
NF15	18.1	24.8	0.976	Up to TACA 364 days
NF30	19.5	11.2	0.952	Up to TACA 364 days
MF30	26.1	-3.1	0.971	Up to TACA 364 days
LF30	31.5	-12.5	0.967	Up to TACA 364 days

Table 7. Results of regression analysis for temperature adjusted concrete age and static Young’s modulus.

Symbol	Regression coefficient		Correlation coefficient	Regression interval
	a	b	R	
N	5.61	35.1	0.964	up to Temperature Adjusted Concrete Age (TACA) 28 days
M	6.70	29.9	0.990	up to TACA 56 days
L	9.69	24.9	0.976	up to TACA 91 days
BB	7.34	32.0	0.972	up to TACA 56 days
NF15	4.02	36.0	0.964	up to TACA 364 days
NF30	4.61	31.0	0.971	up to TACA 364 days
MF30	6.60	26.4	0.974	up to TACA 364 days
LF30	8.66	22.8	0.951	up to TACA 364 days

Table-6 shows the list of calculation results of regression coefficients “a” and “b”. The larger the regression coefficient “a”, the faster the increase in long-term strength, and the regression coefficient “b” represents the initial strength. The regression coefficients “a” for the mixes using FA respectively are close to those of Portland cement as the base material (87～97% to each cement). As is the case with the ranking of “a” of base cement (L> M> N), the ranking of the mix proportions using FA was in the order of LF30> MF30> NF30> NF15, and the regression coefficient “a” for BB was between that of M and L.

On the other hand, it was found from the ranking of regression coefficients “b” that the initial strengths of mix proportions are ranked in the order of N> NF15> NF30> BB> M> MF30> L> LF30. The initial strength of the mix proportion using FA decreases as the initial strength of the base cement decreases and as the FA replacement rate increases.

3.4 Relationship Between Temperature Adjusted Concrete Age and Static Young’s Modulus

Figure 3 shows the relationship between temperature adjusted concrete age and static Young’s modulus, and Table 7 shows the results of linear regression analysis. The range of regression analysis was the same as that of the compression strength regression analysis in Section 3.3.

The static Young’s modulus tended to develop in the same manner as the compressive strength. In other words, in the concretes without FA, the regression coefficient “a” was ranked in the order of L> BB> M> N, and in the concretes using FA, in the order of LF30> MF30> NF30> NF15. However, it was smaller than the regression coefficient “a” of compressive strength, generally with a small difference resulting from the temperature adjusted concrete age. On the other hand, the regression coefficient developed in the order of N> NF15> BB> NF30> M> MF30> L> LF30, and had an almost same tendency as the compressive strength, except for the fact that BB was slightly larger than NF30.

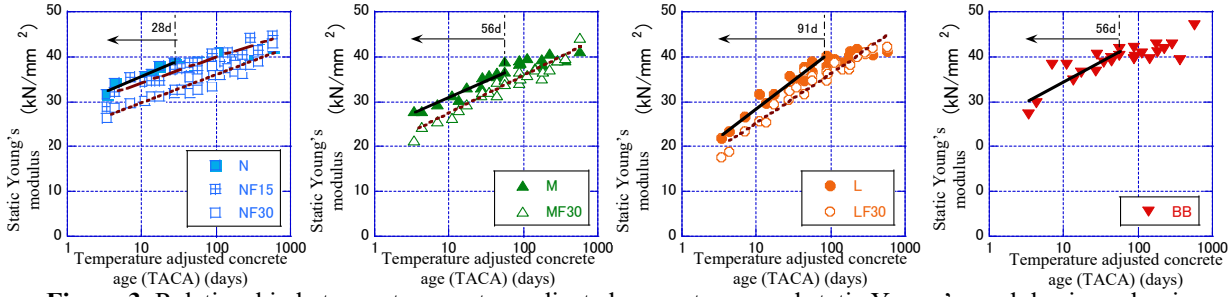

Figure 3. Relationship between temperature adjusted concrete age and static Young’s modulus in each mix

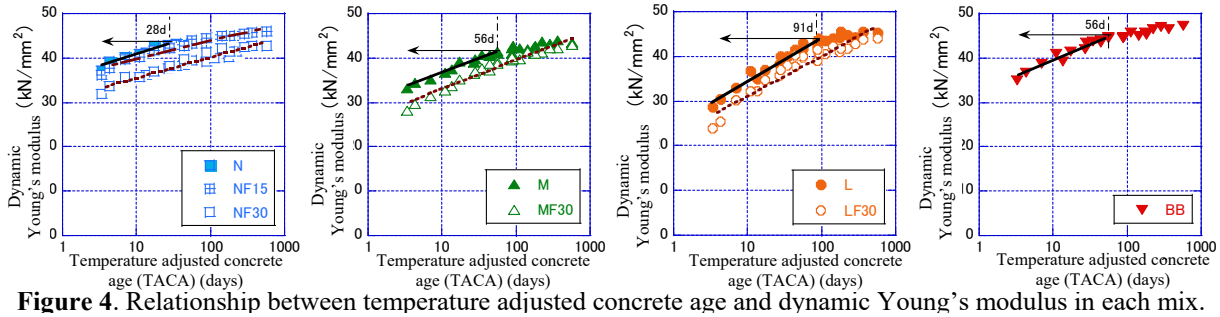

Figure 4. Relationship between temperature adjusted concrete age and dynamic Young’s modulus in each mix.

3.5 Relationship Between Temperature Adjusted Concrete Age and Dynamic Young's Modulus

Figure 4 shows the relationship between temperature adjusted concrete age and dynamic Young's modulus, and Table 8 the results of linear regression analysis. The range of regression analysis was the same as in Section 3.3.

From the difference in regression coefficient of "a", it was confirmed that the dynamic Young's modulus developed earlier than the compressive strength and static Young's modulus and tended to level off earlier with the age. The magnitude relationship of the regression coefficients "a" and "b" demonstrated the same tendency as in the static Young's modulus.

3.6 Relationship Between Compressive Strength and Young's Modulus

Figure 5 shows the relationship between compressive strength and static Young's modulus, Figure 6 shows the relationship between compressive strength and dynamic Young's modulus, and Figure 7 shows the relationship between static Young's modulus and dynamic Young's modulus.

Regardless of the types of binder or the use of FA, the relationship between compressive strength and static Young's modulus and the relationship between compressive strength and dynamic Young's modulus were constant. Moreover, the dynamic Young's modulus tended to fluctuate less than the static modulus.

The dynamic Young's modulus is generally given by the specimen's flexural vibration at which the specimen underwent resonant vibration. Since this modulus represents a status where almost no load works, it tends to grow larger than the static Young's modulus. (Ohmsha, 2004) In this experiment, as shown in Figure 7, the dynamic Young's modulus was larger than the static Young's modulus. This trend was more noticeable at young ages.

Table 8. Results of regression analysis for temperature adjusted concrete age and dynamic Young's modulus.

Symbol	Regression coefficient		Correlation coefficient R	Regression interval
	a	b		
N	5.61	35.1	0.964	up to Temperature Adjusted Concrete Age (TACA) 28 days
M	6.70	29.9	0.990	up to TACA 56 days
L	9.69	24.9	0.976	up to TACA 91 days
BB	7.34	32.0	0.972	up to TACA 56 days
NF15	4.02	36.0	0.964	up to TACA 364 days
NF30	4.61	31.0	0.971	up to TACA 364 days
MF30	6.60	26.4	0.974	up to TACA 364 days
LF30	8.66	22.8	0.951	up to TACA 364 days

4 Conclusion

The following two types of concrete, one using three Portland cements (N, M, L) with no FA and the other using the same cements but partially replaced by FA, at a water-binder ratio of 45% and cured at different curing temperatures, were comparatively studied in terms of the compressive strength up to one year of age as well as of static and dynamic Young's moduli, including an experiment using blast furnace cement B (BB). We compared the data of these specimens to determine their relationship with temperature adjusted concrete age. The obtained results obtained are as follows:

(1) The mix proportion with 30% of cement replaced by FA, despite increasing AE agent, recorded more than 0.5% decrease in air content which is presumably due to the effect of FA's unburned carbon.

(2) In the mix proportions (blending) of N, M, L and BB, the higher the temperature, the faster the strength developed. However, strength increase slowed down early and reached a peak. On the other hand, the mix proportions (blending) using FA steadily developed long-term strength regardless of the difference in binder and curing temperature, exceeding the long-term strengths of N and M. Especially N15, which is a mix proportion of N with 15% FA replacement, did not peak even at about 80 N/mm^2 of compressive strength which is 1.3 times N's peak of 60 N/mm^2, and we learned that FA substitution has a high impact on the compressive strength.

(3) In the mix proportions (blending) using N, M, L, and BB, it was shown that the strength increased highly correlated with the temperature adjusted concrete age (in logarithm) up to the moment its growth rate in strength slowed down. On the other hand, the mix proportions (blending) using FA developed the strength for a long span of time, keeping a close correlation with the temperature adjusted concrete age.

(4) It was found that for the mix proportions (blending) using FA, the lower the initial strength of the base cement or the higher the replacement rate of FA, the slower the strength development and that they demonstrate the characteristics of strength development which correspond to those of the base cement. The mix proportion (blending) using the binder with a slower initial strength development tended to result in the larger strength.

(5) Regardless of the use of FA in the mix, the relationship between compressive strength and static Young's modulus and the relationship between compressive strength and dynamic Young's modulus were constant. The dynamic Young's modulus demonstrated a larger value than the static Young's modulus, and this trend was more conspicuous at young ages.

Abstract. *The volume changes of cement-based composites are significantly exhibited during the hardening process. Initial phases of the hardening are complemented by the expansion due to the heat evolution that is subsequently alternated by the shrinkage. Both could cause the crack initiation causing significant loss of the durability and service-life shortage. The present paper focuses on the experimental investigation of the surface treatment of fresh concrete, which is applied to prevent sudden loss of the moisture during a hardening process, especially during the concrete highway construction. The technology of concrete highway production is extremely costs demanding, but its efficiency is determined by the longer lifespan in comparison with the asphalt pavement. However, negative impacts of the drying shrinkage could significantly reduce the durability. The efficiency of used treatment was investigated in terms of restrained shrinkage tests, water adsorption and mechanical testing. In addition, there were studied two types of conventional Portland cement. Performed program confirmed great sense of the curing on the concrete durability; in addition, there was well illustrated the efficiency of the utilization of blended binder systems in the paper.*

1 Introduction

The concrete is the most used material for the construction of civil infrastructure worldwide. The fundamental part of the structural concrete is Portland cement, which exhibits hydraulic properties and sufficient mechanical and also durability performance. There is a number of various types of cements, that are based on Portland clinker, however these cement types were primarily developed for the specific applications (Aitcin, 2000). For example, blended systems are preferably used for massive structures for the reduction of total hydration heat and also volume changes (Lotenbach *et al.* 2011; Vinkler and Vítek, 2019). On the other hand, due to rapidly increasing price of human work there are currently preferred technologies limiting number of craftsmen on the construction site and approaches significantly accelerating the process of construction.

These technologies often lead to the supressing of specific technological steps, such as curing. Portland cement based concrete is hydraulic material, which is sensitive for a sudden loss of moisture during hydration. Surface treatments in form of thin films are applied to prevent the drying of concrete after its casting, because hardened mass of concrete significantly reduces its diffusivity. The quality of surface layer of concrete is crucial in relation to the durability, because this thin part of structure determine final resistance to the impact of external environment. The deterioration of the concrete "skin" during hardening is the most frequent

reason of the damage during structure operation. Traditional exhibition of the problem in concrete surface layer is the presence of micro cracks or tendency to release dust particles. These failures of concrete surface subsequently lead to the increased transport of water, which significantly contributes to the gradual degradation of the structure (Reiterman *et al.,* 2019; Holcapek *et al.,* 2014). The ingress of deicers and freezing-thawing are the main mechanisms causing the degradation of concrete infrastructure (Glinicki *et al.,* 2016). The effect of frost causes propagation of cracks and their depth, and deicers, mostly on the basis of chlorides, lead to the chemical corrosion of concrete, surface scaling and corrosion of the embedded steel rebars. Hence, the permeability of concrete surface has crucial sense in relation to the lifespan of concrete structures.

2 Experimental Program

Conducted experimental program was focused on the evaluation of the quality of concrete surface layer, of which properties were modified by the application of surface treatment to prevent sudden evaporation of the moisture. This technology is used during the production of concrete pavement by the roller, and also after production of continues concrete guardrails. This effect was studied on standard cement mortars with the fraction of sand to cement 3:1, water to cement ration was set to 0.45. There were used two types of Portland clinker-based cements – CEM I 42.5 (SC) and CEM II 32.2 B-S, of which properties are introduced in Table 1.

Table 1. Properties of used cements.

Properties	CEM I 42.5 R (SC)	CEM II 32.5 B-S
CaO	63.80 %	50.51 %
SiO_2	20.60 %	27.24 %
Al_2O_3	4.80 %	7.85 %
Fe_2O_3	3.40 %	2.72 %
MgO	1.40 %	3.75 %
SO_3	3.20 %	2.85 %
K_2O	0.74 %	0.77 %
NaO	0.20 %	0.36 %
LOI	1.40 %	1.1 %
Blaine	311 m^2/kg	345 m^2/kg

CEM I 42.5 (SC) is a specific type of Portland cement, produced in Czech Republic, which is intended for the utilization during the construction of road pavement and transport structures. Its significant feature is low content of C_3A and lower value of specific surface by Blaine. CEM II 32.2 B-S performs cement with the content of blast furnace slag, which stands out from low hydration heat, low shrinkage and long-term evolution of mechanical properties.

Fresh mortars were prepared in laboratory mixer and sets of specimens were casted. Standard prismatic specimens 40×40×160 mm were used for the determination of mechanical properties in terms of EN 196-1.

Transport properties of cement mortars were studied using cylindrical specimens of height 50 mm and diameter 150 mm. A half of these samples were approximately 5 minutes after casting sprayed by surface agent to prevent evaporation. A commercial product Novapor HV,

on the basis of ethoxylated alcohol was used in the program. Recommended amount of the treatment is 200 – 250 g/m^2. A second half of samples served as a reference set. These cylindrical specimens were subsequently weighed to monitor the loss of the moisture in time. After 28 days were cylinders extracted from plastic molds, sealed on the lateral sides and they were subjected to the determination of water adsorption test to assess the surface quality. Samples were partially wetted into the water basin with downward orientation and the gradual ingress of water mass was gravimetrically determined.

The loss of the moisture has direct influence on the values of the shrinkage, respectively to drying shrinkage, because ultimate level of shrinkage is affected also by the mineralogy and properties of used cements (Davidova and Reiterman, 2020; Deboucha *et al.*, 2017; Nili and Ehsani, 2015). The dimensions of the ring are rather small, which enables quicker testing of mortar susceptibility to cracking. The method consists of casting a ring of mortar around a polished ring of steel and its following spontaneous hardening and drying under normal laboratory conditions. As the mortar attempts to contract against the restraint of steel ring, tensile stress develops in the mortar ring and it might crack. The crack initiation is usually monitored visually in selected time intervals. The mortar rings had cross-section 25 mm in radial thickness and 38 mm deep. With respect to nature of testing, fresh surface of a half of samples was treated by surface agent as well. Subsequent drying was conducted only through upper part of the ring, because the rings were kept in the mold during to test to prevent drying of the part, which cannot be treated.

3 Results and Discussion

The conducted experimental program was focused on the properties of concrete surface in terms of the restrained shrinkage and transport properties, which determine final durability of the concrete and life-span of the structure. Part of the samples was treated by surface agent, which protect fresh concrete surface from the sudden loss of the moisture. Also two types of cement with different properties and hydration kinetics were studied in the paper.

Obtained results of the loss of the moisture of all sets of samples are introduced in Figure 1. It is evident, that reference and treated samples are very sensitive for the evaporation of the water during initial hours of the hardening, where the effect of the treatment is very low. However, after the setting, when solid structure occurs, the studied process is controlled by the diffusion, what well declare obtained curves. There is evident contribution of used treatment from the long-term point of view. There is also visible difference in the efficiency for single cement types. In case of blended system was the improvement over 20 %, however in case of pure Portland cement is the improvement only just about 5 %. It is caused by the different hydration kinetics; rapid setting is more suitable.

Determination of mechanical properties confirmed expected slower development of mechanical performance in case of blended cement. Detailed values are introduced in Table 2. On the other hand, values of compressive strength after 28 days of curing are relatively high. Nevertheless, high kinetics of the setting usually lead to the cracking. Conducted tests of restrained shrinkage did not confirmed this hypothesis, what is well visible on Figure 2.

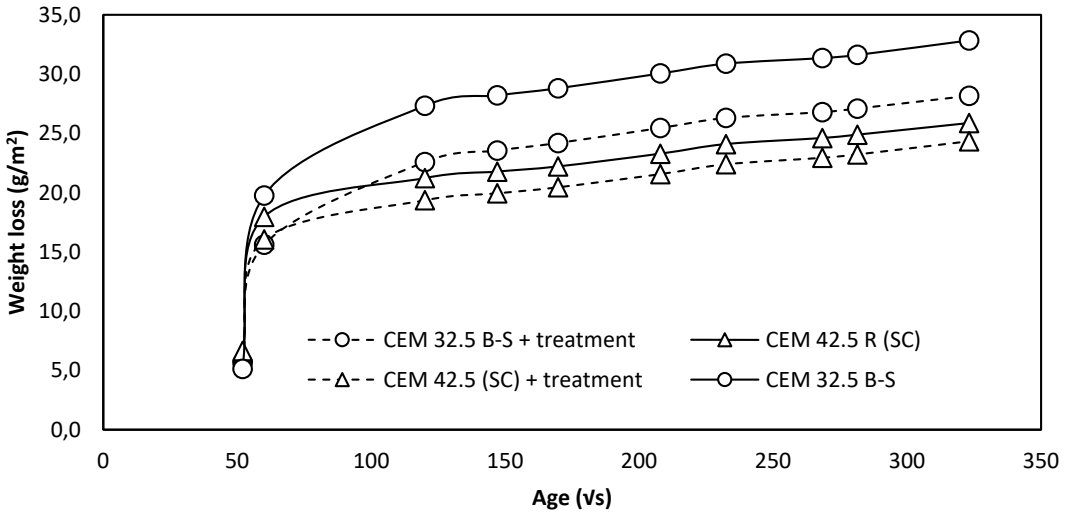

Figure 1. Monitored loss of the moisture in time.

Sudden change of the strain signalizes the moment of the rupture of mortar ring. The measurement of shrinkage declared, that mortar made of CEM I 42.5, which is specially prepared for transport structures, treated by surface agent is well resistant to the cracking. The remaining set of samples cracked approximately after 30 days of drying. However, it is necessary to note, that the time of rupture is dependent on the organization of the test. Only upper surface was exposed to the drying, what significantly extended the rupture time. Previous experiment declared, that in case of three-side drying, the rupture time could achieve a few days.

Table 2. Mechanical properties of used cement mortars.

Flexural strength [MPa]	CEM I 42.5 R (SC)	CEM II 32.5 B-S
1 day	2.9	1.8
3 days	8.1	2.7
7 days	9.7	5.7
28 days	9.8	9.5
Compressive strength [MPa]		
1 day	27.4	4.6
3 days	49.4	12.7
7 days	57.0	24.2
28 days	68.1	52.7

Results of water adsorption test are shown in Figure 3, there is well visible an improvement of the impermeability due to applied surface treatment, used type of cement respectively. On the other hand, obtained differences in non-treated samples are very low, especially up to 15 minutes. Just this short-term water adsorption has significant sense in case of the durability. For both set of samples was the achieved level of improvement about 20 %.

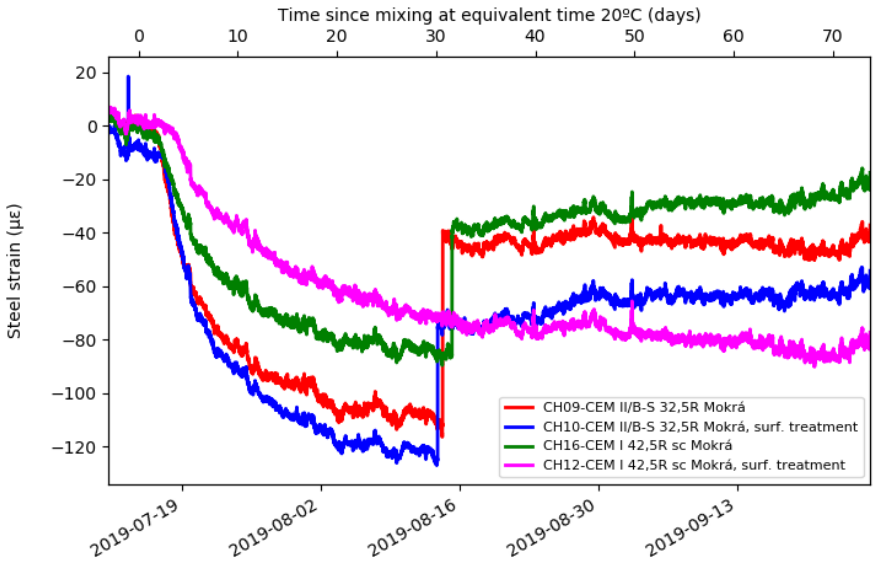

Figure 2. Results of the restrained shrinkage tests.

These results document the problem of concrete cracking during production of concrete pavement. Drying shrinkage, which is controlled by the diffusion, motivates to use binder with higher kinetics of hydration. On the other hand, higher kinetics contributes to the evolution of hydration heat and initial chemical shrinkage resulting in microcracks initiation. Generally, it is necessary to balance both preventive intervention. During past years CEM II 42.5 N/ B-S was often used during production of concrete pavement, the motivation for the selection of this type of cement was lower hydration kinetics, which positively mitigates risks of cracking. However, number of cracks has occurred shortly after the casting. It was caused by increased finesses of the cement to fulfill a required mechanical parameters, which caused higher hydration kinetics in comparison with CEM I 42.5.

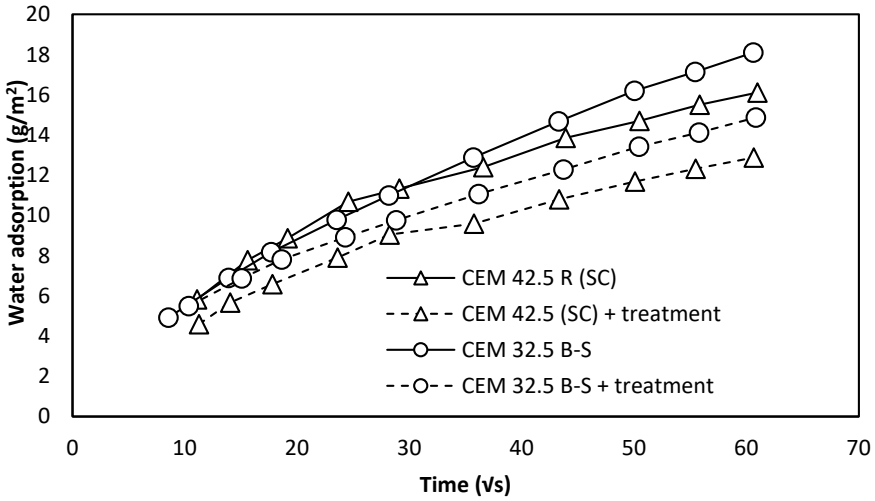

Figure 3. Results of water adsorption test.

4 Conclusions

Performed experimental program was focused on the evaluation of the efficiency of surface treatment, which is applied to prevent sudden evaporation of the water and subsequent progress of cracks due to drying shrinkage. The program conducted on standard cement mortars declared, that blended binding systems are prone to loss of the moisture. In addition, blended cement exhibited higher tendency to cracking in terms of restrained shrinkage test, the studied surface treatment did not improve this property as well. Achieved results confirmed the improvement of water impermeability, however short-term water adsorption was nearly similar for all sets of samples, except of samples made from road cement, which were treated on their surface; they exhibited slightly lower permeability of the surface layer. Obtained results indicate suitability of Portland cement, which is produced for the specific application in transport concrete structures.

Abstract. *The accelerated mortar bar test (AMBT) is used to evaluate the potential expansion of the aggregate for the alkali-silica reaction. In this test, the aggregate should meet a certain distribution of particle size. In Uruguay it is usual that for concrete the fine aggregate is constituted by a mixture of sands, one of coarse size and another of fine size. Therefore, coarse sand must be crushed for the test and the fine sand is weighted accumulated in the smallest sieve in which there is enough material according to its particle size distribution. The aim of the work is to evaluate the influence of the particle size distribution of natural coarse sands, without crushing, in the result of the AMBT test. Mortars with different grading composition and single particle size were elaborated, and the differences obtained in the expansion, in the formation of efflorescence on the surface of the bars and in the presence of the reaction gel in the solution where the bars were immersed were analyzed. A greater expansion was observed in the samples with a continuous size distribution, compared with a single particle size. In addition, in the bars elaborated with the largest particle size, a greater amount of gel on its surface and in the solution was observed. The relevance of the work was to improve the reliability of the result in the AMBT test to evaluate the reactivity of the natural coarse sand. Natural sands of siliceous quartz-feldespathic origin were evaluated, without pessimum effect.*

Keywords: *Alkali-Silica Reaction, Accelerated Mortar Bars Test, Natural Sand, Grading Composition.*

1 Introduction

Concrete is subject to numerous pathological manifestations during its service life. The origin of these pathologies is commonly related to their constituents and their interaction with the environment. The alkali-silica reaction (ASR) is an internal reaction in concrete that occurs between certain components of aggregates considered “reactive” (opal, chalcedony, quartz, tridymite, cristobalite, chert and volcanic glass) and ions form the pore solution of concrete (hydroxyls, alkalis and calcium ions). The reaction products expand in presence of moisture, causing cracking, displacements, structural deformations, pop-outs and reduction in mechanical performances. Service life of structures may be severely affected. In addition, the reaction products can cause leaching stains on concrete surfaces (Nixon and Sims, 2016).

Great efforts have been made to develop test methods to evaluate the aggregate reactivity and the deleterious degree of the reaction. Nowadays, there are several internationally recognized standardized tests, such as the accelerated mortar bar test (ASTM, 2014; IRAM, 1997; ABNT, 2009; AENOR, 2018) the semi-accelerated concrete prism test (IRAM, 2013; Nixon and Sims, 2016) and long-term concrete prism test (with a duration of one year or more) (ASTM, 2015; IRAM, 2013; ABNT, 2009b). The criteria to define the reactivity of the

doi:10.23967/dbmc.2020.085

aggregate arises from the expansion obtained after the mortar or concrete bars have been submitted in an aggressive environment for a predetermined period of time (Nixon and Sims, 2016; IRAM, 2016; IRAM 2013; ASTM 2018; ABNT, 2009b).

In Uruguay, given the availability of natural sands, the fine fraction of the aggregate in the concrete – portion of an aggregate passing 4.75mm sieve and predominantly retained on the 0.15mm sieve - usually is obtained by two sands, one identified as "fine sand" and the other as "coarse sand". Coarse sands present large particle size generally the highest proportion in these is retained in the sieves of greater aperture (between 2.36 mm and 0.30 mm). The fine sands usually present particle size between 0.30 mm and 0.15mm. Both types of fine aggregates must be mixed to form a suitable particle size distribution to be used in concrete.

The accelerated mortar bar test AMBT test consists in evaluating the variation in length of mortar bars immersed in an aggressive solution of sodium hydroxide at (80±5) °C for a period of 14 to 28 days. This standard procedure indicates that the aggregate under evaluation shall have a specific size distribution. The material must be used in a dry condition, previously washed, with all particle passing through sieve 4.75mm and retained at sieve 0.15mm (10% retained at 2.36mm, 25% retained at 1.18mm, 0.60mm and 0.30mm and then 15% retained at 0.15mm).

In cases where it is necessary to evaluate the reactivity of a coarse sand-without the presence or with low quantity of the smallest fractions, the standard's procedure indicates that it should be crushed to obtain these fractions. However, the aggregate's textural and microstructural characteristics are altered by the crushing process, affecting its reactivity (Cosentino et al. 2011). In addition, when the process is carried out with a jaw crusher, it is difficult to reach the necessary quantities for the test in particle size smaller than 0.6mm.

The aim of the work was to analyses the influence of the particle size distribution in aggregate in the expansive behavior of the mortar in the AMBT test and to evaluate the amount of material leached to the NaOH (sodium hydroxide) solution in which the bars are immersed. The relevance of the work was to improve the reliability of the result to evaluate the reactivity of the natural coarse sand, without the need to grind the material.

2 Methodology

2.1 Materials

Two natural sands (identified AGA and AGB) of siliceous quartz-feldespathic origin were taken from the Santa Lucía river. Both sands present potentially reactive component to ASR and after being evaluated in the AMBT test have a higher expansion than the limit of 0.10% at 14 days of immersion and 0.19% at 28 days. They do not have a pessimum effect. Table 1 shows the characteristics of the sands used.

Both samples have a Fineness Modulus greater than 2.70 and contain a low quantity of particles smaller than 0.30mm (0.6% in sample AGA and 1.5% in sample AGB). At the same time, the AGA sand has only 11.9% of particles smaller than 0.60mm. For this reason, they are identified as coarse sand. In Uruguay these sands are used to produce concrete mixture combined with another fine sand.

Table 1. Characteristics of the sand used for the analysis.

Sample Id.	AGA	AGB
Origin	Paso Pache, Canelones	Aguas Corrientes, Canelones
Summary description	Natural coarse sand. Quartz-Feldespathic sand.	Natural coarse sand. Quartz-Feldespathic sand.
Potentially reactive component to ASR	5% of quartz microcrystaline (smaller size than 0.15mm)	4% of quartz microcrystaline (smaller size than 0.15mm)
Expansion in AMBT test (IRAM 1674)	0.147% (14d) – 0.236% (28d)	0.124% (14d) – 0.208% (28d)
Sieve distribution		
Retained at 4.75 mm (%)	6.0	0.2
Retained at 2.36 mm (%)	15.5	2.2
Retained at 1.18 mm (%)	31.3	16.4
Retained at 0.60 mm (%)	35.2	47.7
Retained at 0.30 mm (%)	11.3	31.9
Retained at 0.15 mm (%)	0.4	1.4
Plan	0.2	0.1
Fineness Modulus	3.69	2.86

A Normal Portland Cement - identified as CPN by the standard UNIT 20 (UNIT, 2017) - was used to produce the mortars. This cement is for general use in concrete and contains only clinker as the main component, without additions. The samples used have an equivalent alkali content (Na_2Oeq) between 1.16% to 1.29%, an average autoclave expansion of 0.11% and a specific surface (Blaine) of 330 m^2/kg.

2.2 Accelerate Mortar Bars Test (AMBT)

The accelerated mortar bars test was performed according to IRAM 1674 (IRAM, 1997) except for the particle size distribution of the aggregate which was conformed as indicated in item 2.3. Three bars were casted for each mortar. The bar sizes were in all cases 25x25x285 (mm x mm x mm) with a nominal length of 250 mm.

The initial length, the one at intermediate test times - 3, 7, 10, 14 and 21 days - and the one at the end of the immersion period were recorded for each bar during 28 days of immersion in the aggressive solution of 1N NaOH at (80±5) °C. The expansion of each bar at a certain immersion age *ti* was calculated as the difference between the length at the age *ti* and the initial length at *t0.* This was referred to the nominal length of the bar (250mm) in percentage.

The mortar expansion is calculated as the average expansion of the three bars tested. The coefficient of variation per sample was calculated to verify the accuracy of measurements of the different bars, according to the limits indicated by the ASTM C1260 (ASTM, 2014).

2.3 Particle Size Distribution in AMBT Test

Five particle size distribution were analyzed for each sand: four mixtures were fabricated with a single grading size (2.36 mm, 1.18 mm, 0.60 mm or 0.30 mm) and one mixture (identified as reference) was fabricated with different grading size composition according to the particle size distribution and considering the standard procedure but without crushing the sample (Table 2).

Table 2. Particle size distribution for mixture in AMBT test.

Sieve size		AGA sample					AGB sample				
passing (mm)	retained (mm)	AGA (reference)	236 AGA	118 AGA	600 AGA	300 AGA	AGB (reference)	236 AGB	118 AGB	600 AGB	300 AGB
4.75	2.36	10	100	-	-	-	10	100	-	-	-
2.36	1.18	25	-	100	-	-	25	-	100	-	-
1.18	0.60	65	-	-	100	-	25	-	-	100	-
0.60	0.30	-	-	-	-	100	40	-	-	-	100
0.15	pan	-	-	-	-	-	-	-	-	-	-

The AGA sample presented low quantities of particles smaller than 0.6 mm. For this reason, the reference mortar included 10% retained at 2.36 mm, 25% retained at 1.18 mm and 65% retained at 0.60 mm. In the AGB sample the reference mortar included 10% retained at 2.36 mm, 25% retained at 1.18 mm and 0.6 mm and 40% retained at 0.30 mm.

2.4 Concentration and Chemical Composition of Leachate in NaOH Solution.

The suspended solid content in the NaOH solution in which the bars were previously immersed during 28 days in AMBT test was determined. This was made by filtering a fraction of the solution on Filter Paper Grade 43 and quantifying the mass of solids retained in dry condition.

The elemental chemical composition (percentage referred to the mass of the suspended solid in dry condition) was then determined using a portal X-ray fluorescence spectrometer. The main interest of this analysis was to detect the presence of silica (Si) in the NaOH solution. This would be indicating that alkali silica reaction took place, but the gel leached into the solution, eventually without causing expansion.

The equipment used was considered adequate for this determination. However, it only quantifies elements with an atomic number greater than or equal to 12 (among the elements that cannot be detected are sodium, oxygen and calcium).

This analysis was carried out in AGA (reference), 236AGA, 600AGA and 300AGA mortars.

3 Results

3.1 Expansion and Appearance of the Bars in AMBT Test

Figure 1 shows the expansion evolution for mortar bars fabricated with AGA sand samples and Figure 2 shows the expansion evolution for mortar fabricated with AGB samples.

For AGA (reference) with particle size composition two identical mortars were fabricated (identified as AGA M1 and AGA M2). At 236AGA three identical mortars were fabricated (identified as 236AGA M1, 236AGA M2 and 236AGA M3). For 118AGA one mortar was fabricated (id. as 118AGA M1). For 600AGA two identical mortars were fabricated (id. as 600AGA M1 and 600AGA M2). For 300AGA one mortar was fabricated (id. as 300AGA M1).

For AGB (reference) with particle size composition two identical mortars were fabricated (identified as AGB M1 and AGB M2). For 236AGA three identical mortars were fabricated (identified as 236AGB M1, 236AGB M2 and 236AGB M3). For 118AGB two mortars were fabricated (id. as 118AGB M1 and 118AGB M2). For 600AGA two identical mortars were fabricated (id. as 600AGB M1 and 600AGB M2). For 300AGA two identical mortars were

fabricated (id. as 300AGB M1 and 300AGB M2).

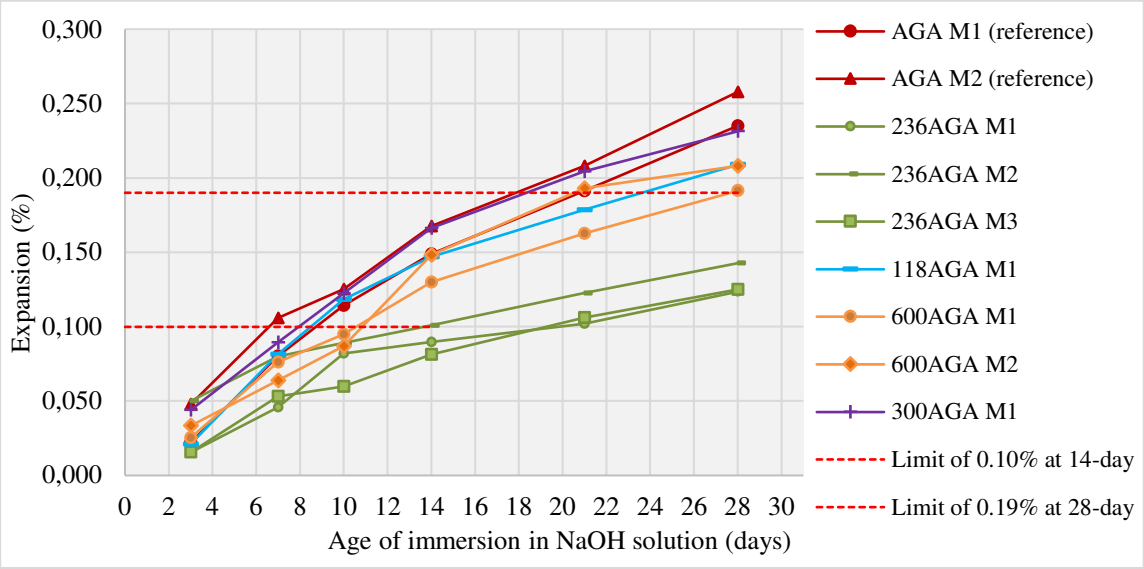

Figure 1. Expansion evolution in AMBT test. AGA sand sample.

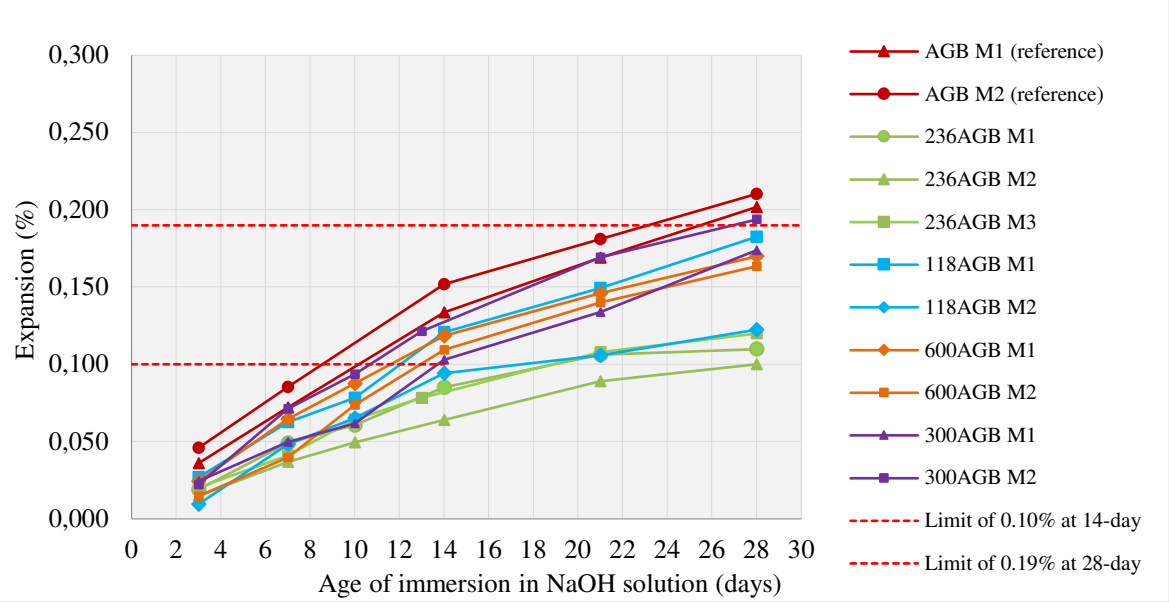

Figure 2. Expansion evolution in AMBT test. AGB sand sample.

Mortar fabricated with grading composition size (reference) according to Table 2 presented the greatest expansion in both AGA and AGB sand. In these cases, the expansion is above standard limits considered in AMBT test (0.10 % at 14 days and 0.19 % at 28 days).

Mortars fabricated with a single particle size of 2.36 mm (identification 236AGA and 236AGB) presented the slowest expansion in both sand samples. In both cases, the expansion is below the standard limits.

Mortar fabricated with a single particle size of 0.60 mm (600AGA, 600AGB) and 0.30 mm (300AGA, 300AGB) presented an intermediate expansion. In these cases, all mortars exceeded the expansion limit at 14 days; while at 28 days some samples present an expansion above and others below the limit.

In the case of the 118AGA and 118AGB mortars fabricates with a single particle size of 1.18 mm, two of them presented an intermediate expansion (118AGA M1 and 118AGB M1) and one (118AGB M2) presented a low expansion, similar to 236AGB M1.

During the test and once it was finished, the bars were visually inspected. Cracking on its surface was not observed to the naked eye but different efflorescence degrees, depending on the mortar, were observed (Figure 3). In addition, a leachate to the NaOH solution was observed in some mortars.

	AGA (ref.) (28 days)		AGB (ref.) (28 days)
	236AGA M3 (28 days)		236AGB M2 (28 days)
	118AGA M1 (14 days)		118AGB M1 (28 days)
Without Image	-		118AGB M2 (28 days)
	600AGA M1 (28 days)		600AGB M2 (14 days)
	300AGA M1 (28 days)		300AGB M2 (28 days)

Figure 3. Images of bars fabricated with different particle sizes at the end of the AMBT test.

Bars fabricated with a single particle size of 0.30 mm (300AGA and 300AGB) had a small amount of tiny efflorescence on their surface.

Bars fabricated with a single size of 0.60mm (600AGA, 600AGB) and 1.18mm (118AGA and 118AGB M2) had the highest amount of efflorescence. However, the surface of the 118AGB M1 mortar looked different from the 118AGB M2 mortar but it was similar to mortars

fabricated with a single particle size of 2.36mm (236AGA and 236AGB). In those cases, a discoloration of the surface and leached material in the NaOH solution were observed.

The bars fabricated with the reference mortar (AGA and AGB) presented a discoloration of the surface, similar to 236AGA and 236AGB.

3.2 Concentration and Chemical Composition of Leachate in NaOH Solution

Concentration and chemical composition of the leachate from the bars to the NaOH solution were determined. The evaluation was carried out only in mortars fabricated with AGA sand (Table 3).

Table 3. Leachate in the NaOH solution analyzed.

Id. sample	Concentration	Chemical composition of elements with an atomic number greater than or equal to 12 (% referred to the mass of the suspended solid in dry condition)					
	g/l	Si	Ca	K	S	Al	Fe
AGA (ref.) M2	0.91	22.7	55.2	2.1	1.5	4.6	0.9
236AGA M3	1.34	18.8	32.9	2.0	1.3	2.1	0.5
600AGA M2	0.81	8.1	14.1	1.2	2.4	0.4	0.3
300AGA M1	0.01	-	-	-	-	-	-

The 300AGA M1 bars did not present significant amounts of leached material to the solution (0.01 g/l).

Bars fabricated with 600AGA M2 presented leached material (0.81 g/l). The presence of Si (silica) was detected in 8.1% using the X-ray technique.

Bars fabricated with 236AGA M3 presented leached material (1.34 g/l). The presence of Si (silica) was detected in 18.8%.

Bars fabricated with AGA (reference) M2 presented leached material (0.91 g/l). The presence of Si (silica) was detected in 22.7%.

4 Conclusions

- The influence of the particle size distribution on the expansion of the mortar in AMBT test was observed. The potential reactivity of the aggregate arises from the expansion parameter. This could lead to erroneous conclusions when evaluating natural sands considering they do not present a continuous particle size distribution. For both sand samples, the greatest expansion was presented in mortars fabricated with different grading size composition (reference) and the lowest expansion was presented in mortars with a single size of 2.36mm.
- At the same sand sample, different behaviors - discoloration, efflorescence, leached material- were observed to the naked eye according to the particle size composition in both sands included in the analysis. This difference was caused by a change in the mortar microstructure. The greatest surface efflorescence was presented in mortars fabricated with a single particle size of 1.18mm and 0.60mm.
- The evaluation of the leachate concentration and its chemical composition allowed detecting the presence of the silica in the NaOH solution. Bars fabricated with the smallest size particle of 0.30mm exhibited negligible leachate. However, the bars

fabricated with the largest particle size of 2.36mm presented the largest amount of leached material. In this cases silica was detected in the NaOH solution so the alkali silica reaction took place, but the gel leached into the solution. The evaluation was performed only on a sand sample (id AGA).

Innovative Approaches to Increase Service Life of Poplar Lightweight Hardwood Construction Products

Joris C.R. Van Acker, Xiuping Jiang and Jan B.B. Van den Bulcke

Ghent University (UGent), Laboratory of Wood Technology (UGent-Woodlab), Coupure links 653, 9000 Ghent, Belgium, joris.vanacker@ugent.be

Abstract. *During the second half of last century the forestry-wood chain has evolved and today ecosystem services in a sustainability framework are important. Forests are intended to provide services for the bio-economy, human health, biodiversity and climate control. An increased need for more renewable resources both for material and energy use has initiated extra interest for the potential to produce more lignocellulosic biomass, in short to increase wood production. One option is to provide in complementary production in planted forests. Both forestry and agriculture can take part in this. The cultivation of poplar hybrids in the temperate regions is a key option for the current and future bio-economy. These fast-growing trees are producing lightweight hardwood with a low natural durability, but with an important potential as construction material especially as engineered wood products. All wood protection methods are of interest to be evaluated for this wood resource, making it suitable even for high quality applications. Poplar, for many reasons, has been nominated as hardwood with the best potential to perform similarly as softwoods for applications in wood construction. Benchmarking with wood species like spruce is relevant for several engineered wood products like plywood, LVL and even CLT. Wood treatments to increase durability have evolved from traditional wood preservation towards modification techniques such as thermally modified timber. Innovative poplar based products have been assessed on their performance and are designed to fit for purpose in relation to a specific combination of use class and service life. Introducing innovative poplar based construction product for green building requires adequate testing tools. Performance based assessment should allow to integrate different protective measures. Related to moisture dynamics and the linked fungal decay risk, opportunities to extend service life are manifold. Treatment can be differentiated e.g. for cladding (building envelope) and loadbearing construction components. Simple or sophisticated modification processes can alter the equilibrium moisture content. The use of wood based panels and new engineered wood products allow for better moisture control impacting fungal decay risk, but also alter the probability of insect damage. This paper intends to present several innovative poplar based construction products and show some cases of benchmarking in relation to an integrated service life approach.*

Keywords: *Poplar, Engineered Wood Products, Wood Protection, Wood Modification.*

1 Introduction

In recent decades, the interest for building taller all-timber structures using engineered timber materials such as cross-laminated timber (CLT) has increased substantially, especially in the framework of sustainable use of resources and the positive carbon footprint of wood materials. The specific structure of CLT panels improves the dimensional stability, bending strength and other mechanical properties, thus enabling its use as load-bearing elements in various constructions. Especially in Europe, mainly spruce (*Picea abies*) is used for this purpose, while other wood species have been largely overlooked. Poplar, for example, is considered a potential species to be used in CLT as a substitute of spruce. Poplar is of interest as fast-growing tree

species providing lightweight material. It is a majorly important tree species in planted forests and agroforestry worldwide.

However, since poplar in general has a very low natural durability, we need to acquire sufficient knowledge on its behavior when incorporated in CLT. Therefore there is a need to focus on moisture dynamics (Van Acker 2017), which are in direct relation to the fungal susceptibility and thus decay resistance and service life of the product. Hence investigations should deal with moisture sorption properties (including *e.g.*, equilibrium moisture content, fiber saturation point and thermodynamic analysis) of unmodified and modified poplar products, and test the fungal susceptibility as well, aiming at incorporation in CLT products.

2 Durability Challenges for CLT (Cross Laminated Timber)

Wood, as a renewable and environmentally friendly material, has been widely exploited and used in the construction industry. However, sawn wood, timber and lumber have limited dimensions related to the tree's dimensions. This can be overcome by producing engineered wood products and especially mass timber. In recent decades, the interest for building taller all-timber structures using such EWPs has increased substantially. Engineered wood, also called composite wood, man-made wood or manufactured board, includes a range of derivative wood products which are manufactured by binding or fixing the strands, particles, fibers, or veneers or boards of wood, together with adhesives, or other methods of fixation to form composite materials. Mass timber construction uses large prefabricated engineered wood members for wall, floor and roof construction that replace steel and reinforced concrete in many building projects. These products include for example glued-laminated timber (glulam or GLT), nail laminated timber (NLT) and cross-laminated timber (CLT). While GLT is considered a 1D element (bar/trusses), CLT is mainly used as 2D element (plate/slab) as shown in Figure 1.

Figure 1. GLT ('1D' elements at the left hand side) vs CLT('2D' element at the right hand side). (Canada Wood, 2018)

GLT exists since long and more recently also CLT has become popular. The production of CLT is about 0.8 million m³ worldwide, with 90% of the CLT production in Europe. An increase of 10% on an annual basis of CLT as a building product shows potential for not only softwood species, but also hardwood species. Within the next decade, therefore, CLT could become as important as glue-laminated timber, and it is likely to extend the limits of tall wooden buildings upwards. At present, most central European producers are using spruce (*Picea abies*) as main wood species in CLT. New studies began to focus on hybrid CLT, where the hybrid build-up can be designed as a rigid composite with small error on exact analysis. The novel investigations reveal the potential to overcome low rolling shear properties in cross layers of mixed softwood-hardwood (*e.g.* beech and spruce) CLT build-ups for structural elements in

the building sector (Aicher *et al.* 2016). These approaches show potential to use also other species than spruce. New technologies such as CLT (cross laminated timber) have accelerated the construction of multi-story wooden buildings and weather protection during construction has not always been used but moisture safety remains important (Mjörnell and Olsson, 2019).

Although CLT is clearly an engineered wood products with great potential and by many considered adequate for high rise buildings in relation to mechanical and structural properties as well fire safety (Brandner *et al.* 2016, Barber 2018) the topic of sensitivity to wood rotting fungi might be underestimated. Several authors have already indicated that increased moisture in the framework of building physics, both condensation and leakage cannot be fully avoided and some preventive protection or monitoring might be required. Treatment options for mass timber products, particularly cross laminated timber (CLT) remain however to be addressed (Mankowski *et al.* 2018). Since wood species currently used to fabricate CLT are non-durable, and current design standards do not properly address incorporation of preservative treatments into these systems some experiments using a ground proximity test were proposed. Using mass timber such as CLT, but also GLT (glulam) and related engineered wood products require special attention when used in exterior applications (Morris 2015). Already some recommendations on feasible treatments of CLT have been compiled to increase awareness of decay risk and possible preventive measures (Wang *et al.* 2018). For tropical regions this could even be extra underpinned (Oliveira *et al.* 2018).

3 Assessing the Potential of Poplar

With the increasing demand of wood materials, plantations or planted forest consisting of fast-growing tree species increasingly contribute in providing a complementary wood resource and as such lower the pressure on natural forests. The cultivation of hybrid poplar is an eminent fast-growing species. As a fast-growing tree species in China (8.5 million ha) and Europe (close to 1 million ha), the major poplar hybrid plantations are now mainly focusing on plywood production. For traditional products like plywood, but also constructional timber, poplar or aspen are readily available. Aspen-OSB is an established product since decades in North-America. Specific strength and stiffness are interesting characteristics, but the ability to select quality trees with a major impact on production yield are an asset as well. Today researchers are reassessing the potential of solid timber products using poplar wood. Dimensional stability and biological durability are improved using modern wood modification methods besides traditional treatments. In this respect both glulam and CLT (cross laminated timber) show major potential eventually in combination with *e.g.* thermal modification.

In literature, it has been assessed that poplar and poplar products like plywood are considered non-durable (De Boever *et al.* 2008), thus protection can be necessary to comply with service life expectations in harsh environments (Zannutini *et al.* 2003; De Smet and Van Acker 2006; Van Acker 2008). When considering moisture dynamics some plywood products can perform quite well in outdoor conditions without ground contact (Van den Bulcke *et al.* 2011, Li *et al.* 2016). The potential of poplar is worth exploring. In some studies, poplar has been assessed as alternative for softwood to produce glulam, and combinations with other hardwoods are investigated. One study revealed that the beams composed using a specific eucalyptus clone, by its own or in combination with poplar, showed outstanding mechanical performance and the best structural efficiency. Additionally, the bonding quality, at the interface between the two

species, proved to be excellent (Castro and Paganini 2003). Clearly, poplar is a promising wood species to obtain enhanced quality in very good products based on both thermal and chemical wood modification, as well as by several other treating processes used adequately (Fraanje 1998). As such wood protection and modification can increase the potential use of poplar and poplar products considerably. Some Garnica plywood products developed recently are good examples (Sufrategui *et al.* 2016) and prove that they can be used to produce building products in a fit-for-purpose concept.

4 Innovation and Treatments to Enhance Service Life

Plywood has been the model material to investigate the impact of moisture dynamics on service life prediction. Plywood outperforms in practical circumstances what can be expected from fungal testing (Van den Bulcke *et al.* 2011, De Windt *et al.* 2018). Although in many cases low durability wood species are used and the impact on fungal growth of the glue is only temporarily, many plywood products last quite long in outdoor out of ground contact applications. The fact that such wood products under use class 3 (EN 335) circumstances can exhibit limited moisture uptake in combination with ease to dry, is not yet fully considered as an extra resistance to decay. These moisture dynamics can be assessed as time of wetness (ToW) and simulated using exterior continuous moisture measurements (CMM) as well as soaking – drying lab methods as defined in the standard CEN/TS 16818 (Van Acker *et al.* 2017b). The service life approach combining performance in relation to end use based on biocidal components, structural properties and moisture dynamics allows anyhow to provide more info than the simple material resistance only based on natural durability as in EN 350. This will provide a tool towards better integration of wood protection in the forestry wood industry chain (Van Acker 2019).

Although poplar CLT based on a range of poplar hybrid timber resources is providing important parameters for design, a second focus is to select treatments with focus on low level biocidal treatments, and on low impact thermal and chemical modification that improves moisture dynamics up to levels suitable for overall or specific conditions in a timber construction based on poplar CLT. Such treatments need to be explicitly selected based on minimal requirements and can relate to less than perfect wood protection but fit for purpose (Van Acker *et al.* 2017a). Recently Singh *et al*. (2019) showed that untreated OSB and CLT based on radiate pine were very susceptible to decay, while LVL was less susceptible. Simple boron surface treatments are suggested as potential option to lower the risk for decay. Furthermore this research indicated that moisture sorption behavior is important for experimental work especially when products treated by selected protection or modification methods. Such experiments under different experimental conditions (by changing the temperature and relative humidity) allow to provide equilibrium moisture content (EMC) modeling based on statistical analysis linked to identified significant effects from the modification. Empirical models can be compared and selected to fit the data (Jiang 2019) providing moisture sorption isotherms (MSI). Based on these data hysteresis will be analyzed and a thermodynamic analysis will be carried out.

To face the durability performance, fit for purpose and environmental challenges, the concept of introducing innovative engineered wood products is to focus on lightweight poplar, being at one hand strategically important in European forestry, while at the other hand the

technology can be transferred to other lightweight hardwoods, as well as softwoods. To achieve the performance requirements with increased cost-effectiveness, an integrated approach is applied combining wood modification (wood engineering), protection (preservation and coating) and fire resistance, the latter governing for many high-end building applications such as multi-story buildings. This leads into a specific new generation of products which are emerging: engineered and multi-level treated wood in the form of LVL, CLT, LSL and I-beam or I-joists made thereof.

Wood modification technologies like acetylation, furfurylation and different thermal modifications are intended anyhow to alter chemical and physical properties. When carried out to a sufficient level throughout the wood, these processes protect it from rot by making it "inedible" to most micro-organisms and fungi, without requiring biocides. It greatly reduces the wood's tendency to swell and shrink, making it less prone to cracking and ensuring that, when painted, it requires dramatically reduced maintenance. The innovation potential of engineered wood products from modified poplar wood is huge. TMT (thermally modified timber) poplar is already considered a SoA product. However it is always critical on lower mechanical strength, and therefore a load bearing application can be hard to achieve. Specific research on THM (thermo-hydro-mechanical) densification treatments on trembling aspen and hybrid poplar can alter some mechanical properties in a positive sense (Fang *et al.* 2019) and is considered an opportunity for future environmentally friendly wood products (Sandberg *et al.* 2013). This type of treatments are often considered of interest for low density hardwoods (Bao *et al.* 2017). Some treatments even do not focus on fungal decay resistance but are intended to improve delamination resistance (Han *et al.* 2017).

Contrary to thermal modification, chemical modification of poplar is not yet fully established. Treatability of poplar can be considered rather straightforward but still requires some technicalities due to difficult to impregnate transition zones. Chemical impregnation processes, *e.g.* with self-polymerizing and crosslinking agents can furthermore imply that the mechanical strength will be preserved (or even increased) and thus giving the innovative potential of creating renewable structural building materials from European poplar. Similarly, the use of low molecular resins can be applied on solid wood but is also valuable for *e.g*. stand based products like OSB (Wan and Kim 2004). Chemical modifications and in particular the curing step when resin treatments are applied, can lead to some embrittlement (Xie *et al.* 2013).

Building with poplar can be considered a forgotten reality that is picked up recently in an attempt to use lightweight hardwoods in construction (Kesteloot and Hudel 2016). Poplar CLT has been explored alongside GLT by several researchers (Kramer *et al.* 2014, Wang *et al.* 2014) and several companies in Europe have recently started producing this product at pilot scale. For poplar we can integrate all these trends by combining a fast growing wood resource from specific poplar cultivation, introducing this for construction and applying fit-for-purpose treatments to enhance material resistance. An example being explored in this context is poplar CLT, optionally thermally treated when decay could be a risk. Thermal treatment of poplar wood has been identified as having good potential (De Boever *et al.* 2016), being however only one of the options to increase service life under different use classes.

In Table 1 an overview is provided on how the service life of different engineered wood products could be increased. The different engineered wood products are subdivided in categories depending on the components constituting the product: strands, veneer and timber. For each category a wood based panel product as well as a beam like product is used as example.

The use of durable wood species is clearly related to the use of primarily heartwood which is often difficult to achieve in full. Vacuum pressure based wood preservation of the final product is often limited by the treatability. Glue-line additives are mainly useful when thin veneers or strands need to be protected. A third option related to wood preservation technology is spraying a diffusible component based product (*e.g.* borates) on the surface. Modification technologies might have some impact on mechanical properties and hence not fully adequate for loadbearing applications, but thermal modification for full panel products and chemical modification of strands prior to incorporation in a panel is potential technology. Finally resin treatments have similar or even better potential than glue-line additives and could also be applied as modification methods for timber based products. Applying coatings to control moisture dynamics is mainly useful for veneer and timber based products.

Table 1. Options to increase service life of Engineered Wood Products (EWP).

Component	EWP	Durable wood	Vacuum pressure[1]	Glue-line additive	Surface spray[2]	Thermal modification	Chemical modification	Resin[3]	Coatings
Strand	OSB	-	-	±	+	+	+	+	-
	LSL	-	-	±	±	-	-	+	-
Veneer	Plywood	+	+	+	+	+	±	+	+
	LVL	±	±	+	±	±	±	+	+
Timber	CLT	+	+	-	+	+	±	±	+
	GLT	+	+	-	±	±	±	±	+

Legend: +: existing option, ±: feasible option, -: less probable option

[1]: deep impregnation with biocides; [2]: surface biocide application with potential diffusion, *e.g.* borates, [3]: analogue to glue used for production or a hydrophobing agent; Abbreviations: EWP = engineered wood product; OSB = oriented strand board; LSL = laminated strand lumber; LVL = laminated veneer lumber; CLT = cross laminated timber; GLT = glue laminated timber or glulam.

5 Conclusions and Future Perspectives

The overall concept of introducing innovative engineered wood products based on fast growing plantation trees like hybrid poplars to achieve results, relate to the following objectives: (1) to link methodology (service life prediction) and product development (poplar EWP's – glulam & CLT; plywood & LVL; OSB and LSL); (2) to focus on European hardwood species; and (3) to integrate options for untreated and protected products through both biocidal and non-biocidal treatment. A holistic approach is needed to combine resistance to fungal decay, insect attack, fire, dimensional stability; in due consideration of different applications: construction (both loadbearing and not) from damp up to marine environments, interior and exterior applications (cladding, garden furniture,…), transport (caravans, containers, automotive,…) and their requirements in terms of time of wetness, aesthetics, weathering, maintenance, long-term mechanical properties (creep, mechano-sorptive behaviour, impact of treatment), as well as in terms of life cycle assessment and life cycle costing performance. All wood protection and modification methods are of interest to be evaluated for this plantation wood resource, making it suitable even for high quality applications. Poplar, for many reasons, has been nominated as

hardwood with the best potential to perform similarly as softwoods for applications in wood construction. Benchmarking with wood species like spruce is relevant for several engineered wood products like plywood, LVL and even CLT. Wood treatments to increase durability have evolved from traditional wood preservation towards modification techniques such as thermally modified timber depending on the performance required or fit-for-purpose in relation to a specific combination of use class and service life.

Abstract. *Excessive mold development in interior spaces can be the cause of health problems in their users, as well as of a decrease in the comfort of use of internal spaces. The aim of our study was the development of a service that can ensure the long-term elimination of the cause and effects of mold in buildings by using new compositions of materials and finish application techniques. For this purpose, the most mold-resistant variants of construction material compositions and the technology of their application were selected. The study features an analysis of 18 variants of samples taken from climatic boards with various building finishes, which were tested for resistance to three species of mold: A. versicolor, Ch. globosum and P. funiculosum, under different climate and humidity combinations. The results of the study pointed to the most effective anti-mold technology. One comprehensive solution that can improve the conditions of the use of interior spaces is an external wall interior thermal insulation application system that employs silicate and lime sheets.*

Keywords: *Mold, Durability, Interior Finishing, Silicate and Lime System.*

1 Introduction

Fungi and the remediation of living quarters have been a problem that has accompanied mankind for many years. Exposure to harmful biological agents in the interior environment of living quarters has been identified by the WHO as a significant health risk. There is mounting evidence that mold growth in damp buildings is an important risk factor in the development of respiratory diseases. Air contamination by biological agents is associated with moisture and inadequate ventilation. A WHO study (2007) showed that there is a significant number of European homes that can be affected by mold and damp. Available publications indicate that in European Union Member States, the problem of mold or damp affects 10% of social housing (over 14 million cases) (Bonnefoy *et al.* 2003).

Worldwide observations indicate that in newly-built buildings, over 60% of mold problems apply to bathrooms, up to 40% to kitchens and only a few percent in other rooms. The dynamics of the indoor microclimate are related to the finishing materials and the organisms

themselves, which can in turn affect the materials. For example, porous substances can retain moisture and provide a reservoir for it, creating spaces with high humidity that are convenient for mold growth in otherwise dry indoor conditions. Molds are an extensive taxonomic group. Some of them need small amounts of organic nutrients and can grow on plasters, walls and construction materials in places with increased humidity (Fedorczak-Cisak *et al.,* 2019; Fedorczak-Cisak *et al.,* 2020; Radziszewska-Zielina and Śladowski, 2017). Molds develop actively at elevated mass humidity values, which differ between the species of mold and type of material (Gutarowska, 2010). Molds cause the biodegradation of building materials, reduce the aesthetics of the interior, destroy stored products and adversely affect the well-being and health of people and animals. They develop on surfaces, forming variegated mycelium deposits, the coloration being usually caused by numerous conidial spores (Gutarowska and Piotrowska, 2007). The second important factor affecting mold growth is the pH of a material. In particular, the alkaline nature of materials *e.g.* a high pH value of around 12-14, has been observed to show a lack of active growth of mold, which resulted from the existence of conditions unfavorable to the development of these microorganisms (Andersson et al., 1999). Excessive development of molds in utility spaces has been observed to cause health problems. The disease factor, in the form of spores, mycelium or metabolites, enters the human body by inhalation, ingestion or through the skin. The effects of these factors are not always immediate, many of them are revealed after a longer period of time (WHO 2009; Nielsen *et al.* 1999; Guo *et al.* 2004).

Control of the occurrence of molds in buildings and its reduction requires a holistic approach to the construction and occupancy process, taking into account the aspects of thermal insulation, heating, ventilation and proper finishing of materials, as well as the proper maintenance of indoor spaces (Radziszewska-Zielina *et al.* 2020). The use of comprehensive solutions consisting of the improvement of thermal and humidity conditions in an indoor space can lead to the elimination or reduction of the causes of fungal infestations. Using an internal insulation system comprised of Epatherm silicate-lime slabs is one such comprehensive solution.

2 Materials

Several dozen samples were prepared in laboratory conditions, using various finishing materials (mortars, thin coat plasters, paints (KFI, etf, acrylic (ap), latex (lp), emulsion (ep)), while the base consisted of silicate and lime sheets of varying thickness (from 15 to 100 mm). The proposed thermal insulation sheets include silicone in their composition, which gives them hydrophobic properties, making them more resistant to dampness and therefore the development of microorganisms (Hippelein and Rügamer 2004). The resistance of the analyzed sheets to the effects of molds was also a result of the existence of conditions that are unfavorable to the development of these microorganisms, particularly stemming from the alkaline character of the proposed set of materials, *e.g.* their high pH value of 12-14. In addition, based on laboratory studies, a lack of application differences was observed in the case of using these material compositions in atmospheric conditions, i.e. in temperatures ranging between 5˚C and 30˚C, with a relative air humidity of 40% to 80%. The materials used in the system are mineral products, composed of lime, quartz sand and water, which

results in a lack of toxins or other substances that are not allowed in construction.

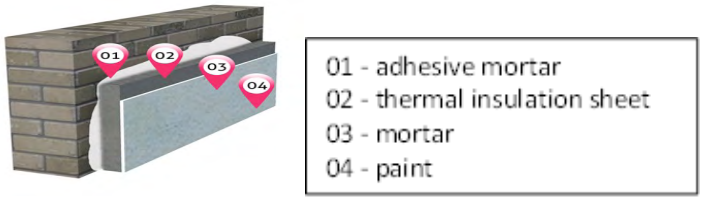

Figure 1. Layers of the proposed interior thermal insulation application system (www.eximreno.eu).

45 compositions of material and ready-made application solutions with different construction finishes (Table 1) were examined in the study:

Table 1. Material samples and technologies of their application and finishing.

3 Methods

3.1 Resistance to Molds

The study used 18 sets of 45 samples taken from climate boards with different construction finishes, which were treated with three species of mold: *Aspergillus versicolor*, *Chaetomium globosum* and *Penicillium funiculosum* in 9 climate combinations. The test was performed in compliance with American standards (ASTM C1338-08; ASTM International E104-02; ASTM International D6329-98). According to this document, stable humidity conditions are

provided by saturated solutions of selected inorganic salts, while the temperature is provided by external devices. In this study, a refrigerator chamber and an incubator were used. Radio-controlled thermohygrometers in an environmental chamber were used for the control. The conditions of the experiment and the means of ensuring them in the environmental chambers have been presented in the Table 2.

Mycological tests were carried out based on prepared spore suspensions of three selected molds with a density of 10^6/ml in two types of media (sterile distilled water and a liquid medium), which were sprayed on the test samples. The inoculated materials were placed in environmental chambers with humidity, which were then placed at three temperatures (Table 2). In total, 18 sets of 45 samples with different finishes were used in the study. A mycological evaluation of the cultures was performed after two days of incubation - 0 - determining the recovery of mold without the influence of climatic conditions. Further assessments of the size of the cultures were performed at 1 and 2 weeks of incubation. Cultures were extracted from the samples through a 1 cm^2 smear of the top layer of the sample and, after the disinfection of the surface, scraping the material from a depth of 0.5 cm on a surface of 1 cm^2. The cultures were cultivated on two media: Malt Extract LAB-AGAR™ (MEA) and Rose Bengal LAB-AGAR™ (RBA) in triplicate. When assessing the susceptibility of materials to mold, a total of over 20,000 cultures were assessed, while the total number of records in the database was about 82,000 in total, nearly 823,000 mold colonies were counted. The results were subjected to a statistical analysis.

Table 2. Conditions of the experiment.

Temperature [ºC]			Relative Humidity (%)		
Categories	**climatic conditions**	**Value**	**Categories**	**climatic conditions**	**Value**
Low	refrigerator chamber	2.6 ±1.0	Low	silicate	44.5 ± 11
Low		3.9 ± 0.6	Medium	magnesium nitrate	80 ± 1
Low		4.7 ± 1.0	High	potassium chloride	92 ± 1
Medium	room temperature	22.1 ± 1.4	Low	silicate	53 ± 1
Medium		21.8± 1.2	Medium	sodium nitrite	77 ± 1
Medium		22.6 ± 1.3	High	potassium nitrate	96 ± 1
High	laboratory incubator	36.4 ± 0.3	Low	silicate	23 ± 8
High		36.9 ± 0.2	Medium	sodium nitrite	57 ± 6
High		36.0 ± 0.3	High	potassium sulfate	86 ± 2

3.2 Statistical Analysis

The authors used one-way analysis of variance (ANOVA) to analyze the relationship between the number of mold colonies (dependent variable) and the tested variant sample "plate number" (grouping variable). The dependent variable was measured in various configurations. An ANOVA test was performed for the following configurations of experimental conditions. Afterwards, Fisher's multiple comparison tests were conducted for all identified relationships between the dependent and grouping variables, in order to detect differences between the means. A default significance level of 0.05 was adopted. The dependent variable was measured in configurations that were selected based on an analysis of the literature and the observations made during the seed test. It was found that the samples most exposed to mold fungi were those with average temperature "TEMP = SR" and high humidity "RH = WYS"

(Pasanen, 2000) conditions. The statistical analysis took into account the results after the maximum incubation time of samples from inoculation, i.e. after a period of two weeks of incubation in the above climatic conditions, "Culture = 2". A suspension in the spore medium in the MEB medium "IV = P" was selected, at which a higher number of spores was obtained relative to the spore suspension in sterile water. Spore collection from the sample surface was carried out using two methods (selected for analysis): a swab from the sample surface "V = W" and a sample groove to the depth "V = S". RBA "VI = R" medium was selected for analysis because of the low amount of impurities/infection. It has been proved that filamentous fungi depend on the presence of organic matter in the environment, they can even use house dust as a source of nutrition in conditions of high humidity (Buchmiet and Żakowska, 2009). Primary colonizers of building materials include xerophilic species that also develop in dry conditions, *e.g.* fungi of the genera *Penicillium* and *Aspergillus* (Gutarowska and Piotrowska, 2007). The dependent variable analysis was performed separately for three species of molds: "VII = A" - *A. versicolor*, "VII = P" - *P. funiculosum*, "VII = Ch" – *Ch. globosum*.

4 Results

One of the assumptions of the project was to develop a method of long-term mold removal in variously used internal spaces, one that could be introduced to the construction market. Over the course of laboratory research, material compositions with the greatest resistance to mold growth were selected and then various methods of applying them in actual construction conditions were analyzed. An analysis of the method of base surface preparation for the application of the system's sheets was performed, as well as that of their finishing depending on the type of internal space and the manner of its use. A significant relationship was found between the variable dependent number of colonies and the sample number (p value <0.05).

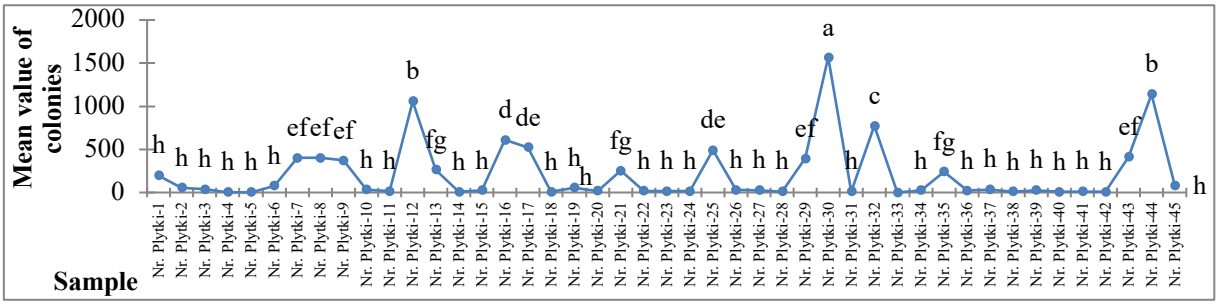

Figure 2. Experimental setup (sampling - Scraping, *A. niger*), TEMP = SR, RH = WYS, Culture = 2, IV = P, V = S, VI = R, VII = A.

For the experimental system (sampling - Scraping, *A. versicolor*), the analysis of multiple comparisons includes all samples in which the average number of colonies does not exceed 82.67 in one homogeneous class, H (this corresponds to sample 45). Samples in a homogeneous class H showed the highest resistance to *A. versicolor*. Samples 30, 44 and 12 proved to be the least resistant to *A. versicolor*, etc. (Fig. 2). Compared to variants not resistant to *A. versicolor*, samples in the G-F class also showed fungistatic activity against the

tested mold (Fig. 2). In the case of samples treated with *P. funiculosum*, variants for which the average number of colonies does not exceed 31. 33 (this limit is determined by sample No. 5) were observed to be the most resistant (Figure 3). Analysis of samples exposed to *Ch. globosum* found no significant difference between the samples (p value 0.52). Thus, all samples were observed to behave homogeneously (well) under the selected experimental setup (Fig. 4).

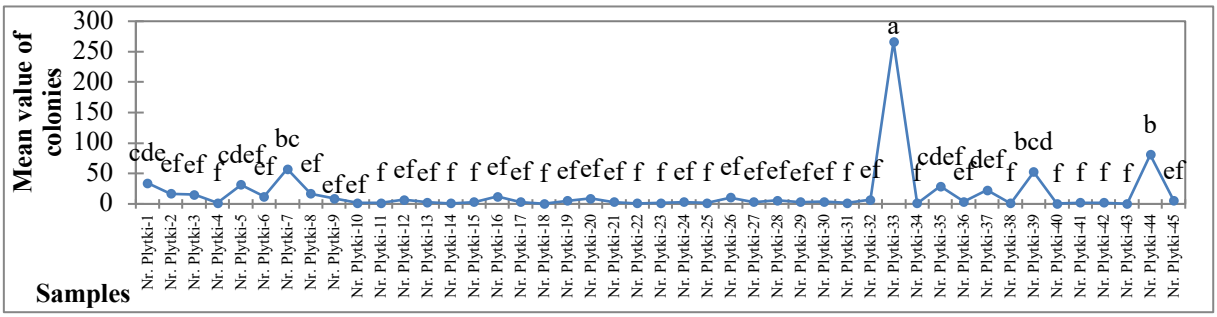

Figure 3. Experimental setup (sampling - Scraping, *P. funiculosum*), TEMP = SR, RH = WYS, Culture = 2, IV = P, V = S, VI = R, VII = P.

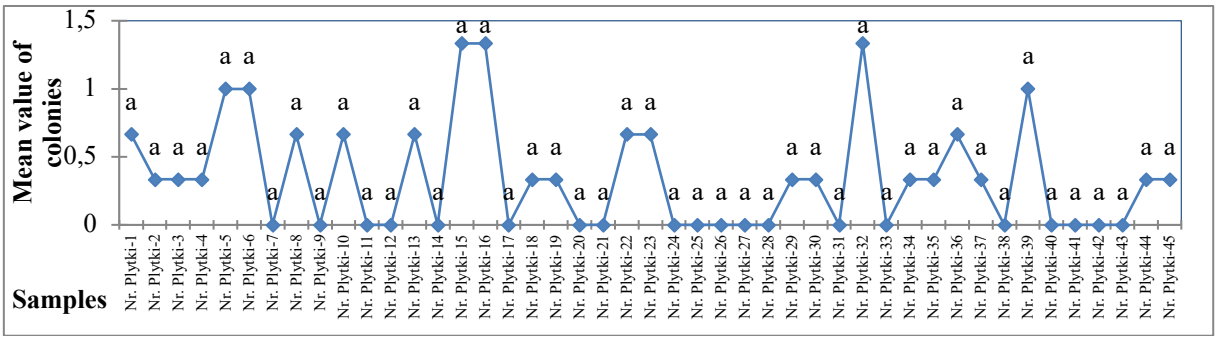

Figure 4. Experimental setup (sampling - Scraping, *Ch. globosum*)

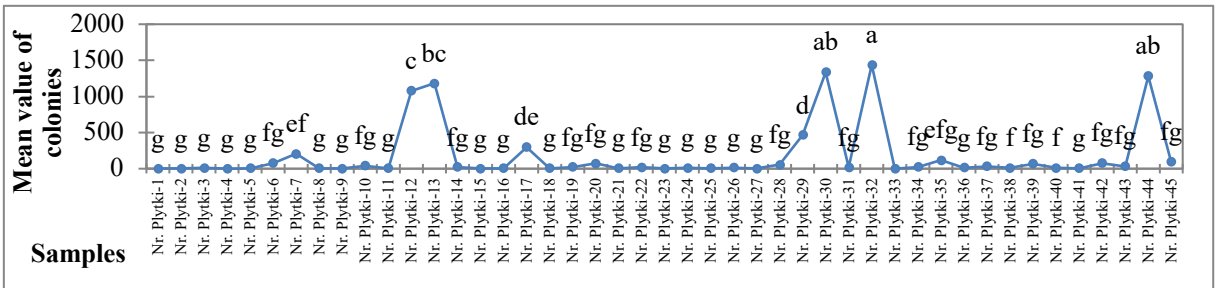

Figure 5. Experimental setup (sampling - Swab, *A. niger*), TEMP = SR, RH = WYS, Culture = 2, IV = P, V = W, VI = R, VII = A.

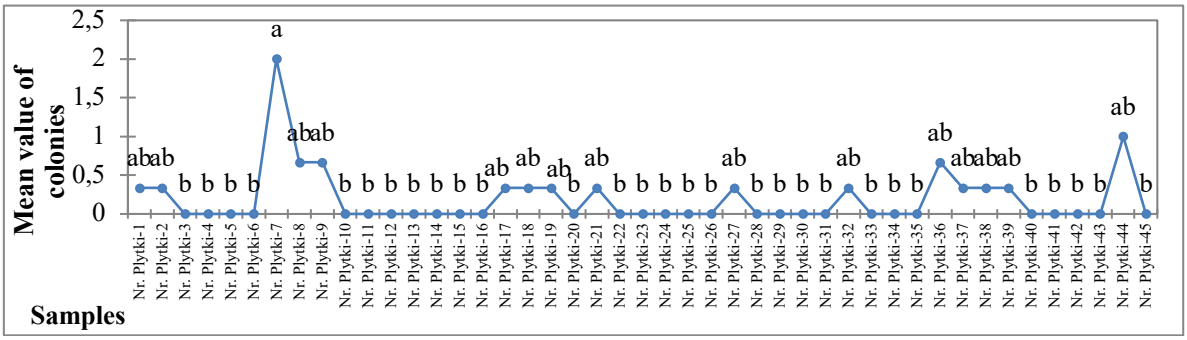

Figure 6. Experimental setup (sampling - Swab, *Ch. globosum*).

For the experimental system (sampling - Swab, *A. versicolor*), multiple comparison analysis classified all samples resistant to *A. versicolor* into one homogeneous class, G. The limit of the most resistant samples is determined by option No. 35 (Fig. 5). Additionally for the experimental system (sampling - Swab, *P. funiculosum*), multiple comparisons analysis determined the variants that were the least resistant to the action of *P. funiculosum*, which include variant No. 33. The remaining samples were within homogeneous classes B or C (not presented in figure).

Sample No. 7 was found to be the least resistant to *Ch. globosum* in this experimental setup, which is a separate class. For the remaining samples, no significant differences were observed, placing them all in the B homogenous class (Figure 6).

5 Conclusions

A review of the obtained results has shown that all building materials can be a convenient substrate for the growth of molds that contribute to their destruction. Therefore, it is necessary to know the susceptibility of currently used construction materials to colonization by these microorganisms, as well as the factors that facilitate this process.

Most often, the presence of mold was observed on samples numbered 7, 8, 9, 12, 13, 16, 17, 30, 32, 33, 44. Differences between the ability to grow mold in laboratory conditions were observed in inorganic materials (gypsum, plaster). The reason for these differences in fungal growth may have been the presence of additional sources of nutrients that stimulate said growth, e.g. in the form of dust or a microbial medium.

The results show that variants number 35 and 40, which are characterized by high vapor permeability (water vapor diffusion coefficient = 3), prevent the development of mold on their surface. Climatic boards, which have silicone in their composition, which gives them hydrophobic properties, will be more resistant to moisture, and thus to the development of microorganisms.

Abstract. *Reinforced concrete (RC) specimens were treated using different combinations of surface coating and/or patch repair methods and materials, left in a coastal region with frost damage risk, and their properties characterized after 25 years of exposure. Specimens were prepared by chipping away concrete from one section of concrete block with embedded reinforcement bars to expose the bars, followed by patch repair and then surface coating. Four types of material were used for patch repair: cement mortar, styrene–butadiene rubber (SBR) polymer cement mortar, rust-resistant SBR polymer cement mortar, and lightweight epoxy mortar. Two types of material were used for surface coating: multi-layer textured and thin textured coating. Following exposure, cracks were visible only on the surfaces of untreated specimens, apparently due to rebar corrosion; they were absent from all specimens that had undergone surface coating and/or patch repair. In addition, the corrosion resistance of these methods and materials was investigated by measuring and comparing the surface areas of corroded rebar between three segments: the repaired part, the unrepaired part, and the boundary between them. Concrete carbonation and rebar corrosion were greatly dependent on surface coating material, with the multilayer-textured coating especially effective at blocking chloride penetration. In addition, rebar corrosion was more effectively prevented by patch repair with the SBR polymer cement mortar than with the lightweight epoxy mortar.*
