TABLE OF CONTENTS

PREFACE

Built environment (buildings, bridges, dams, highways...) is facing a dramatic increase of deterioration cases worldwide, mainly due to the lack of proper inspection and maintenance. Maintaining the safety and serviceability of the infrastructure assets is of crutial importance for the owners/stakeholders, and the society in general, but at the same time still limited resources remain available to this end. Academics, professionals and owners involved in the management of the built infrastructure have taken positive steps to develop more comprehensive measures and conduct better maintenance activities to better invest the limited funds. However, correct funding policies require a proper knowledge of the deterioration and damaging processes involved in the aging buildings. To this end, the series of conferences devoted to the Durability of Building Materials and Components (DBMC) have provided an excellent state of the knowledge and advancement since many years on the subject of durability and performance of the built environment. In fact, along more than 40 years, the main focus and topics of the different conferences have evolved according to the evolution of the existing and the appearance of new problems to be faced by the architectural/engineering community regarding durability of the construction assets.

Following the success of previous conferences, the 15th International Conference on Durability of Building Materials and Components (DBMC 2020) held in Barcelona from 20th to 23th of October 2020, covered all major aspects related to durability, from the more traditional ones such as building physics and durability, service life prediction, durability of historical buildings, to the most recent requiring the attention of the construction community as life-cycle assessment and sustainability, BIM technology and durability, and the influence of natural hazards and climate change on the durability of new and existing structures. Also new in this conference is the creation of awards to the student´s contribution (best paper, best poster and best oral presentation) and the launching of a grant for non-profit organizations of students in a projects contest for funding collaborative projects related to built infrastructures in developing countries.

However, the novelties in this edition of the conference have not been only restricted to the content of the scientific/technical/social subjects. In fact, the format has been also completely changed from the previous editions due to the impact of the COVID-19 pandemic situation. The declaration of the pandemic just few months before the celebration of the conference in June of 2020, provoked not only the shift to the new dates in October, but also the need to derive on a fully online conference. In this sense, DBMC 2020 has become the first fully online conference of the series.

The Organizing Committee has devoted its main efforts to prepare an attractive conference in the new online format in a limited period of time. We thank the confidence and collaboration of the prospective participants, which, in turn, had to accomodate themselves to the new scenario in a short time. The effort from all of us, organizers and participants, and the interest of the international community has been confirmed by the high response to the call for papers despite all negative constraints for travelling and networking. At the end, 368 preliminary abstracts were received at the Conference Secretariat. About 85 percent of them (313 in total) were invited by the Scientific Committee to submit extended abstracts and full papers, for oral or poster presentations in DBMC 2020. Finally, the scientific programme consisted of five keynote plenary sessions, 242 contributed papers (allocated in 13 special sessions and 23 conference topic sessions -in four parallel tracks- and one poster session) and a final round table on the

implications of a changing climate on a sustainable built environment. In total, 351 participants (30 percent of whom were students), from 41 different countries, have made DBMC 2020 an unforgettable experience.

Abstracts and full papers, including keynote lectures and technical papers have been assembled in a printed Book of Abstracts and an e-Book of Proceedings, respectively. They become a permanent record of the DBMC 2020 scientific contribution. This record is an effort to serve as a valuable reference on the recent developments in durability of the built environment. All the contents is also available at the webpage of the conference http://congress.cimne.com/DBMC2020, and in open access at https://www.scipedia.com.

As a DBMC 2020 Organizing Committee, we would like to take this opportunity to express our sincere thanks to all participants (keynotes, discussants, special sessions organizers, chairs, authors and attendees) for their contributions, to the membres of the Scientific Committee for their dedicated work and to the members of the Local Organizing, UPC Institutional, and Steeering Committees for the time and effort they have devoted to making DBMC 2020 a successful event despite the pandemic constraints and for their unconditional support to all important decisions we had to make along all the preparation process, and mainly in the last eight months. Last, but not least, our kind acknowledgement on one hand to the CIMNE Conference Secretariat, led by Bea, for their constant and helpful collaboration, and on the other hand to Cristina for her invaluable assistance. Thank you all!

Barcelona, October 2020

STEERING COMMITTEE

Organizing Members

- Geert De Schutter, RILEM (Chair)
- Jennifer Keegan, ASTM
- Jorge De Brito, CIB
- Christopher C. White, NIST
- Michael Lacasse, NRC-CRC

Members at Large

- Robert Amor, The University of Auckland, New Zealand
- Carmen Andrade, CIMNE, Spain
- Christian Brischke, University of Göttingen, Germany
- Bruno Daniotti, Politecnico de Milano, Italy
- Vasco Peixoto De Freitas, FEUP, Portugal
- Peter Flüeler, m ETH/EMPA, Switzerland
- Dariusz Gawin, University of Lodz, Poland
- Julien Hans, CSTB, France
- Vanderley John, USP, Brazil
- Chun-Qing Li, RMIT University, Australia
- Isabel María Martínez, IETcc-CSIC, Spain
- Hiroyuki Miyauchi, BRI, Japan
- Shiro Nakajima, Utsunomiya University, Japan
- Carles Serrat, Universitat Politècnica de Catalunya-BarcelonaTECH, Spain
- Kiang Hwee Tan, NUS, Singapore
- Nil Turkeri, ITU, Turkey

UPC INSTITUTIONAL COMMITTEE

- Francesc Torres (Chair), President of UPC-BarcelonaTECH
- Jordi Berenguer, Vice-rector for Knowledge Transfer and Innovation of UPC-BarcelonaTECH
- Inmaculada Rodríguez, Dean of Barcelona School of Building Construction (EPSEB)
- Pedro Díez, Dean of Barcelona School of Civil Engineering (ETSECCPB)
- Félix Solaguren-Beascoa, Dean of Barcelona School of Architecture (ETSAB)
- Albert Cuchi, Dean of Vallès School of Architecture (ETSAV)
- Eugenio Oñate, Chair of Executive Council of the International Center for Numerical Methods in Engineering (CIMNE)
- Carles Serrat, Chair of the DBMC 2020 Conference

SCIENTIFIC COMMITTEE

Chairs
- Joan Ramon Casas (Co-Chair), UPC-Barcelona TECH, Spain
- Carmen Andrade (Co-Chair), CIMNE, Spain

Vice-Chairs
- Antonio Aguado, UPC-Barcelona TECH, Spain

SPECIAL SESSIONS

Approaches to Hygrothermal Simulation for Assessing Durability Related to Climate Change

Organized by Travis Moore (NRC, Canada) and Michael Lacasse (NRC, Canada)

Biomimetic and Bioinspired Approaches for Enhanced Durability of Cementitious Materials

Organized by Wil Srubar (University of Colorado Boulder, USA)
and Zeynep Basaran Bundur (Özyegin University, Istanbul, Turkey)

Degradation of Coating Materials and its Relation to Durability of Structures

Organized by Takafumi Noguchi (University of Tokyo, Japan) and Kei-ichi Imamoto (Tokyo University of Science, Japan)

Durability and Field Tests of Thermal Insulating and Innovative Constructive Solutions

Organized by Ines Flores-Colen (IST, University of Lisbon, Portugal) and Nuno Ramos (FEUP, University of Porto, Portugal)

Durability and Performance of Building Envelopes

Organized by Klodian Gradeci (SINTEF Building and Infrastructure, Trondheim, Norway) and Petra Rüther (SINTEF Building and Infrastructure, Trondheim, Norway)

Durability Considering Climate Change and Natural Hazards

Organized by Michael Lacasse (NRC, Canada) and Travis Moore (NRC, Canada)

Environmental Factors and Durability

Organized by Tomasz Blaszczynski (Poznan University of Technology, Poland)

Life Cycle Costs in Construction Projects

Organized by Vít Hromádka (Brno University of Technology, Czech Republic) and Edyta Plebankiewicz (Cracow University of Technology, Poland)

Modern Sustainable Building Materials and Technologies

Organized by Elzbieta Radziszewska-Zielina (Cracow University of Technology, Poland)

Performance Over Time of High-Performance Insulation and Reflective Building Envelope Materials

Organized by Umberto Berardi (Ryerson University, Canada) and Marco Perino (Politecnico of Turin, Italy)

Remote Sensing of Building Condition

Organized by Joanna Janicka (University of Warmia and Mazuri in Olsztyn, Poland) and Jacek Rapinski (University of Warmia and Mazuri in Olsztyn, Poland)

Slags in Cement-based Materials

Organized by Flora Faleschini (Università degli Studi di Padova, Italy) and Amaia Santamaria (Universidad del País Vasco, Bilbao, Spain)

Soft Computing Tools and Sustainable Building Construction and Maintenance

Organized by Diana Car-Pušic (University of Rijeka, Croatia) and Ivan Marovic (University of Rijeka, Croatia)

CONFERENCE TOPICS SESSIONS

Asset and Maintenance Management

Organized by Ana Silva (IST, Lisbon, Portugal)

Building Pathology and Durability

Organized by Túlio Bittencourt (University of São Paulo, Brazil)

Building Physics and Durability

Organized by Antonio Aguado (UPC-BarcelonaTECH, Spain)

Durability Approach for Historical and Old Buildings

Organized by Elisabetta Rosina (Politecnico di Milano, Italy)

Durability of Materials, Systems and Components

Organized by Ravindra Gettu (IIT Madras, India)

IT / BIM and Durability

Organized by Rade Hajdin (IMC GmbH, Zürich & Belgrade Univ)

Large Sample Size Studies in Durability

Organized by Fernanda Rodrigues (Universidade de Aveiro, Portugal)

LCA, Sustainability and Durable Construction

Organized by Nele De Belie (University of Ghent, Belgium)

Service Life Prediction Methodologies

Organized by Alfred Strauss (BOKU, Vienna, Austria)

Prescription of Maintenance Interventions by the New Generation of Eurocodes for Climate-Change Resilient Structures

Maria Nogal[1]

[1] Faculty of Civil Engineering & Geosciences, Delft University of Technology, Netherlands
m.nogal@tudelft.nl

Abstract. *The new generation of structural Eurocodes will include climate change adaption measures in order to enhance the climate resilience of infrastructures across Europe. This paper discusses the impact that climate change might have on reinforced concrete structures subjected to corrosion, and the associated challenges of the standardisation of adaptation measures. A resilience-based framework is proposed for the adaptation of structural codes to climate change-induced actions. Such an approach aims to provide the required adaptive capacity to the new structures in order to be able to respond to the uncertain future minimising the investment under unlikely scenarios. In that way, the strategy can be summarised as a climate change-adapted design plus an in-design maintenance plan. Future actions, such as mapping the future climate-related drivers of corrosion, the determination of the design values of these drivers, and the prescription of maintenance activities, should be further investigated. Although this paper focuses on the new structures that will be designed with the new codes, some of the insights can be extrapolated to the existing structures.*

Keywords: *Corrosion, Climate change, Resilience, Maintenance, Eurocodes.*

1 Introduction

The pressure imposed by climate change has reached all sectors within the European Commission, which is now forced to take adaptation measures. In Union Innovation (2013), they acknowledged action gaps in a context where late responses could result in non-affordable economic, social, and environmental costs. Consequently, they proposed a road-map to include climate change adaptation considerations where technical standards were identified as an effective strategy to enhance the climate resilience of infrastructures across Europe.

In the construction sector, the first generation of EN Eurocodes was launched in 2007 with the aim to homogenise structural design within the Member States. The second generation of Eurocodes is planned by 2023, which will reflect the new market needs (e.g., new materials and construction techniques) and also the European commitment with the sustainable development goals. Therefore, the second generation of Eurocodes is planned to incorporate the adaptation of structural design to climate change.

Within the long list of impacts upon structures caused by climate change, corrosion has been identified as a priority theme, as it has been estimated that the increased maintenance and repair costs worldwide resulting from the acceleration of the corrosion process due to climate change might be of hundreds of billions of dollars annually (Bastidas-Arteaga & Stewart (2015)).

doi:10.23967/dbmc.2020.241

In this context, this paper discusses the adaptation strategy to be applied to the new generation of Eurocodes in relation to the corrosion of reinforced concrete (RC) structures. At present, the structural corrosion is addressed in EC2 (2005).

It is noted that the impact of climate change on man-made systems has a large component of uncertainty, given that the future climatic scenarios mainly depend on the evolution of the global sociopolitical context. Therefore, including climate change adaptation measures in the design phase of buildings and infrastructure is challenging because underestimating its impact would result in significant societal consequences, whereas overestimating it would imply an unnecessarily waste of resources. A resilience-based approach is proposed to address the issue, where the adaptation measures included in the design phase should tackle part of the impact of climate change, and during the service phase, upgrading mechanisms should be implemented to guarantee the system is prepared for the non-accounted impact of climate change if the evolution of climate change requires it.

Therefore, this work aims to provide an overview of the problem of corrosion induced by climate change to better understand the need for a resilience-based approach to address the standardisation process. The general framework proposed for the adaptation to climate change by the new generation of structural Eurocodes is outlined and the associated challenges are further discussed.

The remaining document is organized as follows; Section 2 provides an overview of the impact of climate change in Europe on the main drivers of the structural corrosion, Section 3 presents the corrosion problem in the context of climate change. In Section 4, the need for a resilient-based approach is discussed in the context of the standardising process. Finally, in Section 5 some conclusions and future research lines are drawn.

2 Climate Change in Europe

The durability of RC structures is threatened by the increment of carbon dioxide (CO2) concentration levels and climate change entailing variations in temperature and atmospheric humidity. These three parameters are the principal environmental drivers of corrosion.

To study the expected variations of air temperature and relative humidity (RH), the Representative Concentration Pathways (RCPs) proposed by IPCC (2014) are used. They are the so-called RCP2.6, RCP4.5, RCP6.0, and RCP8.5 scenarios, with RCP2.6 being closer to the scenario aimed by the Paris Agreement and RCP8.5 relating to the business-as-usual scenario. There exists a consensus amongst climatologists that RCP2.6 is naively optimistic, thus in practicality, the RCP4.5 is very often proposed as the potential optimistic scenario.

The definition of each scenario allows climatologists to determine the general atmosphere patterns and oceanic circulation dynamics at the global scale. Then, through complex processes of downscaling, climate changes at a regional level can be estimated with a significant level of confidence for each scenario providing a horizontal resolution of up to 0.11^o (about 12 km).

In Europe, it is clear that climate change will increase air temperature. The extent of the variation will depend on the geographical location, period of the year, and scenario considered; for instance, North Europe, which is the most affected area when analysing air temperature,

Table 1: Variation of air temperature due to climate change in Europe. The level of agreement among climatic models is given in brackets: L-low, M-medium, H-high, V-very high.

Area	Winter	Summer	Autumn	Spring
	(DJF)	(JJA)	(SON)	(MAM)
	RPC4.5			
North Europe	2^o-8^o (M)	0^o-6^o (H)	2^o-6^o (H)	2^o-6^o (M)
Central Europe	0^o-4^o (H)	0^o-4^o (H)	0^o-4^o (M)	0^o-2^o (V)
Mediterranean area	0^o-4^o (H)	2^o-4^o (H)	0^o-4^o (H)	0^o-4^o (H)
East Europe	2^o-6^o (H)	0^o-4^o (M)	0^o-4^o (H)	0^o-4^o (H)
	RPC8.5			
North Europe	4^o-10^o (M)	2^o-6^o (H)	2^o-6^o (H)	2^o-8^o (H)
Central Europe	2^o-4^o (V)	2^o-4^o (V)	2^o-6^o (H)	2^o-4^o (H)
Mediterranean area	2^o-4^o (V)	2^o-6^o (M)	2^o-6^o (H)	2^o-4^o (V)
East Europe	2^o-6^o (M)	2^o-6^o (H)	2^o-6^o (H)	2^o-6^o (H)

presents increments ranging between 4^o-10^o during the winter months (December to February) under the RCP8.5, whereas the RCP4.5 provides increments of 2^o-8^o during winter. The range of values is given by the use of different climatic models. Table 1 summarises the variation of air temperature due to climate change in Europe.

The impact of climate change on the RH is smaller. Regardless of the climatic scenario considered, only during the summer months (JJA), Europe might experiment reductions of up to 10% of the RH.

It is noted that an important source of the uncertainty of the climate estimations is linked to the uncertainty regarding the trajectory of greenhouse gas emissions (i.e., the RPC considered), which depends on factors such as the economic and societal trends. In the present context, this type of uncertainty cannot be reduced. Nevertheless, considering one or another scenario might differ in billion of euros in the long term. This should be kept in mind when updating the structural codes.

3 Impact of Climate Change-Induced Corrosion

3.1 Corrosion Mechanisms

RC corrosion refers to the phenomenon of the corrosion of the steel reinforcement of concrete caused by the infiltration into the concrete members of carbon dioxide, which reduces concrete pH till values below the steel passivisation threshold, and chloride, which reduces concrete alkalinity. Both processes are affected by temperature and RH.

When studying the RC corrosion, the stage characterised by the ingress process of the CO2 and chloride ion into concrete is known as the initiation stage. In this stage, it is of interest to determine the chloride concentration at the rebar level and also when the carbonation reaches this level, that is, the carbonation depth.

Several studies have analysed the impact of climate change in the carbonation ingress process when assuming different CO2 levels, RH, and temperature conditions. As shown in Table 2, the estimated increments of the carbonation depths are up to 45% by 2100 under the RCP8.5

Table 2: Effect of climate change on the carbonation and chlorine ion ingress processes in RC structures.

Ref.	Location	Assumptions	Estimation		Scenarios	
			Target	Value	Baseline	Target
CARBONATION INGRESS PROCESS						
Talukdar et al. (2012)	Canada	(a) increasing mean yearly temperature, (b) increasing duration of the hot season, (c) constant RH over time, and (d) increasing concentration of CO2	carbonation depths of non-pozzolanic, unloaded concrete structures	increment of 45%	year 2000	A1FI, year 2100
Talukdar & Banthia (2013)	Mumbai, London, New York City, Sydney, Toronto, Vancouver	(a) time dependent temperature	carbonation depths	increments between 27% and 45% (15 and 35 mm)	year 2000	A1FI, year 2100
Saha & Eckelman (2014)	Boston metropolitan area	(a) increasing temperatures, (b) increasing concentrations of CO2	carbonation depths	increment of 40%	year 2000	A1FI, year 2100
Peng & Stewart (2014)	China	(a) CO2 concentration, (b) local temperature, and (c) RH variable over time	carbonation depths	increment of 45%	year 2010	RCP8.5, year 2100
Mizzi et al. (2018)	Malta	(a) increasing CO2 concentration, and (b) increasing temperatures	carbonation depths for different concrete grades	increment up to 40%	RCP 2.6	RCP 8.5, year 2070
CHLORINE ION INGRESS PROCESS						
Saha & Eckelman (2014)	Boston metropolitan area	(a) increasing temperatures, (b) increasing concentrations of CO2	chloride penetration depths	increment of 12%	year 2000	A1FI, year 2100
Xie et al. (2018)	China	(a) increasing temperatures	chloride concentration at the rebar level of offshore RC bridges	increments of 6%-15%	year 2000	RCP8.5, year 2100
Khatami & Shafei (2017)	U.S. Midwest region	(a) increasing temperatures, (b) decreasing, constant and increasing RH, and (c) increasing surface chloride concentration	chloride concentration at the rebar level	increment of 37%	RCP2.6, year 2100	RCP8.5, year 2100

scenario (or the equivalent A1F1 scenario given by the SRES, Nakicenovic et al. (2000)) when comparing with the year 2000. It is noted that the results are very sensitive to local exposure conditions (Talukdar & Banthia (2013)).

In the case of the impact of climate change to the chlorine ion ingress process, the studies report more modest values, though still relevant, for the increment of chloride concentration at the rebar level when comparing the 2000-year values to the RCP8.5 by the end of century, reaching values around 15% (see Table 2). Khatami & Shafei (2017) report larger values, as they introduce in their model an increment of use of de-icing salts as a consequence of the observed consumption in the USA, which increased 200% in the last 25 years.

The second stage of the corrosion is known as propagation stage, which occurs once that the corrosion of the reinforcing steel is initiated, and finishes with the loss of steel area, cover cracking and spalling, and loss of the bond between steel and concrete. Whereas the initiation stage dominates the service life of the structure, the propagation stage lasts only a few years. For instance, Xie et al. (2018) report that the corrosion propagation stage of the offshore RC structures in China designed according to MOHURD (2008) would last less than one year considering future climatic conditions.

3.2 Impact on Reliability and Service Life

As a consequence of climate change, both the reliability and service life of RC structures are highly impacted. The extent of this impact depends on the geographical location, the structural codes used for design, and the climatic scenario considered. Table 3 summarises some of the findings regarding the impact of climate change on the reliability and service life of RC structures by the end of this century if the most pessimistic scenario, i.e., the business-as-usual scenario, is considered. Even when the compound effect of the carbonation- and chlorination-induced corrosion has not been studied yet, the enormous impact that climate change has on structural durability cannot be ignored.

Table 3: Impact of climate change on reliability and service life of RC structures.

4 Structural Codes

4.1 Adaptation Measures

The limit state of RC corrosion should include two phenomena, the cracking of concrete due to the sub-products generated by the corrosion and the reduction of effective steel cross-section, both occurring during the propagation stage. While the first is more related to aesthetic issues and the latter is linked to the structural integrity, the functionality of the structural member will determine which of the two phenomena is more critical. Given that the integrity of a structural member affected by corrosion will depend on the applied loads and structural configuration, its study becomes very case-specific and difficult to be generalised. Thus, when defining standardised strategies to adapt to climate change, it is better to focus on the initiation stage, which implies a larger portion of the structural service life and is less dependent on the applied loads and structural configuration.

Structural codes worldwide share a similar rationale when addressing the problem of corrosion; they focus on structural durability. Figure 1 generalises this approach. There exist two decision variables in regard to the structural design affecting the RC corrosion, that is, materials

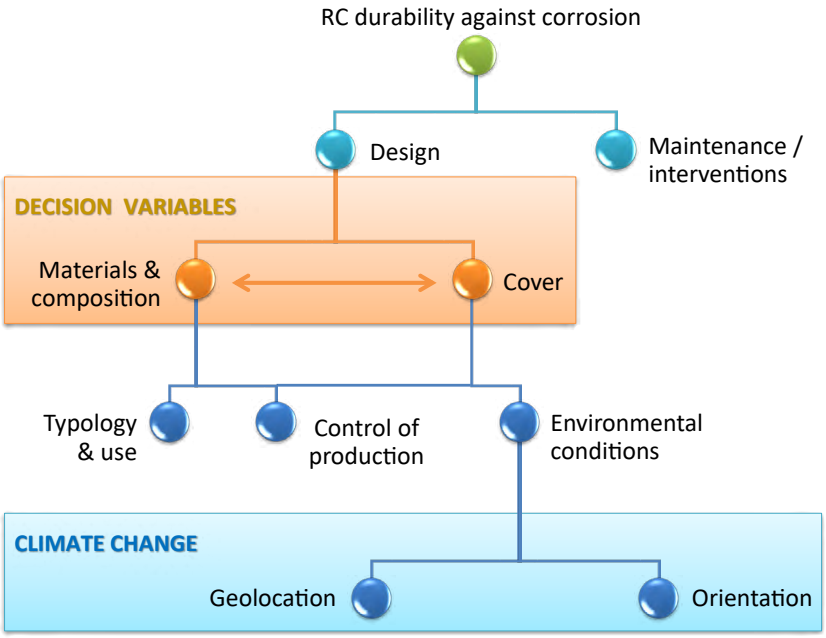

Figure 1: Rationale of structural codes to guarantee the structural durability against RC corrosion.

and composition and cover depth. Both of them are related, as the selection of a more dense concrete allows for a reduction of the cover depth. To determine these values, aspects such as typology and use, the control of production and the environmental conditions must be considered. Initially, the new environmental conditions given by climate change should be reflected here.

Regarding the materials and composition, two possible solutions can be taken, either improving steel corrosion resistance, e.g., through low carbon, stainless or galvanised steel reinforcement and glass-fiber reinforced polymer rebars, or improving concrete durability by increasing the concrete grade, the water-cement ratio or applying concrete coatings. In addition, other concrete mixes, such as blended and alkali-activated (AA) cement, can be used that present higher density matrices than the standard and commonly used Portland cement (PC). The structure of their matrices reduces the permeability of the harmful substances. In addition, the AA slag cement, where the slag substitutes part of the PC, presents higher resistance to corrosion and its production generates lower greenhouse gas emissions than PC. Despite the slag cement has been used in the USA for more than 100 years, the feasibility of replacing PC blinders should be further investigated.

Nevertheless, it is estimated that the measures required to adapt to climate change, such as increasing design cover by up to 8 mm or increasing concrete compressive strength by one grade would imply an increment of 1-3% of the construction costs (M. Stewart et al. (2012)). Other authors (Bastidas-Arteaga & Stewart (2016); M. Stewart & Bastidas-Arteaga (2019)) have addressed the cost-benefit analysis of increasing the cover thickness to 5 or 10 mm in

different structural components under different climate scenarios. They conclude that in many cases, this measure is not cost-effective. The factors affecting the efficiency of this type of adaptation measures do not depend only on the structural typology and member size, but also on the climatic conditions and the future discount rate.

Keeping in mind the impact that Eurocodes has in the economy of the State Members, standardising adaptation measures in a context of high uncertainty, where if the impact of climate change is underestimated by considering very optimistic scenarios, it would result in a significant reduction of the service life of new infrastructure and buildings, or if it is overestimated, in unnecessarily expensive investment. Apparently, there is not a fair solution.

4.2 Resilience-Based Approach

In the last years, there has been a clear shift from the traditional risk-oriented approaches to a perspective based on resilience. The need for a resilience-based approach has been made evident in those cases where either, the lack of knowledge about the potential hazards or their level of uncertainty was so large that the existing risk was underestimated. For that reason, the problem of climate change along with its associated uncertainty is pushing decision-makers to implement measures that boost resilience (Nogal & O'Connor (2018a); Val et al. (2019)). In this point it is important to note that risk- and resilience-based approaches are not incompatible; on the contrary, the latter complements the first one by adding a temporal dimension to the problem (Nogal & O'Connor (2018b)) and proposing a number of strategies to increase the preparedness level of the system and so allow for an adaptive response over time.

Therefore, to approach the issue of climate-change induced corrosion from a resilience-based view, the adaptation measures should be twofold. On the one hand, the measures addressing the impact of climate change that is certain should be implemented in the design stage, through cost-effective measures. More sustainable concrete mixtures might play an important role in this stage. On the other hand, the uncertain impact of climate change should be covered in a post-design stage, that is, through maintenance. In that regard, Eurocodes should prescribe specific maintenance in relation to climate change. It is clear that there is room for improvement in terms of maintenance in the present standards, as they merely define maintenance, mentioning that the structure will be adequately maintained.

Such an approach implies a number of challenges. The values of CO2 concentration levels, temperature and atmospheric humidity associated with low values of uncertainty should be determined based on the climate models for the end of the structural design life. Let's call them certain thresholds (CTs) of the corrosion drivers.

The maintenance strategies, which should be studied during the design phase, should state the frequency of the maintenance activities in which the updated information regarding climate change will be used to determine the short- and medium-term actions. Also at the design phase, a number of potential actions should be included considering the future climatic scenarios along with their economic cost. Finally, an economic program to face the potential structural upgrades should be included to guarantee the economic viability of the project. It is noted that some of the required maintenance interventions are usually less cost-effective than the measures adopted

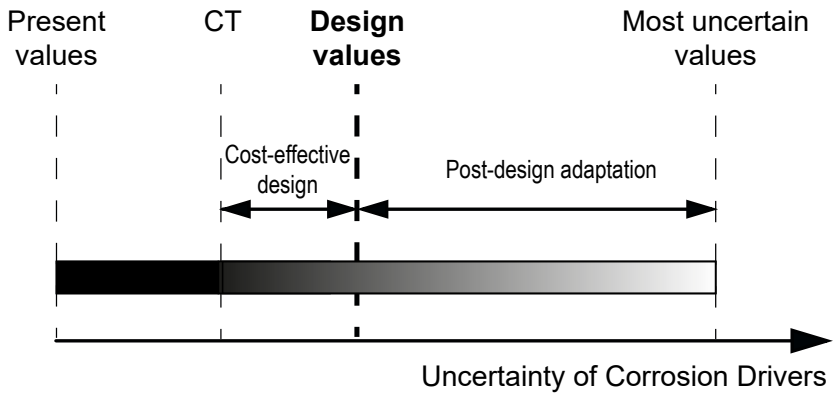

Figure 2: Representation of the design value of the corrosion drivers based on the cost-effectiveness of the adaptation measures and the uncertainty regarding the future value of the corrosion driver.

in the initial design. Therefore, the most cost-effective design should not cover only the CTs of the corrosion drivers, but more uncertain values in order to minimise the life cycle cost (see Figure 2). In other words, the new generation of Eurocodes should provide a design value of the corrosion drivers that will be established based on both, the uncertainty regarding the future value of the corrosion driver and the cost-effectiveness of the adaptation measures.

5 Conclusions

Beyond the geographical differences across countries, the main challenge of standardising "low-cost and no-regret adaptation measures" (Union Innovation (2013)) in the context of structural codes is posed by the uncertainty related to climate change, which mainly depends on the trajectory of greenhouse-gas emissions. For this reason, a resilience-based strategy for coping with climate change-induced corrosion has been suggested in this paper. Such an approach aims to provide the required adaptive capacity to the new structures in order to be able to respond to the uncertain future minimising the investment under unlikely scenarios. In that way, the strategy can be summarised as a climate change-adapted design plus an in-design maintenance plan. It is highlighted the need for an improvement of the structural Eurocodes in the area of maintenance.

Although the impact of climate change on temperature and atmospheric humidity is of interest in the context of RC corrosion, the CO2 levels should be also considered. The maintenance activities, which will be defined according to the on-going weather-related variables and CO2 emissions will further motivate countries to reduce their CO2 emissions in order to minimise their medium and long-term investments. Note that whereas climate change is a global issue, CO2 concentrations have an important local component, and thus, the proposed strategy will penalize more heavily those areas producing a larger amount of CO2.

This paper has shown a general framework for the adaptation of structural codes to climate change-induced actions under a resilience-based approach. Specific actions, such as mapping the future climate-related drivers of corrosion, the determination of the design values of these drivers, and the prescription of maintenance activities, should be further investigated.

Keywords: *Climate Change, Durability, Air Barrier, Moisture Response, Condensation.*

1 Introduction

In the 1980's and early 1990's, extensive analysis on air barrier system performance was conducted (Lux and Brown, 1989, Ojanen and Kumaran, 1995, Di Lenardo *et al.,* 1996) such that rational reference points for wall assembly design could be developed under historical Canadian climate patterns. The underlying intent was aligned with the fundamental needs to a) reduce energy use, and b) control condensation within moisture sensitive materials of a wall assembly.

This research work led to the development of the CAN/ULC S741 *Standard for Air Barrier Materials – Specification* and CAN/S742 *Standard for Air Barrier Assemblies – Specification*. Within these standards, performance criteria was established for the performance rating of air barrier materials and performance classification of air barrier assemblies based upon maximum allowable air leakage rates. The final component of this work was intended to be the development of a design approach that would integrate air barrier assembly performance with a building's design needs. Unfortunately, funding for the completion of this research and integration into building codes was halted before this work could be completed and published.

In the preparation of the 1995 National Building Code of Canada, under Part 5 *Environmental Separation*, there was a desire to define performance criteria for air barrier materials and air barrier assemblies. Since the research was not yet completed on air barrier assembly requirements, the ability to educate the design community on meeting minimum criteria was not yet possible. Hygrothermal computer modelling was still in its infancy and required significant assumptions on material performance to predict water vapour and moisture movement through assemblies, let alone the physics of air movement and condensation deposition. It was therefore accepted that codification of air barrier assembly performance was not reasonably practical.

By 2011 the Canadian Commission on Building and Fire Codes determined that it was

doi:10.23967/dbmc.2020.183

appropriate to consider air barrier assembly performance criteria in the National Building Code of Canada. The Standing Committee on Environmental Separation was tasked to:

> "*Develop quantifiable/explicit air leakage requirements for assemblies …and investigate the feasibility of creating a design approach to air leakage that would mimic the risk-based approach used for structural design where assemblies are designed to resist specified loads.*" (CCBFC 2011)

Parallel with this activity was the initiative to update CSA S478 *Guideline for Durability of Buildings*, with an emphasis on how appropriate building envelope design could be accomplished using the breakthroughs and improvements in computational hygrothermal modelling and analysis that had occurred in the intervening 20 years.

2 The Problem

In the development of the necessary changes to the National Building Code of Canada to adopt and implement a rational air barrier assembly design approach, it was identified that an exterior wall assembly durability risk assessment must assess whether various agents of deterioration will result in the;

- Shortening of the expected predicted service life of associated structural components, with resulting structural damage or risks of collapse, and/or
- Promotion of mold growth within the assembly, with resulting occupant health risks.

Air leakage through an exterior wall can be a significant contributor to these increased risks if resulting condensation moisture within the assembly leads to corrosion of metals, promotion of organic component deterioration, eg., wood decomposition, and/or promotion of mold growth. In order to assess the sensitivity of various wall assemblies to rates of air leakage, the following analysis methodology was developed.

3 Analysis Methodology

An analysis methodology was developed as described below. This paper focuses this analysis on one set of the variables to allow for assessment of the validity of the methodology.

Air leakage and its impact on wall assembly durability related to condensation and mold growth is a relative function of the following criteria:

1. Building occupancy characteristics – the internal hygrothermal loads imposed on the wall assembly. Different occupancy types affect interior hygrothermal loads. For the preliminary analysis in this paper, a residential occupancy was selected.
2. Building height – Building height directly influences wind loads and, therefore, air leakage rates (Shaw and Tamura, 1977). For this preliminary analysis, a single building height group was selected; a "low rise", 3½ storey residential property (<10 m tall).
3. Wall assembly composition – In this methodology, wall assemblies are assessed by the level of moisture tolerance of specific materials, the ability of the assembly to redistribute moisture within the assembly, and the ability of the assembly to dissipate moisture before it can cause deterioration or mold growth. For this preliminary analysis, a single wall assembly type was selected; a wood-framed wall with brick cladding reference wall, W1, as described in Section 3.1. Being of wood-frame construction, with the exterior masonry

cladding structurally attached to the wood studs, this assembly configuration is considered at relatively higher risk of potential negative impacts from moisture.

4. Building location climate characteristics – the historic and predicted future climate characteristics taken from a selected location in Canada. For the purposes of this initial analysis, the historic and future climate loads for the city of Winnipeg, Manitoba were selected as a baseline; Climate Zone 7A, 5670 HDD (NBC 2015). See Section 3.3.
5. Wall assembly air leakage rate – Variations in air barrier assembly air leakage rate were used to assess durability response. For the purposes of this initial analysis, air exfiltration due to imperfections in the air barrier system was calculated assuming air leakage rates of 0.05, 0.15 and 1.0 L/(s•m^2)@75 Pa. The first two represent air barrier assembly classifications A1 and A3 (CAN/ULC S472, 2011), while the final value was used to provide a quality check on the modelled results. An air leakage rate of 0.0 was also modelled to give a baseline for comparison of results and the ability to assess the impact of wind-driven rain without air leakage. The air leakage path is described in Section 3.2.

3.1 Reference Wall (W1)

Figure 1 shows the configuration of reference wall (W1). This wall assembly was chosen as an initial reference since a similar wall assembly was analyzed during the development work of the early 1990's (Ojanen and Kumaran, 1995, Di Lenardo *et al.,* 1996). This provided an initial comparison of this new methodology to the approach taken previously. The reference wall W1 has an effective RSI of 3.0 W/(m^2•K), which just meets current minimum thermal performance requirements for a low-rise residential Canadian building in Zone 7A that uses heat recovery ventilation (NBC, 2015). The results of this initial analysis should not be used to make design decisions. This approach was selected to facilitate comparisons of the results to earlier work.

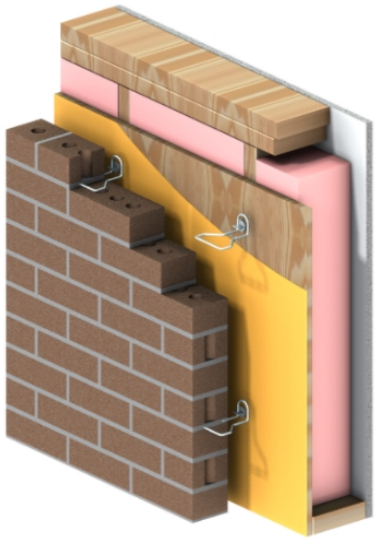

Figure 1. Reference wall (W1) schematic.

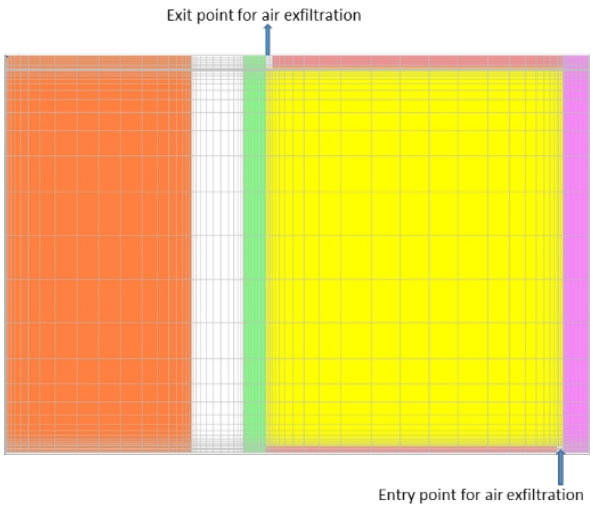

Figure 2. Modelled path of air movement.

The reference wall W1 comprises, from exterior to interior:

- Brick masonry (90 mm)

- Drainage cavity (25 mm)
- Exterior sheathing membrane (30-min building paper, 0.22 mm)
- Exterior oriented strand board sheathing (11 mm)
- Wood stud (spruce, 140 mm)
- Cavity insulation (glass fibre batt, 140 mm)
- Vapour barrier (6-mil polyethylene, 0.15 mm)
- Gypsum wallboard, primed and painted (12.7 mm)

3.2 Air Flow Path

To implement the air flow calculations, it was assumed that the air exfiltration occurs through an orifice in the air barrier system. The area of the orifice was estimated using the equation for sharp-edged orifice (ASHRAE, 2017). The orifice area was computed for each air leakage rate, assuming a rectangular orifice shape with a width of 0.05 m, the thickness of the opening was computed for each air leakage rate.

The risk of moisture condensation increases when the exfiltration path is longer, i.e., when air enters the insulation cavity at the bottom right corner and exits at the top right corner or vis-versa (Ojanen and Kumaran 1995). For this paper, it was assumed that air penetrates the cavity through a crack between the interior drywall and the flooring via imperfect contact between the bottom plate and the vapour barrier and exits through an opening between the top plate and the OSB sheathing, as shown in Figure 2.

3.3 Climate Data

Climate change weather data has been developed by the National Research Council that allows for balanced hygrothermal assessment of future building design needs (Gaur *et al.*, 2019). The data is comprised of hourly time-series of climate variables necessary to undertake hygrothermal simulations for a baseline time-period spanning 1986–2016 and 31-year long future time-periods when global warming of both +2°C and +3.5°C are projected (referenced to the baseline time-period). The climatic datasets were generated to capture the effects of the internal variability of the climate on future climate projections in fifteen hourly realizations that are part of the datasets derived from the large ensemble of climates simulated by the Canadian Regional Climate Model, version 4 (CanRCM4), each initialized under a different set of initial conditions in the CanESM2 global climate model. The generated datasets do not capture the uncertainty in climatic projections that may arise from the use of other global and regional climate models in simulating the regional climate and future climate projections.

For this study, only the 31-year time-periods corresponding to global warming of +3.5°C were considered; 1986-2016 Historical (“H”), and 2062-2092 Future (“F”). Each timeline comprises 15 realizations or runs. Since it can be onerous to consider all runs, it was decided that, for this preliminary study, only the median run (based on moisture index, MI) was selected from each timeline. The moisture index (Cornick and Dalgliesh, 2003) of a run was calculated as the average of the 31 yearly MI of that run.

For hygrothermal simulations in this study, two representative years were selected from the median run of the Historical and Future climate data. Since the purpose of the simulation is to address condensation risk, the first and second years were; 1) the year with the average annual temperature, and 2) that with the lowest annual temperature, of the 31-year data of the run. They

correspond respectively to the years 2008 and 2003 for Historical data, and 2092 and 2063 for Future data. Figure 3 compares the temperature, rain, relative humidity and wind speed profiles for the city of Winnipeg in the two years selected. The trend observed for the whole run is also present in the two-year data. It can be observed that; average temperature increases between the two timelines, while the wind speed decreases marginally. Rain and RH do not vary in average between the two timelines but more extreme annual RH values will be present in the future.

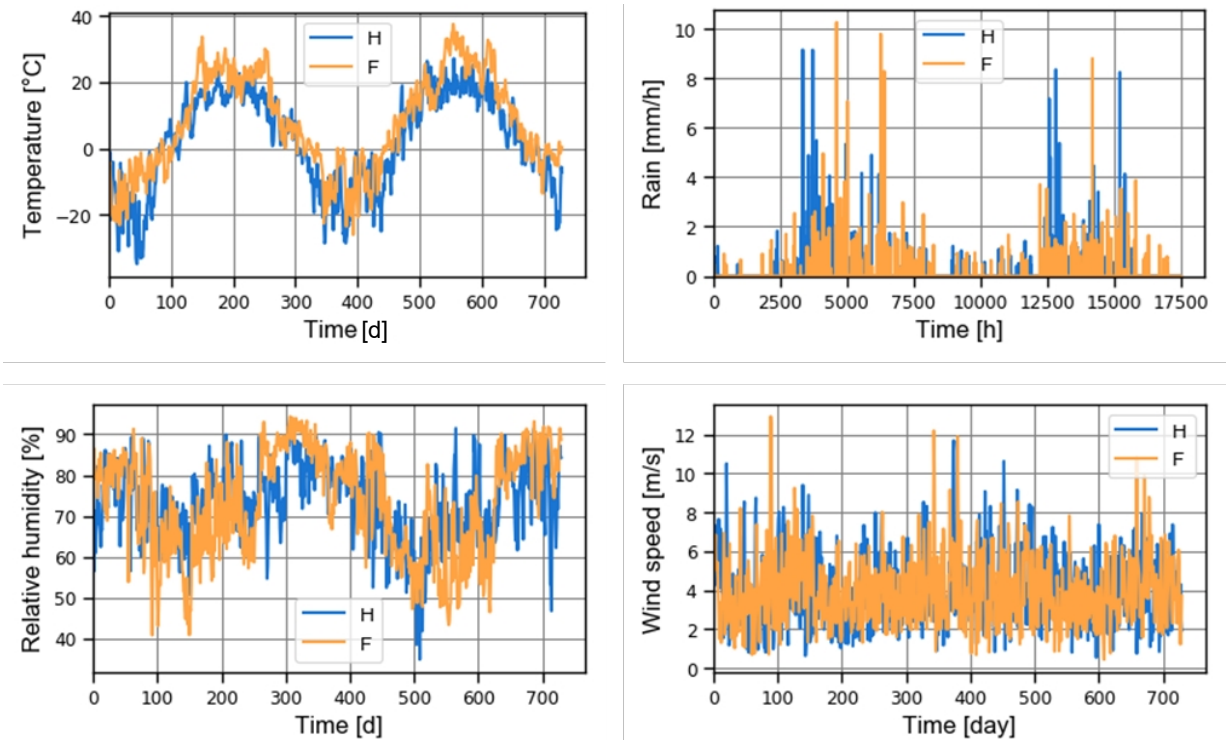

Figure 3: Comparison of the temperature, relative humidity, wind speed, and hourly rain distributions for the two years of historical and future climate data selected for hygrothermal simulations. Day 0 or hour 0 corresponds to January 1st of the first year.

3.4 Hygrothermal Model Used

DELPHIN 5, v5.9.4, was used for hygrothermal simulations. Important features of DELPHIN are its ability to handle wind-driven rain deposition and shortwave/longwave radiation as part of boundary conditions, as well as air leakage, moisture, and heat sources. A 2D configuration of the wall consisting of the vertical section passing through the insulation cavity was considered. This excludes the wood studs.

3.5 Boundary Conditions

Hourly data of climate loads (temperature, RH, wind velocity, wind-driven rain, shortwave and longwave radiations) on the cladding exterior surface were prepared according to DELPHIN specifications. Wind-driven rain was calculated using the ASHRAE (2016) standard method. Outdoor and indoor pressures were derived from differential pressure. The indoor T and RH were computed assuming that the building is equipped with heating and air conditioning with a

dehumidifier. Using ASHRAE (2016) formula, the indoor T varied from 21°C to 24°C and the indoor RH varied from 46% to 50%. For initial conditions, the T and RH of all layers were set to 21°C and 50% RH. As well the initial pressure was set to 101.3 kPa. Other parameters used for boundary conditions are summarized in Table 1. All material properties were obtained from the NRC material property database (Kumaran *et al.,* 2002).

Table 1. Boundary Conditions.

Boundary Conditions	Outdoor	Indoor
Heat transfer		
Convective heat transfer coefficient, α (W/m^{2}K)	$5.82 + 3.96\,V$*	8**
Shortwave absorption coefficient	0.6	-
Cladding longwave emission coefficient	0.9	-
Ground longwave emission coefficient	0.9	-
Ground albedo	0.1	-
Moisture transfer		
Water vapour transfer coefficient β (s/m)	$\alpha \times 7 \times 10^{-9}$	5.9 x 10^{-8}
Air leakage		
Air convection coefficient (s/m)	2	2

*: V is the wind velocity (m/s)
**: Indoor heat transfer coefficient encompasses both the convective and the radiative components

4 Results

The results of the preliminary analysis work relate to a combination of the following variables in the overall evaluation matrix:

- Residential occupancy
- Higher risk wall assembly
- Historical and Future weather data
- Low-rise building height
- Colder climate zone
- Air leakage rates of 0.0, 0.05, 0.15, and 1.0 L/(s•m^2)@75 Pa

The initial year was considered a conditioning year to allow stabilization after the initial boundary set points. Results are presented for relative humidity only, as the conditions for mold development were not reached over the two year simulation. Only results for the second year are discussed.

Preliminary results show that, based on the air path used, either; a) the bottom portion of the OSB in contact with the insulation, or b) the top left surface of the bottom plate, are more susceptible to condensation. For this paper, the results for the top left surface of the bottom plate was used to compare the impact of air leakage rates and climate change.

4.1 Effects of Air Leakage Rate and Climate Change

Figure 4 and 5 show the relative humidity profiles for each air leakage rate for the top left surface of the bottom plate for the reference wall (W1), for Historical (Figure 4) and Future (Figure 5) climate scenarios. Some key observations can be made:

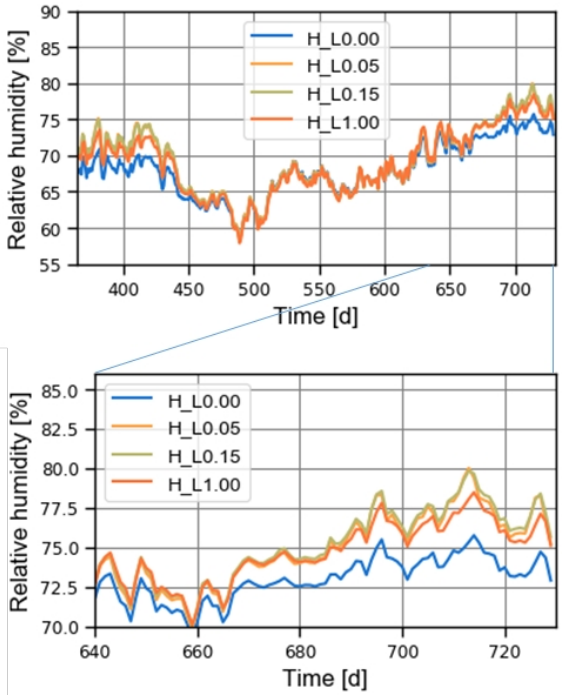

Figure 4. RH profiles, top left surface of bottom plate, reference wall (W1). Historic weather data.

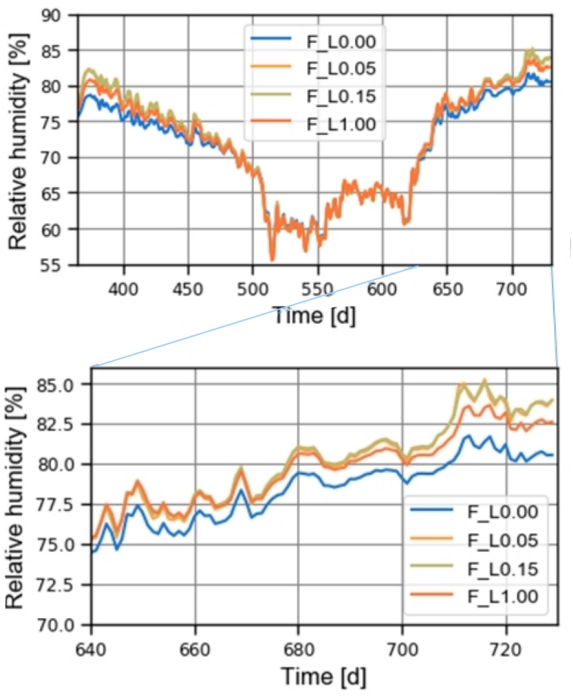

Figure 5. RH profiles, top left surface of the bottom plate, reference wall (W1). Future weather data.

Air Leakage Rate:

- All curves follow the same general profile as the 0.0 air leakage rate.
- All curves indicate that they have not normalized after the conditioning year, suggesting the length of simulation is insufficient to identify the final trends in moisture loading.
- Air leakage rates of 0.05 and 0.15 give almost identical results, regardless of climate scenario. Both of these air leakage rates show increased RH over the 0.0 rate.
- Air leakage rate of 1.0 has lower RH compared to 0.05 and 0.15. This is due to the cavity warming from the higher rate of warm air leakage (Ojanen and Kumaran 1995)

Climate Change:

- Differences of up to 4% for Historical climate and 5% for Future climate are found between the case with no air leakage and the cases with leakage rates of 0.05 and 0.15.
- The Future climate model shows that up to 85% RH is reached in wood materials, while in the Historical climate model, up to 80% is reached.
- Future climate data shows an increase of up to 8% in RH over Historical climate.
- Future climate shows sustained increase in RH versus Historical climate after the 710 day mark in the simulation. Historical climate shows a decrease in RH while Future climate shows sustained increase.
- The RH has not normalized for both climate scenarios, suggesting that the length of simulation is insufficient to provide suitable information on moisture loading.

5 Conclusions

This preliminary work is intended to document a methodology for assessment of air leakage rate and climate change on wall assembly durability. The initial assessment demonstrates that results that indicate the relative wall assembly performance under different air leakage rates can be used to establish inputs into a durability analysis. The results also demonstrate that differences between historical and future climate data suggests the methodology has merit.

However, it was also determined that conducting hygrothermal simulation using two years of climate data does not provide sufficient output data to assess stabilized moisture trends and mold development risks. Since mold development risk is a key criteria for long term durability assessment, future analysis work must use longer simulation durations.

Also critical is the length of the simulation "conditioning" time frame to allow the assembly component normalization of temperature and moisture conditions. Longer simulation timeframes will provide a better understanding of required conditioning durations.

Future work must analyze different; climate zones, building heights, building occupancies, wall assembly composition, and formal durability risk assessments for each result to understand the importance of air barrier performance on durability in a changing climate.

Abstract. *Hygrothermal simulations are commonly used to evaluate the moisture damage risk of building envelopes over the long-term. For such assessment to be accurate, a proper selection of representative climate data is required. A common method is the selection of a moisture reference year from a set of available long-term climate data. For instance, the IRC-led research consortium MEWS (Moisture Management of Exterior Wall Systems) developped the Moisture Index (MI) approach, which consists of a wetting and a drying function. Therefore, the reference year selection would be based on the MI ranking. ASHRAE 160 is adopting a procedure named "the severity index" for the selection of moisture reference year. Combining climate loads and durability criteria, this method allows to select more "severe" weather years, thus providing a more representative ranking of the weather data. The objective of this paper is two-fold. First, to compare the selection of the moisture reference year based on two different approaches for both historical and future climate loads. Second, the effect of chosen representative years is evaluated and compared to long-term simulation periods (of 31-years) based on the durability of building assemblies. The methodology includes hygrothermal simulations of two different types of wall assemblies located in three different Canadian cities under a changing climate. In general, higher mold index values were obtained by the long-term simulation and MRYs using Isev. Comparing the results of different models under future climates, the three methods were in good agreement, except for a brick wall facing WDR in Ottawa and Vancouver. This might be due to the Isev correlations were developed based on a north-facing stucco wall. In addition, for a north-facing wall, an extremely low mold index was predicted for Vancouver, compared to WDR direction. Thus, considering a north-facing wall as a criterion for performance evaluation might misrepresent the reality in some locations. Hence, both WDR and North orientations should be considered. A further study will be carried out to investigate the performance evaluation of Isev method for different types of wall systems and orientations.*

Keywords: *Moisture Reference Year, Durability,Wind-Driven Rain, Mold Index, Climate Change.*

1 Introduction

With the increased concern of climate change, severe rainfall events are more likely to happen. Therefore, water penetration in wall assemblies, resulting from the coupled action of rain and wind, may cause moisture to accumulate in building envelopes which can lead to degradation

of building materials; thereby, reducing their performance and service life. Heat, air and moisture (HAM) simulation tools are typically used to determine the risk to deterioration of buildings' elements. However, these tools neccessite the selection of representative climate data, as well as a good understanding of the moisture conditions, in order to provide an accurate assessessement (Delgado *et al.,* 2012). Therefore, a moisture reference year is usually selected from existing long-term climate data to represent a climate that allows a correct evaluation of the moisture stress on the building envelope (Zhou *et al.,* 2016).

Different methods were introduced in the past and have been used to define moisture reference years (Hagentoft and Harderup, 1993; Harderup, 1994; Geving, 1997; Kalamees and Vinha, 2004; and Zhou *et al.,* 2016). The IRC-led research consortium MEWS (Moisture Management of Exterior Wall Systems) developped the Moisture Index (MI) approach, which includes wetting and drying indices (Cornick *et al.,* 2003). The wetting index (WI) can be represented by the mean annual total horizontal rainfall or the annual wind-driven rain load. The drying index (DI) is based on the yearly evaporation potential – meaning the total hourly difference between the saturation vapor ratio and actual vapor ratio of the ambient air. Besides, ASHRAE (2010) has further developed MRY selection measures, combining climate loads and durability criteria to select more "severe" weather years, thus providing a more representative ranking of the weather data. This new approach – the Severity Index (Isev), consists of a simple equation that would be used to calculate the predicted damage function value for each year. Salonvaara *et al.* (2010) have demonstrated that Isev is the most reliable and the most accurate among all available methods in selecting the most severe years in terms of hygrothermal performance for climates in North America.

The objectives of this paper is to compare the selection of the moisture reference year based on the moisture index (MI) and the severity index (Isev) methods for both historical and future climate loads. The effect of representative years on the durability assessment of building assemblies is evaluated under different moisture loads including rain leakage. A comparison is thus made between the effect of selected representative years and the long-term simulations on the durability of building assemblies.

2 Methods

2.1 Weather Data

Weather data were provided by the National Research Council of Canada (NRC). A continuous time-series[1] of hourly climate data was prepared for a baseline time-period spanning from 1986-2016 and a 31-year long future time-period selected for when projected global warming of 3.5°C is expected to be reached in the future (Gaur *et al.,* 2019). According to projections from Environment and Climate Change Canada (2018), future projected data of a 3.5°C increase, will be reached between 2062-2092. Each data set includes 15 realizations; however, only the median realization based on MI was used.

[1] The full dataset can be accessed from: 10.17605/OSF.IO/UPFXJ.

2.1.1 Selection of Reference Years

The selection of reference years was made with the intention to test wall assemblies under more representative design weather years in the selected timelines. Moisture Index (MI) and severity index (Isev) have been chosen as the indices for selecting the reference years. Both methods were used to select one (1) year as the reference year.

Following the previous work performed at NRC (Cornick et al., 2003), MI for every hour (MI_h) was calculated as a function of hourly wetness (WI_h) and dryness (DI_h) indices. WI_h is calculated as normalized accumulated hourly rainfall. Dryness index (DI_h) was calculated as a function of the difference between saturation vapor pressure and vapour pressure of the ambient air (Δ_{vp}). The saturation vapor pressure, p_{vs}, was calculated using Equation (1), retrieved from the ASHRAE Handbook of Fundamentals (ASHRAE, 2009).

$$\ln(p_{ws}) = \begin{cases} \frac{C_1}{T} + C_2 + C_3T + C_4T^2 + C_5T^3 + C_6T^4 + C_7\ln(T) & for\ T < 0 \\ \frac{C_8}{T} + C_9 + C_{10}T + C_{11}T^2 + C_{12}T^3 + C_{13}\ln(T) & for\ T \geq 0 \end{cases} \quad (1)$$

Where, C_1 = -5.6745359 E+03; C_2 = 6.392524 E+00; C_3 = -9.6778430 E-03; C_4 = 6.2215701 E-07; C_5 = -5.6745359 E+03; C_6 = -9.4840240 E-13; C_7 = 4.163501 E+00; C_8 = -5.8002206 E+03; C_9 = 1.3914993 E+00; C_{10} = -4.8640239 E-02; C_{11} = 4.1764768 E-05; C_{12} = -1.4452093 E-08; C_{13} = 6.5459673 E+00; and T denotes the ambient temperature (K).

The magnitude of Δp_v is calculated using Equation (2):

$$\Delta p_v = p_{vs} - p_v \quad (2)$$

Wetting and drying indices are normalized following Equation (3):

$$I_{normalized} = (I - I_{min})/(I_{max} - I_{min}) \quad (3)$$

Normalized values of Δp_v were used as DI_h magnitudes. Wetting and drying were assumed to be of equal importance and thus they were given equal weight in the determination of the moisture index (MI_h).

$$MI_h = \sqrt{(1 - DI_{h,norm})^2 + {WI_{h,norm}}^2} \quad (4)$$

Based on ASHRAE (2010), the severity index (Isev) for each year is calculated according to Equation (5):

$$I_{sev} = 108307 - 241.E_v - 1391.I_{cl} - 312326.\phi + 183308.r_{wd} + 15.2.p_v + 27.3.T^2 + 261079.\phi^2 - 0.00972.p_v^2 \quad (5)$$

Where, E_v is the solar radiation (W/m^2) incident on the wall; I_{cl} is the cloud index (0-8); ϕ is the relative humidity; r_{wd} is the wind-driven rain (kg/m^2.h) on the wall; p_v is vapor pressure (Pa), and T is the ambient temperature (°C). As specified by the method, Isev was calculated for the orientation receiving the least solar radiation (North). All the weather parameters were calculated in terms of annual average values for each year; using the number of hours during that year.

Once both annual average MI and Isev values were available, the years comprising the chosen time-period were ranked in ascending order, and the year corresponding to the 97th percentile, (ranked second out of the 31 years) in each time-period was chosen as the MRY. Figure 1 shows the annual average values of MI and Isev at each location, for a wall facing North.

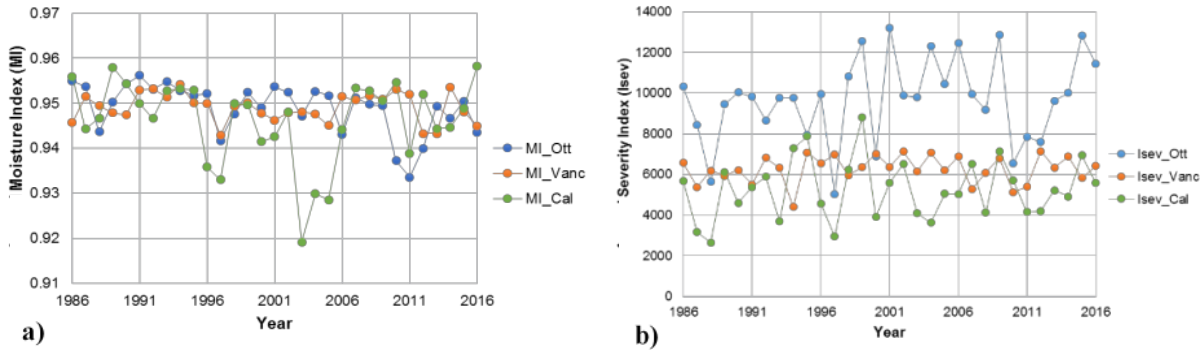

Figure 1. Comparison of annual moisture index MI (a) and Isev (b) in Ottawa (Ott), Vancouver (Vanc) and Calgary (Cal) for a North-facing wall based on historical data.

Table 1 summarizes the selected MRYs based on different locations under historical and future time-periods.

Table 1. Summary of selected moisture reference year and their MI and Isev values.

City	Data	MRY (MI)	MRY (Isev)
Ottawa	Historical	2010 ***(0.937)***	2009 ***(12856.4)***
Ottawa	Future	2085 ***(0.918)***	2069 ***(18720.0)***

2.2 Wall Assemblies

Two (2) wood frame wall assemblies, typical of Canadian residential building practice, were selected for this study. They differ only in their cladding type: stucco (19 mm) and brick (90 mm). A drainage cavity of 25mm and 10mm was designed for the brick and the stucco wall, respectively. Figure 2 shows the configuration of the wall assemblies.

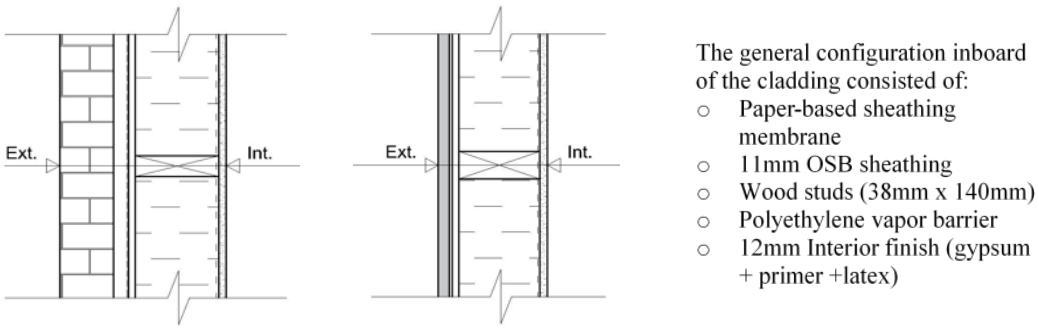

Figure 2. Wall assemblies' configuration for brick (a) and stucco (b).

2.3 Wall Orientation

This study was carried out for two wall orientations for each location: the orientation with the least annual solar radiation – meaning on a North-facing wall (N), and the orientation with the highest amount of annual wind-driven rain, calculated according to ASHRAE (ANSI/ASHRAE, 2016). The critical orientation (WDR) is presented in Table 2 for each city.

Table 2. Characteristis and wall orientation for selected Canadian cities.

City	Lat.	Long.	Climate zone	Time zone	Critical orientation (WDR)
Ottawa	45.25°	75.42°	6	-5	202.5° (SSW)
Vancouver	49.28°	123.12°	5	-8	157.5° (SSE)
Calgary	51.05°	114.07°	7A	-7	337.5° (NNW)

2.4 Boundary Conditions

2.4.1 Indoor Boundary Conditions

The indoor temperature and relative humidity conditions were selected as constants and set to 21°C and 50%, respectively. For the indoor vapour diffusion and the heat conduction, the transfer coefficients were assumed as $1.52*10^{-8}$ s/m and 8 W/m^{2}K, respectively.

2.4.2 Outdoor Boundary Conditions

Outdoor boundary conditions include heat conduction, vapor diffusion, wind driven rain, short wave radiation and long wave radiation. To compute the longwave radiation, the boundary layer method was selected in Delphin. The required longwave emission coefficient of the building surface was set to 0.9, whereas the convective heat transfer coefficient was calculated based on Equation (6):

$$h_{ce} = 4 + 4.v \quad (6)$$

Where, v is the wind speed. The reflection coefficient of the surrounding ground (albedo) was 0.2 and the absorptance coefficient of the cladding surface was equal to 0.6 for brick and 0.3 for stucco.

2.4.3 Wind-Driven Rain

WDR was calculated using the ASHRAE method (ANSI/ASHRAE, 2016) for a 3.5 storey building located in the suburban area. Assuming a medium exposure factor, the rain exposure factor (F_E) and the rain deposition factor (F_D) were set to 1.0 and 0.5, respectively.

2.5 Initial Conditions

The wall was first condionned with suitable climate and simulations were performed for a period of 7 successive years using the average year (based on MI ranking). Once a steady cyclical pattern was observed at the exterior side of OSB, the average temperature and relative humidity for each material were exported and used as initial conditions.

2.6 Performance Attributes for Assessing Wall Performance

One important performance attribute for wood-based building elements is the resistance to mould growth. Under favourable conditions of temperature and relative humidity, mould fungi can grow on building component surfaces and this is often regarded as problematic in respect to indoor air quality (Wang *et al*., 2018). OSB is susceptible to mould growth if subjected to these favourable conditions. The outward layer of the OSB sheathing (~ 0.1 mm) was selected as the critical location for this study. The mould growth index was calculated using Viitanen's model implemented in DELPHIN (Viitanen *et al.,* 2000).

Several trials were made to select the air change per hour (ACH) value in drainage cavities, in a way that the mold index stabilizes around a value of 3 during the long-term simulation. Different values of ACH were set based on the cladding type and the location (Table 3).

Table 3. ACH values selected according to different cladding and locations for North and WDR orientations.

Ottawa		**Vancouver**		**Calgary**	
Brick	Stucco	Brick	Stucco	Brick	Stucco
6	*10*	*12*	*40*	*3*	*5*

2.7 Simulations

Manual discretization was adopted; for the sheathing membrane and the vapour barrier, an equidistant mesh of 3 elements was assumed. Other materials were divided into three sections – with first and last sections of equal thicknesses. A fine and variable mesh was used for the latter, while an equidistant mesh was opted for the middle section.

A moisture source of 1% of the WDR was assumed and applied on the exterior wythe of the sheathing membrane – on the first layer of the membrane (ANSI/ASHRAE, 2016).

Each selected MRY was repeated 5 times; however, evaluation was made only for the 5th year. These results were compared to those of a long-term simulation of 31 consecutive years.

3 Results and Discussion

Figure 3 shows the predicted risk to mold growth on the outer layer of OSB for different types of walls under different climate loads, which were selected based on different reference year methods, i.e., MI and Isev. Results are compared to that of a long-term simulation (31-Y) in three Canadian cities. The 31-Y results were selected for the year having the second highest mold index value. In general, the differences amongst the mold indices vary with the cladding type, the location (climate) and the wall orientation. Comparing the impact of MRY selection method, in most of the cases, the mold index is found higher based on Isev selection – meaning that MRYs selected according to Isev predicted a higher damage risk than years selected based on MI. Moreover, results of the 31-Y seem more in accordance with Isev.

For a brick wall (Figure 3a), mold index values are found higher for Isev and 31-Y, and in some events, especially in Ottawa, results for Isev seem to overestimate the risk. This may be due to the difference between the MRYs selected by Isev and the years corresponding to the 2nd highest mold index value for the 31-Y. It seems that the climate selected based on Isev is more favorable for mold growth. However, for stucco (Figure 3b), results are found to be more consistent; with 31-Y estimating highest mold index values. Moreover, the difference between the methods had a greater impact on the wall performance. For instance, both 31-Y and Isev

estimated a considerable risk to mold growth compared to results given by MI. For a wall facing North in Ottawa, a maximum mold index value of 4.5 and 5 was attained for historical and future climate, respectively for 31-Y. Using the Isev method, values of 4 and 4.8 were reached. However, using MI, maximum values of 1 and 2.8 were attained for different climates. Likewise in Calgary, the difference in mold prediction risk varried considerably between the methods.

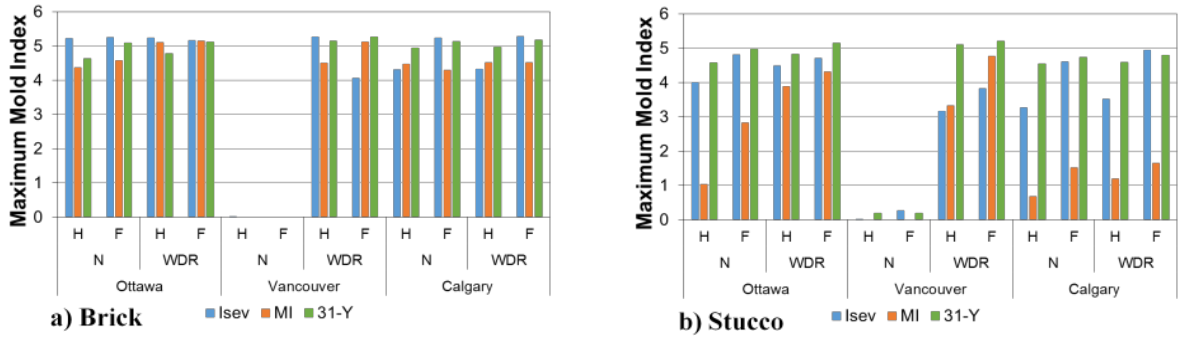

Figure 3. Summary of maximum mold index predicted through a long-term study (31-Y) and using MRYs given by Isev and MI for historical (H) and future (F) climatic loads, for walls facing North (N) and WDR.

It can be also observed that in Vancouver, when the wall is facing North, all three methods predicted no risk of mould growth. This can be explained due to a low amount of WDR impiging on a North facing wall in that city. It is also important to note the effect of the selection method on the assessment of the climate change impact on the hygrothermal response of walls. Mold index values increased under future climate loads in most of the cases, to the exception of a brick wall facing towards the WDR in Ottawa and Vancouver using Isev. Results showed a slight decrease in mold index for Ottawa but a considerable decrease for Vancouver (Figure 3a). The severity index calculated was based on the correlations developed for a North-facing orientation. Discrepancy may exist when the same year is used to evaluate walls oriented towards the prevailing WDR direction for cities with WDR direction distinctly different from the North and for absorptive cladding that is more sensitive to WDR. Further investigation is required on the aspect of wall orientation. The impact of climate change is more consistent for the stucco wall (Figure 3b), where the difference of mold index is increased by up to 2 indices (for the case of a north oriented wall in Ottawa and Calgary).

4 Conclusions

In this study, the effect of selecting MRYs on the expected long-term moisture performance and durability is investigated from results derived from hygrothermal simulations of typical wood-frame wall assemblies in three Canadian cities. The durability performance was assessed based on the potential to mold growth on the OSB sheathing incorporated in stucco and brick veneer clad wall assemblies. Results showed that the use of different climate load indices (*i.e.* MI or Isev) can lead to different conclusions on the moisture performance of these types of wood-frame walls. In general, higher mold index values were obtained from the long-term simulation and MRYs using Isev for both walls in all three locations. Comparing the results of different models under future climates, the three methods were in good agreement, except for a brick wall facing WDR in Ottawa and Vancouver. This might be due to the fact that the Isev correlations were developed based on a North-facing stucco wall (ASHRAE, 2010). In addition,

for a north-facing wall, an extremely low mold index was predicted for Vancouver, compared to the value of the mould index as was attained from simulations when the prevailing WDR direction was used as input to the climate loads. Thus, considering a North-facing wall as a criterion for performance evaluation might misrepresent the actual moisture behavior in some locations. Hence, for each location, both WDR and North orientations should be considered. A further study will be carried out to investigate the performance evaluation of Isev method for different types of wall systems and orientations.

Freeze-Thaw Risk in Solid Masonry: Are 'Hygrothermal Response Based' Analyses Mandatory when Studying the Sensitivity of Building Envelopes to Climate Change?

Isabeau Vandemeulebroucke[1], Steven Caluwaerts[2] and Nathan Van Den Bossche[1]

[1] Building Physics Group, Department of Architecture and Urban Planning, Ghent University, Belgium, isabeau.vandemeulebroucke@ugent.be.

[2] Atmospheric Physics Group, Department of Physics and Astronomy, Ghent University, Belgium, steven.caluwaerts@ugent.be.

Abstract. *The 5th Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) reports important evolutions in the climate system. These changes are likely to affect the durability of the built environment. Although many contemporary studies investigate the future energy efficiency of buildings, research on the impact of climate change on the hygrothermal behaviour and degradation of building envelopes is rather scarce. Using climate projections, we studied the advantage of 'hygrothermal response based' analyses over 'climate based' analyses when assessing the impact climate change on façades. This paper presents a sensitivity study on solid masonry wall assemblies, before and after internal retrofitting, using three RCP (Representative Concentration Pathways) projections of the ALARO-0 Regional Climate Model at the grid point of Brussels (BE). The findings suggest the necessity of a 'hygrothermal response based' analysis to study the sensitivity of the building envelope to climate change. Moreover, the largest sensitivity is observed for RCP 8.5, the scenario having the highest projected greenhouse gas concentrations by the end of the century.*

Keywords: *Hygrothermal Response, Building Envelope, Climate Change, HAM Simulation, Masonry.*

1 Introduction

The Fifth Assessment Report of the Intergovernmental Panel on Climate Change reports significant changes in the climate system (IPCC, 2014). Since pre-industrial times the global surface temperature has increased ca. 1°C, and is projected to rise further during the 21st century. Along with that, extreme events are influenced by the increased greenhouse gas (GHG) emission in our atmosphere. Across Europe, heat waves and extreme precipitation are likely to become more frequent, more intense and separated by longer periods of drought, and the number of freezing days is likely to decrease (IPCC, 2014).

The built environment will be significantly affected by climate change (de Wilde and Coley, 2012; Fatorić and Seekamp, 2017). Many studies focus on the energy efficiency of our building stock regarding climate change. This study investigates the climate sensitivity of retrofitting strategies of historical buildings to increase their thermal resistance and airtightness. As exterior retrofitting of heritage buildings is often not allowed due to the façade's historical value, interior retrofits may be the only solution to improve the energy efficiency of the building envelope (Straube and Schumacher, 2010). Studies on the durability of internally retrofitted solid masonry show that this strategy might increase the risk of moisture-related damages, as freeze-thaw action. However, few studies investigate the impact of climate change on the long term

durability of these retrofits, and there is no sound methodology to implement climate projections in Heat Air Moisture (HAM) simulations.

This paper aims to study the difference between a 'climate based' and 'hygrothermal response based' analysis when assessing the freeze-thaw risk in solid masonry, before and after internal retrofit, with regards to climate change.

2 Methodology

The 1-dimensional HAM simulations in this study are performed in Delphin 5.9.5, which has been successfully benchmarked in the past by the HAMSTAD Benchmark exercises a.o. (Nicolai, Grunewald and Zhang, 2007).

2.1 Climatological Conditions

This work applies the 4-km resolution ALARO-0 Regional Climate Model (RCM) data of the CORDEX.be project (Termonia *et al.,* 2018) to investigate the climate impact. Climate data for the period 1950-2100 are selected for the Uccle gridpoint. For the period 1950-2005 the historical run will be used, while for the 2006-2100 timeframe different climate projections forced by scenarios for future GHG emissions are considered to investigate the climate sensitivity. The Representative Concentration Pathways used in this study are RCP 2.6, RCP 4.5 and RCP 8.5, representing respectively a low, intermediate and high radiative forcing (IPCC, 2014).

The modelled meteorological parameters, used in this study, are air temperature (T_{air}), relative humidity, wind direction and velocity, precipitation, direct and diffuse shortwave radiation and downward longwave radiation. Climate model data are known to be subject to systematic biases. As this manuscript is focussed on the sensitivity (and no absolute values) of the HAM simulations to climate scenarios, no bias correction has been applied on the data.

The indoor T_{air} and relative humidity are calculated based on the standard ISO 13788, and range between 20-25°C and 35-65% respectively, depending on the outdoor T_{air}.

The HAM model is pre-conditioned by repeating the 1st year of the dataset four times, given this year does not represent extremes. The conditioning years are not part of the evaluation.

2.2 Wall Assemblies

Two variants of a solid masonry wall assembly are considered. In both cases the masonry has a width of 300 mm, and is selected from the Delphin Material Library, i.e. 'Historical Brick Cluster 4'. The original wall assembly is finished with 12 mm of gypsum plaster (interior). The second masonry wall (without plaster) is retrofitted at the interior with mineral wool (150 mm), open vapour barrier (sd = 2.3 m) and gypsum board (12 mm). The masonry is assumed homogenous brick, as this simplification is found acceptable by Vereecken and Roels (2013).

The critical degree of moisture saturation for freeze-thaw damage to occur, is not known for the selected brick material. Therefore, the arbitrary value of 25% ice volume rate is used (Straube, Schumacher, & Mensinga, 2010). The critical moisture content (MC_{crit}) for the masonry is 82.5 kg/m³. Note that this is a conservative value, considered as worst-case scenario.

2.3 HAM Simulations

Five situations are analysed: i) the original solid masonry wall facing the south-west (SW) (225°), the prevailing wind-driven rain (WDR) direction in Uccle, for RCP 8.5, ii-iv) the retrofitted wall facing SW for RCP 2.6, 4.5 and 8.5, and v) the retrofitted wall facing the north-west (NW) (315°) for RCP 8.5, to study an orientation receiving less solar radiation and a smaller WDR load.

The climate data and simulation results are analysed using the moving average per period of 30 years. All simulation results are analysed at a depth of 5 mm in the masonry (exterior side), as this is generally a critical depth for freeze-thaw action (Vandemeulebroucke *et al.* 2019).

3 Results

3.1 'Climate Based' Analysis

The moving average of the annual mean air temperature ($T_{air,mean,annual}$) confirms the warming trend over the 21st century especially for RCP 4.5 and 8.5, illustrated by the dotted lines in Figure 1 (IPCC, 2014). For the RCP 2.6 scenario which assumes strong mitigation measures, the temperature reaches a maximum around 2050. The warming over the whole period is ca. 1°C, 1.5°C and 3°C for RCP 2.6, 4.5 and 8.5 respectively. $T_{air,mean,winter}$, i.e. the average temperature during the period December-January-February, confirms the temperature trends. Analysed frost indices are the annual hours of frost and the number of freeze-thaw cycles based on temperature ($FTC_{T,air}$), considering freezing at -5°C and thawing at 0°C. These threshold values are selected anticipating the 'response based' analysis, as Straube and Schumacher (2006) suggest that no significant freeze-thaw damage occurs between 0°C and -5°C. Both the hours of frost (T_{air}) and the number of $FTC_{T,air}$ decrease by one third for RCP 4.5 and two thirds for RCP 8.5. The climate change signal for RCP 2.6 is less clear.

Furthermore, the annual precipitation amount is increasing for RCP 4.5 (7-10%) and 8.5 (9-12%). Again the climate change signal for RCP 2.6 is less clear (Figure 2). Changes are not as uniform as for $T_{air,mean}$, since precipitation has stronger year-to-year variability. The fraction of annual precipitation occurring in winter is ca. 25% and increases by 0-4% for RCP 4.5 and 8.5.

The other climate variables, e.g. as wind direction and velocity, show only small changes over the course of the 21st century (not illustrated here).

3.2 'Response Based' Analysis

The 'response based' analysis indicates that the mean temperature at 5 mm in the masonry ($T_{5mm,mean}$), illustrated by the solid lines in Figure 1, follows the same trend as the $T_{air,mean}$. However, the offset between the climate data and the simulated response of the masonry differs per season, wall assembly and orientation, ranging between -0.3°C–2.2°C. The offset slightly decreases towards the end of the 21st century. Except for the retrofitted walls in winter, $T_{5mm,mean}$ is higher than $T_{air,mean}$. The highest values are observed for the original wall for RCP 8.5 due to the lack of thermal insulation. The differences between the climate and response data are smaller in winter compared to the rest of the year. Whereas wall surfaces can heat up to temperatures higher than 40°C due to shortwave radiation, these surfaces are cooled down below T_{air} due to longwave radiation exchange with the sky hemisphere. Besides, the heat capacity of the brick masonry and embedded moisture both influence the $T_{5mm.}$ Therefore, the

hours of frost (threshold of 0°C) and the number of FTC_T (freezing at -5°C and thawing at 0°C) differ between the climate data (based on T_{air}) and simulation results (based on T_{5mm}), but also between the individual situations (Figure 1).

The hours of frost and FTC_T at 5 mm depth in the masonry follow the decreasing trend of the climate data for RCP 4.5 and 8.5 (Figure 1). Here, the offset between the climate and simulated results ranges between -25% – 20%, and -57% – 6%, respectively for both indices. The hours of frost (T_{5mm}) is the highest for the retrofitted SW-wall, whereas the retrofitted NW-wall entails almost equal values compared to the climate data. The hours of frost (T_{5mm}) is the lowest in the original wall. Moreover, the number of $FTC_{T,5mm}$ is the highest for the retrofitted NW-wall during the historical period. Whereas later on, the retrofitted NW-wall is similar to the retrofitted SW-wall, for RCP 8.5. The number of $FTC_{T,5mm}$ is the lowest for the original wall. Differences become smaller towards the end of the century.

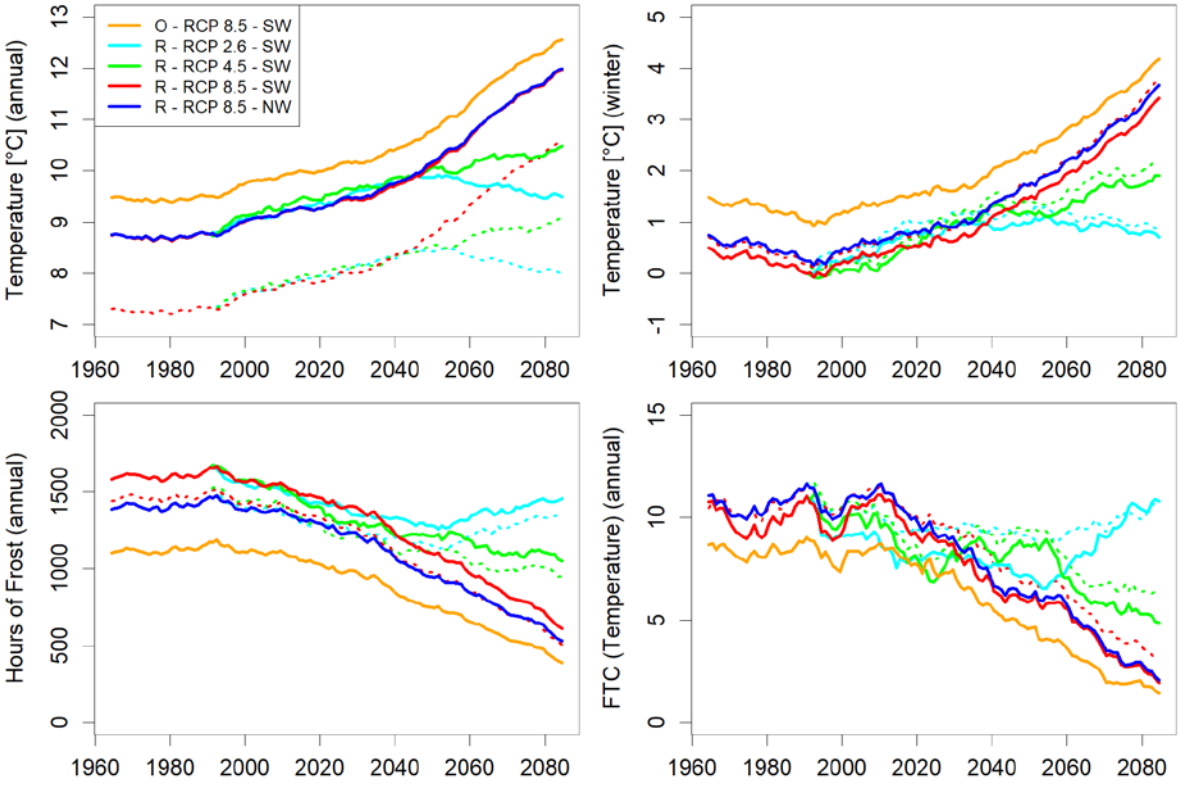

Figure 1. Moving average of the annual mean temperature (top, left), the mean temperature in winter (top, right), the annual hours of frost (bottom, left) and the annual number of FTC (freezing -5°C/ thawing 0°C) (bottom, right) at 5 mm depth in the masonry (O: original, R: retrofitted). The dotted lines present the air temperature climate data (cyan: RCP 2.6, green: RCP 4.5 and red: RCP 8.5).

To analyse the moisture management, WDR load and moisture content at 5 mm depth (MC_{5mm}) are evaluated. The drying potential is outside the scope of this paper. The WDR load depends on a complex relation between precipitation, wind velocity and wind direction, but also on catch ratio, height and wall orientation a.o. (Blocken and Carmeliet, 2010). As expected, the order of magnitude between the precipitation ('climate based') and WDR load ('response based') differs significantly (Figure 2). Besides, there is a large difference in WDR load

between the two orientations. As there is no significant climate change signal for wind direction and velocity, the increase in annual WDR load for the SW-orientation can be related to the increasing precipitation. For the NW-orientation, the WDR load remains low and there is no clear climate change signal. Analysing the percentage of precipitation and WDR load in winter, there can be observed that the percentage is significantly higher for the SW-WDR load (+-40%), than the precipitation amount (+-25%) (Figure 2). For a given precipitation amount, the percentage SW-WDR load in winter is higher because of higher wind velocities during this season. Both the precipitation and WDR load illustrate an increase in percentage during the winter, meaning that the climate change signal is not constant over the year.

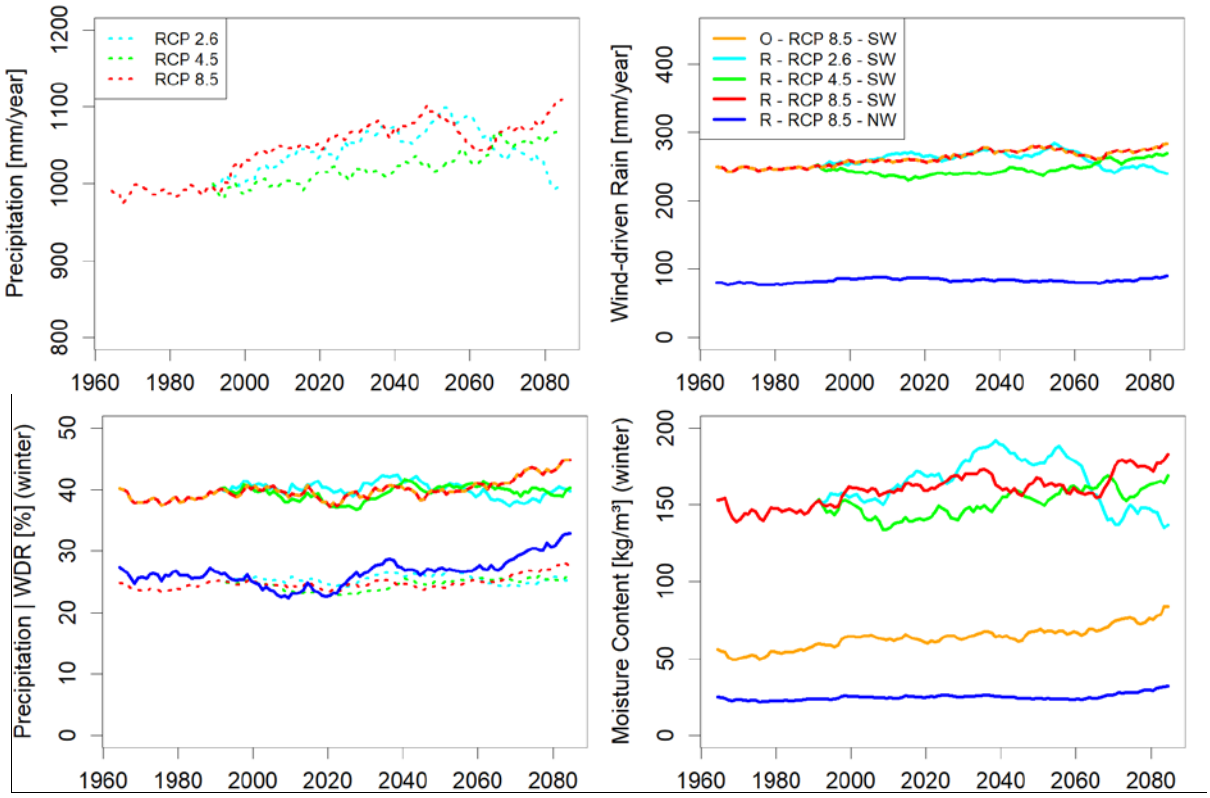

Figure 2. Moving average of the annual precipitation (top, left), the annual wind-driven rain load (top, right), the fraction of annual precipitation or WDR occurring in winter (bottom, left) and the moisture content in winter at 5 mm depth in the masonry (bottom, right) (O: original, R: retrofitted). The dotted lines illustrate the climate data (cyan: RCP 2.6, green: RCP 4.5 and red: RCP 8.5).

The $MC_{5mm,mean,winter}$ increases towards the end of the 21st century for RCP 8.5 (Figure 2). Especially for the original wall, which is SW orientated, and the retrofitted SW-wall, there is a clear climate change signal. The difference between the wall assemblies is significant. The $MC_{5mm,mean,winter}$ of the retrofitted SW-wall is ca. 3 times larger than the original wall, and ca. 6 times larger than the retrofitted NW-wall. The $MC_{5mm,mean,winter}$ in the retrofitted SW-wall exceeds the MC_{crit} for all three RCP projections.

Please note that the differences between the individual RCP projections for the WDR load and MC, considering the retrofitted SW-wall, are smaller than the differences between the wall assemblies and orientations (Figure 2). This means that the uncertainty about the WDR load

and MC induced by the variation in wall assembly and orientation is significantly larger than the uncertainty induced by the RCP projections.

Furthermore, the number of $FTC_{T,5mm}$ cannot be directly compared to the $FTC_{crit,5mm}$ in the masonry, as the latter is related to both the temperature and moisture saturation degree in the pore matrix. However, the trend lines of both indices are analysed. As for the hours of frost (T_{5mm}) and $FTC_{T,5mm}$, a decreasing trend in number of $FTC_{crit,5mm}$ is observed for RCP 4.5 and 8.5, but this trend is less pronounced (Figure 1 and 3). Although the number of $FTC_{T,5mm}$ in the retrofitted NW-wall (RCP 8.5) is the highest in comparison to the other situations (Figure 1), the number of $FTC_{crit,5mm}$ is the lowest for that wall and remains close to zero (Figure 3). The number of $FTC_{crit,5mm}$ for the retrofitted SW-wall in RCP 8.5, on the other hand, is the highest amongst the different situations for the three RCP's. The climate change signal shows a decrease of 20% and 45% for RCP 4.5 and 8.5, respectively. The original wall (RCP 8.5) displays a significantly lower number of $FTC_{crit,5mm}$, but higher than the retrofitted NW-wall. No clear climate signal is observed for the original wall. Additionally, Figure 2 illustrates the number of $FTC_{crit,5mm}$ per year. Please note that the annual variation is very large, even for the original wall assembly.

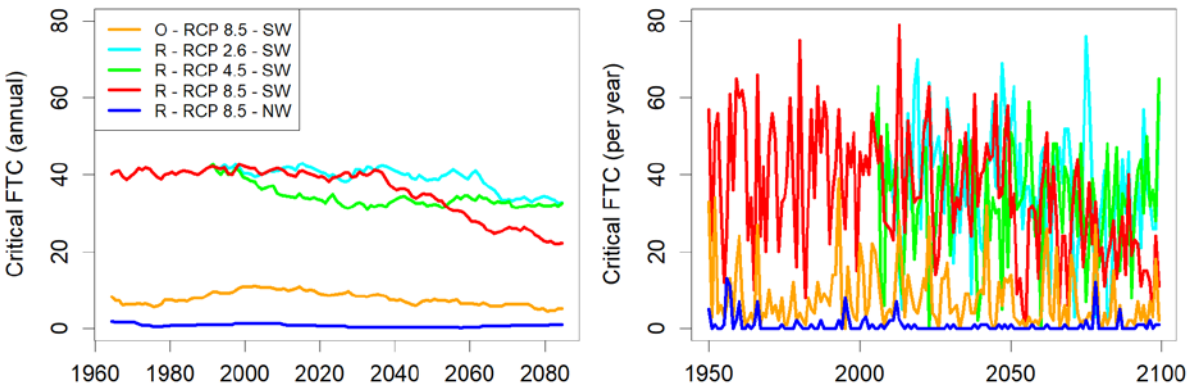

Figure 3. Moving average of the annual number of critical freeze-thaw cycles (FTC) (left) and the number of critical FTC per year (right) (O: original, R: retrofitted).

4 Discussion

The 'climate based' analysis illustrates that there is an increase in T_{air}, leading to a decrease in hours of frost (T_{air}) and $FTC_{T,air}$ by 33% for RCP 4.5 and 66% for RCP 8.5. This suggest that there might be a future decrease in freeze-thaw action in the brick masonry. The precipitation amount, on the other hand, is increasing over the course of the 21st century by about 10% for RCP 4.5 and 8.5. Besides, the percentage of precipitation in winter increases, and so does the precipitation amount during that season. This means that the moisture load is distributed more towards the cold season. An increase in moisture load may increase the likelihood of the MC_{crit} to be exceeded in the masonry upon freezing, potentially increasing the number of FTC_{crit}.

The 'hygrothermal response based' analysis assesses the combined effect of the climate data with a particular wall assembly for a given orientation. Although the T_{5mm} follows a similar trend compared to the climate data, there is an offset between the different trend lines depending on the wall assembly and orientation, but also on the season. As freeze-thaw action is sensitive

to small changes in temperature, this may lead to a different number of FTC_T in the masonry (Grossi *et al.*, 2007). Therefore, also the hours of frost (T_{5mm}) and $FTC_{T,5mm}$ display a significant offset per simulated case, respectively between -25% and 20%, and between -57% and 6%.

The WDR load increases by ca. 10% for RCP 4.5 and 8.5 over the 21st century as for precipitation, and the WDR percentage and load during winter increases. However, whereas the percentage in winter is ca. 25% for the precipitation amount and slightly higher for the NW-WDR load, the percentage SW-WDR load is ca. 40%. The increase in percentage over the century is larger for the WDR load than precipitation amount. Thus, the distribution of moisture load in winter is underestimated by the 'climate based' analysis.

In porous materials, no freeze-thaw damage will occur regardless the number of $FTC_{T,5mm}$ if the critical degree of moisture saturation is not exceeded (Fagerlund, 1973). Therefore, the moisture management of the building envelope is a key factor when assessing freeze-thaw risk. The $MC_{mean,winter}$ cannot be estimated based on only the climate data. The 'hygrothermal response based' results suggest increasing values of $MC_{mean,winter}$ throughout the 21st century, and large deviations between the simulated cases. The order of magnitude of $MC_{mean,winter}$ differs with a factor up to 6 between the combinations of wall assembly and orientation.

The retrofitted SW-wall for RCP 8.5 results in 20-35% more $FTC_{crit,5mm}$ than the original wall (same orientation). The number of $FTC_{crit,5mm}$ remains close to zero for the retrofitted NW-wall throughout the 21st century. Considering the number of $FTC_{crit,5mm}$, the climate change signal ranges between a decrease of 0% and 45%, depending on wall assembly and orientation. This means that the decrease of 66% in freeze-thaw action based on T_{air} (RPC 8.5), is mitigated by the increase in moisture load. Besides, it illustrates that the presence of interior retrofit and orientation induce a large uncertainty about the future freeze-thaw behaviour in solid masonry.

Future research should focus on the influence of biases in the RCM on the climate change signal when performing HAM simulations, especially when considering damage mechanisms at exact threshold values such as the freezing point. Whereas bias correction might seem an appropriate solution, this practice is not evident when dealing with the climate data for HAM modelling. The climate variables are related in a complex, non-linear manner, e.g. temperature and relative humidity. Correcting the variables without altering the correlations as well as maintaining physical laws is a difficult and non-trivial practice. As an alternative to bias correction, climate model ensembles, i.e. combining data from different RCM's, are used to estimate uncertainties and manage biases. Therefore, the results presented in this paper, which only consider one RCM, will be complemented with results from different high-resolution RCM's across Belgium in future studies.

5 Conclusion

Frost indices based on air temperature (T_{air}), i.e. considering the 'climate based' analysis, suggest that there is a decrease in frost action towards the end of the 21st century based on the ALARO-0 RCM. Both the hours of frost (T_{air}) and freeze-thaw cycles ($FTC_{T,air}$) are decreasing by 33% for RCP 4.5 and 66% for RPC 8.5. Precipitation amounts are increasing by about 10% for both RCP projections, and the fraction of annual precipitation occurring in winter is increasing as well. This may lead to higher future moisture loads, increasing the likelihood for the critical moisture content to be exceeded in the masonry upon freezing. The number of critical freeze-thaw cycles at 5 mm depth in the masonry ($FTC_{crit,5mm}$), resulting from the

'hygrothermal response based' analysis, is decreasing between 0-45% depending on wall orientation and the presence of interior retrofit. It is concluded that although freeze-thaw action is reduced, the increase in moisture load could counteract this and lead to an increase in frost related damages. Besides, orientation and presence of interior retrofitting entail large uncertainties about the future freeze-thaw risk of solid masonry. Therefore, HAM simulations, i.e. 'hygrothermal response based' analyses, are required when assessing the freeze-thaw behaviour of solid masonry, before and after retrofitting, with regards to climate change.

Impact of Climate Change in Building Envelope Design: The Performance to Withstand Mould Growth

Klodian Gradeci, Alessandro Nocente, Nathalie Labonnote and Petra Rüther

SINTEF Community, Høgskoleringen 7B, 7034, Trondheim, Norway, klodian.gradeci@sintef.no

Abstract. *Mould growth is a biodeterioration phenomenon that jeopardizes the integrity, functionality and durability of building envelopes. The performance to withstand biodeterioration depends on the critical hygrothermal conditions inside the envelope. These conditions are subject to the configuration of building envelopes, and climate exposure, accounting for both the outdoor weather and indoor environments' conditions. These critical conditions are likely to intensify in response to the changing climate, and hence, modification and adaptation of the envelopes' configuration will be required. An understanding of the implications of envelope configurations' choices is required to set up guidelines for forthcoming building envelope design. Parametric analyses are a potent source of insight to investigate how the input parameters influence the desired outcome. In light of this, a parametric analysis is carried out to investigate the performance of three building envelopes to withstand mould growth. The impact of climate change in the performance evaluation is accounted for by employing both historic and future climate change scenarios in which the global climate temperature change is forecast to be 3.5°C. Input parameters related to the simulation of mould growth are also investigated. Recommendations to current building envelope design guidelines are drawn for the performance evaluation to withstand mould growth.*

Keywords: *Building Envelope, Climate Change, Mould Growth, Performance Evaluation.*

1 Introduction

1.1 Context

Mould growth is a biodeterioration phenomenon that jeopardizes the integrity, functionality and durability of building envelopes. The performance to withstand biodeterioration depends on the critical hygrothermal conditions, on the investigated material within or outside the building envelope, and also on the chosen approach to assess these conditions. The hygrothermal conditions are subject to the configuration of building envelopes on the one hand, and climate exposure, accounting for both the outdoor weather and indoor environments' conditions on the other hand. These critical conditions are likely to intensify in response to the changing climate, and hence, the exposure and strains will increase suggesting that the performance of building envelopes will have to accommodate new exposure. As a consequence, modification and adaptation of the envelopes' configuration will be required. Design approaches to performance evaluation to withstand mould growth available in current guidelines are more qualitative rather than quantitative. In most cases it is stated that mould growth should be avoided; a common criterion is based on a combination of threshold values of maximum relative humidity and a range of temperature values. However, mould growth is a complex biological phenomenon and studies show that its mathematical representation should simultaneously account for at least four factors: temperature, relative humidity, time, and substrate (Gradeci, Labonnote, Time, & Köhler, 2017). Many mould models, mathematical representations of the mould growth process, have been proposed during the past decades, but very few of them have been implemented in standards. ASHRAE 160 is indeed the only norm to base their guidelines on a mould model (VTT), and it suggests the growth not to exceed VTT index 3. Meanwhile, new guidelines which account for the performance to withstand mould growth are being developed

for the design of building envelopes (Lacasse *et al.*, 2018). In light of this, two research question are raised: (i) What are the implications of climate change in the hygrothermal conditions within the building envelopes and how is this reflected in the performance evaluation to withstand mould growth?, and (ii) How can current building envelope design guidelines be improved when considering the performance evaluation to withstand mould growth?

1.2 Aim and Objectives of the Study

The aim of this study is twofold: (i) to understand the implications of climate change in the performance evaluation to withstand mould growth; (ii) to provide recommendation to current building envelope design guidelines regarding the performance evaluation to withstand mould growth. The objectives that address the aforementioned aims are:

- to analyse the variations of the hygrothermal conditions within the building envelope by comparing historical and future climates,
- to investigate the changes of simulated mould growth within the building envelope by comparing historical and future climates.
- to investigate the impact of the selection of input in the simulated mould growth, including the choice of sensitivity and material class, simulation runtime, and performance criteria.

2 Material and Methods

2.1 Building Envelopes

b) Wall Configuration 3

Figure 1. Three different wall assembly configurations.

2.2 Simulation and Evaluation of Mould Growth

2.1.1 Hygrothermal Simulations

The hygrothermal simulations are performed by WUFI 6.3 ® (Hartwig Michael Künzel, 1995), which has been validated by experimental studies for similar constructions (Mundt Petersen and Harderup, 2011). The initial conditions within the wall are set at RH = 80% and T = 20 ºC. Accounting for wind-driven rain falls out of scope of this study. The applicability of current available models for accounting for and determining the exposure for wind-driven rain may be

questionable for ventilated structures (Tietze *et al.*, 2017). The hygrothermal conditions between the wind barrier layer and insulation layer are investigated since they offer most favourable conditions for microbial growth. A monitor is placed in the asphalt impregnated paper for first case study or wood-fibre insulation board for the second case study. A schematic overview of the simulation process is provided in Figure 2. The selected location is Calgary, Canada. Two sets of climate data are implemented. They were generated in (Gaur, Lacasse, and Armstrong, 2019) and include the following: a) 15 historical climate data set, and b)15 climate data set for a climate change scenario in which the global climate temperature change is forecast to be 3.5 ºC. The indoor climate is set up as Medium Moisture Load +5% according to EN 15026 (15026, 2007) for each of the case studies.

2.1.2 Performance Evaluation

The hygrothermal conditions are retrieved for each case study and then processed in WUFI Model Index VTT 2.1 (WUFI-VTT, 2018), which is an add-on developed within a collaboration between the Finnish research institute VTT and Fraunhofer IBP. This add-on allows for calculation according to the VTT model. Three parameters are investigated from the model: the material class and sensitivity class that account for different building materials and the decline rate when mould is exposed to unfavourable conditions (see Appendix).

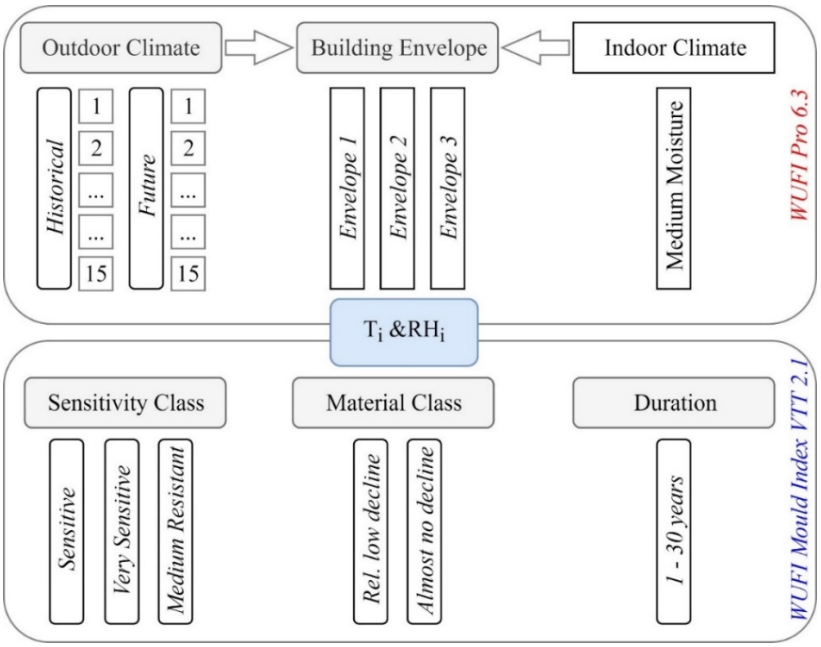

Figure 2. Schematic overview of the simulation process and its parameters.

3 Results

3.1 Implication of Climate Change in the Hygrothermal Performance of the Selected Building Envelopes

3.1.1 Implication in the hygrothermal conditions within the building envelopes

Table 1 shows the number of occurrences in hours of relative humidity and temperature that are usually favourable for the conditions of mould growth. The results are depicted for the three wall assembly configurations for the average of occurrences of the set of 15 historical and future climates. The results show that the effect of climate change is different for the three walls. For

the first wall, it can be observed higher levels of temperature and relative humidity compared to the historic exposure in the investigated layer, asphalt impregnated paper. In the other two walls the difference of hygrothermal conditions between the historic and future climates appears insignificant in the investigated layer, wood fibre insulation board, which lies a bit further away from the outdoor climate exposure, and hence its hygrothermal conditions may be highly dependent on the indoor climate.

Table 1. Comparison of occurrences in hours of higher levels of temperature and relative humidity between historical and future climate files for 30 years simulations.

			Historical				**Future**			
			Temperature							
			15-20	20-25	25-30	30-35	15-20	20-25	25-30	30-35

		95-100	0	0	0	0	0	0	0	0

3.1.2 Implications in the performance to withstand mould growth

The simulated mould growth results for the three wall assembly configurations exposed to 15 different outdoor climate files (both for historic and future) are plotted in Figure 3 and Table 4. The maximum simulated mould growth in a period of 30 years has been selected for each case study. For the first wall, the mould growth is simulated for the asphalt impregnated paper with the assumed sensitivity class '*medium resistant - relatively low decline*'. For the second and third wall, the mould growth is simulated for the wood-fibre insulation board with the assumed sensitivity class '*sensitive - low decline*'. As expected from the previous results, the difference between the simulated mould growth under future climate and historic climate is emphasised only for the first wall assembly configuration. Moreover, the results show that the simulated mould growth is sensitive to the uncertainties of outdoor climate for the first wall configuration assembly. Contrarily, the other two walls do not appear to be sensitive to the uncertainties of the outdoor climate, which may be justified from the fact that the hygrothermal conditions at the monitor position are highly dependent on the indoor climate.

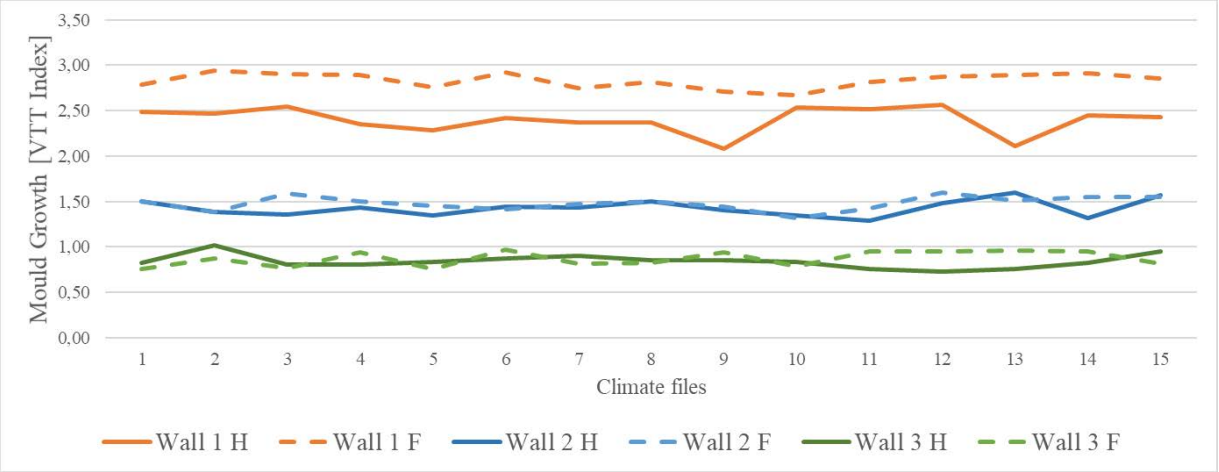

Figure 3. Results of mould growth for three wall assembly configurations simulated under historical and future climate files.

Table 2. Results of mould growth for three wall assembly configurations simulated under historical and future climate files.

Climate File	Wall 1		Wall 2		Wall 3	
	Historic	Future	Historic	Future	Historic	Future
Mean	2,4	2,83	1,43	1,48	0,84	0,87
Standard Deviation	0,15	0,18	0,09	0,08	0,08	0,08

3.2 Implications of Input Parameters in the Mould Growth Calculation

The results of mould growth for wall assembly one and two are shown in the tables below[1] for different selection of the sensitivity classes. For both cases it is also provided the amount of time in years until the peak simulated mould growth is reached. The results show that in both cases, the simulated mould growth and subsequently, the performance to withstand mould growth, are very sensitive to the selection of the material class and the sensitivity class. For example, in the first wall, the mould growth was simulated for the layer asphalt impregnated paper. According to the recommendation in the help guide (WUFI-VTT, 2018), this layer may fall under both sensitivity classes, *medium resistant* or *sensitive* with *relatively low decline* or *almost no decline*. This choice would shift the performance evaluating from acceptable (Mould Index lower than 3) to unacceptable (Mould Index greater than 3). This sensitivity is even more apparent for the second and third wall. Moreover, this sensitivity of the input parameters in the mould model is also reflected in the amount of time the simulated mould growth peak is reached. However, the latter is not the case for the other two walls where the maximum mould growth is reached within the first months, as expected considering the materials that were used in this simulation and that the initial conditions within these materials were assumed RH=80%.

4 Discussion and Recommendations

4.1 Implications of Climate change in Building Envelope Design

The results show that the implication of climate change, as accounted for by the generated climate files, can vary depending on the configuration of the wall assembly and numerical simulations. While the difference in the outdoor historic and future climate files is significant,

[1] The results of the third wall were similar to the second wall and were not shown to save space. In addition, the results are provided only for the first 5 historic climate.

its implications in the simulated mould growth were not. It was observed that mould growth results were intensified for only one among the three selected walls. This implies a potential future case scenario for building materials present in wall assemblies that is different from the current state, and hence underlies the need for a more detailed investigation of the hygrothermal conditions of different wall configurations. The latter can be exploited by carrying out multiple parametric analysis of simulated walls exposed to generated future climate. The results can be useful for direction and ideas of the properties that future building materials should have.

Table 3. Results of mould growth depening on different selection of input parameters of VTT model for wall configuration 1.

Climate	**Max Mould Growth [*VTT Index*] in 30 years**			**Years until peak**	
	S-ND	*S-LD*	*MR-LD*	*S*	*MR*
1	4,65	4,55	2,49	4	20
2	4,70	4,65	2,47	7	21
3	4,70	4,70	2,55	5	20
4	4,70	4,60	2,35	5	22
5	4,60	4,60	2,28	4	26

S- Sensitive, MR – Medium Resistant, ND – Almost no decline, LD- Relatively low decline

Table 4. Results of mould growth depening on different selection of input parameters of VTT model for wall configuration 2.

Climate	Max Mould Growth [*VTT Index*] in 30 years				Years until peak
	S-ND	*S-LD*	*VS-ND*	*VS-LD*	
1	1,5	1,480	4,250	4,150	1
2	1,380	1,290	4,100	3,900	1
3	1,360	1,280	4,100	4,000	1

5	1,350	1,300	3,800	3,750	1

S- Sensitive, VS – Very Resistant, ND – Almost no decline, LD- Relatively low decline

4.2 Recommendations about Building Design Guidelines

Choice of sensitivity class and material class: The study demonstrated that the simulated mould growth is very dependent on the selection of the sensitivity class and material. Shifting from one class to another can change the (un)acceptable performance of the building envelope. Current materials classes and sensitivity classes may not provide the required detailing that can accommodate current materials used in building envelopes. Therefore, the study underlies the need for the provision of a more detailed guideline recommending the categorization of common building materials into the respective sensitivity class of the mould model.

Simulation runtime: This study demonstrated that peak of mould growth can vary depending on wall configuration. In many mould models, the growth is represented as cumulative, with few ones considering optionable decline when unfavorable conditions are met. This underlies the need for connecting the performance criteria to runtime simulation. In other words, if the simulation runtime is short, then the performance criteria should be relative and conservative enough to accommodate the designated service life, otherwise, if the simulation runtime is as long as the designated service life, then the performance criteria should reflect the maximum absolute amount of tolerable mould growth.

Performance criteria: Currently, the only available performance criteria specifying the maximum acceptable level of mould growth is provided in ASHRAE 160, suggesting an amount of mould growth not to exceed VTT Index 3. The World Health Organization (2007) claims that there exists an association between health consequences and occurrence of mould growth; even though, there is no clear evidence that relates the microbial growth and mortality. This would imply that the threshold value should be depending on the case being investigated. For example, the same threshold may not be acceptable as in a hospital or other environments with higher exposure. Hence, the development of performance criteria to withstand mould growth can be approached by merging the following categories:

1. *Mould Index levels.* The mould index can have values from 0 to 6, as in the VTT model.
2. *Direct consequences*. The direct consequences of the mould growth are related to Indoor Air Quality (IAQ) and aesthetics.
3. *Exposure and extension*. Different levels of microbial growth can be associated with different levels of indirect consequences depending on several extents and exposure. They can be categorised based on: the depth of the wall (outer part of the wall, within the wall and inner part or contact with the indoor environment); the height of the building (i.e. underground, first floor, upper floors); part of the building (close to risk spots, the front part of the building); and typology of the building (i.e. hospital, museum, residential, office).
4. *Simulation runtime*. The design criteria should also consider the reference period as argued before.

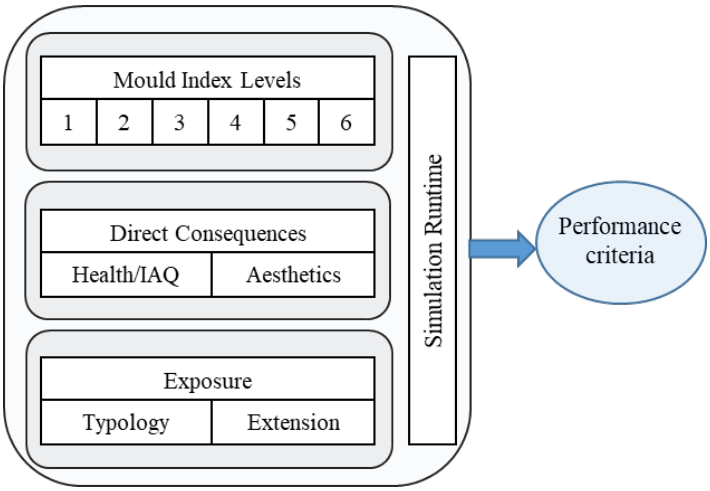

Figure 4. Schematic overview of developing performance criteria for the evaluation to withstand mould growth.

The Future Climate Moisture Susceptibility of Wall Assemblies: Analysis Based on Monte Carlo Simulation Using a Simplified Deterministic Hygrothermal Simulation Model

Carl-Eric Hagentoft[1] **and Pär Johansson**[1]

[1] Chalmers University of Technology, Department of Architecture and Civil Engineering,

SE-412 96 Göteborg, Sweden, carl-eric.hagentoft@chalmers.se

Abstract. *A newly developed generic algorithm to assess moisture susceptibility of simplified wall assemblies has been developed within the CIB-W080 WG 2. This group is focusing on guidelines for design for durability of building envelopes. The algorithm is implemented in a publicly available Matlab code. A simplified wall assembly consisting of up to four material elements is considered. Optional vapor retarder and thermal resistances are located between the elements. In this paper modelling of a ventilated cladding is implemented. Using the simplified numerical model, a probability-based risk analysis using the Monte Carlo method is demonstrated. The risk assessment of the wall assembly considers the interior and exterior climatic load. The moisture transport mechanism accounted for in the analysis is diffusion. The rain load is assumed to be transferred directly to a chosen outer susceptible material element in the construction. An insulated wooden wall structure is analyzed and the probability distribution of the time of wetness is presented for cases using sequence of 31 consecutive climatic years, randomly varying indoor moisture excess, indoor temperature and driving rain leakages.*

Keywords: *Climate, Driving Rain, Simplified Model, Risk Analysis, Monte Carlo Simulation.*

1 Introduction

The performances of buildings can vary quite a lot even if the design look identical in the drawings. The uncertainties are manifold and originate from the selection of the initial condition of materials, dimensions, and material properties. Also, the operation of the building causes uncertainties originating from the actual indoor moisture excess, internal heat gains, air infiltration, and ventilation. Obviously, weather conditions and the exposure to the external environment are also sources of uncertainties; this is illustrated in Figure 1. Because of all the uncertainties and possible variations, the total life cycle cost for the operation and maintenance of a stock of buildings will vary randomly due to the spread in factors such as initial investment, energy use, hygrothermal performances, and performance failures. To make balanced and sound choices of design strategies and investment decisions, all these factors should be included. The results from the IEA EBC project RAP-RETRO (Annex 55) (Hagentoft, 2017; Bednar and Hagentoft, 2015; Hagentoft *et al*., 2015a; 2015b; 2015c; 2015d) are intended to improve methods and tools for the integrated evaluation and optimization of retrofitting measures, including energy efficiency, life cycle cost, and durability.

doi:10.23967/dbmc.2020.197

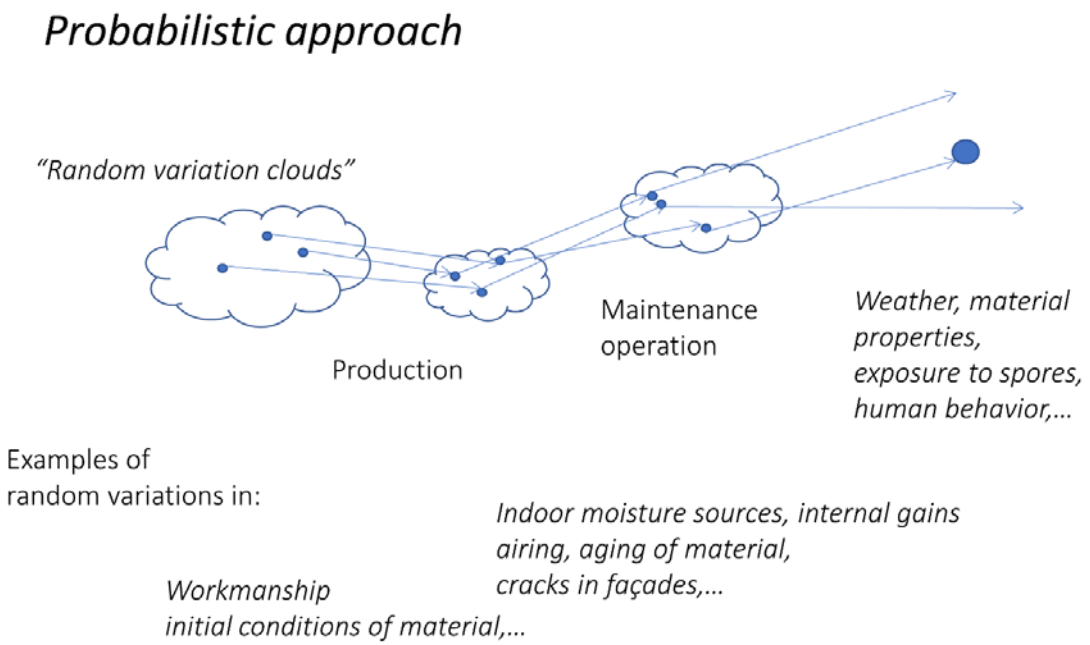

Figure 1. Random variation of cloud type representing variability and uncertainties.

One part of the annex 55 project was to develop and validate probabilistic methods and tools for energy use, lifecycle cost, and functional performance. The scope of this paper is to investigate the possibility to use a simplified numerical model for the heat and moisture transfer in a wall assembly. This model, intended to be used to assess moisture susceptibility of wall assemblies, is based on four material elements, each having resistances for vapor and heat between and at the surfaces, and includes rain intrusion. This approach represents several steps forward in terms of precision compared with the older and more traditional Glaser method and other later proposed models (Sanders, 1996; Hagentoft and Harderup, 1996). It is expected to be well in line with modern detailed moisture calculation models. With the proposed model, a probabilistic assessment of the risk for failure of various performances such as time of wetness, mould growth, and heat loss can be investigated. Also, sensitivity analysis can be performed on different calculation parameters.

The mathematics of the model is explained in detail (Hagentoft and Johansson, 2019) and can be implemented on various platforms such as Matlab or Python.

This work is a part of CIB W080, WG2, for the guidelines on design for durability of building envelopes for use by engineers and designers who are unlikely to have tools at their disposal to determine model inputs. It will provide background knowledge for hygrothermal simulations and long term durability risk assessments considering climate change. Within this work, the National Research Council (Conseil national de recherches Canada), NRC, provides climate data sets for historic and future scenarios.

2 Case Study

The investigated construction in this paper is an insulated wooden wall with an exterior air gap, see Figure 2. The insulation layer, outside the wooden layer, has a thickness of 300 mm and a thermal conductivity of 0.033 W/(m·K) while the wooden boards are 128 mm thick with a thermal conductivity of 0.14 W/(m·K). The material properties for the insulation and the wood are presented in Table 1 and Table 2.

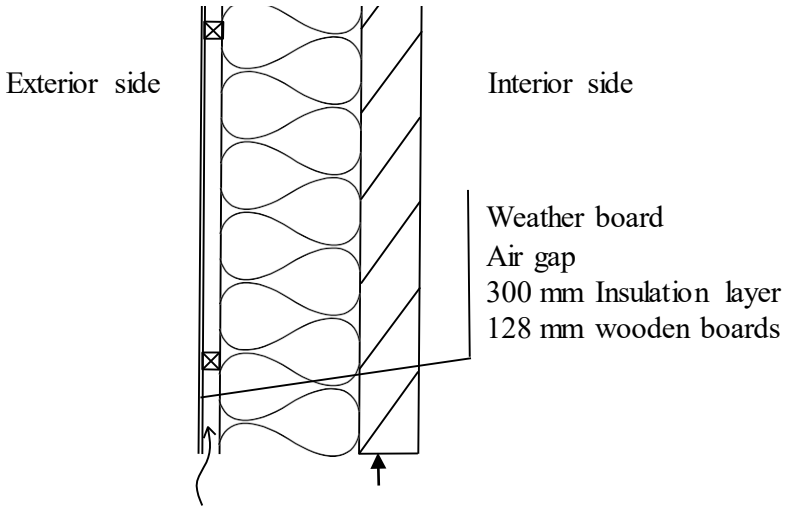

Figure 2. Insulated wooden wall that is investigated. The monitoring position is marked by the arrow.

Table 1. Material data for insulation and wood.

Material	Density (kg/m^3)	Thermal conductivity (W(mK)	Spec. heat capacity (J/kgK)	Diffusion resistance factor (-)
Insulation	200	0.033	800	2
Wood	430	0.14	1,600	30

Table 2. Moisture sorption isotherms.

Relative humidity	Insulation (kg/m^3)	Wood (kg/m^3)
0	0	0
35	0.25	37.5
50	0.40	47.5
70	0.47	65.0
80	0.53	77.5
90	0.60	100
95	1.0	117.5
99.9	10	140
100	100	1000

3 Weather Data

The historical and future climate data for the Canadian cities Toronto and Vancouver, see Table 3, were selected. The data was provided by (Gaur *et al*., 2019) who produced time-series of 30 consecutive years with hourly climate data corresponding to historical time-period (1986-2016) and future time-series corresponding to 2°C and 3.5°C increase in global temperature. In this paper the former climate scenario was selected.

Table 3. Data for Toronto and Vancouver.

City	Latitude (°C)	Longitude (°E)	Population in 2016 (1000s)	Climate zone
Toronto	43.7	-79.4	3731.6	Great lakes/St. Lawrence lowlands
Vancouver	49.3	-123.1	2463.4	Pacific coast/South British Columbia Mountains

3.1 Driving Rain Model

The rather simple and straight forward (Lacy, 1965) model is used to estimate the driving rain intensity, r_v (mm/(m^{2}h)), hitting the façade.

$$r_v = 0.208 \cdot \cos(\theta) \cdot v \cdot r_h \qquad r_v = 0 \; if \; |\theta| > 90° \tag{1}$$

Here, v (m/s) is the average wind velocity. The angle θ (-) is the angle between the wind direction and the normal of the considered wall. The formula relates the intensity of the rain hitting a horizontal surface, r_h (mm/(m^{2}h)), to a vertical one.

The modelling of the rain intrusion, bypassing the insulation layer, into the outer part of the wood, is based on 1% of the driving rain intensity. The leakage is based on a uniform random distribution, meaning that only one tenth of the rain events result in leakage corresponding to an intensity of 1% of the actual driving rain at that event. Table 4 presents the direction dependent driving rain intensity in each 30-year period in Toronto and Vancouver.

Table 4. Toronto and Vancouver driving rain intensity, the total summation of each 30-year period (tonnes/m^2).

Direction	Toronto (historical)	Toronto (+2°C)	Vancouver (historical)	Vancouver (+2°C)
North	6.64	7.97	1.19	1.61
East	7.68	9.41	18.5	19.9
South	9.15	8.65	26.5	26.8
West	7.09	6.25	4.32	4.53

The calculations show that direction South was the dominant direction for driving rain in Toronto, but in the future, this will change to East. In Vancouver, South is the dominant

direction for driving rain, both historically and in the future. In this study, for simplicity, only main compass directions were used and a South facing façade was chosen for both cities and for all the climate time-series.

3.2. Solar Radiation

Direct solar radiation and diffuse solar radiation on a vertical surface was given in the climate files. This was recalculated to hourly solar radiation for an inclined surface facing South based on angle of incidence, horizontal shadow angle and vertical shadow angle on inclined surface evaluated in middle of hour from reference year with hourly radiation data (Duffie and Beckman, 1991). The albedo of the ground was assumed to be 0.2.

4 Simulation Model

In the simplified model, a wall assembly consisting of four material elements is considered. Optional thin elements (zero thickness) with heat and vapor resistances are included in the model that for instance can be used for the representation of a vapor retarder. The risk assessment of the wall assembly considers the interior and exterior climates. The use of an equivalent external temperature permits consideration not only of the air temperature, but also of the effects of the long- and short-wave radiation. A prescribed driving rain intrusion function must be included that accounts for the effect of water leakage to the interior of the wall assembly. Prescribed outdoor and indoor water vapor concentrations are assumed where the moisture transport mechanism accounted for in the analysis is diffusion. The heat transfer is based on heat conduction. Heat and moisture convection are not accounted for. The moisture transfer is assumed to be driven by the gradient in humidity by volume.

The moisture transfer coefficient is treated as a constant, based on an average expected relative humidity in the material being considered. The heat is transferred by conduction, the thermal conductivity of the material is considered constant. The moisture content depends on the relative humidity only, and hysteresis is neglected. The latent heat due to evaporation and condensation is neglected. Many of these restrictions might be added in new coming versions of the model.

4.1 Ventilated Cavity

The following parameters are of importance: $R_{out}, R_a, \alpha_{c,cd}, \alpha_r, Z_{cladding}$. They are the total thermal resistance from the interior cladding surface to the outdoors including external surface resistance, air flow rate of the gap behind the cladding, the combined conductive and convective heat transfer coefficient of the air gap, the radiant heat transfer coefficient across the air gap, and finally the total vapor resistance of the cladding.

$$\begin{aligned} \alpha_c &= 2 \cdot \alpha_{c,cd} \\ \alpha_r &= 4\varepsilon_{12}\sigma T^3 \quad 1/\varepsilon_{12} = 1/\varepsilon_1 + 1/\varepsilon_2 - 1 \end{aligned} \tag{2}$$

In the last formula the emissivity of the surfaces surrounding the air gap is used together with the Stefan-Boltzmann constant. The temperature is in Kelvin.

Network analysis (Hagentoft, 2001) is used to reduce it all to effective resistances and external temperatures. The following expressions for the resistance of the analyzed structure to

the external environment is used, and replaces those used in (Hagentoft and Johansson, 2019):

$$R_0 = \frac{1}{K_a + K_b} + \frac{1}{K_2},\ Z_0 = \frac{1}{R_a + 1/Z_{cladding}},\ T^{eq}_{out,new} = \frac{K_a \cdot T^{eq} + K_b \cdot T_{out}}{K_a + K_b} \tag{3}$$

The humidity by volume, v_{out} (kg/m³), used in the model remains the same. The following parameters are used in the expression.

$$K_a = \frac{1}{R_{out} + 1/K_1} \quad K_b = \frac{1}{1/(R_a \cdot \rho c_{pa}) + 1/K_3}$$
$$K_1 = K_2 = \frac{\alpha_r \cdot \alpha_c}{\tilde{K}} \quad K_3 = \frac{\alpha_c^2}{\tilde{K}} \quad \tilde{K} = \frac{1}{2/\alpha_c + 1/\alpha_r} \tag{4}$$

Here, the volumetric heat capacity of air, ρc_{pa} (J/(m³K)), at atmospheric pressure is used.

4.2 Indoor Climate

In respect to the indoor conditions, the indoor temperature was varied around 20°C with a normal distribution and standard deviation of 1.5°C. The indoor moisture excess was always controlled to be greater than zero and varied with a normal distribution around 2 g/m³ and standard deviation of 1 g/m³.

5 Results

For simplicity in this study, the time of wetness was used as an indicator for the durability. This is the total time over the year that RH exceeds 80% for a specific susceptible element of the construction. Based on the previous study (Hagentoft, Johansson, 2019), the Monte Carlo simulations are run for a total of 600 31-consecutive-year simulations using the simplified model. One 30-year simulation period takes 17 minutes on a PC with a 1.9 GHz Intel® Core™ i7-8650U CPU. The results for Toronto and Vancouver are presented in Figure 3, 4 and 5.

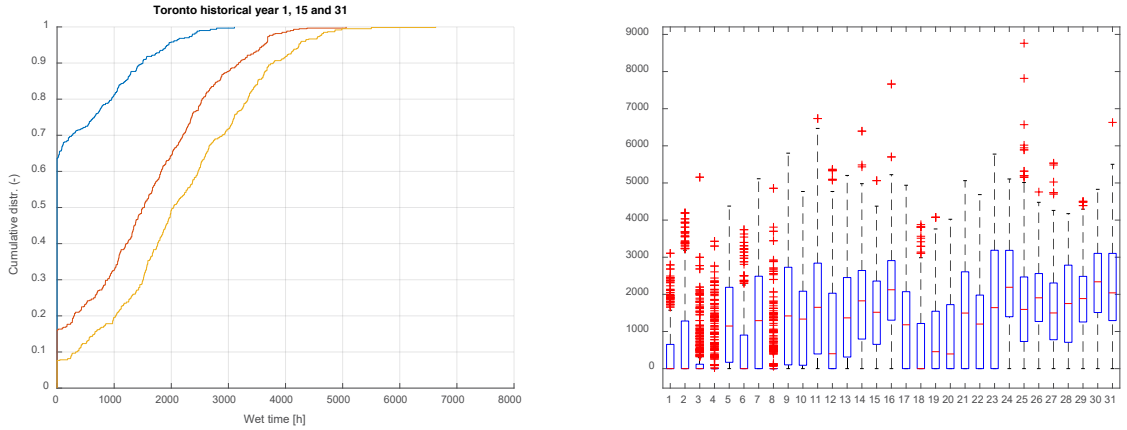

Figure 3. Results for the time of wetness for Toronto historical time-series.

There is a clear trend, visible both in the cumulative distribution and histogram, for Toronto

that the time of wetness was increasing the last 30 years. The average time of wetness for year 1 was 392 hours, while it was 1566 and 2146 hours for year 15 and 31 respectively. The continuing trend can also be found in the future scenarios, where the time of wetness is 2611 hours the first year while it is 2899 and 3831 hours respectively for year 15 and 31.

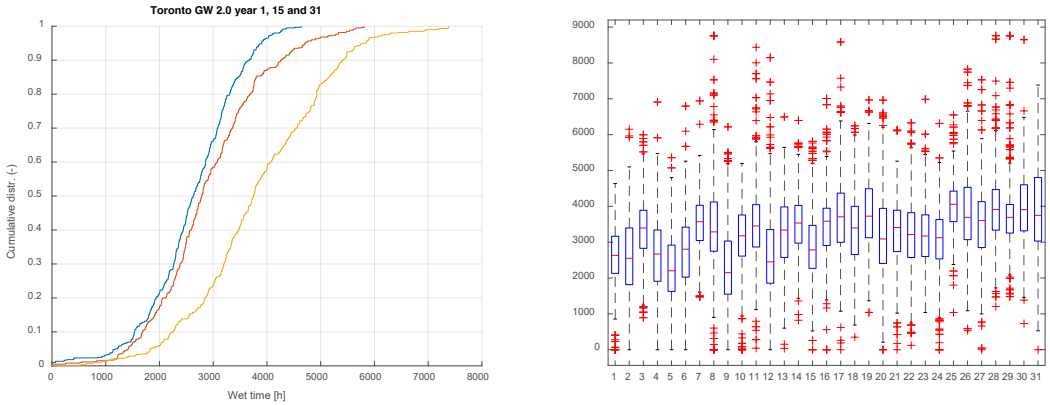

Figure 4. Results for the time of wetness for Toronto future scenario +2.0°C time-series.

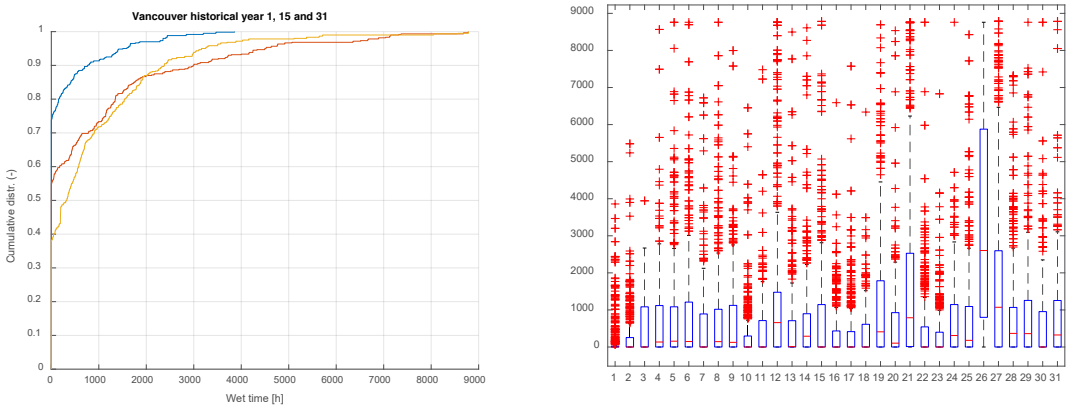

Figure 5. Results for the time of wetness for Vancouver historical time-series.

Also for Vancouver there is a clear trend in the cumulative distribution and histogram, that the time of wetness was increasing the last 30 years. The average time of wetness for year 1 was 219 hours, while it was 853 and 838 hours for year 15 and 31 respectively. It is also interesting to note the significantly larger number of outliers in Vancouver compared to in Toronto.

6 Conclusions

A previously developed simplified model for heat and mass transfer across walls, based on a four-element discretization of a wall assembly has been used in the paper. The simplified model offers good flexibility for representing multi-layer wall constructions with various barriers and

for moisture and heat transfer in between layers. As such, it is suitable to be used for the risk assessment of wall assemblies and similar constructions. In this paper additions to the model are presented that make it possible to analyze structures with a ventilated cladding.

For the case presented in this paper, the impact of rain leakage on the outermost part of the external wood layer of an insulated wooden wall was demonstrated. The risk analysis is based on Monte Carlo simulations of 600 runs of 31-consecutive-year historical and future climate scenarios for Toronto and Vancouver. The expected time of wetness is 5 times higher in Toronto in 2016 compared to in 1986, and 1.5 times higher in 2064 compared to in 2034. In Vancouver the expected time of wetness is 4 times higher in 2016 compared to in 1986. However, for Toronto this may not be the most extreme case considering that south is not the predominant direction of wind driven rain in the future.

Abstract. *Hygrothermal simulations are necessary to permit analyzing moisture performance when designing building envelopes. Owing to the high computing time and cost of the long term simulations, a common approach is to select representative year(s), the Moisture Reference Year(s), from a long-term series of climate data. It is assumed that the use of Moisture Reference Year(s) (MRYs) provides equivalent results as those provided using long-term series. The selection of MRY(s) is by itself based on the one of the methods available in the literature. In the present study, three methods of selecting the MRYs were evaluated i.e. the moisture index (MI), severity index (Isev) and climatic index (CI). Simulations were performed using individual years of historical climate data extending from 1986 to 2016 and projected future climate data representing the scenario with a 3.5°C increase in average temperature which is expected to occur from 2062 to 2092. Brick cladding installed on a wood frame wall assembly subjected to the climate of three different Canadian cities was selected for analysis. The cities selected were Vancouver (BC), Calgary (AB) and Ottawa (ON). These cities have differing levels of moisture loads. The year having the mould index value more than 3 for highest number of hours among the individual years was compared with the MRY given by three selected methods. A method was considered to be accurate in terms of the prediction if the year selected by that method gives the number of hours with mould index more than 3 which lies in the same class as that of year having maximum corresponding value. In general, it was observed that none of the methods provides the worst year with 100% accuracy, however for most of the cases, Isev method performs better than other two methods in terms of MRY selection.*

Keywords: *Moisture Performance, Climate Change, Hygrothermal Simulation, Moisture Reference Year(s) Selection Method.*

1 Introduction

One of the parameters that influences the moisture performance of the wall is the outdoor climate. However, having large number of climate parameters and estimating the effects of these parameters over the entire service life would result in a large simulation effort. One of the approaches to cut down the simulation time and cost is to select a year or combination of years called Moisture Reference Year(s) (MRYs) which is assumed to represent the entire set of long term climate data.

The π-factor method suggested by Hagentoft and Harderup (1996) compares the absolute humidity at the external wall surface with the absolute humidity of the outside air in order to compute the drying potential of the wall surface. They suggested that drying out potential is higher for a higher value of π-factor. Kalamees and Vinha (2004) used a method similar to π-factor method for selecting the MRY in terms of evaluating the risk of water vapor condensation. Carsten Rode (1993) proposed a construction dependent method, which compares the integral moisture content values for different wall constructions and orientations. He suggested that the higher the value of moisture content for a particular year, the more severe the year is in terms of moisture performance of the wall. Cornick *et al.* (2003) used an index called Moisture Index (MI) to categorize the years in terms of the severity. MI method uses wetting and drying function to compute MI and then further categorizes the year as dry, average and wet based on lowest, average and highest MI value respectively. From a dataset of years, the years having MI value in the range of more than one standard deviation (+/-) from the mean MI value are considered as dry and wet years, while those years having a value within (+/-) one standard deviation are referred to as average years. A method suggested by (ASHRAE, 2010) combines the climate load and durability to choose the "severe" weather years and provides a more representative ranking of the climate data. This approach, called the Severity Index (Isev), uses an equation to predict the RHT value as a damage function. Salonvaara *et al.* (2010) suggested the Isev equation as a reliable method of selecting representative years. A regression equation used for computing RHT value considers different climate parameters. The yearly average value of each climate parameter is used in the equation and the years are arranged in the descending order of the RHT values. The year with the third highest (top 10% years among 31 years) RHT value is selected as MRY for the hygrothermal simulations. The authors further compared their method with three other existing methods and concluded that their method performs better in predicting the severe years than other methods. The Climatic Index method suggested by Zhou *et al.* (2016) comprises wetting and drying components. The wetting component depends on the annual wind-driven rain and the drying component depends on the annual potential evaporation. Unlike MI method, this index takes into consideration the effect of many climate parameters such as net radiation, temperature, humidity, wind speed, wind direction and orientation of the façade. The authors made a comparison with MI method in terms of accuracy in predicting the MRY and suggested that the year predicted using climate index gives better result than MI method. However, based on the past research findings, none of the methods can be considered as a universal method for the selection of MRY.

The objective of this study is to investigate three MRY selection methods *i.e.* Moisture Index (MI), Severity Index (Isev) and Climatic Index (CI) in terms of their accuracy in predicting the worst year in terms of moisture performance among a series of long-term climate data. For all the methods, the year corresponding to the 97th percentile, (ranked second out of the 31 years) for each climate scenario was chosen as the MRY and is further compared with the individual year simulations to determine their capability in predicting the extreme year.

2 Methods

2.1 Description of MRY Selection Methods

Cornick *et al.* (2003) suggested the calculation of MI for every hour (MI_h) based on hourly

wetness (WI_h) and dryness (DI_h) indices. Here, WI_h corresponds to the normalized hourly rainfall and DI_h corresponds to Δp_v *i.e.* the difference between the saturation vapor pressure and vapor pressure of the ambient air. The saturation vapor pressure, p_{vs}, as a function of ambient temperature (T), was calculated as suggested by ASHRAE (2009).

The magnitude of Δp_v is calculated using Equation (1):

$$\Delta p_v = p_{vs} - p_v \tag{1}$$

Both the indices are further normalized as per the Equation (2):

$$I_{normalized} = (I - I_{min})/(I_{max} - I_{min}) \tag{2}$$

Where, I is the Index of interest.

Normalized values of Δp_v and accumulated hourly rainfall were used as DI_h and WI_h magnitudes respectively and equal weights are assigned for both the indices.

$$MI_h = \sqrt{(1 - DI_{h,norm})^2 + {WI_{h,norm}}^2} \tag{3}$$

Based on ASHRAE (2010), the severity index (Isev) for each year is calculated according to Equation (4):

$$\begin{aligned} I_{sev} = 108307 - 241.E_v - 1391.I_{cl} - 312326.\phi + 183308.r_{wd} + 15.2.p_v + 27.3.T^2 \\ + 261079.\phi^2 - 0.00972.p_v^2 \end{aligned} \tag{4}$$

Where, E_v is the solar radiation (W/m^2) incident on the wall; I_{cl} is the cloud index; ϕ is the relative humidity; r_{wd} is the wind-driven rain ($kg/(m^2.h)$ on the wall; p_v is vapor pressure (Pa), and T is the ambient temperature (°C). The method is explicitly valid for the orientation with highest amount of yearly Wind-driven-rain (WDR) and least solar radiation *i.e.* North orientation. A yearly average value is used for each climate parameter for each year.

Zhou *et al.* (2016) suggested calculation of CI based on annual wetting and drying. The wetting component includes annual wind-driven rain and drying component is based on the potential evaporation calculation based on Penman equation shown below:

$$E = \frac{\Delta}{\Delta + \gamma}\frac{K + L - A}{I} + \frac{\gamma}{\Delta + \gamma}h_m(e_a - e) \tag{5}$$

Where, $\frac{\Delta}{\Delta+\gamma}\frac{K+L-A}{I}$ represents the radiation term and $\frac{\gamma}{\Delta+\gamma}h_m(e_a - e)$ represents the turbulence term. E is the drying Index, K is the net short-wave radiation (Wm^{-2}), L is the net Longwave radiation (Wm^{-2}), A is the conductive heat flux to the porous material (Wm^{-2}), I is latent heat of vaporization (Jkg^{-1}), γ is the psychometric constant (PaK^{-1}), Δ is the slope of the relationship between saturation vapor partial pressure and air temperature, e_a is the saturated partial vapor pressure of the air, e is the vapor partial pressure in the air (Pa) and h_m is the convective vapor transfer coefficient (sm^{-1}). In the calculation of drying index, the conduction heat flux and long wave radiation were neglected since their values are much smaller in comparison to short wave radiation. Finally, the yearly sum values were taken and the CI was calculated as the ratio of Wetting Index and Drying Index.

2.2 Cities Selected & Wall Orientation

For the analysis, three cities were chosen from 3 different provinces of Canada: Ottawa (ON), Vancouver (BC), and Calgary (AB). Furthermore, the selected cities vary significantly in terms of their climate conditions. Amongst these cities, based on MI value; Vancouver and Calgary are the wettest and driest cities respectively and Ottawa being the city with an intermediate value of MI. The study was made for the orientation receiving least annual solar radiation *i.e.* a North-facing wall (N) for each city. Further details for these cities are listed in the Table 1.

Table 1. Characteristics of the selected cities.

City (Province)	Latitude	Longitude	HDD18	MI	Annual rain (mm)
Ottawa (ON)	45.25°	-75.42°	4440	0.84	750
Vancouver (BC)	49.28°	-123.12°	3100	1.93	1850
Calgary (AB)	51.05°	-114.07°	5000	0.37	325
HDD18 – heating degree days below 18ºC			MI – moisture index		

2.3 Wall Configuration

The modeled building was assumed to be a 3.5 storey type located in a suburban setting. Light weight wood frame wall assembly with brick cladding was simulated and the wall was assumed to be perfectly air tight. A detailed description of chosen wall assembly is shown in Figure 1.

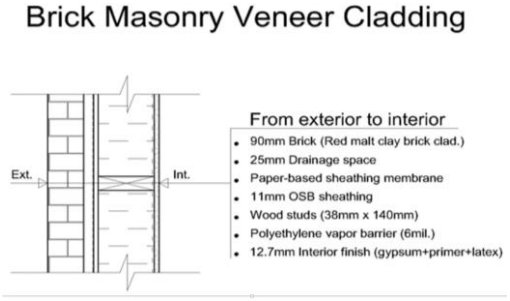

Figure 1. Description of the wall assembly.

The material properties were obtained from NRC material property database (Kumaran *et al.* 2002). For the air cavity, same value of Air Changes per Hour (ACH) was used for each city and climate scenario. Table 2 illustrates ACH values for different claddings and locations.

Table 2. Selected ACH values for different claddings and locations.

Ottawa		Vancouver		Calgary	
Brick	Stucco	Brick	Stucco	Brick	Stucco
6	10	12	40	3	5

Extensive trials were made for selecting an appropriate ACH value. For this purpose, simulations were made by repeating the average year (based on MI ranking) for 7 times and mould index value was computed at the exterior layer of the OSB. The aim was to choose a

value of ACH that results in having mould index stabilizes around a value of 3.

2.4 Climate Data and Wind Driven Rain

The climate data used for the present study includes hourly climate for a consecutive 31 years: from 1986-2016 for historical scenario; and, similarly 31 years when the global temperature will increase by 3.5°C. (Gaur *et al.* 2019). An increase of 3.5ºC global increase is expected to transpire between the years 2062-2092 as per the projections made by Environment and Climate Change Canada (2018). It was observed that, there is a minimal variation in RH value and an increase of approximately 5°C (annual average) in temperature from historical to future climate conditions for each city. Wind Driven Rain (WDR) was calculated using the ASHRAE method (ANSI/ASHRAE, 2016) assuming a medium exposure with the rain exposure factor (FE) and the rain deposition factor (FD) set to 1.0 and 0.5, respectively.

2.5 Boundary Conditions and Initial Conditions

Indoor temperature and relative humidity were assumed constant and set to 21ºC and 50% respectively. The indoor exchange coefficient for heat conduction was set to 8 W/m^{2}K and the indoor vapor diffusion coefficient was set to 1.52*10^{-8} s/m. As per the EN ISO 6946 standard, the convective heat transfer coefficient is $h_{ce} = 4 + 4v$, where v is the wind velocity at 10 m height. The convective vapor transfer coefficient is related to the convective heat transfer by the use of the Lewis analogy $\beta_v = 2.44 * 10^{-8} + 2.44 * 10^{-8}\ v$. The reflection coefficient of the surrounding ground (albedo) was 0.1 and the absorption coefficient for the brick cladding was equal to 0.6. The wall was conditioned with suitable climate by completing a consecutive seven (7) year simulation, repeating the average year (based on Moisture index ranking). At the end of simulation, the average value of temperature and RH for all the layers in the wall configuration were noted and used as initial conditions.

2.6 Simulations

Simulations were run over the individual years spanning a period of 31 years for historical and future climate using the Heat, Air and Moisture (HAM) simulation tool DELPHIN V5.9. For this study, only one-dimensional horizontal configuration of the wall was simulated. The water infiltration through the assembly was assumed to be 1% of the wind-driven rain and was applied to the exterior side of the sheathing membrane, as per ASHRAE 160 (2016). Manual meshing was opted for all the layers except sheathing membrane and vapor barrier. For these two layers, an equidistant mesh of 3 elements was assumed. For other layers, they were divided into 3 sections with first and last sections having equal thicknesses. For these two sections, a fine and variable mesh was used and an equidistant mesh was opted for the middle section.

2.7 Performance Indicator

For analyzing the moisture performance of the wall assembly, the mould index was computed at the exterior of the OSB layer (0.1mm thick element size) using the method proposed by Ojanen *et al.* (2010). The calculations were made assuming the sensitive class for material and surface and a decline factor of 0.5 (assuming significant decline) when the conditions become unfavorable for mould growth. Furthermore, for performance analysis, one way is to use the

maximum mould index value to compare different results. However, this can be misleading, especially in a situation when there is only one peak followed by set of low values. To tackle this situation and capture the trend, a better idea would be to count the number of hours when mould index value is above a threshold value and use that value as a performance indicator.

3 Results and Discussion

The accumulated number of hours when mould index (MoI) value is more than 3 was calculated for each year of the 31-year series. Figure 2 shows the results obtained for the brick cladding wall in Calgary exposed to future climate. It shows the total number of hours throughout the year when the MoI value was above 3. On the secondary axis, the maximum MoI for a particular year is shown. Furthermore, the year selected by each MRY selection method is marked on the chart. For this particular case, it was observed that Isev method predicts the year which performs the worst when simulated for moisture performance analysis. The years predicted by the other two methods are far away from the extreme year (based on simulation) in that dataset.

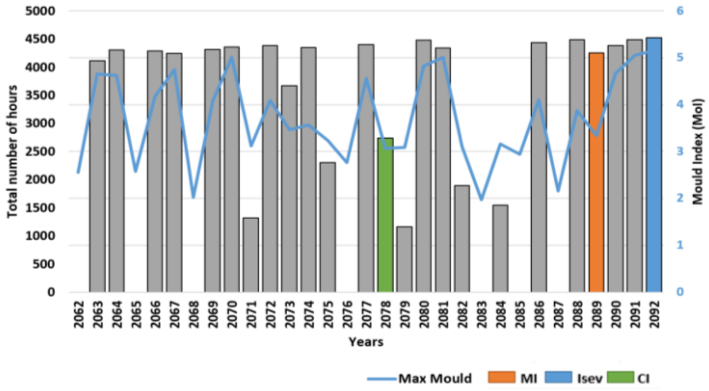

Figure 2. Total number of hours with MoI>3 for Brick wall in Calgary for future climate. Secondary axis shows the maximum value of MoI for each year.

To analyze the results in a more lucid way, further grouping was made wherein the hours were divided into classes having a range of 200 hours starting from 0 and ending with hours above 5000. The reason behind choosing a nominal value of 200 hours is to distinguish the years selected by different selection methods.

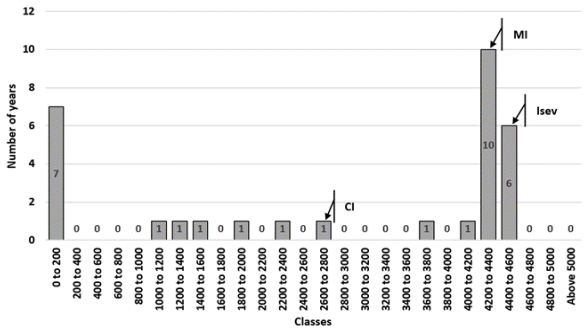

Figure 3. Grouping of years in terms of number of hours when MoI>3 for Brick wall in Calgary for future climate. Year given by three methods lies in one of the classes and are marked in with arrow in the chart.

Figure 3 shows the distribution of the 31 years among the different classes for brick cladding wall in Calgary exposed to the future climate. It is clear from Figure 3 that the year predicted by the Isev method falls in the same class as that of the year with maximum number of accumulated hours using simulation. For this case, the worst year is more in accordance with the year suggested by Isev method.

Similar analysis was made for different cities considered for historical and future climate scenarios. As a general trend, it was observed that the selection of year based on severity index method always lies closer to the class belonging to the worst year among the series of the years. It was observed that in Vancouver for a North facing wall, there is no risk of mould growth. This could be explained by the fact that in Vancouver, there was a very low amount of WDR falling on a North facing wall which in turn imposes almost no risk of mould growth.

Table 3. Summary of all the simulated cases. Year shows the year predicted by the method and class shows the range in which the corresponding year lies. (*Ott: Ottawa, Van: Vancouver, Cal: Calgary, H: Historical, F: Future).*

Case	Simulation		MI		Isev		CI	
	Year	Class (in 100s)	Year	Class (in 100s)	Year	Class (in 100s)	Year	Class (in 100s)
Ott_H	2009	42-44	2010	0-2	2009	42-44	2004	30-32
Ott_F	2081	>50	2085	0-2	2069	38-40	2070	46-48
Van_H	--	--	--	--	--	--	--	--
Van_F	--	--	--	--	--	--	--	--
Cal_H	1999	40-42	2005	34-36	1995	40-42	2014	40-42
Cal_F	2092	44-46	2089	42-44	2092	44-46	2078	26-28

Table 3 represents the results for all the considered cases. It shows the year selected by various methods and the year which actually performs the worst. Moreover, the table illustrates the class in which each method lies. Closer the class of each method to the simulation results, better the method is in its prediction. From the table it is clear that 3 out of 4 times, the year predicted by the Isev method lies in the same class as that of extreme year using simulations.

4 Summary and Conclusions

For analyzing the moisture performance of the wall assembly, 3 different Canadian cities were selected based on the different climate conditions. Number of hours when the mould index was more than 3 were calculated for each year and were then compared with the corresponding values for the MRY predicted using different methods. Different classes were made based on the number of hours and the years falling in the same class were grouped together. None of the three methods predicts the worst year with 100% accuracy when compared with the results from the simulation over the individual year for the 31 year data set. Furthermore, when the methods were compared against each other, it was observed that the severity index method was better in predicting the extreme year than the other two methods for both set of climate data *i.e.* historical as well as future climate scenario.

The study is limited to only 3 Canadian cities and it is of utmost importance to test more cities with varying climatic conditions. Furthermore, among the three MRY selection methods

chosen for the study, Isev method is limited to only North facing walls. Finally, the study uses total number of hours when MoI>3 as the damage criteria for one set of historical and future climate. The study could be further extended to analyze other damage functions for different sets of historical and future climate scenarios. Future work will be to incorporate the abovementioned limitations along with developing the moisture performance data for different wall systems obtained by completing hygrothermal simulations over a consecutive 31-year series of historical and future climate data. Later step will be to validate the (MRY), or a series of MRYs using the results from the consecutive year simulations.

Abstract. *Nowadays the sustainability and safety requirements of structures inspire the study of new self-healing materials and preventive repair methods on cementitious elements. To achieve this undertaking, this research replaces widely employed synthetic polymers by biodegradable ones as consolidants and water-repellents, and assesses the protection and consolidation effect of biopolymers (obtained by using waste biomass of mixed microbial cultures from polyhydroxyalkanoates production processes) as eco-friendly healing agents by analysing the water absorption of two kind of materials. The first group of samples are cement mortar specimens whose external surface has been treated with biopolymer products and subsequently evaluated by water drop absorption test. The second group of samples are cement mortar specimens formulated with biopolymer products included in its mixing water and later the waterproofing efficiency is analysed by capillary water absorption tests. The water absorption behaviour of both kind of samples shows a potential improvement of cementitious elements durability, since water absorption results have decreased for treated samples in comparison with untreated ones.*

1 Introduction

During historic and prehistoric period, the use of biopolymers from plants and natural sources was a common technique in the manufacture of construction materials. They developed suitable behaviour in terms of reducing the water content of the binding materials, accelerating the hardening process of the binders and achieving a compaction desirable in the production of compacted hardened structures with appropriate durability. Thereby a suitable binder to keep the structural integrity of aggregate-based materials used in ancient structures is reaching. In addition, these natural biopolymers can exhibit biocidal and insecticidal properties leading to resistance of the constructed structure to bio-corrosion as well as termite resistance (Karandikar *et al*., 2014). However, nowadays the usage of biopolymers has disappeared in the most of developed countries around the world, only in some rural areas of underdeveloped countries these eco-friendly techniques are still practised, where the knowledge has been inherited from one generation to another.

Demand for construction materials has been rising in recent decades in many countries, with

the intense industrialisation and urban development induced by economic and demographic growth, then self-healing materials and repair methods are required in construction sector.

Cement-based materials are inert, however, currently a number of chemical products are generally added to mortar and concrete mixes to control several parameters (plasticity, pumpability, setting time, water content, freeze-thaw resistance, strength, colour, etc.) Because of these chemical admixtures, today cement-based materials could become more harmful to the environment. They require more energy to be produced and more raw materials. The use of various synthetic admixtures in cement-based materials has been proved to have contributed to the emission of toxic species into the atmosphere (Hazarika *et al*., 2016).

The replacement of synthetic admixtures by natural polymers would pave the way for more green construction. The use of natural materials as opposed to non-renewable and petroleum-based products has been identified as a potential means for reducing the embodied energy and carbon footprint of buildings, as well as helping to create healthy and comfortable indoor environments (Dove, 2014; Felton *et al.*, 2013). Natural polymers are polymers synthesized by living organisms (plant, animal, algae, fungus or bacteria) and consist of long chains made of repeating, covalently bonded units, such as nucleotides, amino acids or monosaccharides. Biopolymers have the potential to reduce carbon emissions since the CO_2 released when they degrade can be reabsorbed by crops grown to replace them, making them close to carbon neutral.

Several publications have studied the usage of these natural products in the production of earthen buildings: vegetable oils (Ogacho *et al*, 2003; Balo and Yucel, 2013), plant gums and resins (Ruskulis, 2002), molasses (Vilane, 2010) or animal products (Ruskulis, 2002; Eires *et al*.,2013; Beas, 1991). However, there are few studies where this kind of additions are used on cement-based materials. In this study, the potential of a novel biopolymer from biodiesel by-product is evaluated to realize self-sealing of cement-based materials, on one hand, and surface repairing development of cement mortar samples, on the other hand.

2 Material and Methods

The bioproducts used as surface repairing agents were eco-friendly, being obtained by waste biomass from a microbial mixed culture (MMC) for polyhydroxyalkanoates production using crude glycerol (biodiesel by-product). MMC cell walls were disrupted by sonication (Sonicated bioproduct, B-S) or not (Non-sonicated bioproduct, B-NS). For comparison, different control samples were prepared: i) untreated; ii) specimens in which the bioproduct was replaced by the same volume of tap water. Table 1 shows the different treatments for external addition of biopolymers.

Table 1. Description and short names of bioproducts/biotreatments and controls.

Surface treatments		Short name
Controls	Control (no treatment)	Control
	Reference (tap water)	H_2O
MMC-glycerol bioproducts	MMC grown with crude glycerol	B-NS
	MMC grown with crude glycerol after sonication	B-S

Cement mortar to test the surface repair effect was produced with a cement CEM II/A-L-32.5 N (EN 197-1, 2011), from Secil Group, Portugal, with a loose bulk density of 1.18 kg/dm^3. The mortar was formulated with a cement:sand mass proportion of 1:1.9, that corresponds to a volumetric proportion of 1:3.

Triplicate specimens were prepared and tested. Bioproducts were applied onto the surface of mortar samples by dropping into a 3 x 3 grid of 9 addition points in a surface of 40 mm x 40 mm in a total of 2 cm^3 of each bioproduct suspensions using a pipette. To simulate degraded surfaces, a cut surface of samples was treated. Samples were located on a test room one week before biotreatments to establish uniform laboratory conditions (20 ± 2 °C and 40 ± 5% relative humidity).

Five days after the treatment, the repairing effect was assessed by a water-drop absorption test. This test allows evaluating the permeability variation of biotreated surfaces by monitoring the rate of absorption of a 0.1 cm^3 drop of water, that is, the time required for a material to fully absorb a water drop under open air conditions (Figure 1). The absorption period of time was video-recorded.

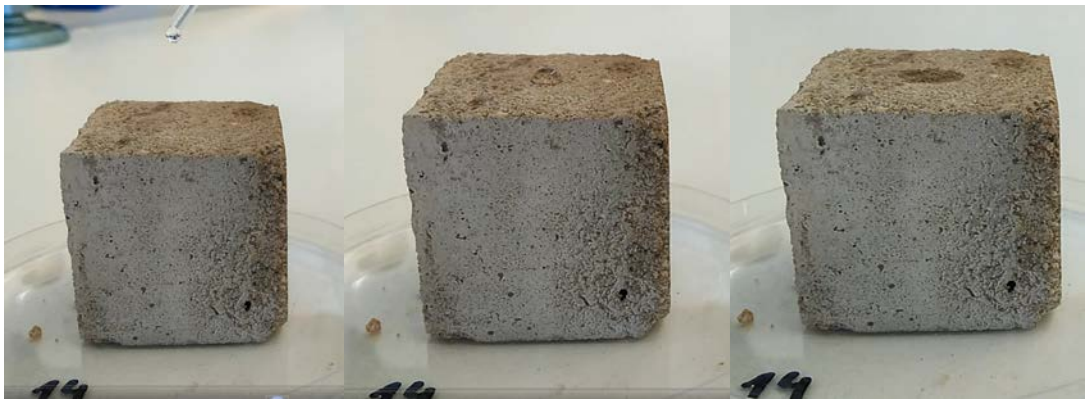

Figure 1.Steps of water drop absorption test.

Regarding internal addition of bioproducts, the cement mortar samples to test the self-healing effect of the biopolymer at different ages was bioformulated with the composition shown in Table 2.

Table 2. Composition and code of the cement mortar samples.

Sample	Code	Sand (g)	C (g)	Water(ml)	B1 (ml)	B2 (ml)
Control (Cement mortar with water formulation)	CW	4	627.13	530	0	0
B1 (Cement mortar with bioproduct formulation)	CB1	4	627.13	0	530	0
B2 (Cement mortar with older bioproduct-3 days old formulation)	CB2	4	627.13	0	0	530

Six months after the cement mortar manufacture, the healing effect was assessed by a water-drop absorption test, following the same steps explained previously for the surface treatment

samples. Triplicate specimens were tested, which were located on a test room one week before measurements to establish uniform laboratory conditions (20 ± 2 °C and 40 ± 5% relative humidity).

3 Results and Discussion

The results of the water drop absorption time of surface biotreated samples are represented in Figure 2, which showed that the samples exposed to only water (H_2O sample) reduced the time until water drop absorption, being a negative effect on the mortar durability, as expected. However, when the cement mortar was treated with non-sonicated bioproduct (B-NS), a waterproof effect was observed, since the water drop absorption time increased 601% in comparison with control sample. If the mortar surface is treated with the sonicated bioproduct (B-S), the waterproof response is even greater, since B-S sample showed a water absorption time 912% higher than the control sample. The development of a waterproof film in the external part of the sample (surface and external cracks), due to the biopolymer deposition is the reason of the better performance of treated samples in comparison with Control and H_2O samples.

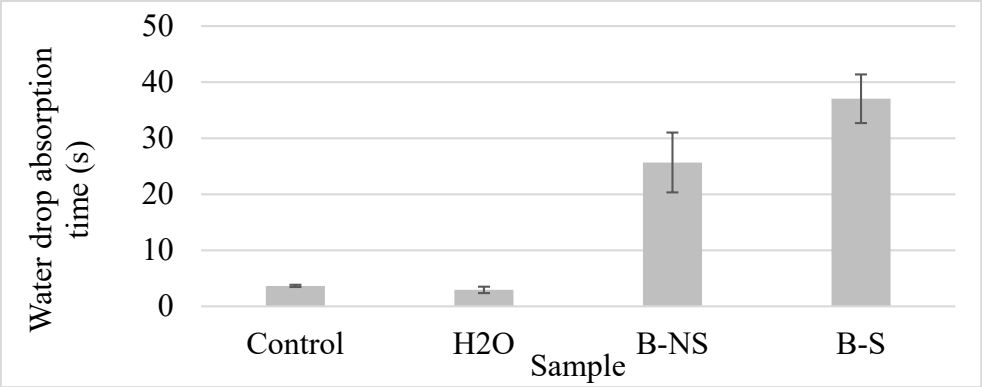

Figure 2. Water drop absorption time of surface treated cement mortar samples.

Authors as Subbiah *et al*. (2018) used silane enriched with nanomaterials as water-repellent on cement mortar, obtaining a 10% water absorption decrease. Treatment of cement mortars with nano-silica was tested by Hou *et al*. (2014) and they observed a water permeability decrease, by reducing the volume of pores larger than 50 nm and the threshold value of the pore network. Other authors as Chandra *et al*. (1998) applied water extracts of cactus to biotreat the surface of Portland cement mortar samples, achieving up to 83% improvement in water resistance.

The Figure 3 shows the water drop absorption time for the cement mortar with water (CW) and the bioformulated cement mortar with the biopolymer at different ages (CB1 and CB2). Although, deeper studies should be developed to decrease the standard deviation in the data, the results of this test state that the self-healing effect of biopolymer presence, since CB1 samples spend 12,5% more time to absorb the water drop than the CW sample. When the age of the biopolymer is increased (CB2 sample), the self-healing effect is even greater, raising the water drop absorption time until 16,7% in comparison with the control sample (CW). The better performance of bioformulated cement mortar than the conventional mortar in water drop

absorption test can be related with the low water accessible porosity on bioformulated samples due to the polyhydroxyalkanoates production on cement paste, which apparently increased over time, considering short periods of time.

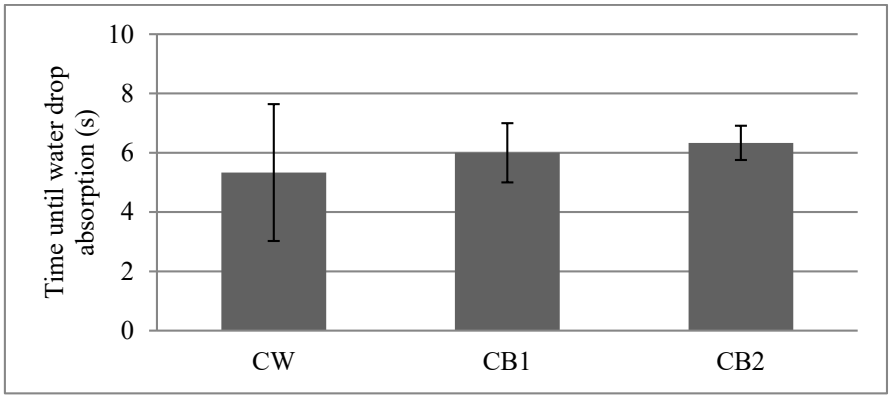

Figure 3. Time until water drop absorption of CW, CB1 and CB2 samples.

Previous results have already shown that addition of ecofriendly polymers on cement-based materials generated positive findings on material durability, such as Chandra et al (1998), who used the water extract of cactus in preparation of Portland cement mortar and this natural polymer improved water absorption and freeze-salt resistance. Also Chandra and Aavik (1983) used black gram as binder in cement mortar and stated that it worked like air entraining agent, improving the hydrophobicity of cement mortar. They also tested the addition of oil along with black gram, which worked as a defoaming agent and substantially improved the hydrophobic property of cement mortar. Hazarika *et al*. (2018) used a plant based polymeric material as a low cost chemical admixture in cement mortar and concrete preparations. The addition of this bio-admixture decreased the water absorption capacity as well as the porosity of the mortar samples.

In addition, the two approaches tested on this study showed that external treatment of mortar samples with biopolymers are more effective than when bioproducts are incorporated like mixture addition (bioformulation).

4 Conclusions

- The treatments with MMC bioproduct from glycerol showed a significant decrease of the permeability on the surface biotreated samples. The sonicated biopolymer exhibited a greater repairing effect than the non-sonicated one.
- Addition of MMC bioproduct on the formulation of cement mortars implied a positive effect on its durability and this result was greater when the bioproduct solution was older, involving a relatively short period of time (few days).

Abstract. *Ice is one of the few substances on Earth that expands when it freezes. Consequently, this phase change causes damage to porous cementitious materials that absorb water and undergo freeze-thaw cycling. Inspired by nature, the objective of this work is to characterize biomimetic antifreeze polymers (BAPs) that explicitly mimic the behavior of antifreeze proteins (AFPs) and antifreeze glycoproteins (AFGPs) naturally found in plants, fish, insects, and bacteria for use as a concrete additive. The ultimate goal of this work is to enhance the freeze-thaw durability of ordinary portland cement (OPC) concrete without the use of traditional air entraining agents (AEAs). This work will highlight recent research that has shown that small additions, less than 0.1% by wt. of cement, of BAPs that exhibit ice recrystallization inhibition (IRI) activity can mitigate freeze-thaw damage in OPC paste and concrete while entraining less than 3% air.*

Keywords: *Biomimetic Antifreeze Polymer, Freeze-Thaw Durability.*

1 Introduction

1.1 Freeze-Thaw Damage

Concrete exposed to cyclic freezing and thawing temperatures is susceptible to damage. It is commonly accepted that hydraulic, osmotic, and crystallization pressures develop when ice forms in the pore structure of concrete leading to internal micro-cracking (Powers, 1975; Scherer *et al*., 2005). The internal damage reduces the durability by decreasing overall compressive strength, increasing susceptibility to water and ion ingress, and increasing susceptibility to additional freeze-thaw damage.

1.2 Mitigation of Freeze-Thaw Damage in Concrete

The default method used to mitigate freeze-thaw damage in OPC concrete since the 1930s has been through the creation of an entrained air void system via the addition of air entraining agents (AEAs). Research into other methods include super absorbent polymers to create properly sized and spaced voids (Lausten, *et al*., 2015), supplementary cementitious materials (Sabir, 1997; Duan, *et al*., 2013) and nanoparticles (Behfarnia, Salemi, 2013; Gonzalez, *et al*., 2016) for reducing porosity, hydrophobic materials to reduce water ingress (Liu, Hansen, 2016), and polymeric fibers for containment of crack propagation (Nam, *et al*., 2016).

doi:10.23967/dbmc.2020.176

1.2.1 Air entraining agents

AEAs stabilize air voids during the mixing process through a surfactant mechanism. The air voids provide pressure relief sites and preferred locations for ice formation in hardened concrete. In the field it is commonplace to only measure fresh state air content to predict the effectiveness air entrainment, with prescribed values being 3-7.5% by volume of concrete (ACI Committee 201, 2016). However, much research has shown that a proper pore size and pore size distribution, spacing factor, and minimum water saturation level (<86%) must be met for the air void system to be effective (Li, W, *et al*., 2012; T. C. Powers, *et al*. 1954; L. Du, *et al*., 2005; S. Chatterji, *et al*., 2003). AEAs can be highly effective when properly used but notable drawbacks include a reduction in mechanical strength, increased permeability, and retardation of set time (X. Chen *et al*., 2013; H. S. Wong *et al*., 2011). Additionally, it is difficult in the field to obtain a proper size distribution and spacing factor. Recent research has indicated that even when an air void system is properly created, that after a minimum water saturation level is met damage is inevitable (Li, W *et al*., 2012).

1.3 Biomimetic Antifreeze Polymers

Nature produces antifreeze proteins (AFPs) and antifreeze glycoproteins (AFGPs) to allow a variety of cold climate species to survive. Although AFPs display excellent antifreeze properties, they are currently not an economical option due to limitations in production and they are known to lose functionality in the highly basic and ionic environment of concrete (E. Delesky *et al*. 2019). There are a variety of polymeric materials that have shown similar behavior to AFPs and AFGPs, primarily ice recrystallization inhibition (IRI) activity, with PVA being the most widely studied (T. Congdon *et al*. 2013). IRI activity results in the reduction or even prevention of ice crystal grain growth over time (*i.e*., Ostwald ripening). The chemical functionality of PVA mimics the highly hydroxylated carbohydrates of AFGPs. Although PVA is soluble in water, it requires mild heat to go into solution. To this end, a more soluble polymer like polyvinyl alcohol-polyethylene glycol graft copolymer (PEG-PVA) is of interest. Recent work (Frazier *et al*., in review) showed that PEG-PVA displays IRI activity which was expected due to the fact that it is composed of 75% PVA (E. A. Fouad *et al*. 2011).

2 Experimental Methods

2.1 Specimen Preparation

Specimens were prepared using the mix compositions described in Table 1. Specimens were divided into three test groups and labeled according to their PEG-PVA content. One test group, AEA in Table 1, contained a commercially available liquid AEA.

The components of each test group were mixed and poured into cylindrical and prismatic molds. Three 4”x8” cylinders were made for compression testing. Four 3”x3”x16” prisms were made for each test group where three were subjected to freeze-thaw cycles and one kept at ambient conditions for the duration of the freeze-thaw testing. All specimens were stored at room temperature in a vibration-free environment and covered to prevent evaporation of

water. After 48 hours, specimens were removed from the molds and transferred to a saturated $Ca(OH)_2$ solution for the remainder of the curing process. Water was saturated with calcium hydroxide per ASTM C511 (ASTM 2003) to prevent leaching of calcium hydroxide. Cylindrical specimens were cured for twenty-eight days per ASTM C 192 (ASTM 2006) and prismatic specimens for 14 days per ASTM C 666 (ASTM 2008).

Table 1. Mix compositions used for all analysis.

Material (per cubic yard)	Test Group		
	Control	PEG-PVA	AEA
Cement (Type I/II) (lb.)	521	521	521
Fine aggregate (lb.)	1011	1011	1011
Coarse aggregate (lb.)	2040	2040	2040
Water/cement ratio (%)	50	50	50
PEG-PVA/cement ratio (%)	0	0.066	0
Air entraining agent (mL/100 kg cement)	0	0	15

2.2 Fresh State Concrete Properties

Slump and fresh state air content of mixed concrete were measured according to ASTM C143 (ASTM 2011) and C231 (ASTM 2010), respectively. The slump test was performed using a slump test set (Humboldt H-3645). Fresh state air content was determined using a concrete air meter (Humboldt H-2783).

2.3 Hardened State Concrete Properties

The hardened state air content was estimated by measuring the volume of all voids with a diameter greater than 15 μm from micro X-ray computed tomography (MXCT, ZEISS Xradia 520 Versa) scans. The diameter of 15 μm was chosen based on the accepted size range of air voids (P. K. Mehta *et al*., 2006), previous research (Kim, K.Y., *et al*., 2012), and resolution capabilities of MXCT. Cubes with a volume of ~1 in^3 were cut from samples before exposure to freeze-thaw cycles and used for the scans. The MXCT source voltage was set to 140 kV and the power to 10 W. The source and detector locations were varied to obtain a desired resolution of ~ 6 μm. Dragonfly 3.1 software (Object Research Systems) was used to identify voids and calculate their cumulative volume within the scanned volume.

To determine the compressive strength of samples, three cylindrical samples per test group were used in accordance to ASTM C39 (ASTM 2016b). Samples were tested using an ELE International compressive strength testing machine with 10 ksi capacity at a rate of 110 lb./sec.

2.4 Freeze-Thaw Resistance

Rapid freeze-thaw cycling was performed according to ASTM C666 Procedure A (ASTM 2008). Three prismatic specimens per test group were tested for 300 cycles. The freezing portion of the cycle had a duration of three hours and reached a minimum of -18 °C ± 2 °C. The thawing portion of the cycle had a duration of one hours and reached a maximum of 4 °C ± 2 °C. Freeze-thaw resistance was evaluated by measuring the fundamental transverse

frequency and length change of specimens every 36 cycles for up to 300 cycles. Fundamental transverse frequency was determined using forced resonance method in accordance to ASTM C215 (ASTM 2014). The length change was also measured every 36 cycles for the duration of testing.

3 Results and Discussion

3.1 Fresh State Properties

Table 2 provides the fresh state air content (%) and slump (in.) values that were measured at the time of mixing for each test group. Both the slump and fresh state air content increased with the addition of PEG-PVA. It was observed during mixing that the workability improved and concrete was easier to finish with PEG-PVA addition, relative to unmodified concrete. Air bubbles within PEG-PVA modified concrete in the fresh state were visually observed (data not shown) during mixing and finishing processes. It can be concluded that the addition of PEG-PVA entrains some air in the fresh state but less than the AEA dosage used indicating that PEG-PVA has mild surfactant properties. The stability of entrained air in PEG-PVA-modified concrete was investigated in this research and discussed in section 3.2. It is worth noting that the fresh state air content for PEG-PVA modified concrete is less than the 6% recommended for extreme conditions and a nominal maximum aggregate size of 1 in. per ACI Guide to Durable Concrete (ACI Committee 201, 2016).

Table 2. Fresh and hardened state properties of each test group.

Test Group	Slump (in.)	Fresh State Air Content (%)	Hardened State Air Content (%)	Compressive Strength (psi)	Unit Weight (pcf)
Control	0.375	2.1	2.7	5,229	146.13
PEG-PVA	1.625	4.2	2.3	5,086	145.98
AEA	0.625	7.0	4.0	4,902	145.50

3.2 Hardened State Properties

Table 2 presents hardened state properties of samples tested in this research. The air content of PEG-PVA-modified samples decreased from 4.2% in the fresh state to 2.3% in the hardened state which indicated that not all air voids generated by the addition PEG-PVA were stable. The reduction further indicates that the polymer only has a mild surfactant effect. In a similar fashion the samples containing air entraining agent saw a reduction in air content of 7.0% in the fresh state to 4.0% in the hardened state.

Compressive strength was tested for three 4”x8” cylinders per test group after 28 days of curing. The addition of PEG-PVA at an addition 0.066% by weight of cement was found to slightly reduce the average compressive strength by 2.73% compared to unmodified concrete. The addition of AEA at 15mL per 100 kg of cement was found to reduce average compressive strength by 6.25% compared to unmodified concrete. Unit weight at hardened state was found to not be impacted by the addition of PEG-PVA or air entraining agent with reductions of 0.10% and 0.43% compared to the unmodified samples respectively.

3.3 Freeze-Thaw Resistance

3.3.1 Relative dynamic modulus of elasticity

Three specimens per test group went through freeze and thaw cycles (P1, P2, and P3) while one stayed at room temperature (P4) for the duration of testing. Figures 1 shows the relative dynamic modulus of elasticity (P_c) with respect to the increasing number of cycles. Also shown is a constant horizontal line at 60% P_c which signifies failure as specified by ASTM C666. Figure 1a shows that the value of P_c for the unmodified specimens started to significantly decrease after around 75 cycles until failure at 125 cycles indicated by a reduction below 60%. As expected, the P_c for sample P4 maintained 80-90% of the initial measurement indicating that the performance of sample P4 has not changed. Figure 1b and 1c show that the behaviour of PEG-PVA and AEA modified both maintain a Pc above 80% for samples exposed to freeze-thaw cycling (P1-P3) and above 90% for the sample exposed to ambient conditions (P4). These results indicate excellent freeze-thaw resistance for both PEG-PVA and AEA. The fluctuations observed between each data point is likely due to variation in moisture content of each sample.

3.3.2 Durability factor

Figure 2a shows the average durability factor for each test group. Durability factor is a measure that indicates the performance of concrete exposed to freeze-thaw conditions. It is a function of the relative dynamic modulus of elasticity and the number of cycles at which freeze-thaw cycles are terminated as specified in ASTM C666. The average durability factors were 19.1%, 88.6%, and 86.2% for unmodified concrete, 0.066% PEG-PVA, and AEA test groups respectively. The durability factor of unmodified concrete indicates poor performance, which was visually apparent by the loss of paste and aggregate and general loss of structural

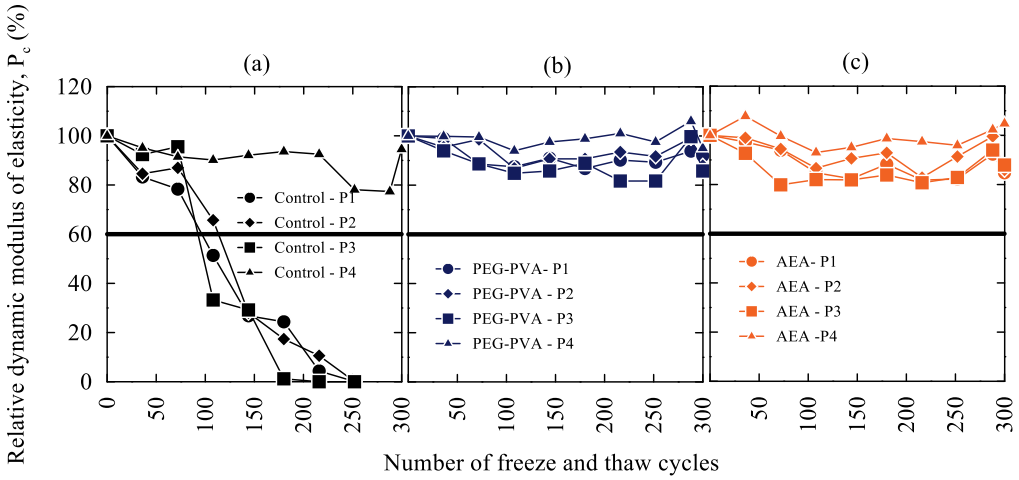

Figure 1. The relative dynamic modulus of elasticity (P_c) for each test group studied up to 300 freeze-thaw cycles. For each test group, samples P1-P3 were exposed to cyclic freeze-thaw temperature while P4 was kept at ambient temperature for the duration of testing. (**a**) 0% PEG-PVA/cement ratio addition (Control). (**b**) 0.066% PEG-PVA/cement ratio addition (PEG-PVA). **(c)** Air entraining agent addition (AEA). The line at P_c equal to 60% represents failure.

integrity of specimens with each subsequent set of cycles. On the other hand, durability factor values for 0.066% PEG-PVA and AEA modified concrete indicate excellent performance, which was also visually observed.

3.3.3 Length change

Measurement of length change during freeze-thaw cycling is described in ASTM C666 as an optional measurement to indicate performance. A length change of 0.1% maybe used as a trigger to stop freeze-thaw cycles and terminate testing. The greater the length change in concrete the more degradation it has experienced and the lower the performance. Figure 2b shows the change in length with increasing number of cycles. The figure indicates that unmodified samples experienced large expansion at the time of failure. 0.066% PEG-PVA and AEA modified samples experienced significantly less length change, less than 0.1%. According to ASTM C666 the unmodified concrete samples have failed while modified samples have passed.

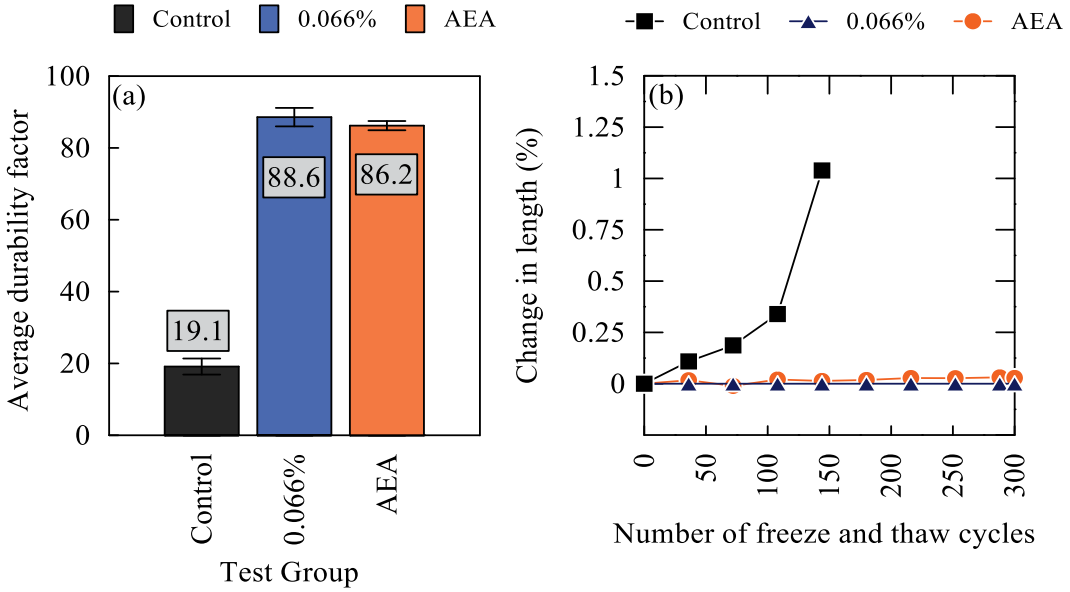

Figure 2. (**a**) Average durability factor for each test group. Error bars indicate standard deviation for n=3. (**b**) Average length change for each test group up to 300 freeze-thaw cycles. Average for n=3 samples per test group.

4 Conclusions

PEG-PVA was found to be as effective as a commercially available AEA at mitigating freeze-thaw damage while entraining minimal air. The addition of PEG-PVA was found to increase fresh state air content and slump compared to unmodified concrete. Although the fresh state air content increased with the addition of PEG-PVA, micro X-ray computed tomography has shown that hardened state air content was less than that of unmodified concrete, 2.3% for PEG-PVA addition. We can conclude that air entrained in the fresh state due to PEG-PVA addition is not stable and the air voids collapse during concrete consolidation and hardening. PEG-PVA-modified and AEA samples were proven to improve freeze and thaw resistance as

indicated by relative dynamic modulus (greater than 80%), durability factor (greater than 85%), and length change (less than 0.1%). Addition of PEG-PVA at a concentration of 0.066% was found to have no influence on compressive strength compared to AEA which experienced a 6.25% reduction.

Abstract. *In recent years, many projects have been carried out to enhance the durability of concrete structure from the influence of cracks. Generally, managing cracks should be a rather preventative method for sustainable development. Based on that, Bacillus subtilis natto - a local bacterium in Japan was found to have the ability to form $CaCO_3$, which can be used as healing materials for cracks in the concrete structure. The bacterial biomineralization immobilized in lightweight aggregate was studied to improve the compressive strength by healing the cracks and densifying the structure. Moreover, as an essential parameter for durability enhancement, the water permeability of self-healing concrete through a water-flow system was carried out. Experimental results on the behavior of the materials indicate that Bacillus subtilis natto could lead the compressive strength to 40 % higher than the controls. Promising result in preventing the water through the cracks confirmed the self-healing effect with more potential in larger-scale.*

Keywords: *Self-Healing Concrete, Calcium Carbonate, Crack, Bacteria, Bacillus Subtilis Natto.*

1 Introduction

Although concrete is probably the most commonly used construction material, cracking in concrete structure has been experienced by both the research community and the industrial engineers. Cracking can lead to many problems, such as water leakage and reinforcement corrosion. For many years, although various repairing methods have been developed with deliberate external intervention, it is difficult in the case of the micro-cracks or cracks embedded deep in concrete structures. Therefore, an automated method to repair cracks is necessary for sustainable concrete infrastructure. Hence, bacteria-based self-healing concrete can be a promising solution to extend the service life and durability of concrete structures. According to previous studies, limited strains of bacteria can be used for self-healing concrete, such as *Bacillus cohnii* (Jonkers, 2007), *Bacillus pasteurii* (Ramachandran et al., 2001), *Bacillus pseudofirmus* (Jonkers and Schlangen, 2008), *Bacillus subtilis* (Matsushita et al., 2010; Huynh et al., 2017).

In this study, *Bacillus subtilis* natto - Japanese microorganism was selected and applied with a suitable proportion of nutrients to form $CaCO_3$ and prevent adverse effects on concrete durability. Based on the urea hydrolysis, bacteria become negatively charged, leading to the rapid attraction of surrounding calcium ions for the biomineralization. Also, bacteria can degrade organic compounds included lactose, as a carbon source for growth and activation.

doi:10.23967/dbmc.2020.024

These processes controlled the adverse effects of nutrients on the properties of fresh and hardened concrete. Moreover, the cement matrix and concrete structure can be enhanced by the densifying process with the generation of $CaCO_3$ and bacterial bioproducts, associated with the high mechanical resistance and high ability of water permeability. Besides, *Bacillus subtilis* natto does not cause disease (Brenner and Miller, 2014), and almost safe to work within the laboratory. Moreover, *Bacillus subtilis* natto would be an economical solution because of the low cost of bacteria spores, compared to the other microorganisms. We aimed to evaluate the strength improvement as well as the self-healing ability of concrete specimens with the bacteria immobilized in lightweight aggregate as a mixture component. This technique was expected to improve the self-healing capacity and extend the life span of bacteria. In addition, the water permeability of self-healing concrete was also investigated by a water-flow testing system.

2 Materials and Experiments

2.1 Compressive Strength Improvement Using Bacterial Lightweight Aggregate

Table 1. Mixture proportion and materials properties for 1 m^3 of concrete.

Group	W/C	Water (kg)	Cement (kg)	Sand (kg)	LWA (kg)	Bacteria (kg)	Flow Upper:no falling motion (mm)	Air content (%)	T (°C)
Natto	0.4	147	370	953	618	0.163	100.8x97.9 119.2x110.8	11	22.3
Controls	0.4	147	370	953	618	-	104.5x102.9 153.4x144.0	3.9	19.3

Percent passing (%)			100		99		47		8

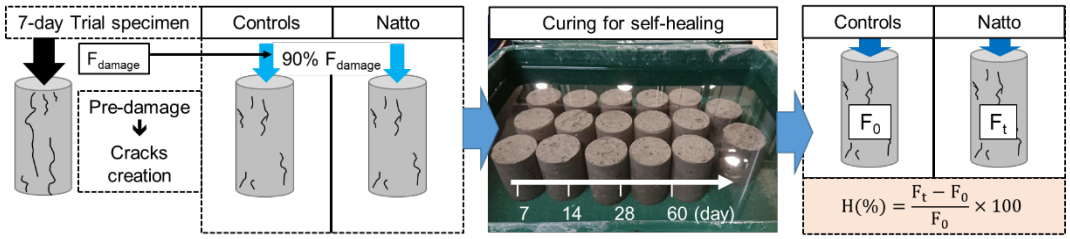

Figure 1. Flow chart for the preparation of lightweight aggregate immobilized bacteria and the continuous strength recovery test.

Table 1 shows the mixture proportion for concrete specimens (Φ = 50 mm, H = 100 mm). The lightweight aggregate (ρ = 1.68 g/cm^3, water absorption = 29.5 %,) immoblized bacteria was prepared as following steps: (i) mixed and stirred the bacterial solution (m_{urea} = 0.45 %m_{cement}, $m_{bacteria} \leq$ 0.5 %m_{cement}, m_{CaCl2} = 0.45%mc_{ement}); (ii) immersed the LWA in solution

for 24 hours; (iii) dried the LWA at 40 ºC for 24 hours. Based on the bacterial concentration in the mixture for 1 m^3 of concrete ($1.1x10^{12}$ CFU/m^3), the bacterial concentration for each specimen was calculated and estimated to $3x10^7$ CFU. Also, the dosage of urea and $CaCl_2$ was controlled with a safety limit according to ACI 318 for maximum chloride ion content in concrete to prevent the corrosion of reinforcement. For the group "Controls", the lightweight aggregate without bacteria was used as the reference. Figure 1 describes the flow chart of the continuous compressive strength improvement test. The load was defined based on the 7-day compressive strength of the "trial-specimen" with the mixture as the controlled. We used the value of 90 % of this value (F_{Damage} = 11 N/mm^2, loading rate = 1.17 kN/s) to create the crack for all of the specimens. The self-healing effect was expected to occur over curing time. The compressive strength was measured after each curing period of 7 days, 14 days, 28 days, and 60 days to compare with the controls for healing capacity calculation. The recovery of the compressive strength of concrete specimens can translate into the self-healing efficiency, and then gives information about the relation between self-healing capacity and curing time.

2.2 Water Permeability of Concrete Using Bacterial Lightweight Aggregate

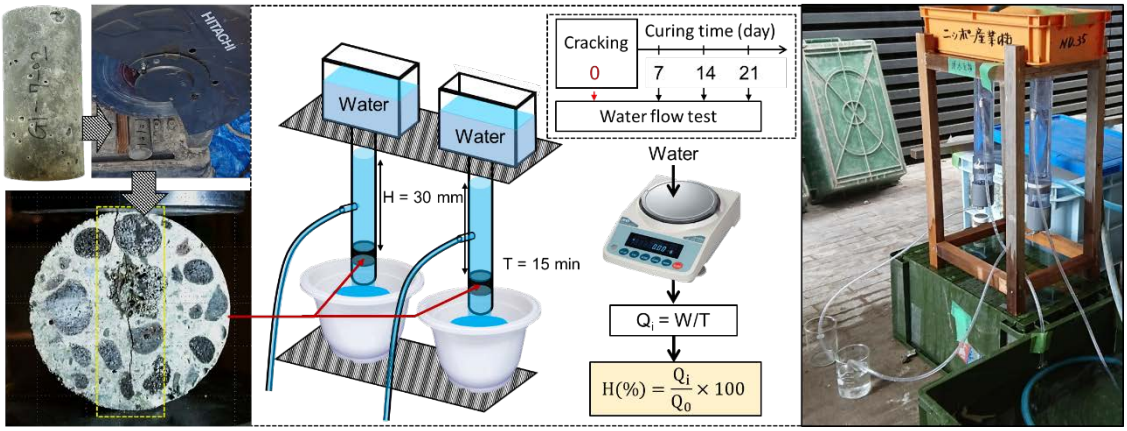

Figure 2. Flow chart for the water-flow test.

In both the cases of using capsule/microcapsule or vascular-based systems, capillary flow through discrete cracks is the primary mechanism (Gardner et al., 2017) for healing agents transporting in cement/mortar to damaged position and create the self-healing effect. Besides, the interaction between the healing fluid, in this case, is $CaCO_3$, and the matrix is rough and more complex than the fluid mechanical theoretical behavior. Therefore, as the description in Figure 2, the test system for evaluating the self-healing effect on water permeability was investigated. The 14-day concrete specimens (mixture as Table 1) were cut into slices (Φ = 50 mm, T = 30 mm) and then cracked under the splitting test. The crack width was measured by using an optical microscope. In the testing system, a continuous water flow with the water head of 30 mm was applied in 15 minutes. The water flow was measured after 7, 14, and 21 days of curing. The Hagen-Poiseuille's law was also used to compare and analyze the change of water flow and crack width under the healing effect. Based on the Hagen-Poiseuille's law, we calculated the water flow after 7 days and 28 days with the crack width by microscope observation. Then, we made the ratio of these values to the initial water flow (Q_T). With the

same method, we made the ratio of measurement value (Q_M). A comparison between the theoretical value and measured value in the experiment was expected to show the structural changes within the cracks, including crack width and crack depth. Also, one group of 1 mm-crack concrete slice was prepared to clarify the mechanism of the effect of biomineralization on the crack healing and reinforcing ability. These specimens were injected by commercial $CaCO_3$ paste ($CaCO_3$ powder and water) and then measured the water flow. The difference between the bonding of concrete substrates and minerals provided from outside and forming in the cracks can demonstrate the bacterial self-healing ability.

3 Results and Discussion

3.1 Compressive Strength Improvement Using Bacterial Lightweight Aggregate

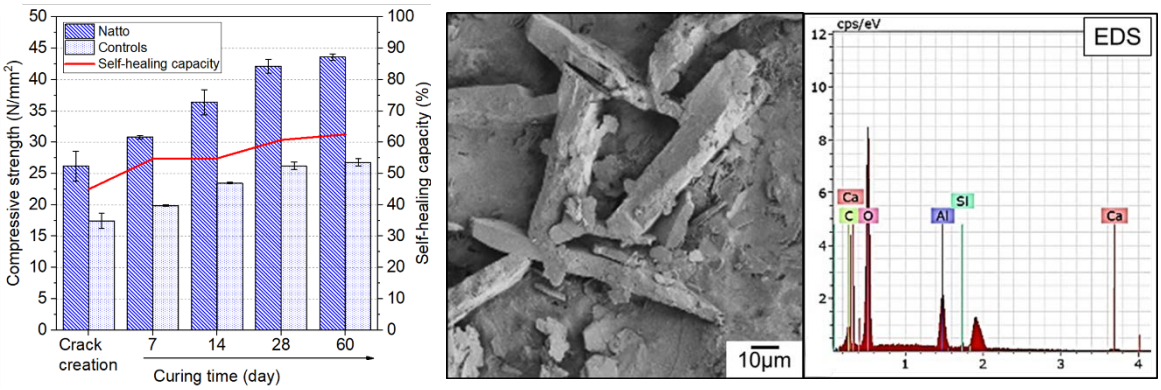

Figure 3. Compressive strength of concrete specimens in the continuous strength recovery test (a), and SEM/EDS result of precipitated $CaCO_3$ inside the crack (b).

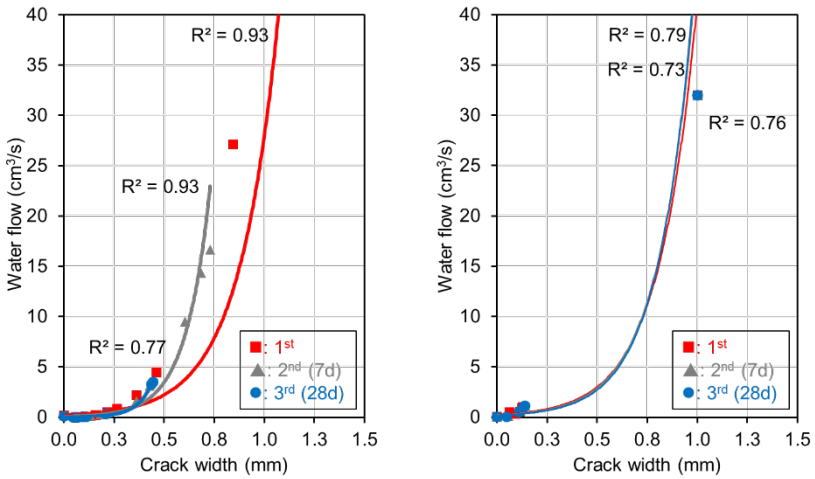
Figure 3(a) shows that the longer the curing time, the higher the compressive strength. Also, the compressive strength of the group "Natto" was significantly higher than the "Controls" at every period. This difference could be caused by the self-healing effect with the capacity of over 40 % just after 7 days curing before the cracking day. This result is higher than the previous study in 2017 (20 %) when using *Bacillus subtilis* JC3 (Rao et al., 2017) directly with a concentration of 10^5 CFU/ml as mixing water; and the study in 2015 (Sarkar et al., 2015) using *Bacillus subtilis* with tryptone (16.6 %). Therefore, the immobilization of bacteria and nutrients in lightweight aggregate could not only prevent the disruption of concrete with the presence of organic matter but also fill the cracks and densify the pore structure. Besides, with this technique, the higher initial concentration of bacteria can be used for a longer duration and higher healing capacity. Moreover, from the 14-day curing period, the gap of compressive strength between the group "Natto" and "Controls" became higher. This result was relevant in the self-healing process with the increasing of $CaCO_3$ over time.

As expected, Figure 3(b) shows a massive amount of $CaCO_3$ formed inside the cracks by the biomineralization of *Bacillus subtilis* natto after 28 days. According to SEM observation, the shape of $CaCO_3$ crystals was similar to the finding of the study using *Sporosarcina pasteurrii* bacteria (Ameri et al., 2019). These rod-shaped crystals could be a reinforced component in

cracks, similar to the strength improvement mechanism of cementitious composite through whisker $CaCO_3$ (Cao et al., 2019). Also, the forming of $CaCO_3$ in the pores of concrete structure could densify the matrix contributes to the high compressive strength.

3.2 Water Permeability of Concrete Using Bacterial Lightweight Aggregate

Figure 4 shows the decrease of water flow with a decrease of crack width after three measurements. Under microscopic observation, the crack width range became smaller and smaller since the first test (Figure 4(a)). In contrast, the controlled specimens show a nearly constant result of water flow (Figure 4(b)) and a slightly reduced crack width. Note that the 0.10 mm or smaller cracks in the controlled specimens can be regarded as smooth and can be closed by the natural self-healing process by late hydration and the reaction of $Ca(OH)_2$ with CO_2. These results can be observed in both cases of test specimens with high correspond between Q_T and Q_M. For the large-sized cracks, it can be seen the increase of crack closing by the decrease of water flow over curing time by the biomineralization (Figure 5(a)). In contrast, the controls show the higher value of Q_M than Q_T after 28 days as a result of the opening inside the cracks with damage by water flow (Figure 5(b)). Also, the significant reduction of measured water flow in the case of bacterial specimens (Figure 5(c)) indicated that the cracks were healed from the internal subsurface. This result was confirmed by the optical microscopic analysis of the crack depth (Figure 5(d)).



(a) (b)

Figure 4. Water flow-crack width relationship after curing time of bacterial specimens (a), and the controls (b).

It can be seen that although water could pass through the specimen, the microscopic images (Figure 6(a)) show that surface crack over 1.5 mm could be healed almost 100 % after 21 days of curing. Note that in the case of controlled specimens, cracks could only be healed within the maximum width of 0.1 mm by the late hydration effect. This result demonstrates that not only the internal subsurface but also the surface cracks could be healed with a high capacity over curing time.

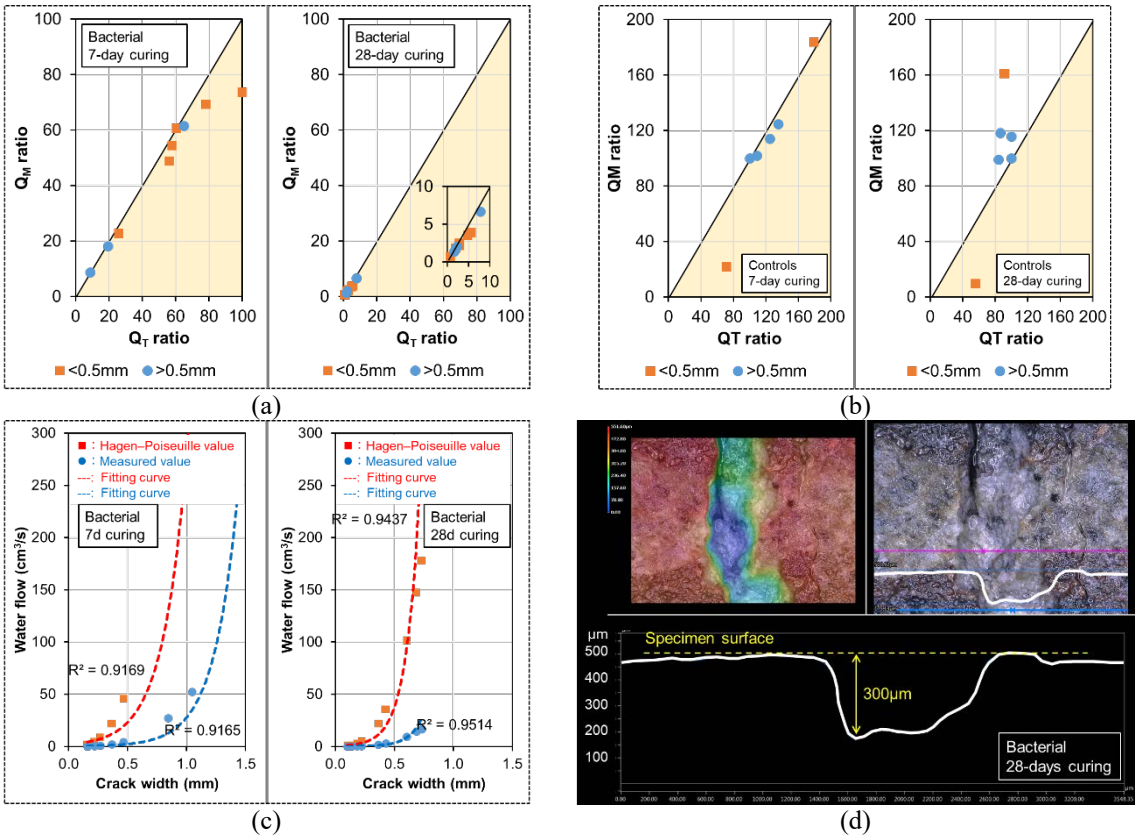


Figure 5. The relationship between the water flow by Hagen Hagen–Poiseuille's law (Q_T) and the measured water flow (Q_M) in the case of bacterial specimens (a), and the controls (b). The change of water flow-crack width over time (c) and the depth of healing crack by optical microscopic analysis (d).

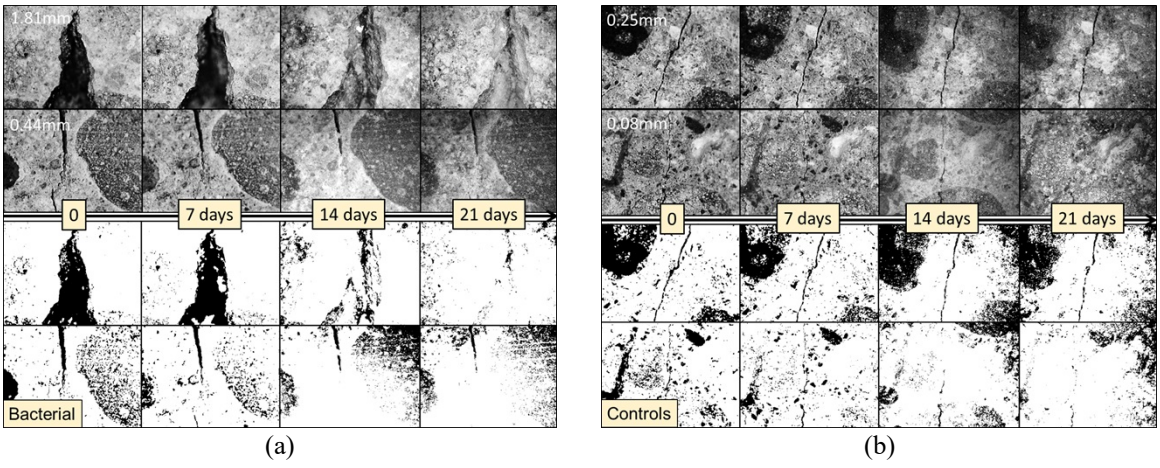

Figure 6. Crack width reduction over curing time in the case of bacterial specimens (a), and the controls (b).

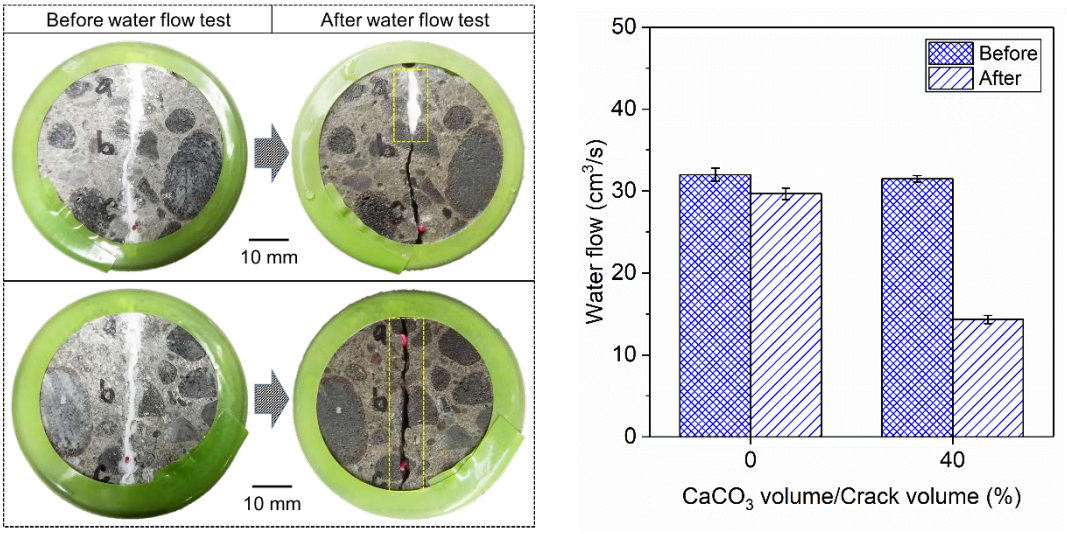
Focus on the 1 mm-crack case; it can be seen the mechanism of $CaCO_3$ forming inside the crack by the activation of bacteria. The result of injected-$CaCO_3$ into the crack shows the significant low effectiveness on prevention water from passing to the upper face of the concrete

slice. This consequence is closely related to the bond between the concrete substrate and the $CaCO_3$ inserted into the crack. Harden concrete after setting period apparently cannot connect paste of $CaCO_3$ by chemical reaction. In this case, only physical force as friction played the role of glue the two surfaces. This temporary cohesiveness decease with the removing of water in the paste. Hence, after natural drying, concrete substrate and injected-$CaCO_3$ separated almost, and immediately be washed away from the crack. Note that a small part of $CaCO_3$ could be adhesive, particularly on the rough surface of the concrete crack. Although this phenomenon occurred nearly in the volume of 40 % of the total crack volume, a considerable amount of water was interrupted from continuously flowing (Figure 7(b)). This result indicates that large amounts of $CaCO_3$, especially rod-like crystals, as well as strong bonding to the concrete surface, can be an effective healing agent for waterproofing targets. Overall, therefore, the reducing of water flow over curing time in the case of using bacteria could be demonstrated clearly. The continuous water flows with 20 mm in height helped to remove the dust, sand, or broken piece of the concrete specimen from the crack position. Also, water pressure was enough to break down any weak bonding between concrete broken surfaces, and organic or inorganic matter potentially appeared. Rod-like $CaCO_3$ crystals precipitated layer by layer under the biomineralization of *Bacillus subtilis* natto may not only fill out the crack but also reinforce the damaged structure.



(a) (b)

Figure 7. The camera photos of injected-$CaCO_3$ specimens surface before and after the water flow test (a). The relation between the water flow of injected-$CaCO_3$ specimen and the estimating volume ratio (b).

4 Conclusion

Experimental results in this study indicate the following concluding remarks:

- Compressive strength after cracking could be improved in the case of using lightweight aggregate immobilized bacteria in the mixture. The healing capacity increased over curing time with the increasing of compressive strength.
- The massive amount of self-healing products could be observed by using SEM/EDS, and optical microscopic images played an essential role in closing the cracks and

densifying the concrete structure.
- The water permeability of specimens using lightweight aggregate immobilized bacteria was significant lower than the controls. Healing capacity increased with the decrease of water flow through cracks over curing time.
- Surface cracks around 1.5 mm could be healed after 21 days, while the internal cracks were closed little by little over curing time.

Abstract. *Anaerobic digestion is a renewable energy production process based on the fermentation of biodegradable biomass. The industrial digesters are usually made of cementitious materials. However, the microbial production of several aggressive compounds (CO_2, NH_4^+ and volatile fatty acids) during the digestion leads to the deterioration of the concrete structure. The growth of microbial biofilm on the surface of concrete is suspected to generate an even more severe biodeterioration. The goal of this study is to provide a better understanding of the biofilm involvement in the biodeterioration of cementitious materials during an anaerobic digestion process. More precisely, this study is focused on the biofilm heterogeneity and its development on cementitious materials in anaerobic digestion. Lab scale anaerobic bioreactors mimicking industrial anaerobic digestion medium were carried out to immerge CEM I cement pastes in this medium during 2, 3, 4 and 5 weeks. The deterioration of cement pastes was evaluated by using a scanning electron microscope to determine the deteriorated thickness and to quantify the volatile fatty acids in the medium. Biofilm attached on the surface of cement pastes was analyzed through molecular biology techniques, such as 16s rRNA gene sequencing analysis and qPCR.To assess the biofilm heterogeneity, successive stalls of the layers of the biofilm were realized using physical biofilm removal techniques. Three microbial fractions are defined: the planktonic microorganisms, the lousy attached and the strongly attached ones. Results showed that the methanogenic Archaea are found mainly in the medium while around half of the microbial population strongly attached is made of acidogenic bacteria. These results suggest that the biofilm could increase the biodétérioration of concrete since the fatty acids are massively produced at the proximity of the surface of the cementitious samples.*

Keywords: *Biodeterioration, Cementitious Material, Biofouling, Biofilm, Bacteria, Anaerobic Digestion.*

1 Introduction

Anaerobic digestion is a renewable energy production process based on the fermentation of biomass. It consists in the succession of four microbial reactions: hydrolysis, acidogenesis, acetogenesis and methanogenesis, leading to the transformation of the biomass into two valuable interest products: the biogas and the digestate. The biogas is mainly constituted of CH_4 and CO_2 at a concentration of about 40-75% of CH_4. The digestate can be used as a fertilizer for agronomic purposes (Bharathiraja *et al.*, 2018).

In the current period of energy transition towards non fossil renewable energies, the anaerobic digestion process shows a growing interest (Salvador *et al.*, 2019), especially on aspects of improving production performance and enriching CH_4 level. In this respect, the focus is on tracks that could increase its durability and thus its performance. One of those tracks could be the durability of the anaerobic digestion tanks (digesters) since it is linked to their lifetime and costs of maintenance. Industrials anaerobic digestion tanks are usually made out of concrete as it is a low cost material, easy to use and adapted to several m^3 tanks. However, anaerobic digestion media is known for being aggressive towards the cementitious materials. The microbial metabolism produces aggressive compounds (CO_2, NH_4, volatile fatty acids), which deteriorate the cementitious matrix. In addition, the formation of microbial biofilms on the concrete surface is highly suspected to increase the kinetics of this deterioration (Voegel *et al.*, 2015, 2016). Microbial biofilms can be described as an aggregation of microorganisms on solid surfaces embedded in a self-produced extracellular matrix; called EPS (extracellular polymeric substances). This microbial organization in biofilms allows the formation of micro-environments locally within the biofilm, as a result of the heterogenic repartition of the different microbial communities, their metabolisms and the diffusion properties of biofilm. Even though the deterioration mechanisms behind the biofilm fouling effects on concrete are not yet clearly identified, there is a strong hypothesis that it is linked to the existence of hyper-aggressive conditions locally on the concrete surface, i.e. at the scale of micro-environments located at the interface between the microbial biofilm and the external surface of the concrete (Bertron, 2014; Magniont *et al.*, 2011).

The present work aims at giving more insights in the biofilm implication in the biodeterioration process of concrete in the specific context of anaerobic digestion tanks. More precisely, this study is focused on the visualization and kinetics monitoring of the development of anaerobic digestion biofilms on cementitious materials, and the exploration of bacterial population heterogeneity in the different biofilm layers.

2 Material and Methods

2.1 Cement Paste Pellets Fabrication

Ordinary CEM I cement pastes were made with a water/cement mass ratio of 0.30. Cylindrical moulds of 2.8 cm of diameter and 6.5 cm height were used. A plastic straw was inserted inside the cement paste at the cylinder central axis, in order to leave an empty space necessary to suspend the paste in the medium during the biodeterioration assays. The cement pastes were then cured for 28 days at 20°C inside their closed moulds. After curing, cement paste pellets with a thickness of about 2.5 mm were obtained by cutting under water the cylindrical cement paste with a circular saw (Prezi, Mecatom 180). The pellets were then polished with a silicon carbide polishing wheel (ESCIL, P800-22 µm).

2.2 Microbial Inoculum and Anaerobic Digestion Culture Medium

Both microbial inoculum and culture medium were chosen to mimic industrial anaerobic digestion, according to the protocol and methods already described by (Voegel *et al.*, 2016). The medium was a synthetic biowaste made up of different organic fractions which have been blended for 5 min at 20°C (Table 1). The inoculum used was an activated sludge sampled from a municipal wastewater treatment plant in Toulouse (France). The volumic ratio microbial inoculum/medium was 2.5/1.

Table 1. Composition of the synthetic biowaste.

Organic fractions	Mass (%)
Water	75.6
potatoes	8.1
tomatoes	3.4
Minced meat	8.1
Milk powder	0.7
Crackers	4.1

2.3 Anaerobic Biodeterioration Assays

The protocol of the cement paste immersion in the culture medium is made to mimic the operating conditions of anaerobic digestion (Voegel *et al.*, 2016). The immersion of the cements pastes pellets were tested in two types of reactors: type A and type B reactors containing respectively eight pellets and one single pellet of cement paste (Figure 1). Type A and type B reactors contained 525 and 66 mL respectively. Therefore, the ratio of the surface of solid cement paste and the volume of the liquid phase was 220 $cm^2.L^{-1}$ in the two types of reactor. These reactors were carried out in the same conditions, at 37°C during 5 weeks for the type A

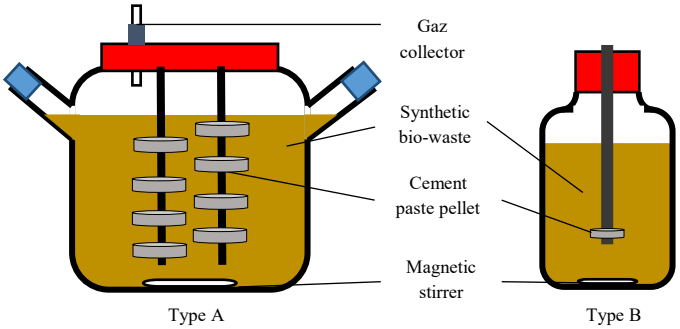

Figure 1. Experimental designs of the anaerobic digestion cultures.

reactor and 2, 3, 4 and 5 weeks for the type B reactor (triplicates for each duration tested). The gas phase (biogas) was collected continuously in the type A reactor and every day in the type B reactor with a collection bag connected to a needle.

2.4 Chemical Analysis

Samples of the medium were taken at the end of each culture and then filtered at 0.2 µm. Ammonium ions concentration was measured using Hach kit LCK 304, following manufacturer instructions. Dissolved organic carbon was determined with a TOC analyzer (TOC-SHIMADZU Combustion). Acetic, butyric and propionic acids concentrations were measured through high performance liquid chromatography (Thermo Scientific, Accela system, column Rezex ROA H^+ 8%, eluent H_2SO_4 10 mM, flow rate 170 $\mu L.min^{-1}$).

2.5 Microbial Populations Analysis

Concerning the biofilm sampling on the surface of cement paste pellets, two types of biofilm layers were defined: the “lousy attached” biomass and the “strongly attached” biomass. The “lousy attached” biomass was removed from a biocolonized cement paste pellet through an immersion of the pellet in 3 mL of phosphate buffered saline (PBS, 0.1M, pH 7.4) for 15 minutes. The “strongly attached” biomass was removed from a biocolonized cement paste pellet with a sonication treatment of 3 minutes in 5 mL of PBS. Removing treatments were not done successively, thus the “strongly attached” biomass should also contain the “lousy attached” one. 2 mL of the culture medium were as well sampled in triplicate. The samples of biocolonized cement paste originated from a type A reactor after 5 weeks of culture. Each removal protocol has been performed in triplicate, i.e. starting from three different biocolonized cement pellets. DNA extraction was performed on the three types of samples (liquid, strongly “attached and lousy attached” biomass) obtained using a DNeasy power biofilm kit, according to manufacturer instructions. Sequencing of the 16S SSU RNA was done using 515F and 806R primers targeting both bacteria and *Archaea*. The sequencing and its statistical analysis were performed by RTlab (USA).

2.6 Physical Analysis

Cement paste pellets from the type A reactor were taken out after 2, 3, 4 and 5 weeks. A cut of the cement paste pellets was realized with a circular saw, in order to divide the cylindrical sample into two identical parts. A part of the pellet was then impregnated under vacuum with epoxy resin (Araldite, 2020) in circular molds (diameter = 2.6 cm). After hardening of the epoxy resin, the surface was polished under water using several polishing disks having decreasing particle sizes of 200, 68, 27 and 15 µm. A thinner polishing was then done using several diamond-covered polishing disks with a decreasing particle sizes (6, 3 and 1 µm). Samples were carbon coated before observation under a scanning electron microscope (Hitachi S-4300 SE/N) coupled with a EDX detector (Thermo Scientific Ultradry) running at 15 kV.

3 Results and Discussion

3.1 Deterioration Profile of the Cement Paste

The evolution of the concentrations of volatile fatty acids (VFAs), ammonium ions and inorganic carbon from 2 to 5 weeks of anaerobic digestion process are shown on (Figure 2).

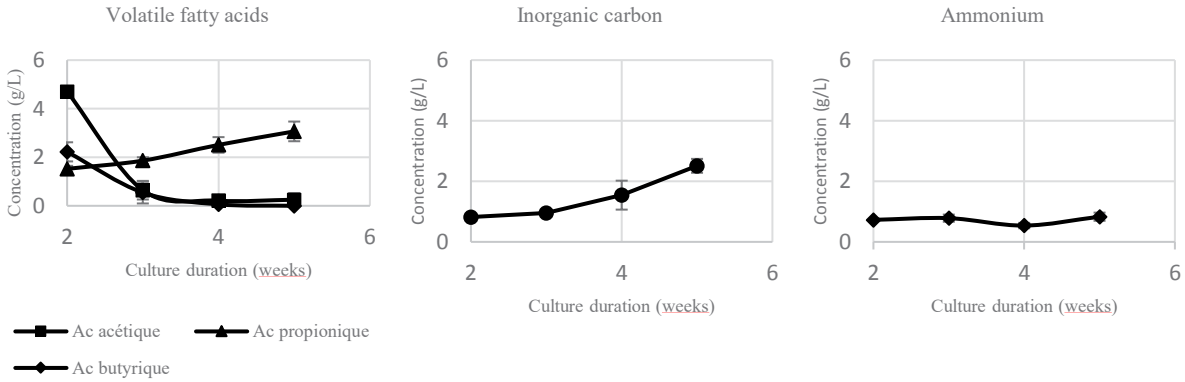

Figure 2. Evolution of concentrations of the aggressive metabolic compounds for a period of 5 weeks of anaerobic digestion process.

After two weeks of anaerobic digestion, the concentration of acetic and butyric acids were of 4.7 $g.L^{-1}$ and 2.2 $g.L^{-1}$ respectively. Their concentrations strongly decreased between week 2 and week 3 to finally stabilize around 0 g/L at end of the fourth week of anaerobic digestion. The propionic acid concentration evolved differently, since it was still increasing constantly from 1.5 to 3.0 $g.L^{-1}$ in the period of time between the 2nd and the 5th week (Voegel *et al.*, 2016). After 2 weeks, both acetic and butyric acids were consumed. This result corroborates those of Voegel *et al.* (2016), who showed that volatile fatty acids are accumulated during the first two weeks of the anaerobic digestion of biowaste, and finally consumed in the following weeks. More curiously, the propionic acid concentration did not drop in the weeks following the 2nd week, suggesting that this VFA has not been reused or metabolized by acetogenic microbial populations or that its production rate was seriously higher than the consumption rate. The dissolved carbon dioxide production increased from 0.8 $g.L^{-1}$, measured at the end of the week 2, to 2.5 $g.L^{-1}$ after 5 weeks. The concentration of ammonium has remained very stable, around 0.7 $g.L^{-1}$, from week 2 to week 5. Since ammonium ions are byproducts of amino acid fermentation (Ramsay and Pullammanappallil, 2001), it should be produced only during the acidogenesis stage occurring mainly during the first two weeks. In this way, we can make the hypothesis that the aggressive nature of the anaerobic digestion environment was at its maximum during the first two weeks of the experiment, since the concentration of aggressive compounds should be at its peak during this period.

Figure 3 allows the localization of the biodeteriorated zones in the depth of a cement paste sample exposed for 5 weeks in an anaerobic digestion medium.

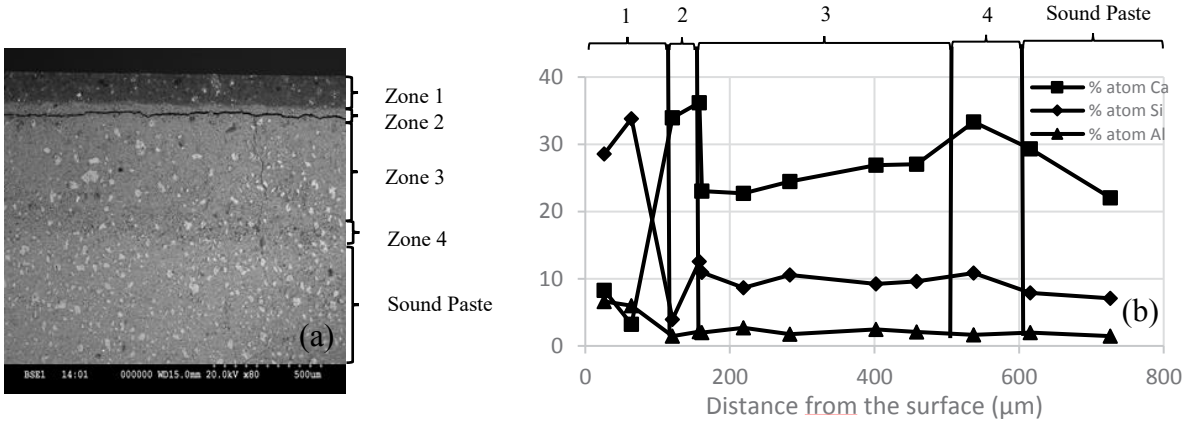

Figure 3. Repartition of the deteriorated zones within the depth of a cement paste (a) and the deterioration profile of a cement paste immerged for 5 weeks in an anaerobic digestion medium (b).

Four zones can be identified (Figure 3): a first layer darker than the others, of about 100 µm. A second zone, about 20-30 µm, can be identified around the crack. The third zone has a variable thickness among the different duration tested from 150 to 400 µm. A fourth zone darker than the third one is also observed, its thickness also changes from a duration to another from 150 to 430 µm, and finally at the heart of the cement paste there is a last zone corresponding to the sound paste. Figure 3(b) shows the evolution of the relative proportion of calcium (Ca), silicium (Si) and aluminum (Al) from the outer surface to 800 µm in the depth of biodeteriorated cement paste sample. The composition in Ca, Si and Al completely changes from a zone to another. All of those zones were found in every duration of exposition tested with the same global composition in each zone. The zone 1, the closest to the cement surface, had a low Ca proportion, around 10 %, a high Si proportion, around 30 %, and a high proportion of Al, about 7 %, in regard to the other zones. The zone 2 had a particularly specific composition: the Ca proportion was significantly higher than in any other zone, up to 70-76 % in both the samples immerged 3 and 4 weeks (data not shown), and a lower proportion of Al and Si around 1 and 5 % respectively. The presence of Phosphor was also observed in the first two zones (data not shown). In the three other zones (zones 2, 4 and 5), only a very small divergence in composition was detected: between 20 and 30 % of Ca, around 10 % in average of Si and 1.5 to 2 % of Al. Those results are representative of a Ca leaching and a P enrichment in the layers close to the surface. However, chemical element proportion analysis can not precisely show every change in mineral composition, as proportion could remain the same while the quantity could change.

Analysis with other techniques, such as X-Ray Diffraction, could give more information, particularly on the residual anhydrous grains. Those results are in accordance with the observations already reported by (Voegel *et al.*, 2016), who studied also cement paste biodeterioration after exposition to digested biowastes. These authors identified Ca leaching as part of the biodeterioration mechanisms.

Table 2 shows the evolution of the thickness of the total biodeteriorated zone for increasing time of cement paste exposition to anaerobic digestion environment. The thickness of the total biodeteriorated zone was determined by the Ca cartography obtained by SEM.

Table 2. Evolution thickness of the total biodeteriorated zone with the exposition time in anaerobic digestion medium.

Exposition time (weeks)	2	3	5
Thickness of the total biodeteriorated zone (µm)	554	594	619

The thickness of the total biodeteriorated zone increases from 2 weeks to 5 weeks of exposition time, from respectively 554 µm to 619 µm. The same kind of observations on cement pastes exposed for longer period, 10 and 15 weeks, should in the future make it possible to confirm this pattern.

3.2 Microbial Populations of the Biofilm

Figure 4 shows the repartition of the different bacterial phyla within the liquid fraction and in the "lousy attached" biomass and the "strongly attached" biomass collected on the surface of a cement paste after 5 weeks in type B reactor. Planktonic and sessile (attached) bacterial populations were different. Indeed, the proportion of *Archaea* was fairly higher in the liquid fraction, *i.e.* 22.0 % against 3.4 % in the attached biomass.

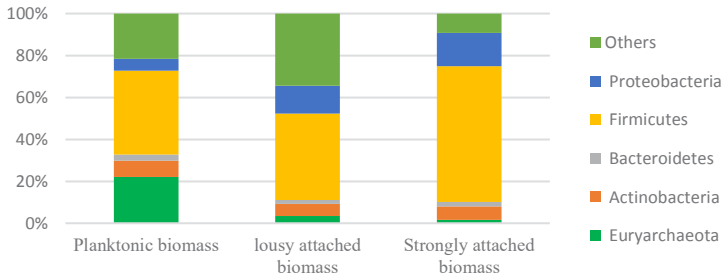

Figure 4. Relative repartition of the bacterial population in the planktonic biomass and in the cement paste attached biomass of a 5 weeks aged anaerobic digestion culture.

Among the *Archaea* highlighted in the liquid fraction, 17.7% belonged to the *methanosarcina* genus, which are anaerobic methanogens found in a multitude of environments and capable of producing methane by the three metabolic modes of methanogenesis (hydrogenotrophs, acetotrophs, methylotrophs) (De Vrieze *et al.*, 2012). The biofilm developed on the surface of the cement paste, and more specifically the "strongly attached" biomass, was rich in *Firmicutes*. Around 50% of the DNA sequences from the "strongly attached" biomass belonged to acidogenic populations. Among them, *Clostridium butyricum* (5.4%), is known to specifically produce butyric acid and *Megasphaera eldesnii* (29.5%), is described as able to produce acetic, propionic and butyric acids (Marounek *et al.*, 1989). Those results suggest that the acidogenesis step of the anaerobic digestion may mainly occur in the biofilm, while the methanogenesis step would take place in the liquid fraction. Beyond these considerations based essentially on the physical organization of communities (biofilms vs. suspended/planktonic populations), would not there be a major effect of pH behind this whole phenomenon? If the pH at the surface is too alkaline for bacteria to easily grow on it, perhaps only acidogens are able to lower the pH through the acids they produce to allow a biocolonization of the surface of material.

4 Conclusion

The SEM analysis of the cement pastes exposed from 2 to 5 weeks to an anaerobic digestion medium showed a biodeterioration of the cement paste characterized by a depth up to 700 µm with calcium leaching and phosphor enrichment in the first 100 µm. Bacteria present in the biofilm colonizing the cement paste are mainly acidogens, which may confirm the hypothesis that the microbial fouling of the cement paste is caused by the local production of aggressive compounds, such as organic acids acting on reducting the surface pH of cementitious materials. The use of fluorescent dyes could help measure the pH both in the biofilm and on the surface of the cement paste through fluorescence microscopy observation techniques.

Abstract. *Material degradation of our civil infrastructure is inevitable, and regular maintenance is required to mitigate against failure during the service-life. However, understanding and knowledge of composites is now leading to the creation of concretes with autonomic self-healing capabilities. This development will transform our infrastructure by embedding self-immunity and resilience so that structures evolve over their lifespan enhancing durability and serviceability, improving safety and reducing maintenance costs. Research in the UK under the auspices of Resilient Materials for Life (RM4L) has developed a suite of multiple-scale biomimetic self-healing concretes that can adapt and respond to damage without external intervention. This paper discusses the development of bacteria to precipitate calcite in cracks in concrete. Whilst bacteria-based healing is possible through several pathways, it is only now that a better understanding is permitting the optimization of the process. There are two key technologies for including bacteria healing in concrete: (i) encapsulation and (ii) vascular flow networks. Vascular flow networks permit continuous unlimited delivery of healing agents to internal areas of damage, facilitating repair on a reoccurring basis. However, in order to use them effectively human intervention is required to identify cracking and trigger healing processes. A more biomimetic approach is to provide the concrete with a form of self-sensing capability to enable it to initiate crack healing itself. Research using PZT sensors to detect cracking is described.*

Keywords: *Bacteria, Self-Healing, Self-Sensing, Flow Networks, PZT, Electromechanical Impedance.*

1 Introduction

Concrete remains the principal construction material used in buildings and infrastructure worldwide. However, it is susceptible to degradation which, given current design guidance, is nearly always inevitable over its lifetime. This means that intervention and mitigation, in the form of maintenance and repair, is necessary to retain and recover high levels of performance and durability. However, in recent years a range of 'smart' concretes has been developed, including those with autogenous and autonomic self-healing and self-repairing capabilities. Consequently, it is now possible to embed self-immunity and resilience in our concrete buildings and structures such that they evolve over their lifespan. This has significant implications for enhancing durability and serviceability, improving safety and reducing maintenance costs.

Research to develop a biomimetic approach to the repair of concrete is being undertaken in the United Kingdom as part of the £5M multi-disciplinary research project, Resilient Materials for Life (RM4L), a collaboration between Cardiff University, and the Universities of Bath, Bradford and Cambridge (Al-Tabbaa *et al*., 2018). RM4L has a broad remit to focus on tailoring

self-healing cementitious systems for use in specific applications and to address different damage scenarios and conditions. Furthermore, important damage scenarios have been identified, including time-related and cyclic damage as well as chemical damage, including corrosion. In addition to self-healing attributes, RM4L is initiating novel research aimed at embedding self-sensing, self-diagnosing, self-immunisation and self-reporting capabilities into cementitious systems in order to develop truly biomimetic responses in our infrastructure materials and structures.

This paper reports on current research being undertaken within RM4L by the University of Bath in the areas of bacteria-based self-healing concrete (BBSHC) and self-sensing concrete. We also introduce the concept of a smart biomimetic self-healing concrete formed from the integration of three technologies: (i) bacteria-mediated calcium carbonate precipitation, (ii) vascular flow networks (VFN) and (iii) electromechanical impedance (EMI) that could deliver long-term maintenance and repair of concrete buildings and structures without the need for human intervention.

2 Bacteria-Based Self-Healing

In order to achieve autonomic healing in concrete, a wide range of healing agents have been studied over the last 20 years. These healing agents need to be compatible with the cementitious matrix and their speed of reaction has to be appropriate to eliminate ingress of harmful pollutants (chlorides, sulfates etc.). In general, healing agents with low viscosity and high sorptivity have been preferred. Whilst cyanoacrylates and epoxy resins have these required properties, they are generally incompatible with the cementitious matrix. Consequently, there is a search for a suitable cement-like material. Research at the University of Cambridge is having some success with sodium silicate (Giannaros *et al.*, 2016) .

However, an alternative is to use of bacteria to aid with the precipitation of calcium carbonate within the crack. Calcium carbonate occurs naturally in concrete as it ages, and consequently its use as a healing compound is entirely appropriate.

Bacteria-based self-healing is achieved by embedding bacterial spores within the concrete and providing them with the nutrients that they need to grow. Whilst the bacteria are in their spore form, they are inactive. However, when conditions become favourable, they germinate into active cells and these multiply. These more favourable conditions occur when a crack forms in the concrete and water and oxygen ingress.

The presence of bacteria near a crack will aid the formation of calcium carbonate should the local environment be rich in dissolved inorganic carbon (DIC) and Ca^{2+} ions (Figure 1). For this reason, growth media containing both carbon and calcium sources are normally used simultaneously with the spores as healing agents. In general, bacteria-based self-healing of concrete can occur because of either ureolytic or non-ureolytic metabolism.

Research at Bath has performed a comparison between how ureolytic and non-ureolytic environmental bacteria precipitate calcium carbonate in order to understand how these mechanisms differ and how we can apply this knowledge to the improvement of self-healing concrete (Reeksting *et al.*, 2020). In this study, environmental bacteria were surveyed for their ability to precipitate calcium carbonate and both the mechanism and resulting precipitates were examined. It was shown that while ureolytic bacteria cause the most rapid precipitation, non-ureolytic bacteria were capable of producing similar amounts of calcium carbonate. In addition,

the crystals resulting from non-ureolytic carbonate precipitation appeared to have more organic components and subsequently occupy larger volumes (Figure 2, left), this is likely beneficial for crack sealing application as for the same amount of calcium a larger precipitate can be formed. Indeed, non-ureolytic bacteria caused a more consistent crack healing and subsequent recovery of water tightness (Figure 2, right).

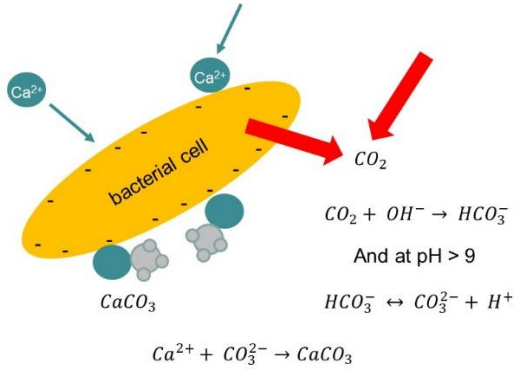

Figure 1. Process of calcium carbonate precipitation in a concrete crack (adapted from Dhami *et al.*, 2013).

To date, self-healing of cementitious composites at Bath has focused on non-ureolytic bacteria, *e.g.*, *Bacillus pseudofirmus* and *Bacillus cohnii* (Sharma *et al.*, 2017). The spores of the bacteria have been encapsulated under vacuum in a lightweight fine aggregate (*e.g.* perlite). The growth media, yeast extract and a calcium salt (calcium acetate or calcium nitrate) have been added either directly to the concrete, or encapsulated in lightweight fine aggregates, depending on the application.

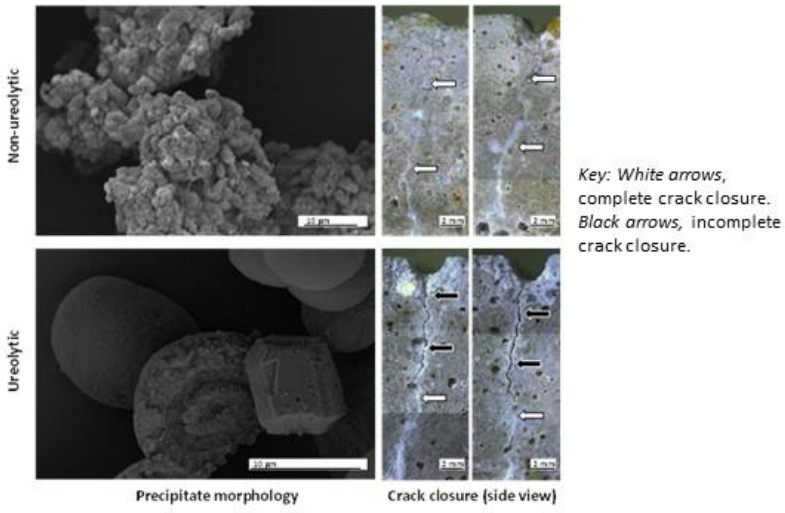

Figure 2. Crystal morphology and crack sealing in mortars containing either non-ureolytic or ureolytic bacteria. *Left*, electron micrographs of representative precipitate produced by non-ureolytic (top) and ureolytic (bottom) bacteria. *Right,* crack healing down the side of cement mortars at 8 weeks healing.

It has been shown that the lightweight fine aggregates rupture on cracking releasing the healing agents in a form that enables calcium carbonate precipitation and healing to take place and that the concrete recovers its water tightness (Alazhari *et al.*, 2018).

However, a concern with the use of lightweight aggregates is that they may not distribute homogeneously throughout the matrix. Consequently, there are some concerns (although not to date replicated in laboratory tests) that cracks may entirely miss the aggregates. For this reason, research at Bath has also considered supplying the spores and/or the growth media in microcapsules (Paine *et al.*, 2019). We have shown that the encapsulation of spores by, for example, the complex coacervation technique, creates few technical issues and that high yields of spores can be obtained in small microcapsules (180 μm). However, encapsulation of growth media is more difficult and only low loadings could be obtained and the microcapsules were much larger (~ 609 μm). In both cases, however, it was shown that the microcapsules rupture upon cracking of the concrete and that crack closure and recovery of water tightness occurs. That said, whilst the encapsulation of bacteria and growth media in concrete has proven successful there are some elements of this technique that could still be improved upon.

Firstly, the use of encapsulation means that the quantity of growth media in the concrete is fixed, limiting the amount of bacterial growth and the volumes of calcium carbonate precipitated. The addition of further growth media, such as yeast extract, directly into the concrete will substantially retard the cement hydration; whilst the calcium source is likely to carbonate and be unusable by the bacteria. The encapsulation of these growth media in lightweight aggregates will lead to unreasonable losses in strength.

Furthermore, recent research has shown that the degree of bacteria-based calcium carbonate precipitation in concrete is limited by the availability of oxygen (Nielsen *et al.*, 2019). Whilst researchers have attempted to overcome this by encapsulating calcium peroxide in the concrete (Zhang *et al.*, 2016). this has had limited success and creates additional complexity.

Consequently, it has been considered that there may be some benefit in providing a vascular flow network (VFN) within the concrete that can supply oxygen and nutrients to the crack when healing is required. Furthermore, this VFN could be used to resupply the concrete with further spores and nutrients to permit it to self-heal again should the crack reoccur at the same place.

3 Vascular Flow Networks

VFN systems have been considered as a viable technique for providing self-healing in materials as they more readily simulate the way flora and fauna heal themselves (White *et al.*, 2001). A wide range of healing agents or supplies can be pumped through a VFN to the site of damage as and when required. The reservoir of healing agent can be readily topped up allowing for multiple healing events and the healing agent can be varied to suit the type of damage.

However, until recently the use of VFN for concrete had created problems; primarily because the glass used to create the channels tended to break during casting. For this reason, a novel approach has been developed at Cardiff University (Davies *et al.*, 2015). Here, shrinkable polyurethane tubes are embedded in the concrete that can easily be removed after the concrete has hardened around them. This leaves a hollow network within the concrete. When healing is required, air can be removed from the VFN and the healing agents then added remotely and pumped through under pressure.

The addition of a 2-dimensional VFN to a bacteria-based self-healing concrete wall was trialled as part of a large-scale demonstration of self-healing techniques carried out as a forerunner to the RM4L project (Paine *et al.*, 2018). The wall consisted of both bacteria-based self-healing concrete and conventional concrete as shown in Figure 3. Bacteria-based self-healing concrete was only added to the wall at the section where cracking was designed to occur (Figure 3b). A vascular flow network consisting of 4 mm diameter channels was placed in the zone most susceptible to cracking. The network was created using polypropylene tubes which were removed from the concrete once it had hardened. The network channels were joined using 3D printed joints made from polylactic acid. Whilst the VFN was included to permit later addition of further growth media, bacteria or oxygen as required it was never actually used in this way and bacterial healing was allowed to progress without interference

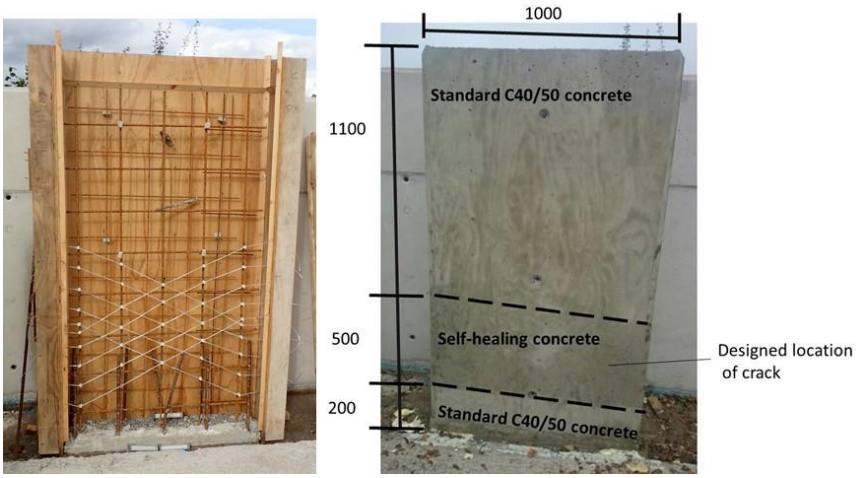

Figure 3. Large-scale demonstration of a bacteria-based self-healing concrete with: (a) VFN installed prior to casting of the concrete, (b) finished wall (dimensions in mm) (Paine *et al.*, 2018).

However, a principal problem with a VFN is that the release of the healing agents is not initiated by the cracking of the concrete. In general, it requires some form of monitoring system, often just visual observation, to detect the cracking and then human intervention is required to upload the healing agents and pressurize the system to pump the those healing agents through the network. However, recent research at Bath has been investigating the suitability of self-sensing systems that may detect and diagnose the formation of cracks, and their repair, within concrete. This sensing could potentially be used to trigger the healing system.

4 Triggering Healing Systems

Whilst there has been much research into the use of sensors for structural health monitoring, as far as we are aware there has been no research where autonomic self-healing responses have been triggered by sensors embedded within concrete. This is therefore a novel area of research.

Piezoelectric materials are popular sensors due to their ability to detect a wide range of parameters (stress, temperature, cracks and damage) and due to their high sensitivity, stability

and low cost. There has been significant research with lead zirconate titanate (PZT) transducers. Of note is the use of electromechanical impedance (EMI) in which the PZT transducer works as both an actuator and detector simultaneously. Damage in a structure can be observed from fluctuations in the admittance/impedance signature which are caused by changes in the intrinsic material properties such as mass, stiffness and damping.

To better understand how a sensing system could be used to trigger healing once damage occurs and deactivate after repair, research has been carried out at Bath to understand how the EMI response of a PZT responds in both damage and repair scenarios (Taha *et al.*, 2019).

This research has shown that localized damage in mortar beams, can be detected by a surface mounted PZT transducer located up to 220 mm away from where the damage has occurred. It was further observed that as the damage level increased, and approached the PZT, that the difference between the initial admittance signature and subsequent signatures increased, see Figure 4(a). This behavior was quantified by the root mean square (RMSD) response shown in Figure 4(b). On the other hand, when the damage was repaired, using a cement paste, it was observed that the RMSD gradually decreased (Figure 5). This indicated at least a partial recovery of properties due to the repair.

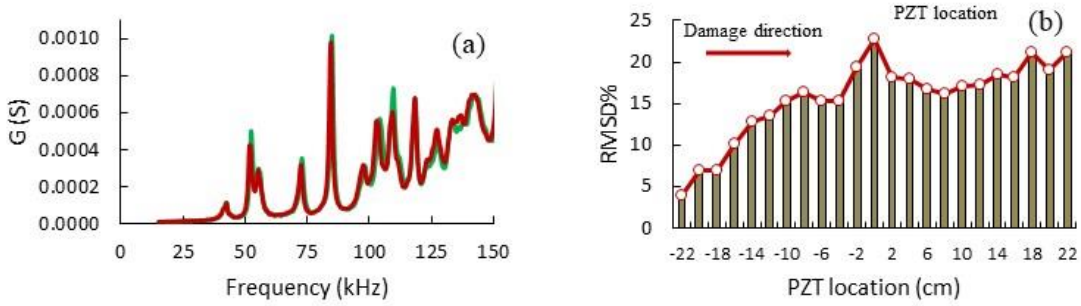

Figure 4. (a) Admittance signature for PZT before and after damage, (b) RMSD% as the damage approaches and distances from the PZT sensor.

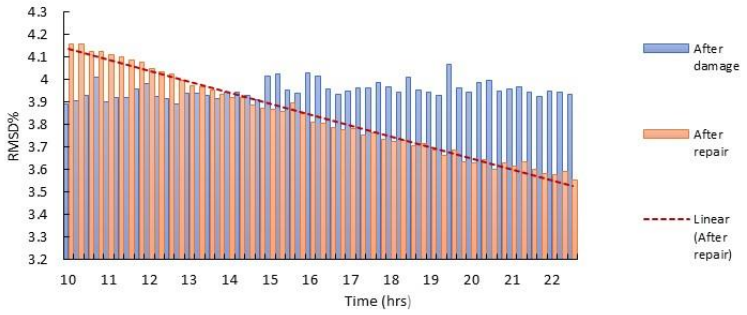

Figure 5. RMSD behavior 10 hours after repair as compared with the RMSD after damage.

5 Integration of Technologies

As described above research is being undertaken at the University of Bath and partner universities within the RM4L programme grant to develop these three technologies. Whilst these developments are primarily taking place individually, there is a proposition that they could be integrated to form a smart biomimetic self-healing concrete, as shown schematically in Figure 6. Here a concrete building or structure can be cast using BBSHC around an embedded VFN, with PZT sensors, or some other form of sensing, strategically placed within or on the surface of the concrete. When a crack occurs the bacterial activity autonomically heals the cracks by precipitating calcium carbonate. However, simultaneously, a sensor detects that cracking has occurred. If it detects, after a given period, that the degree of healing is insufficient it triggers through an interface the activation of the VFN. Consequently, oxygen and/or further growth media are pumped through the VFN to the site of the crack from an external reservoir. Once the sensors have identified that healing is sufficient, they stop supplying oxygen and/or growth media. It is possible that at this point further spores and nutrients could be pumped to the site of the crack to permit further autonomous healing and for the cycle to recommence should a crack reappear at the same location at some further point in time.

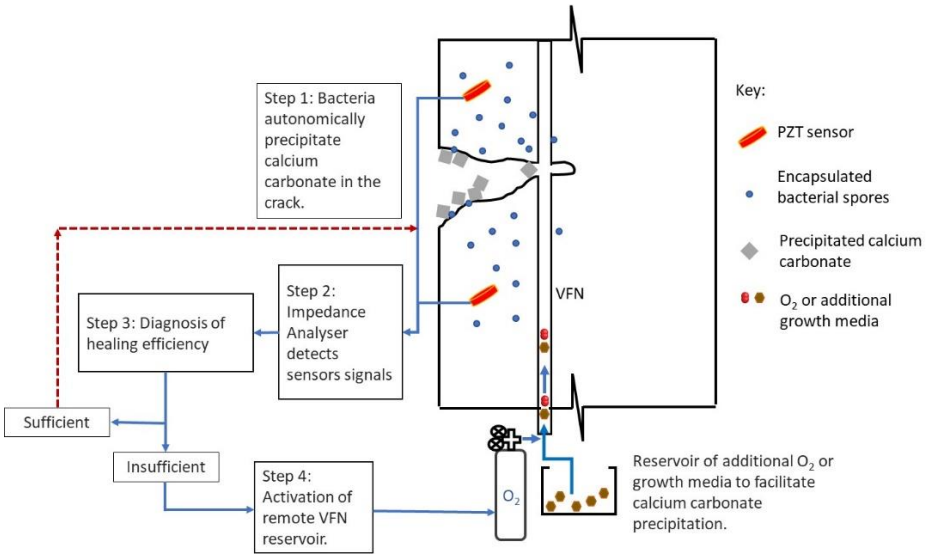

Figure 6. Schematic showing the integration of BBSHC, VFN and sensing technologies for biomimetic smart self-healing concrete.

6 Conclusions

- BBSHC, consisting of encapsulated spores and growth media, can be used to autonomically self-heal cracks in concrete as soon as they occur by precipitating calcium carbonate. However, the quantities of calcium carbonate precipitated may be limited by the availability of the growth media and oxygen.
- VFN can be formed in concrete and they permit remote healing agents and supplies to be pumped to the site of cracks to assist with bacteria-mediated calcium carbonate precipitation.

- EMI has potential as a sensing technology to identify the degree of healing (quantity of calcium carbonate precipitated) in cracks. When interfaced with appropriate software it can be used to trigger the supply of healing agents through the VFN.

Two-Part Bio-Based Self-Healing Repair Agent for Cement-Based Mortar

Mustafa Mert Tezer[1] **and Zeynep Başaran Bundur**[1]

1 Department of Civil Engineering, Ozyegin University, Cekmeköy, 34987, Istanbul, Turkey
zeynep.basaran@ozyegin.edu.tr

Abstract. *Factors affecting durability of concrete structures are generally associated with each other. Due to its brittle nature, concrete can crack under stress and these cracks are one of the main reasons for a decrease in service life in concrete structures. Therefore, it is crucial to detect and recover microcracks, then to repair them as they were developed to wider cracks. Recent research in the field of concrete materials suggested that it might be possible to develop a smart cement-based material that is capable of remediate cracks by triggering biogenic calcium carbonate ($CaCO_3$) precipitaton. This paper summarizes a study undertaken to investigate the self-healing efficiency of Sporosarcina pasteurii (S. pasteurii) cells immobilized on both diatomaceous earth and pumice, to remediate flexural cracks on mortar in early ages (28 days after mixing). To obtain a two-phase bio additive, half of the minerals were saturated with a nutrient medium consisting of urea, corn-steep liqueur(CSL) and calcium acetate and the cells with immobilized to the other half without nutrients. Screening of the healing process was done with ultrasonic pulse velocity (UPV) testing and stereomicroscopy. With this approach, the cracks on mortar surface were sealed and the water absorption capacity of the so-called self-healed mortar decreased compared to its counterpart cracked mortar samples.*

Keywords: *Self-Healing, Biomineralization, Diatomaceous Earth, Pumice, Mortar.*

1 Introduction

Concrete is the most widely used material in the construction industry due to its high compressive strength, durability and cost efficiency compared to the alternative building materials. Nevertheless, early age cracks occurring in concrete can decrease the strength of the materials and limit the service life of the concrete structures. These cracks can create pathways for hazardous chemicals and excessive water and increasing permeability of concrete. Conventional repair methods like, epoxy sealing or grouting are applied from the outside and expected to penetrate into the cracks. While this approach is feasible for repairing large cracks, penetration of the abovementioned sealants to the inner parts of small and deep cracks is very limited. Therefore, for narrow microcracks, there is a need for an alternative repair method by mostly means of self-healing.

Recent studies in the field showed that it might be possible to develop a bio-based self-healing system where bacterial cells are being used to remediate cracks by triggering microbial induced calcium carbonate precipitation (MICP) (De Muynck *et al*. 2010; Wang *et al*. 2016; Zhang *et al*. 2015). MICP is a biochemical process in which microorganisms stimulate the formation of calcium carbonate ($CaCO_3$) (Mann 2001) . With this approach, tensile or flexural cracks as wide as 0.7 mm was remediated and the water permeability of mortar was reduced (Jonkers and Schlangen 2007; Wang *et al.* 2012c, 2014b; Wiktor and Jonkers 2011). Crack healing through MICP requires a suitable bacterial culture and the nutrients to support metabolic activity and create the proper environment for crack closure. The main challenge of the application is to find a microorganism that can tolerate highly alkaline conditions of cement

paste, can survive the mixing process, and can remain viable with limited access to nutrients (Tiago *et al.* 2004) . A simple approach by means of limiting the labor work in processing is adding the vegetative bacterial cells directly to the mix Previously, Bundur *et al.* (2017) showed that vegetative *S. pasteurii* cells could survive in mortar up to 11 months when they were added to the mix without any encapsulations. These remaining cells were found to be effective in remediation of the microstructure when internal microcracks (Liu *et al*. 2016) and flexural surface cracks in 7 day old samples (Amiri *et al.* 2018). However, limited viability and lack of O_2 decreased the performance of $CaCO_3$ yield through all crack the depth. Instead, the precipitation was found to be limited to the crack mouth in microscale cracks (Amiri *et al.* 2018). However, considering the larger surface cracks, the amount of retained viable cells may not be able to precipitate sufficient biogenic $CaCO_3$ to seal the cracks. Thus, it is crucial to develop a simpler and natural protection system to improve the robustness of the bacterial cells against the restrictive environment.

Concerns regarding the viability of the cells and limited crack healing led researchers to propose various encapsulation methodologies, particularly for dormant state endospores. The encapsulation methods consist of embedding the endospores in a protective covering, e.g. inorganic lightweight porous aggregates (LWAs) (Wiktor and Jonkers 2011), polymeric membrane (Bang *et al*. 2010; Wang *et al*. 2012a), microcapsules (Wang *et al.* 2014b), hydrogels (Wang *et al.* 2014a) and natural minerals (Alazhari *et al.* 2018; Wang *et al.* 2012b). Amongst all these approaches, LWAs and hydrogels have shown the most promising developments regarding the viability. The methods were promising in terms of healing cracks at various ages of concrete, but to-date most of the studies revealed that cracks could be healed in samples as old as 28 days.

Instead of using synthetic encapsulation covering, a more sustainable approach could be achieved by using natural additives or natural lightweight aggregates. Throughout the literature, studies showed that among several alternatives such as diatomaceous earth (DE), metakaolin, zeolites and expanded clay could be suitable for protection of the bacteria based on their effects on compressive strength and setting, in particular DE was found to be effective in self-healing of cracks (Erşan *et al*. 2015; Wang *et al*. 2012b). Nevertheless, considering the natural resources, the list of these natural protective barriers could be extended. A correct choice of the protection barrier and application methodology are of crucial for further development of self-healing concrete. This study presents a comparative study on the possible use of a mineral additive (DE) and a porous lightweight aggregate (pumice) as a protective barrier for bacterial cells.

2 Materials and Methods

2.1 Microorganism Selection and Growth

Leibniz Institute- German Collection of Microorganisms and Cell Cultures: S. pasteurii (DSMZ 33) cells were selected and used as a self-healing agent in cement-based materials. *S. pasteurii* cells were grown in a Urea-corn steep liqueur (CSL)-sodium acetate nutrient medium (UCSL) which includes tris base (0.13M), CSL (15 g), sodium acetate (10g) and urea (20 g) per liter of distilled (DI) water. The pH of the medium was adjusted to 9. First, the nutrient medium was sterilized at 121°C for 45 minutes. The cells were incubated aerobically in sterilized liquid

medium with shaking conditions (175 rpm) at 30°C until the stationary phase (10^9 CFU/mL) was reached. Then, the cells were collected from the culture by centrifuging at 6300g for 15 min. The cells were washed twice by PBS (Phosphate buffered solution) and stored at 4°C until immobilizing.

2.2 Material Composition

DE (Diatomaceous Earth), and pumice were used to immobilize bacterial cells. DE was provided regionally from a source in Turkey. DE particles used in the experiments were raw materials without any further treatment and having irregular shapes. A Mastersizer 2000 particle size analyzer with a Hydro MU 2000 (Malvern, Worcestershire, United Kingdom) wet dispersion unit was used to measure the particle size distributions of cement and DE. To prevent hydration of the cement particles, the cement particles were dispersed in ethanol. The average particle sizes of DE and cement were determined as 19.20 and 23.2 μm, respectively. The particle size was ranging from 0.375 to 90 μm for DE and it was ranging from 5 to 90 μm for OPC. DE was used as an addition to the mix by 5% of cement weight. The absorption capacity of DE was found to be almost 100% by its weight. Pumice was used as aggregate replacement such that 5% of the sand used in mortar mixes. The particle size of light weight pumice aggregate was in between 0.3 to 2.5 mm, while the absorption capacity was 45% by its weight.

Besides the additions or replacements, mortar samples were prepared using OPC CEM I 42.5R and standard sand accordingly to the norm EN 196-1. A polycarbooxylate superplasticizer was used to maintain the same workability criterion for all samples. The water to cement ratio (w/c) was kept at 0.45.

2.3 Immobilization Procedure

The immobilization was achieved by simply submerging the DE or pumice to a bacterial suspension. To immobilize the cells on DE, 2 grams of viable *S. pasteurii* cells were collected as it was stated in Section 2.1, and they were resuspended in a sterilized 50 mL PBS solution. Then, 22.5 g of DE was added to the suspension. Sixty-seven grams of pumice was added to the 6 grams of cell suspension in 80 mL PBS. Immobilization for both materials was achieved with shaking conditions (175 rpm) at 30°C for 24 hours. Then, the slurry was removed from incubation and kept at 40°C in an oved for an additional 12 hours. Excess PBS content on DE and pumice was calculated by subtracting the known weight of DE/pumice, bacterial cells and theoretical absorbed PBS from the final weight of oven dry slurry. This value was subtracted from the mixing water content. To ensure the immobilization was achieved, the morphology of the DE and pumice was evaluated before and after treatment by a FEI-Philips XL30 Environmental Scanning Electron Microscope with Field Emission Gun (FEG). Figure 1 and 2 show the SEM images obtained before and after immobilization procedure, respectively.

2.3 Experimental Planning

2.3.1 Preparation of mortar samples

Mortar samples were prepared by ASTM C305-14. Samples were made with a water- to-cement ratio of 0.45 and a sand-to-cement ratio of 3. The mortar samples were then cast into 40 x 40 x 160 mm molds and kept in humid environment at 21°C for 24 h. Then the molds were removed, and the samples were further cured in moist environment until testing (22°C). To provide flexural resistance during crack initiation, 12-mm micro synthetic fibers were added to mortar (4 g/m^3 of mortar). A polycarboxylate ether (PCE)-based superplasticizer (BASF) was used to maintain the required workability of mortars in terms of flow table diameter based on ASTM C1437-15. To quantify the workability, a flow table test was conducted based on ASTM C1437-15 (ASTM International 2015). The workability of pastes was adjusted using PCE superplasticizer when necessary. PCE was added into mortar mixes until the desired flow reached (±10% of the control neat mortar). Average flow values were calculated from triplicates of samples from 5 batches (15 samples in total). Table 1 summarizes the composition and flow behavior of different mixes used in this study.

Table 1. Summary of mixing ingredients and flow (%). PBS: Phosphate buffes solution; SP: Superplasticizer; DE: Diatomaceous earth; Pum: Pumice. C: Only includes air dry minerals; Bac: all mineral content was saturated with bacterial cells and PBS; 2P: Two-phase bio additive containing bacterial cells and nutrients. Flow values were given average ± standard deviation.

Sample	*Cement*	*Sand*	*S. pasteurii cells*	*Mineral content*	*PBS*	*Nutrient solution*	*SP*	*Flow (%)*
Kontrol	450 g	1350 g	-	-	-	-	3 g	21 ± 0.4
DE-C	450 g	1350 g	-	22.5 g	-	-	4.5 g	30 ± 0.4
Pum-C	450 g	1282.5 g	-	67.5 g	-	-		15 ± 0.4
DE-Bac	450 g	1350 g	2 g	22.5 g	90 g	-	3 g	36 ± 0.4
Pum-Bac	450 g	1282.5 g	6 g	67.5 g	90 g	-		25 ± 0.4

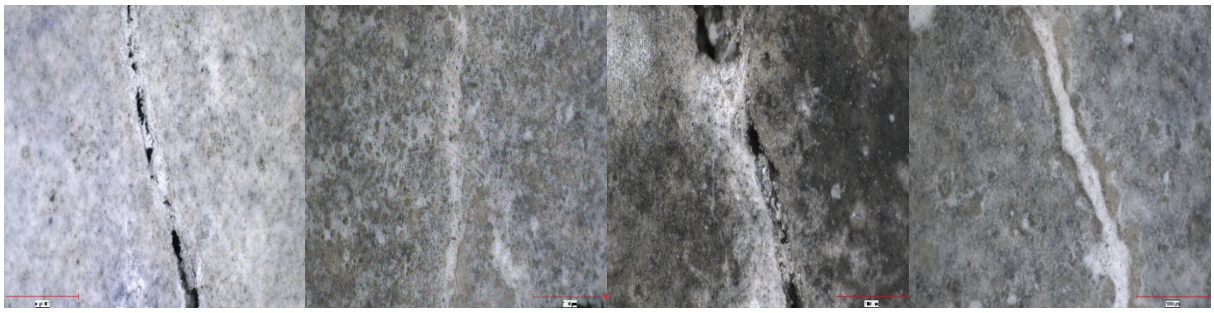
Pum-2P	450 g	1282.5 g	6 g	67.5 g	45 g	45 g		32 ± 0.4

2.3.2 Crack formation, curing and evaluation of crack healing

At the end of the 28th day of mixing, the samples were removed from the curing environment and cracked under flexural loading using a servo hydraulic displacement-controlled device (0.05 mm/sec). The sample was unloaded once the crack was formed visually, which corresponded to 50 ± 3% of the ultimate flexural strength of samples. Upon unloading, the remaining crack width ranged from 0.30 mm to 0.35 mm. A set (3 samples) of control samples were not cracked for further analysis. Once the cracks were formed a set of cracked samples were cured in water and another set was cured in nutrient medium. Curing process was done by submerging the samples into curing solutions for 2-days and then, subsequently leaving them at ambient conditions for 2 days. This 2- day period curing process was applied until at least 90% crack sealing was observed. To investigate the self-healing in cement-based mortar, cracked beams were periodically observed under NIKON Inc. SMZ745T Stereomicroscope and analyzed with CLEMAX visual analysis system. Air dried samples were analyzed weekly for $CaCO_3$ crystal formation within cracks. Complementary quantification was done by Ultrasonic Pulse Velocity (UPV) test.

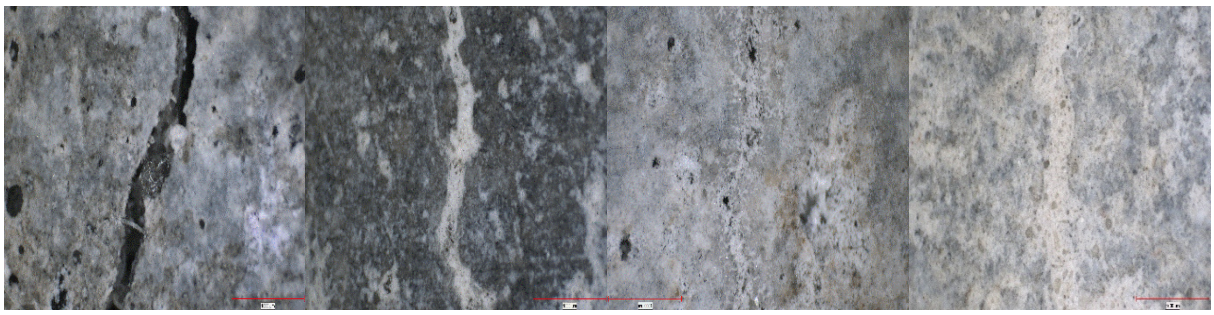
3 Results and Discussion

Upon 14 to 28 days of curing, the cracks were visually sealed in specimens containing bacterial cells (*DE-Bac; Pum-Bac; DE-2P and Pum-2P*) when additional nutrients were provided with curing. There was not any visual crack closure or any crystal precipitation in control samples without any bacterial cells regardless of the sample age and type of curing (within the 28-day observation period). From each set, triplicates of samples were cast and the specimens in the same sets showed similar crack- filling trend. Since the visual crack healing was almost the same for each set, one representative image of series with 28-day old samples containing bacterial cells is shown in Figure 3 and Figure 4.



(a) (b) (c) (d)

Figure 3. Stereomicroscopy images of the cracks (0.3 to 0.4 μm) in 28-day old specimens containing diatomaceous earth (a) DE-Bac after 28-days of water curing (b) DE-Bac after 28-days nutrient curing (c) DE-2P after 14 days of water curing and (d) DE-2P after 14 days nutrient curing.



(a) (b) (c) (d)

Figure 4. Stereomicroscopy images of the cracks (0.3 to 0.4 μm) in 28-day old specimens containing pumice (a) Pum-Bac after 28-days of water curing (c) Pum-Bac after 28-days of nutrient curing (c) Pum-2P after 14-days of water curing and (d) Pum-2P after 14-days of nutrient curing.

Based on the visual crack evaluation, both DE and pumice was found to be effective in terms of immobilizing the bacterial cells and trigger self-healing. The possible mechanism of these minerals could be attributed to their relatively high capacity to absorb and hold bacterial cells on the surfaces. In addition, it could also be noted that additional nutrients as urea and [Ca^{+2}] source should be provided either during the mixing or in the curing solution. DE was already known to be a good mineral agent to immobilize and protect the cells from high pH environment of cement paste. This could be attributed to its relatively higher absorption capacity and high specific surface area which could enable a more homogenous. Since DE is also a microbiological formation, it could also provide a more suitable microenvironment for the bacterial cells compared to cementitious environment and thus bacteria could still decompose urea (Wang *et al*. 2012c). Even though, both minerals were effective in terms of remediating the cracks, however pumice was slightly more efficient compared to DE in terms of crack closure, particularly in samples containing 2-phase mineral additives. This could be directly related to the number of bacterial cells added to the mix. Since pumice have larger particle size, it was used as a sand replacement which was 3 times more than DE addition. Relatedly, the amount of bacterial cells and nutrient solution was also tripled. This might lead to a more efficient crack healing in pumice containing samples compared to DE modified samples.

UPV test results also confirmed that healing was occurred in cracks. Figure 5 shows the UPV test results for mortar samples cured in different conditions after crack initiation. There was a full crack closure in Pum-2P and DE-2P samples in 14 days, thus the evaluation of the sample was further done by water absorption test. Similar to the visual inspection, healing was observed in almost all samples containing bacterial cells. In particular, for samples containing DE, a higher self-healing was only observed in *DE-Bac* and *DE*-2P samples when they were cured in nutrient medium. However, there was also a change in UPV reading in DE-Bac and DE-2P samples cured in water. This might indicate that there might be an internal crack healing process occurred in the samples rather than crack mouth sealing, which might not be detected via visual inspection. Similar results were also obtained with *Pum-Bac* sample in which a higher UPV reading was observed without any visual crack sealing. Further investigations are being done in terms of quantifying self-healing through water absorption.

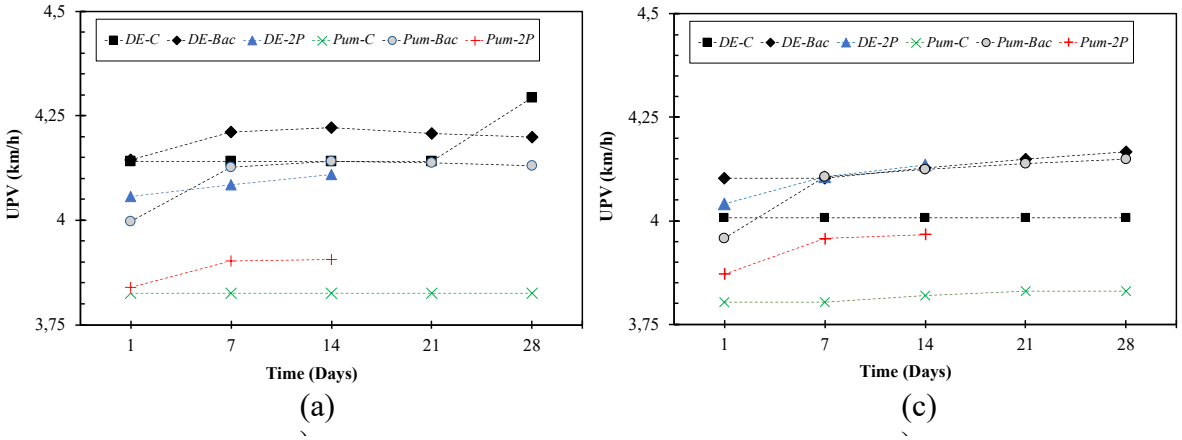


Figure 5. UPV record after crack healing (a) 28-days of water curing (b) 28-days of nutrient curing

4 Conclusion

This study was undertaken to investigate the possible use of diatomaceous earth and pumice as an immobilization barrier for bacterial cells to trigger crack remediation in mortar. Cracks with an average width of 0.4 mm in 28-day old mortar specimens were almost completely filled by bio-based precipitate depending on the curing regime. Results showed that cells require additional nutrient source as urea and calcium acetate either in the mix or as curing regardless of type of the immobilization barrier. Cracks were sealed even in sample including relatively smaller dosage of nutrients and bacterial cells in presence of moisture. Moreover, the duration of crack healing was approximately 21 days, which was almost half of the duration to remediate the cracks when cells were directly incorporated to the mix. Further investigation has to be done to characterize the precipitate and evaluate the influence of crack sealing on permeability.

Abstract. *Organic repair products for concrete can be exposed to accidental incidents, like fire. The increase of temperature produces a modification in some of their properties. In general, these types of repair products have organic fibers to increase their tixotropic properties, but they are more sensible to the high temperature than the Portland cement or aggregates. In order to analyze the behavior of organic repair mortars with temperature three types of repair mortars are studied. These repair products have the organic components composed by acetate fiber of polyvinyl like Vinyl Acetate Acrylate (VAA), Copolymer of Vinyl Acetate Vinyl Versatate (VeoVA) and Acrylic polymers fibres. The repair products are tested increasing the temperature from 1.7ºC /min until 200ºC, 400ºC or 600ºC respectively during 20 minutes. After that, the samples are cooled in four different cooling conditions two of them slow and two others fast, and with and without oxygen. These conditions are used in order to simulate the different conditions that can occur during the cooling after fire. After the testing the visual aspect, the color and brightness and the open porosity is analyzed in each condition of test. In this work the relationship between the temperature of exposition, the cooling conditions and the change in some physical properties are studied.*

Keywords: *Organic Repair Mortar, Fire Resistance Test, Color Change, Open Porosity.*

1 Introduction

The progression of the temperatures in the interior of the fire area is greatly conditioned by a series of very varied parameters, such as the type and density of the fire, the capacity for thermal dispersion of the epidermis, the level and disposition of the ventilation, etc. Kucera, P. (2007). Although it is possible to model or predict the thermal evolution of the gas in the affected area to a greater or lesser degree during the project, and from there and design sufficiently safe structures (with viable criteria for its use). The evaluation of the residual capacity of existing structures affected by a fire usually require a more realistic determination of the distribution of the temperatures in the different elements of the structure, Kodur, V.K.R. and Phan, L. (2007). It must be borne in mind that the real conditions of the fire (strength of the fire, ventilation, etc.) are difficult to determine precisely and a theoretical prediction not contrasted with real data

could give rise to significant deviations in areas relative to the thermal analysis of the structure and hence the mechanical evaluation.

The distribution of the temperatures in the interior of the area affected by the fire is not homogeneous, which is why the determination of the number of testing points, their distribution, etc., so that the results are representative and constitute a sound basis for the structural analysis is a relevant question. However, when samples taken from a real fire are analysed it is not always possible to have the suitable number or disposition samples available.

On the other hand, in order to determine the residual resistant capacity of the elements of the structural concrete affected by the fire, it is important to find out not only the distribution of the temperatures in the elements, but also how the effect on other relevant mechanical properties come about from exposure to fire, such as the steel-concrete adhesion. Within the series of temperatures that are produced in the interior of the section, there is an important significance from the mechanical point of view, as are 500ºC. On the one hand, the average value of the resistance to compression losses of the concrete (with lime aggregate) contemplated at a regulatory level is in the order of 40%, which would correspond approximately to the admissible loss in a residential or administrative building in a strict reinforced position (EN-1992 – Eurocode 2: Design of concrete Structures). It is the basis for one of the most used simplified calculation methods in the verification of concrete structures in the case of fire, which is known as the simplified 500ºC isothermal method, Ashely, E. (2007).

The cement based materials have a low thermal conductivity and an elevated specific heat, which is why ambient temperature constitutes a suitable protection for the reinforcement. However, when it becomes subject to higher temperatures it goes through a series of physical-thermal transformations that bring about a modification in the products of the hydration of the cement. From 300ºC, a loss of water comes about as a result of the decomposition of the CSH gel, which brings about a contraction as a result of this loss, even though it is necessary to exceed 900ºC in order to bring about a complete decomposition. Likewise, a decomposition of the portlandite comes about at between 450 – 550ºC, as does a loss of CO_2 of the carbonates from 600ºC. For its part, the siliceous aggregates also go through a physical-thermal transformation from 573ºC, while the lime experiences a decarbonisation at temperatures greater than 600ºC. Although it is important to indicate the possible changes in the aggregate as an effect of the temperature, it also depends on other factors such as size, porosity permeability, etc. – the less porous the aggregate, the less susceptible it is to the action of the fire, Charreau, G.L., Luna, F. (2000). The decomposition of portlandite in cement based materials can be used as an indicator of progression of temperature inside of the material and situate the isotherm 500 in the material, Menéndez, E., Vega, L. (2012).

The physical-thermal transformations undergone by the concrete as an effect of the temperature are translated into a loss of performance, especially when the material exceeds 600ºC. As the temperature increases, a modification in the creep comes about, which can also be seen as a strong dependency on its resistance and elasticity, Schneider, U. (1976). On the other hand, the conditions of putting out the fire must be taken into account, as the speed of cooling or the contact with the water has a significant influence on the physical-mechanical conditions present in the concrete once the fire is extinguished, Nassil, A. (2006). Specifically, the physical-thermal transformations that the components of the concrete go through serve to characterise it after it has been subject to the fire Colombo, M. and Felicetti, R. (2007). In this case, X-ray diffraction, thermal analysis and scanning electron microscopy techniques have

been used with the aim of analysing the behaviour of the concrete exposed to a real fire. Some of these instrumental techniques, such as thermal analysis, are usually used to study the behaviour of certain materials when exposed to the action of fire and high temperatures. As a rule, the fundamental objective of these analyses is to look at the possible improvements that could come about through the use of certain materials that could substitute or complement others, Zhong, H., Wei, P., Jiang, P. and Wang, G. (2006).

Polymer-modified mortar (PCM) contains synthetic resins and/or combustible polymers such as rubber. Hence, the combustibility of PCM is strongly affected by the type and amount of combustible polymer, S. Akihama, *et.al* (1973). The combustible properties of several types of PCMs at high temperatures can be tested using JIS A 1321 (a testing method for incombustibility of internal finish material and procedure of buildings), Y. Oham, S. Suzuki and H. Ozawa (1980). The influence of a polymer admixture on the fire resistance of PCC and analysis of peeling and explosion of PCMs by fire tests are carried out Chandra, S., Berntsson, L., and Anderberg, Y. (1980). On the other hand, the incombustibility of polymer-modified mortars is strongly affected by the polymer type rather than the polymer-cement ratio or polymer content. Some authors have been performed tests about heat release of PCMs Ohama, Y., Shirai, A., and Imamoto, K. (2011).

In the present work, studies of different polymer-modified mortars have been done. The repair mortars have exposed at 200ºC, 400ºC and 600ºC during 20 minutes and are cooling quickly or slowly. The visual aspect, open porosity and colorimetry is analysed in the different samples tested to take conclusions on their behaviour at different temperatures.

2 Raw Materials

Repair mortars were made from three products that were previously selected. Repair mortars, suppliers, characteristics, visual appearance, as well as the organic components that make up the fibers (main components), are shown below in Table 1.

Table 1. Information of repair mortars.

Product	Codification	Type of polymer	Visual Aspect
PLANITOP HDM MAXI	PHM	Acrylic polymer	
MAPEGROUT EASY FLOW GF	MEF	Copolymer of Vinyl Acetate Vinyl Versatate (VeoVA)	
MASTER EMACO S 5400	S5400	Vinyl Acetate Acrylate (VAA)	

3 Manufacturing, Curing Process of Repair Mortars and Test Procedure

Repair mortars were manufactured following the procedure described in the manufacturer's instructions, the mixture is kneaded, poured into the molds and the specimens are cured at 20° C and 60% humidity. Next, in Figure 1, the general appearance of the cured specimens is shown. Samples were tested at temperatures of 200 ° C, 400 ° C and 600 ° C. The exposure time as well as the thermal gradient of the test is shown in Figure 2 below. Four samples of each product

were tested, two in the presence of oxygen and another two in the absence of oxygen respectively. The cooling conditions are shown below:

- Slow cooling: Condition that allows the sample to cool inside the oven until it reaches room temperature (20ºC).
- Fast cooling: Condition that consists of suddenly removing the sample from the oven, so that it loses temperature quickly, while the sample is reserved in a desiccator.

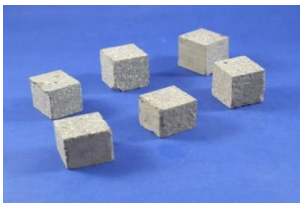

Figure 1. Visual Aspect of the repair mortar.

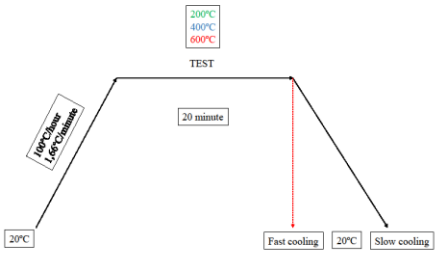

Figure 2. Heating curve proposed for the test.

4 Porosity Accessible to Water

The porosity of the mortars that have been made with the repair products is determined. For this, the porosity of samples that have not been subjected to heat treatment (reference) is determined, and the porosity of the samples subjected to the fire resistance test is determined. Procedure that allows to study the behavior of the porosity as the test conditions change.

The methodology described in the UNE EN 1936 standard is used to determine the porosity accessible to water. Next, Table 1 shows the test conditions that the samples are subjected to.

Table 2. Test conditions.

Temperatures	**200ºC**	**400ºC**	**600ºC**
Test conditions	Slow cooling without O_2 **(SC)**		
	Slow cooling with O_2 **(SCO)**		
	Fast cooling without O_2 **(FC)**		
	Fast cooling with O_2 **(FCO)**		

4.1 Porosity of Mortars as a Function of the Product Used

Next, Figures 3 shows the porosity values obtained from this test are plotted. Some dispersion in the porosity values is observed for each of the mortars tested. Porosity increases as the test temperature increases; the apparent increasing of cracking in mortars can causes this effect.

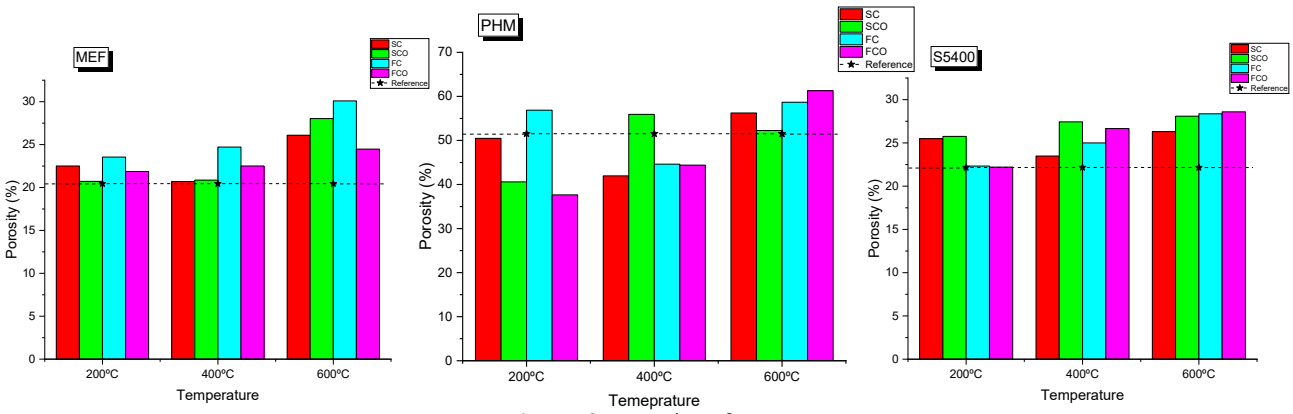

Figure 3. Porosity of mortars.

4.2 Porosity Variation as Function of the Test Temperature

In order to study the behavior of the products tested, at each test temperature, the variation of the porosity as a function of the study temperature is shown below (Figures 4).

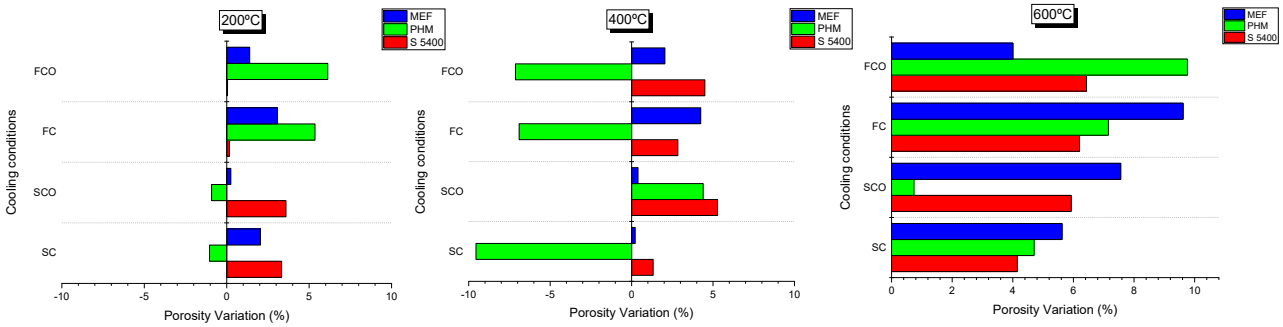

Figure 4. Porosity variation of mortars tested at **2**00, 400 and 600 ºC.

In general, an increase in porosity is observed as the test temperature increases. Samples subjected to 600°C contain fibers composed of polymers that decompose at temperatures above 500°C, forming gases such as methane, carbon dioxide and carbon monoxide among others. These gases increase the pressure inside the mortar, causing tensions in the areas where the pressure is higher, this effect can cause cracking, increasing the porosity of the mortar.

On the other hand, a decrease in the porosity in the PHM mortar is observed, at 400°C, caused by the fusion and diffusion of the fibers through the pores, filling the air pores, an effect that would explain this behavior.

4.3 Porosity Variation as Function of the Cooling Conditions

The increment of the porosity is shown depending on the test condition, it should be noted that the values shown below are values that reflect the increase in porosity with respect to the reference porosity values for each mortar tested. In any case, the most favorable scenario (least increase in porosity) is in which the mortar tested is cooled slowly. Although between the two scenarios in which it cools slowly, the one performed without oxygen shows less increase in porosity.

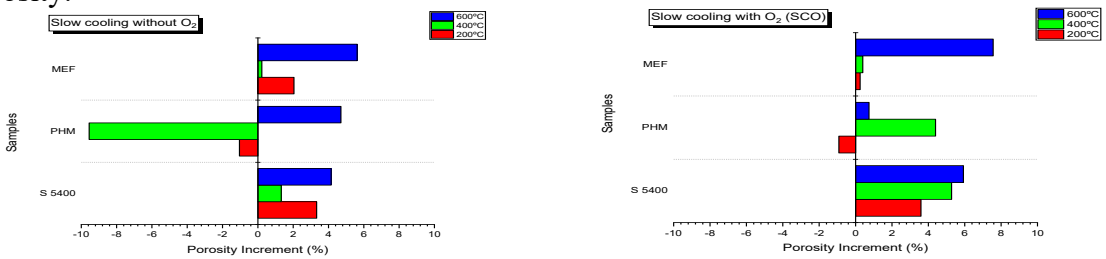

Figure 5. Porosity increment of mortars that were cooled slowly with and without O_2.

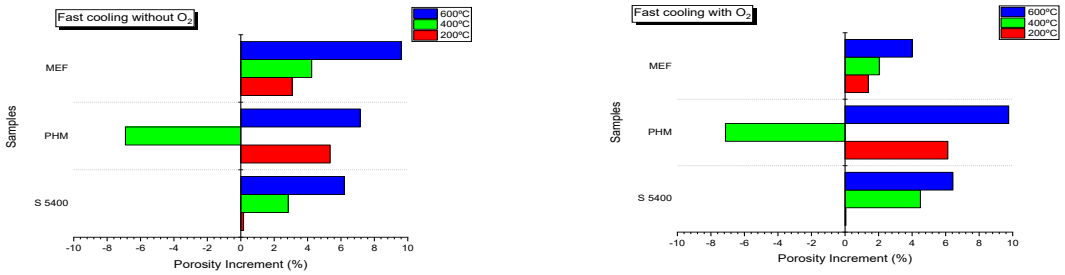

Figure 6. Porosity increment of mortars that were cooled suddenly with and without O_2.

5 Colorimetry

Colorimetric techniques are based on the measurement of radiation absorption in the visible area by colored substances. All systems that quantify color from three variables have colorimetric aspects: Luminance, Length and Purity.

With this technique, the color behavior of the mortars tested is studied, the color is measured in the mortars that have not been subjected to the test conditions, and then the color is measured in those mortars that have been analyzed in the test conditions shown in Table 3.

Table 3. Test conditions.

Temperature	**200ºC**	**400ºC**	**600ºC**
Test conditions	Slow cooling without O_2 **(SC)**		
	Slow cooling with O_2 **(SCO)**		
	Fast cooling without O_2 **(FC)**		
	Fast cooling with O_2 **(FCO)**		

5.2 Colorimetric Variation as Function of Test Temperature

Next, a data processing is carried out. The color variation of the tested products is determined, compared with the color tones of the reference (product without heat treatment).

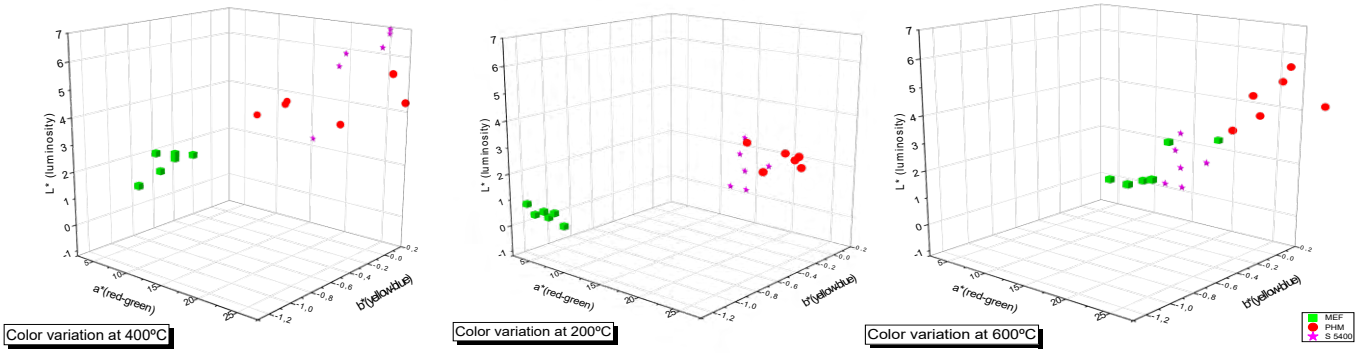

Figure 7. Color variation of the mortars tested at 200, 400 and 600°C.

At 200ºC and 400ºC, it is observed that the MEF product does not show variation around the

reference colorimetric values. As for the temperature of 600 ° C, the color variation of the products tested show a linear trend around the blue color when the brightness increases.

6 Conclusions

The following conclusions are obtained from the tests performed:

- The repair mortar that has the lowest porosity is MEF; on the other hand, the product that has the highest porosity is the PHM.
- In temperatures, at 200ºC and at 400ºC a good behavior is observed in the materials tested, while at 600ºC the behavior is very unfavorable in all cases, because at 600ºC, the increase in porosity is significant and it can cause reduction of mechanical strength. On the other hand, the PHM mortar is the one that shows the highest porosity, but it is the only one in which the porosity decreases when tested at temperatures between 200ºC-400ºC. This behavior may be caused by the composition of the fibers. The melting temperature of fibers is in the range 200° C - 400°C, causing diffusion of the fibers through the pores of the cementitious paste, filling capillary pores, and decreasing the porosity.
  In general, a linearity is observed between the increase in temperature and the decrease in brightness, approaching darker tones as the test temperature increases.

Comparative Life-Cycle Analysis of Two Repair Measures for Chloride Contaminated Concrete Structures

Sylvia Keßler

Helmut-Schmidt-University/ University of the Federal Armed Forces Hamburg, Chair of Engineering Materials and Building Preservation, Holstenhofweg 85, Hamburg, 22043, Germany, sylvia.kessler@hsu-hh.de

Abstract. *Often the mere mention of the word "Sustainability" leads to the reflection of the effect of our actions on environment and future generations. Especially the application of reinforced concrete as the most used construction material has a huge impact on a society being sustainable. Thus, the construction industry focuses on the design of environmentally- and resource-friendly buildings. However, due to our aging infrastructure and expected high demand of maintenance and repair in future, a further look on the sustainability of different repair measures for reinforced concrete structures has been neglected in the past. This paper presents a comparative case study of the life-cycle analysis of two different repair measures for reinforced concrete affected by chloride-induced corrosion. The selected repair measures – removal of the chloride-contaminated concrete and cathodic protection – are the most common repair measures in Germany. In future way concrete repair measure could be selected not only by the costs but as well by their environmental impact. This paper provides first information to achieve this target.*

Keywords: *Reinforced Concrete Structures, Repair Measure, Life-Cycle-Analysis, Reinforcement Corrosion.*

1 Introduction

Our infrastructure is the backbone of our society and economy. Bridges and tunnels maintain our mobility and enable the transportation of constantly increasing number of goods. Additionally, in dense inner city areas multi-storey and underground car parks are of greatest importance to provide space keeping the traffic flowing. However, most of these reinforced concrete structures have achieved already their designed service life or the designed service life is shorten due to durability issues. Consequently, these structures need repair measures.

Especially, chloride-induced corrosion require maintenance actions as major reason for structures deterioration. Chlorides from sources such as de-icing salt or marine environment penetrate into the porous concrete and as soon as a critical chloride concentration accumulates at the reinforcement, corrosion initiation becomes likely. Consequences of reinforcement corrosion are the loss of rebar cross section and in an advanced stage cracking and spalling of the concrete cover. Thus, this deterioration process impairs the serviceability and the load bearing capacity of our infrastructure.

The standard, EN 1504-9 provides several repair principles for chloride-contaminated concrete structures with the aim to stop and to prevent reinforcement corrosion. The most commonly applied repair principles are:

- Principle 7: Preservation or restitution of the coat passive layer (RP)
- Principle 8: Increase of concrete resistance (IR)

doi:10.23967/dbmc.2020.021

- Principle 10: Cathodic protection (CP)

The principles 9 (cathode control) and 11 (anodic areas control) have no conceptual meaning in Germany since their effectiveness have not been proven yet.

The approach achieving corrosion control of each repair measure is different. For preserving and restoring the reinforcement's passivity, the chloride-contaminated concrete is removed and replaced by new, alkaline and chloride-free concrete. The high alkalinity of the fresh concrete leads to the repassivation of the former anodic areas and reinforcement corrosion is impaired. The repair measure is by far the most common one even though it is a significant intervention in the structure's integrity.

The increase of concrete resistance aims to dry out the concrete, *e.g.* by application of a concrete coating, until the electrolytic corrosion process is no longer possible and the corrosion velocity comes to a negligible rate.

In recent years, cathodic protection systems gain more and more attention and one standard (EN ISO 12696) focuses exclusively on this repair measure. Cathodic protection suppresses the anodic reaction by applying an electric potential. The polarization of the reinforcement forces the reinforcement to act electrochemically as a cathode. Consequently, no anodic reaction – no loss of cross section – can take place even though the chloride concentration is on a critical level. In addition, cathodic protection diminishes the driving potential between former anodic and cathodic rebar areas providing supplementary protection against corrosion.

Each repair principle can be pursued by different repair procedures/ methods that vary in the execution following the same objective.

The demand of maintenance and repair of reinforced concrete structures will increase tremendously in the upcoming year. We need a further look on their sustainability to support the decision-making of choosing an adequate repair principles and corresponding repair method. Thus, this paper presents a first approach comparing the life cycle analysis of two repair methods for a specific case study. The aim is to evaluate the category indicators (a) global warming potential, (b) abiotic depletion and (c) ozone layer depletion when applying cathodic protection and concrete replacement as repair measure.

2 Life Cycle Assessment

The Paris Agreement from the United Nations urges especially the developed countries to deliver an overall mitigation in global emissions. This goal is only achievable, if we are aware of our environmental impacts. This applies in particular to the construction industry as one of the major emitters due to e.g. the energy-intensive production of cement/ concrete and steel. One option to identify the most sustainable repair measures of reinforced concrete structures is the implementation of a life cycles assessment (LCA) according to DIN EN ISO 14040 and DIN EN ISO 14044.

The LCA study consists of several steps starting with the definition of the scope followed by the inventory analysis and impact assessment and ends with the interpretation of the results. The scope of the LCA should be described as precise as possible including all considered boundary conditions to ensure consistency. The inventory analysis collects all data involved such as the quantification of the relevant inputs and outputs of the repair action during the defined life cycle. The inputs and outputs should be broken down to the elementary level.

During the impact assessment phase, the impact of the repair measure on the environmental is estimated based on category indicators. Impact categories are the consumption of primary raw materials; water consumption, primary energy consumption, global warming potential, acidification potential, photochemical ozone creation potential and material recyclability. The final step is the discussion of the outcome taken into account the objective of the study.

Conclusions and recommendations complement the LCA study leading to a clear decision-making basis for more sustainable rehabilitation of concrete structures.

3 Case Study

The objective of the life-cycle assessment of two different repair measure is to support future decision-making for the most sustainable repair measure. Secondly, the study aims to identify missing data we need to collect in future to enable comprehensive sustainability analysis of repair measures.

3.1 Functional Unit

The functional unit for this sustainability assessment of repair measures is a very common constructive element: one square meter of reinforced concrete plate. This plate could be e.g. part of a bridge superstructure or part of a multi-storey car park. Consequently, the functional unit is assigned to exposure class XD3 (DIN EN 206), which considers chloride exposure from de-icing salts in combination with cyclic wetting and drying. Since the element is part of an aged, deteriorated structure the used cement type is Portland cement. The concrete cover is about 55 mm and therefore in compliance with the current standards. The same applies to the water-to-binder ratio of 0.45 and the cement content of 320 kg/m³. The designed service life is 75 years with a target reliability index of 0.5 (DAfStb, 2008). This target reliability corresponds to a corrosion probability of 30 %. No additional protection such as polymer concrete coatings are applied and possible cracking of the concrete cover, respectively crack repair is neglected.

3.2 Service-Life Assessment

First, a probabilistic service life prediction assists the decision making to estimate when and how often the functional unit requires repair actions. Figure 1 shows the results of the initial probabilistic service life prediction according to fib Model Code for Service Life Design (fib bulletins 34 and 76).

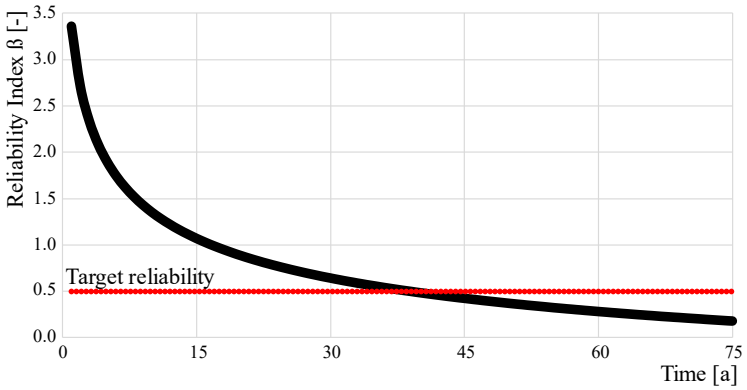

Figure 1. Service life assessment of the case study.

Even though, the durability design of the functional unit complies with the standards the target reliability of $\beta = 0.5$ is achieved after around 40 years. This result is in line with literature data (fib bulletin 76), which revealed that the durability design rules cannot ensure consequently a design service life of normally 50 years without the need of repair actions. However, the presented case study requires repair action within the designed service life of 75 years.

3.3 Repair Measures

As mentioned above the most common repair measures of chloride-contaminated concrete are based on the Principles 7 and 10 (EN 1504-9). Therefore, the life-cycle assessment includes one repair method from both principles:

- 7.2: Substitution of the chloride-contaminated concrete
- 10.1: Application of an electric potential

3.3.1 Repair measure 7.2

Roughly, the application of the repair method 7.2 consists of the mechanical removal of the chloride-contaminated concrete and the refill with fresh and alkaline concrete until the former or newly requested concrete cover is achieved. This procedure can be an intrusive intervention in the structure's integrity. On the other hand, it is an effective method to inhibit reinforcement corrosion.

However, very little information is available on the service life of this repair measure. Tilly and Jacobs (Tilly et Jacobs 2007) analyzed 230 case studies of concrete repair measures. Concrete replacement were effective only in rd. 50 % of the investigated use cases. The authors listed several reasons for the failure: inappropriate measure or material, execution error, non-conformance of the specifications etc.. After 5 years in service, 20 % of the repair measure needed repair measure, 55 % within 10 years and 90 % within 25 years. Polder et al. (Polder et al. 2016) confirmed the results of Tilly and Jacobs with data of a Dutch study.

3.3.2 Repair measure 10.1

Here, the application of the electric potential is implemented through an impressed current cathodic protection (ICCP) system, where an external power supply generates large potential

differences to enable the current flow needed for corrosion protection. In the electric circuit, the reinforcement acts as a cathode whereas the anode system is applied on the concrete surface layer. Several anode systems are on the market. The most common anode systems for plate elements are mixed metal oxide/titanium (MMO/Ti) anodes in shape of ribbons or meshes, which must be embedded in cementitious material to enable the electrolytic contact to the concrete. The application require several working steps, however, it maintains the structures integrity since the chloride-contaminated concrete remains in the structure.

The whole ICCP system needs to be applied only once and the effectiveness of the corrosion protection is monitored. Nevertheless, the systems includes many electrical components such a power supplies or electrical transformers with limited service life under continuous use. Their replacement is easy to handle and need to be considered for the life-cycle analysis.

The ISO 12696 indicates a service life of the NMO/Ti anodes in the range of 25 to 100 years in dependence of the range of the current density. Polder et al. (Polder et al. 2016) estimated the service life of a CP system of about 50 years and Wilson et al. (Wilson et al. 2013) of about 10 to 120 years, excluding the electric components, which need replacement at least every 20 years. Nevertheless, it is important to mention that cathodic protection systems on concrete structures is a relatively new repair measure (started in the 90's) and current experiences are based on the early, more vulnerable cathodic protection systems.

3.3.3 Repair measure cycles

It appears that very little information is available on the durability of repair measures itself. Based on the literature it is very likely that repair measure needs repair action due to the use of inadequate material or poor execution. These effects are very hard to predict and therefore, the estimation of repair cycles during a service life of a concrete structure is subject to assumptions.

The installation of the CP systems with ribbon anodes takes place earlier in a service life than the replacement of the chloride-contaminated concrete. The reason for that is that the CP system can only be applied when the corrosion damage is not in an advanced stage showing cracks and spalling of the concrete cover. Therefore, the timing of the CP installation is set when the reliability index is 1.3 (corrosion probability 10 %) after 11 years, see Figure 1. Every 20 years, in total for two times, all electronic components will be renewed. In contrast, the time of the concrete replacement corresponds to the time when the target reliability is reached after 40 years. It is assumed that the new concrete shows the same chloride penetration resistance as the former one. Therefore, the repair measure takes place only once until the end of the designed service life of the structure.

3.4 The Inventory Analysis

The objective of the inventory analysis is the collection of all relevant environmental information on the used material and the execution process for each repair measure. Each step includes if necessary the consumption of energy and water and the consideration of the transport (fuel, distance) of the needed material.

3.4.1 Relevant information of repair measure 7.2

The execution of the repair measure 7.2 consists of the following steps, which need to be considered for the LCA:

- Removal of concrete with ultra-high water pressure jetting
- Production of concrete
- Processing of the fresh concrete
- Disposal of concrete

3.4.2 Relevant information of repair measure 10.2

The following inputs and outputs are part of the installation of a cathodic protection system on reinforced concrete with ribbon anodes:

- Production of the titanium anodes
- Production of the embedding mortar
- Production of reference electrodes
- Production of the Electronic components (e.g. power supply, transformer and rectifier, control devices, data management systems and connection boxes, cables)
- Concrete milling
- Installation of the ribbon anodes
- Installation of the reference electrodes
- Installation of the electric contact to the reinforcement
- Processing of the embedding mortar
- Disposal of concrete
- Disposal of electronic waste

It is obvious, that the installation of a cathodic protection system requires much more working steps that the concrete removal. However, the quantity of the processed concrete is much higher for the concrete replacement, whereas only the cathodic protection system needs electric components.

Sometimes, during a concrete removal the structural element (functional unit) needs additional support for static reasons. This step is not included in this analysis.

3.5 Results

The software package SimaPro (Version 8.4.0.0) with the underlying databases of ecoinvent (Version 3) supported the evaluation of this LCA study using the CML-IA baseline method. The following results show the comparison of both repair measures for selected impact categories considering a service life of 75 years, see Figure 2.

In all three categories, the cathodic protection system shows greater impact on the environment than the concrete replacement measure. The greatest difference between both repair measures is in the global warming potential. Here, the impact of the CP systems is more than twice the level of the concrete replacement. The reason for this difference is the impact of the replacement (production and disposal) of the electronic components for the cathodic protection system with a value of 158 $kgCO_2eq$. The highest impact on the global warming potential within the concrete replacement has the removal of the old concrete using ultra-high water pressure jetting with a value of rd. 62 $kgCO_2eq$.

The same dependencies apply for the abiotic depletion. Here, the impact of the CP systems is much greater due to the production of the electronic components with a value of 586 MJ. Again, the ultra-high water pressure jetting during concrete removal has major impact on the

abiotic depletion of the concrete replacement. The difference between both repair measures is less pronounced considering the ozone layer depletion.

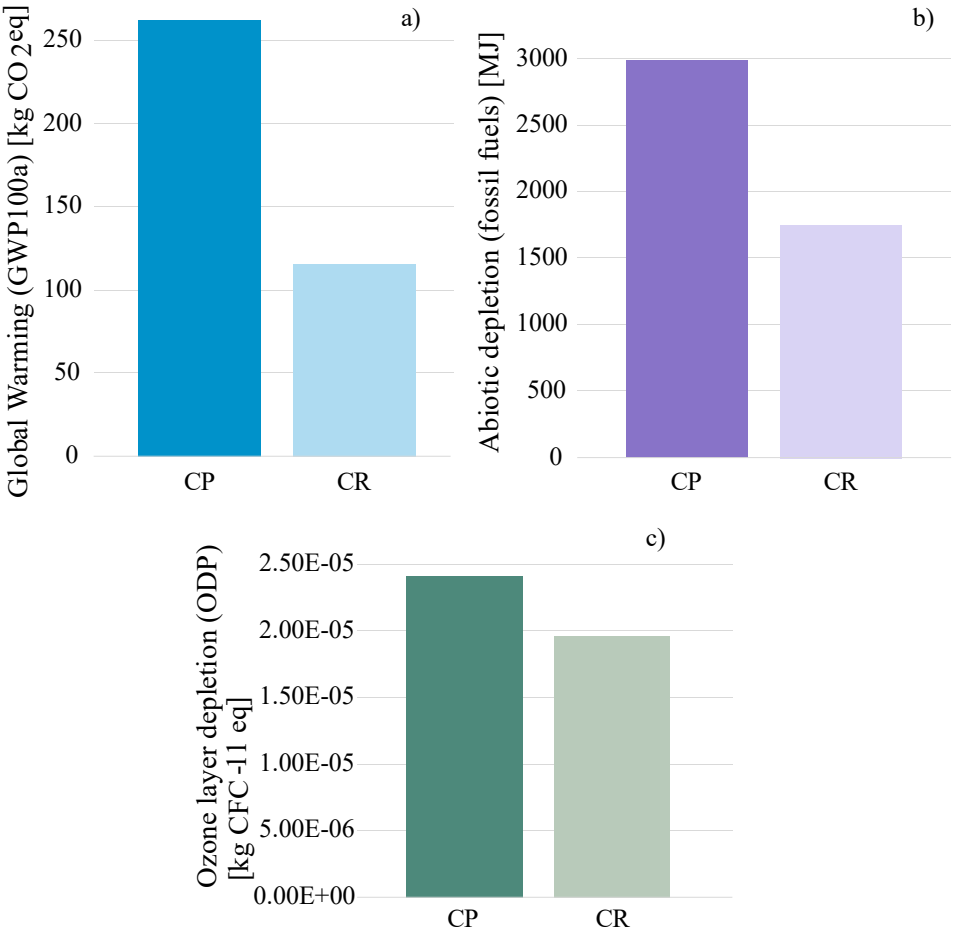

Figure 2. The comparison of the (a) global warming potential, (b) abiotic depletion and (c) ozone layer depletion of the two repair measures CP (cathodic protection) and CR (concrete replacement) on a reinforced concrete plate after a service life of 75 years.

However, the presented results are only of preliminary nature and do not provide a comprehensive study. Very often, the concrete surface needs an additional protection against ingress of chlorides such as polymer coatings if no CP system is installed. These coatings need also replacement in certain intervals. Thus, the consideration of a polymer concrete coating would lead to different LCA results. Furthermore, the service life of the concrete structure and the service life of the repair measure itself have a huge effect in the LCA outcome.

Nevertheless, this study provides a preliminary insight on the environmental impact on repair measures. Even though, the concrete replacement requires the removal and refill of great volume of concrete it is probably in a lot of use cases the most sustainable repair measure. The impact of electronic components or presumably the impact of polymer concrete coatings is much higher than the pure concrete.

Nowadays, the determination of the adequate repair measure depends mainly on other factors

such as costs, applicability, remaining service life, and many more. However, in future we should also be aware of the environmental impact of the chosen repair measure as well.

4 Conclusions

The following conclusions can be drawn from this specific comparative LCA of the concrete repair measures concrete replacement and cathodic protection.

- The environmental impact of the cathodic protection system is greater than the impact of the concrete replacement when comparing the category indicators global warming potential, abiotic depletion and ozone layer depletion.
- Even though, the concrete replacement consumes much higher quantity of energy-intensive concrete it is not necessarily the repair measures with the greatest impact on the environment.
- The high environmental impact of the cathodic protection system is the result of its demand of multiple electronic components.
- The service life of the electronic components is the determining factor of the sustainability of the cathodic protection system.

More generally, more field data on the durability of concrete replacement is required to enable reliable assumptions on repair intervals.

Deterioration Prediction Model of Multi-Layer Coating Material and its Reference Service Life Evaluation in Terms of Carbonation Control Effect

Kotaro Etchuya [1], Keiichi Imamoto [2] and Chizuru Kiyohara [2]

[1]Japan Building Coating Materials Association, ecchuya@nsk-web.org

[2] Tokyo University of Science, Dr.Eng, imamoto@rs.tus.ac.jp

Abstract. *In this paper, authors propose a method to predict deterioration of exterior finishes using Markov Chain Model based on field survey results on cracks of exterior finishes of existing RC buildings. There existed correlation between degradation of finishing and carbonation progress. Authors propose the service life prediction approach to focus on the carbonation suppression effect into the concrete considering progress of exterior finish deterioration.*

Keywords: *Masonry Coating, Visual Survey, Markov Chain Model, Service Life Prediction Method.*

1 Introduction

Carbonation of concrete is one of the factors that determines the life of reinforced concrete buildings. In general, it is possible to prevent the carbonation and extend the life by applying an exterior coating material to the outer wall.

It is difficult to predict the degradation of finishing coatings because type of material, parts used, construction level and maintenance level interactively affect the degradation of coating material.

On the other hand, since the exterior finishing coatings is required to have protection performance against reinforced concrete, its end would be evaluated as a time when the carbonation suppression effect decreases a certain value. However, there are many unknown points about the relationship between the deterioration of the exterior coating material and the reduction of the carbonation suppression effect.

In this study, authors investigate the deterioration state of actual buildings throughout field survey, and propose a deterioration prediction method of exterior coating materials by using the Markov chain model, which is one of the comprehensive probabilistic models based on the results of the survey. In addition, focusing on change of carbonation suppression effect with deterioration of the exterior coating material, authors propose a method for evaluating the service life of the coating material.

2 Development of Deterioration Prediction Method for Exterior Coating Material

2.1 Collection of Deterioration Data of Exterior Coating Materials in Real BSuildings

Four reinforced concrete buildings shown in Table1 were surveyed from 2012 to 2016. It should be noted that "Age from Repaint" means the age of the exterior coating material from renovation year to 2016. In addition, since the four buildings locate in the neighborhood, it would be a

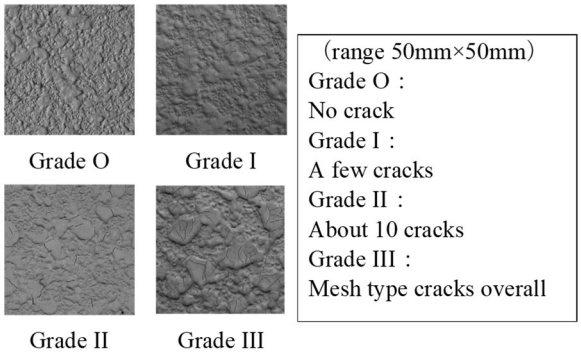
doi:10.23967/dbmc.2020.031

close environmental condition. The number of renovations of the exterior coating material is one, but years of the renovation is different.

Table 1. Surveyed Buildings.

	Survey Buildings			
	A	B	C	D
Construction	reinforced concrete construction			
Stories	4	4	4	12
Design Strength	18 N/mm^2	18 N/mm^2	21 N/mm^2	21 N/mm^2
Year of construction	1978	1977	1977	1977
Year of Repaint	2010	2008	2001	1997
Age from Repaint	6 old	8 old	15 old	19 old
Coating Material (construction)	Multi-layer Coating Material (E Type)			
Coating Material (repaint)	Synthetic Resin Emulsion Paint			
Color of finish	white			

Table 2. Classification of Crack Degradation.



Survey items are as follows.

(1) Cracks: Visual cracks in the outer wall were classified into four grades. About 100 to 200 points with each point of 50mm x 50mm area for each building were surveyed. Grade detection was performed using a standard sample shown in Table 2.
(2) Carbonation: Carbonation depth was measured by phenolphthalein solution method with core specimens.

Fig. 1 shows relationship between elapsed years after the repair of the surveyed buildings and average crack grade of each surveyed location. As an overall trend, it was confirmed that cracking progressed with the passage of time since the renovation.
Fig. 2 shows relationship between elapsed years since renovation and depth of carbonation. It can be seen that the progress of carbonation is delayed as the passage of time from the renovation increases. Since age of each surveyed building is almost the same and the number of repaints is one, it would be thought that not only the aging from the renovation to the time of the survey, but also the aging from the new construction to the renovation affected the progress of carbonation. Furthermore, the carbonation progressed in the buildings where the renovation time was significantly delayed.

Figure 1. Crack Degradation.

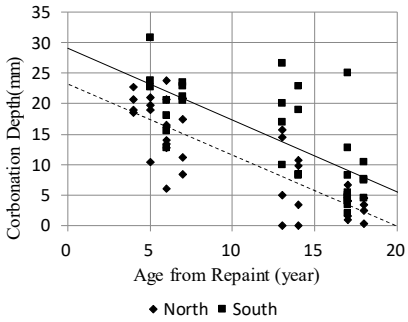


Figure 2. Carbonation.

2.2 Deterioration Prediction of Exterior Coating Materials

The Markov chain model is a probabilistic model for future condition prediction, and it is a

macro model that is used when it is difficult to predict by the accumulation of each affecting factor. Here, in the degradation grades from O to III as shown in Fig.3, the transition probability Xn is assumed to transit from certain degradation grade to the next grade after a certain time t. It is assumed that the distribution of the deterioration grade at any time can be simulated. This model has irreversible features, and its equation is represented in Fig.4.

As shown in Fig. 1, cracking phenomenon, which is the degradation phenomenon of exterior coating, tends to progress with time, and is consistent with the irreversible characteristics of the Markov chain model used in this study.

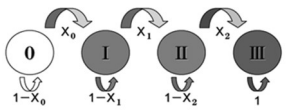

Figure 3. Conceptual Diagram of Markov Chain Model.

$$\begin{pmatrix} O \\ I \\ II \\ III \end{pmatrix} = \begin{pmatrix} 1-x_0 & 0 & 0 & 0 \\ x_0 & 1-x_1 & 0 & 0 \\ 0 & x_1 & 1-x_2 & 0 \\ 0 & 0 & x_2 & 1 \end{pmatrix}^t \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix}$$

Figure 4. Determinant .epresentation of Markov Chain Model.

Average values of the transition probability based on the results of the crack survey from 2012 to 2016 are shown in Table3. In addition, the results of prediction of deterioration of cracks by Markov chain model using the transition probability are shown in Fig.5.

Feature of this model is as follows. At the time of "0 years", crack grade 0 occupies the entire building, but the proportion of crack grade I increases as the age progresses, and the crack grade 0 decreases accordingly. Furthermore, the proportion of crack grade II increases as years progress, and crack grade 0 and I decrease. In the end, the ratio of crack grade III, which is the most significant degradation, increases.

Table 3. Degradation Probability.

	x0	x1	x2
Max	0.384	0.396	0.400
Min	0.016	0.015	0.004
Average	0.108	0.116	0.178

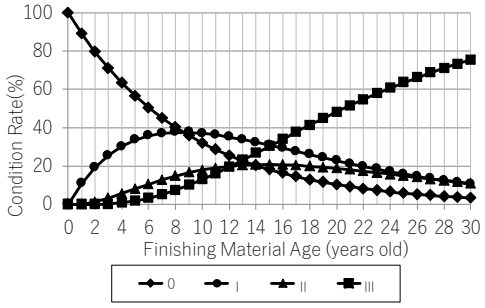

Figure 5. Prediction of Cracking.

3 Relationship between Cracking and Carbonation Suppression Effect

3.1 Decrease in Carbonation Suppression Effect by Cracking

Authors examine relationship between cracking and carbonation suppression effect.

Akio, T. (2013) showed that there is a certain correlation between surface air permeability coefficient and carbonation rate coefficient of existing RC buildings. In this study, time change of carbonation suppression effect of a multi-layer coating coating material was evaluated by the

air permeability test. Crack of the coating material is degradation phenomenon as shown in table 2 and CO_2 induced carbonation would occur at the cracks which strongly affects air permeability of the coating. Hence, the deterioration of the coating material and its relation to carbonation would be evaluated with surface air permeability.

3.2 Verification at Laboratory

Multi-layer coating materials for exterior finishing used in reinforced concrete buildings often composed of three layers that are a top coating layer that protects the outer wall from solar radiation and rain, a main material layer that provides texture and a primer layer that improves adhesion to the frame. Here, in order to confirm the possibility that the protective effect of the coating material would be reduced by cracking of the top coating material, the change of air permeability of the surface layer was measured at laboratory.

An outline of test specimen is shown in Fig.6. First, sewing thread is laid down at different intervals on calcium plate. Next, an acrylic resin emulsion paint as an overcoat layer for the exterior coating material was applied to the calcium plate with a roller. After 60 minutes, the sewing thread was pulled out to reproduce pseudo crack.

Surface permeability was evaluated using a double chamber method (1992) before the sewing machine was laid down.

Fig. 7 shows the ratios of the air permeability coefficient of the test specimen before and after crack initiation.

Here, “crack length” represents the total length of pseudo cracks in the range of the chamber of the measuring apparatus.

It can be seen that the air permeability coefficient increases with the increase of the length of the pseudo crack, and finally the air permeability coefficient approached to that of the calcium carbonate plate before coating.

This might indicate that when the cracks in the top coat layer increase, the air permeation becomes easier and the carbonation suppressing effect decreases. And the close air permeability to the substrate calcium carbonate plate at significant crack state might be same as no overcoat layer applied.

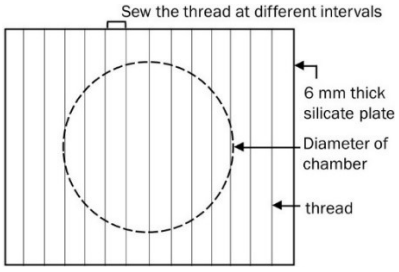

Figure 6. Test Models.

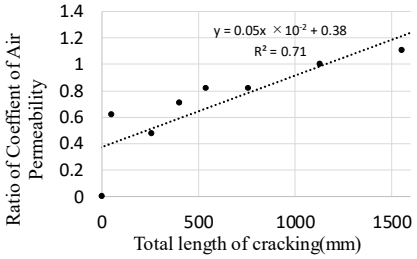

Figure 7. Relation of cracking and Coefficient of Air Permeability.

3.3 Survey of Actual Buildings

Crack and air permeability of actual buildings were surveyed. Nine reinforced concrete buildings estates shown in Table4 were surveyed at a position of about 1.5m height above the ground and a visual inspection of the cracks and surface air permeability tests were conducted

at the same location. As a feature of these buildings, each building is under almost same environmental conditions and age of construction and types of coating materials are same.
Fig. 8 shows secular change of crack grade and surface air permeability. As the years progress, the crack grade and air permeability coefficient tend to increase. As a result, there was a possibility that there was a temporary correlation between the cracks and air permeability of the coating material.

Table 4. Survey Buildings.

Buildings	Building Age	Finishing Material
A	11, 14, 18	Sprayed Tile
B	13, 16, 18	Multi-layer Finish Material (Thick E Type Treated Protrusion)
C	7, 9, 11	Sprayed Tile Thick E Type

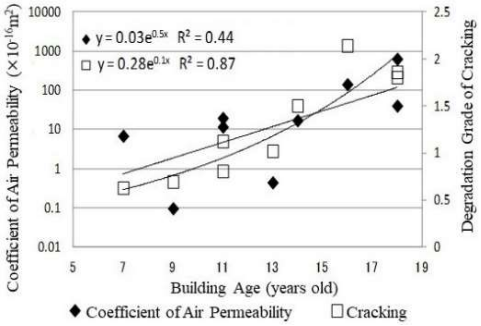

Figure 8. Aging Effect on cracking and Coefficient of Air Permeability.

3.4 Verification Using a Markov Chain Model for Deterioration Prediction Simulation

Kei.M (2013) evaluated period when carbonation rate coefficient of finished concrete became equal to that of exposed concrete due to deterioration of the coating film as the service life of the coating material. It was 13 years according to his study. Here, based on the fact that cracking of the coating material progresses with time in Fig. 1 and that carbonation tends to progress according to time from new construction to renovation, a damage of coating material was assumed to be critical. Hence, "Accumulation of degradation" was set in consideration of the relationship between years that exceeded the limit years and the degree of limit excess of deterioration as shown in the following equation (2). And the relationship between "Accumulation of degradation" and carbonation depth (Kotaro.E(2016)) was examined. Fig. 9 shows a conceptual diagram.

$$D_a = \sum_{n=1}^{N} \sum_{t=1}^{T(n)-L} \left(d_n(L+t) - d_n(L) \right) \tag{2}$$

Here,
Da: Accumulation of degradation", N(times): Number of paintings including when building exterior coating materials, T(n)(year): Number of years from the time of painting to the time of renovation (when n = N, from the time of painting to the time of survey), L(year): Marginal years for exterior coating materials, dn(x): Represents the ratio of degradation grade III (0 <dn (x) <1) of Markov simulation at the time of n times of coating n times, and is considered only when the age exceeds the limit years (x> L).

Based on previous research (2011), the relationship between "Accumulation of degradation" and the mean of the carbonation depth of each building assuming the limit of 13 years is shown in Fig.10 for the surveyed building shown in Table1. It can be seen that the average of the carbonation depth of the building increases as "Accumulation of degradation" increases, and there is a possibility that there is a certain relationship between the crack and the carbonation suppression effect.

Table 5 shows list of the all surveyed buildings. Although these buildings are different specification and subjected to different environmental conditions, design standard strength was close to each other. Hence, "(1) Crack" and "(2) Carbonation depth" using the methods described in chapter 2 were investigated. Fig. 11 shows relationship between "Accumulation of degradation" and carbonation depth for each survey target. Although the correlation of Fig.11 was lower than that of Fig. 10, a certain degree of correlation was kept. Thus, there would be correlation between the cracking and carbonation inhibitory effect of the multi-layer coating material.

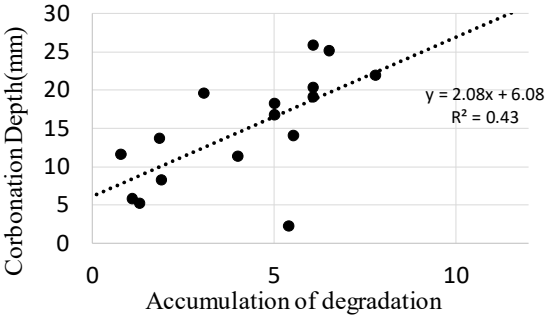

Figure 11. Relation of Accumulation of degradation and Carbonation depth.

4 A proposal for Service Life

In Fig. 10, it would be clear that carbonation depth would be 0, if "Accumulation of degradation" is 0. That means that the regression line should pass through the origin. At this that the regression line passed a bit other point of the figure because the limit age of the coating materials was assumed to be 13 years. Therefore, authors set the new limit years so that the regression line approaches the origin. In the subject of this survey, the regression straight line passed the origin when the limit age was 10 years. Fig. 12 shows the relationship between "Accumulation of degradation" and the carbonation depth with the critical age of 10 years.
When the limit service life is assumed to be 10 years, the deterioration rate shown in Fig. 5 (the

ratio of deterioration grade III) would be 16.0% with transition probabilities shown in Table 3. It would be possible to consider the time when this deterioration rate is reached based on carbonation of concrete.

As described above, the exterior coating materials can be used to minimize or control the carbonation of concrete by repainting within a range that does not cause "Accumulation of degradation" within 10 years. In this sense, it can be situated as a way of service life consideration.

The relationship between age and "Accumulation of degradation" is shown in Fig. 13 by Equation (2) for the survey target in Table 1.

In addition, the relationship between age and carbonation depth is shown in Fig. 14 by using the approximate expression of the relationship between "Accumulation of degradation" when the limit years as 10 years. On the other hands, if the cover thickness of reinforced concrete is 30 mm, this building will face to the end of life in 36 years unless it is repainted. Here, assuming that the required service life of the building is 100 years and the repainting interval at which carbonation does not reach 30 mm within 100 years, life cycle assessment of finishing coating in terms of carbonation would be possible. Table6 shows the prediction of the carbonation depth of buildings when the exterior coating materials are refurbished and the age reaches 100 years. It would be calculated that if the exterior coating material used in this building is repainted every 22 years (Fig.15), carbonation does not reach the reinforcing bars within 100 years.

5 Summary

The findings obtained in this study are shown below.

- Authors investigated four buildings that were close environmental condition, focusing on cracking of multi-layer coating. As an overall trend, Cracking was confirmed that cracking progressed with the passage of time since the renovation.
- Based on the survey results on cracks in multi-layer coating materials applied to reinforced concrete buildings, authors presented a method for predicting crack degradation using a Markov chain model.
- Authors showed a possibility that there was a correlation between the cracks and air permeability of the coating materials by laboratory experiments and surveys of real buildings. In addition, by considering along with the report that there was a correlation between surface air permeability and carbonation rate coefficient of existing RC buildings, authors showed a possibility that there was a correlation between the cracking and carbonation inhibitory effect of the multi-layer coating materials.
- Authors proposed “Accumulation of degradation” considering the time and grade when the crack exceeded a certain value. And Authors confirmed that there is a certain correlation between the "Accumulation of degradation" and the carbonation depth of the buildings.
- By using the relationship between "Accumulation of degradation" and the carbonation depth of the buildings, Authors suggested the service life for the coating materials to use the buildings for the longest years and the required years.

Abstract. *A model building made out of concrete block specimens whose surfaces were coated with various finishing materials was constructed for the outdoor exposure test. After 30 years of outdoor exposure, the deterioration of finishes and their carbonation and corrosion inhibition effects were investigated. As a result, the following conclusions were obtained: Though the deterioration levels differed depending on their types and thickness, all finishing materials showed some kind of deterioration after 30 years' long-term outdoor exposure. The progress of carbonation and corrosion are prevented when the surface is coated with finishing materials of sufficient thickness or waterproof effect. Regarding the relationship between corrosion depth and carbonation depth, corrosion is initiated after the carbonation front reaches the area. It usually takes a while to initiate corrosion in the carbonated area, not immediately after the carbonation reaction. When the concrete surface is properly coated with finishing material, corrosion may not be initiated in non-carbonated area in concrete where the pH level is not lowered.*

Keywords: *Finishing Materials, Outdoor Exposure, Carbonation, Corrosion.*

1 Introduction

The durability of Reinforced concrete (RC) buildings are basically determined by the presence or absence of steel corrosion. In order to prevent corrosion of steel in concrete, degradation factors such as carbon dioxide (CO_2) and chloride ions need to be prevented from penetrating into concrete. In many RC buildings, finishes are applied to concrete surfaces, which prevent the penetration of degradation factors. While many studies have been reported on the preventive effects of finishing materials based on accelerated testing, little is based on the long-term exposure to the outdoor conditions (Hasegawa *et al.*, 2002, 2017).

In this study, a model building made out of concrete block specimens whose surfaces were coated with various finishing materials was constructed for the outdoor exposure test. After 30 years of outdoor exposure, the deterioration of finishes and their carbonation and corrosion inhibition effects were investigated.

2 Experiment Overview

2.1 Outline of Specimens

Table 1 shows the materials used for concrete, and Table 2 shows the mix proportion and properties. The water cement ratio (w/c) is 0.55 and 0.70, and unit water content was 176 kg/m^3. To measure corrosion depth by the corrosion indicator method (Senbu *et al.*, 1987), iron particles were mixed to some concrete specimens before casting to make them serve as corrosion indicators. Chloride ions were also premixed in some specimens of w/c ratio 0.70 at the concentrations of 0.3, 0.6, and 1.2kg/m^3 by dissolving NaCl in water to examine the effect of chloride on concrete. The iron particles had diameters of 0.15 to less than 2.5 mm, used as a partial replacement of fine aggregate at 20%. Concrete specimens of 100×100×400mm in size, whose shapes were designed to be piled up to build the model building, were prepared (Figure 1). After demolding, the specimens were cured in 20℃ water for 28 days, followed by an atmospheric curing period of 42 days at 20℃, 60% R.H. Surface finishing materials were then applied to the specimens.

Table 1. Materials.

Material	Mark	Detail
Cement	C	Ordinary Portland cement, Gravity=3.16g/cm^3
Fine aggregate	S	River sand, Specific gravity=2.60g/cm^3
Coarse aggregate	G	Gravel, Specific gravity=2.64g/cm^3
Iron particle	CI	0.15-2.5mm, Gravity=6.9g/cm^3
Admixture	Ad	Air entrained and reducing agent

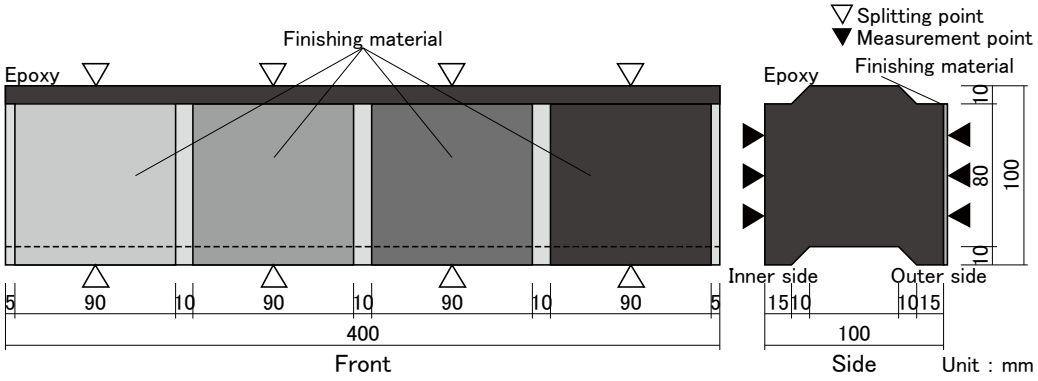

Figure 1. A schematic illustration of the specimen and measuring point of carbonation and corrosion depth.

Table 3 shows the types and amount of finishing materials used in this study. White color finishes (finishing coatings and paint), which are commonly used for the surface coating of RC buildings, were applied to the specimens, with a standard technique. A total of 7 types of finishing materials including penetrant (impregnation) were used. Four different finishes were applied to a 90×400mm surface of each one specimen, in the shapes of 90×100mm rectangular (Figure 1). This made a pair of concrete block specimens covered with 7 types of finishes including one surface area without a finish (fair-faced concrete). The specimens were then coated with epoxy resin, except for the surfaces covered with finishing materials and their opposite sides without finishes. The surface finishes were applied by experts.

Before the application of surface finishes, some specimens were subjected to accelerated carbonation curing for 8 weeks under the conditions of 20℃, 60% R.H. and 5% CO_2, to be examined the iron corrosion in carbonated areas. The prepared specimens were used for constructing the model building and were subjected to outdoor exposure test.

Table 3. Finishing materials.

Mark	Finishing material	Species and dosage (kg/m^2)			Luster
		Sealer	Main material	Top coating

g	Thick coating material E	Water-based 0.08	3.65 Spray	-	N

2.2 Outline of Model Building

Figure 2 shows a photo of the model building. It was constructed on a premise of the Building Research Institute (BRI) in Tsukuba City, Ibaraki Prefecture. The model building was constructed with concrete specimens piled up in a boxy shape, whose outer surfaces were coated with various types of finishing materials. It had a box-shaped metal roof inclined to the north side. Inside of the building was sheltered from rain, and its room air temperature and humidity were not controlled.

Figure 2. A photo of the model building.

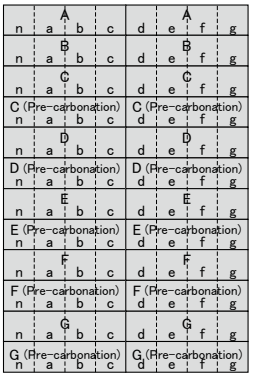

Figure 3. A layout of surface finishes.

Figure 3 shows the layout of surface finishes. The specimens on the south side of the model building were used for the study. From heights of 460mm above the ground, the specimens were piled up in 12 layers. The gap between the top of the wall and the metal roof was covered with plywood. A pair of concrete specimens with the same mix proportions were placed horizontally next to each other. A total of 7 different finishes were applied to the pair of specimens in the same layer. The capital letters in Figure 3 indicate the marks of concrete specimens (Table 2), and the lower-case letters indicate the types of finishes applied to the specimens (Table 3). The lower-case letter "n" indicates the specimens without finishes.

2.3 Test Methods

2.3.1 Evaluation of the surface finish deterioration

The deterioration of finishing materials was evaluated by peeling, cracking, dirt, and chalking. It was graded by multiple experts, using a 6-degree scale from 0 (no deterioration) to 5 (severe deterioration).

2.3.2 Measurement of carbonation depth

As shown in Figure 1, the carbonation depth was measured by splitting a concrete specimen evenly at the center of each finishing material, and then spraying 1% phenolphthalein solution over a freshly exposed surface of the specimen. It was measured at two sets of three points, each of inner and outer side of the model building.

2.3.3 Measurement of corrosion depth

Corrosion depth was measured by the corrosion indicator method. In this method, materials to detect corrosion (iron particles) are mixed to concrete before casting so that the depth of rust can be measured by splitting the hardened concrete specimens. Since the rusted iron particles indicate a condition that may cause rust on reinforcing steel, the corrosion indicator method enables us relatively easily to observe the variation of steel corrosion potential over time. The corrosion depth was measured at the same points as those of the carbonation depth measurement (Figure 1).

3 Results and Discussion

3.1 Deterioration of Finishing Materials

The finishing materials that are the type to form coating film on the surface, except silane-type surface penetrants (e), were evaluated for deterioration in Figure 4.

Acrylic resin enamel (c) shows the highest degree of peeling. One possible reason is that there was a loss of adhesion between the paint and the surface it's placed on due to long-term outdoor exposure, because a paint finish such as acrylic resin enamel has a thickness from several tens to hundred microns, while other ordinary finishes have thickness of 1-5 mm.

Multi-layer coating material E (b), acrylic resin enamel (c), waterproof thin coating material E (d) and waterproof thin coating material E (air permeability type) (f) showed high degrees of cracking. Though small in width (hairline crack), cracks in the specimens are often caused by the degradation of resin contained in finishing materials due to ultraviolet ray.

All finishes showed the deterioration degrees from 2 to 3, except that waterproof thin coating material E (d) remained lower levels of dirt. The adhesion of dirt is affected by the nature of surface finishing materials such as hydrophilicity, hydrophobicity, water absorbability, and water repellency. The smoothness and fineness of surface finishing materials are considered to be lost due to long-term outdoor exposure.

Multi-layer coating material E (b), acrylic resin enamel (c), waterproof thin coating material E (d) and waterproof thin coating material E (air permeability type) (f) showed high degree of chalking. Surface finishing material is usually a composite material containing aggregates and admixture that add thickness to surface, coloring agent to add color, and bonding material to bind them together. Degradation of bonding material and coloring agent is one of the reasons that cause chalking, which refers to the formation of fine powder on the surface of the paint film.

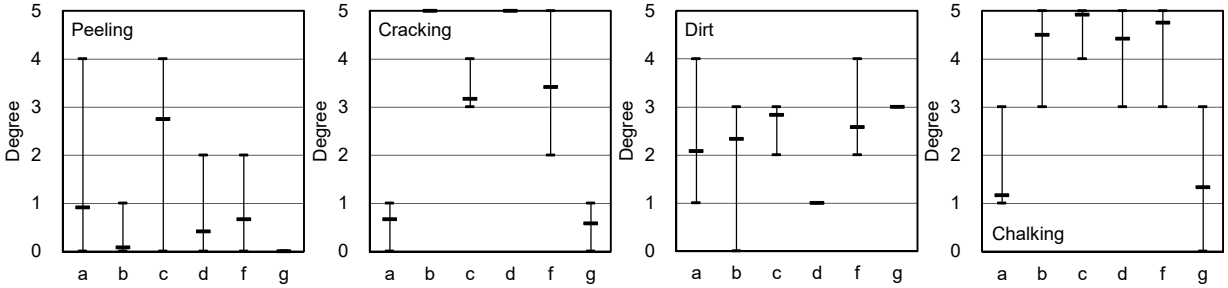

Figure 4. Deterioration degree of finishing materials.

3.2 Carbonation Depth

Figure 5 shows the carbonation depth measured from the outer surfaces of the specimens with different w/c ratios (A, B). The plain specimens without finishing materials (n) were measured from both inner (nI) and outer (nO) surfaces. As a whole, the specimens with higher w/c ratio showed deeper carbonation depth than those of lower w/c ratio. Regarding the plain specimen (n), inner surface (nI) had deeper carbonation depth compared to that of outer surface (nO). This is because the water content of outer surface was increased to some extent due to rainfall, while inner surface tended to dry and were more likely to be carbonated.

Among the carbonation depths measured from outer surfaces, thin coating material E (a), multi-layer coating material E (b), acrylic resin enamel (c), and waterproof thin coating material E (d) showed smaller carbonation depths, while silane-type surface penetrants (e) and waterproof thin coating material E (air permeability type) (f) showed deeper carbonation depths, compared to that of the plain specimen (nO). Having water repellency and air permeability, silane-type surface penetrants (e) and waterproof thin coating material E (air permeability type) (f) prevented water penetration into concrete and allowed evaporation at the same time. It can be assumed that these properties caused lower water content of concrete and deeper carbonation depth than the plain specimens (nO). The graph also shows that thick coating material E (g) with w/c of 0.55 had high carbonation inhibition effect, while that of w/c 0.70 did not. The presumed cause is delamination of the surface layer occurred in w/c 0.70 specimen during outdoor exposure, which allowed carbon dioxide to diffuse more easily from the surrounding environment.

Assume the ratio of carbonation depth of a specimen covered with finishing material to that of a plain specimen not covered with finishing material shows constant value. $S(t)$ is the carbonation rate representing the carbonation inhibition effect, and can be expressed by the following formula (1) (Nagase *et al.*, 2007).

$$S(t) = \frac{C_C(t)}{C_B(t)} \tag{1}$$

Here, $S(t)$ is carbonation rate at the time of exposure (time), $C_C(t)$ and $C_B(t)$ are carbonation depth of concrete covered with and without finishing material, respectively (mm).

Figure 6 shows the carbonation rate of finishing materials at the age of 30 years applied to the model building. Among them, multi-layer coating material E (b) and waterproof thin coating material E (d) showed particularly low rates, suggesting they have high carbonation inhibition effects. In addition, thick coating material E (g) would also have high carbonation inhibition effect, if it demonstrated its potential efficacy.

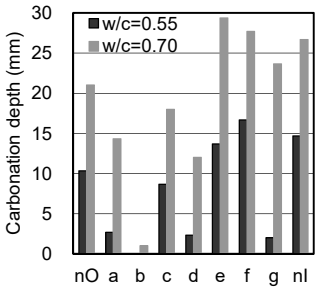

Figure 5. Carbonation depth.

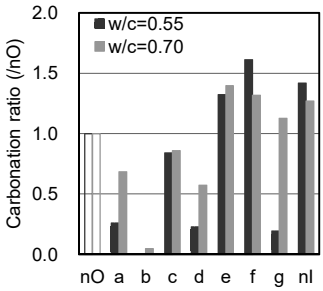

Figure 6. Carbonation rate.

3.3 Corrosion Depth

Figure 7 shows the corrosion depth measured from the outer surface (covered with finishing materials) of the concrete specimens (C, D) in which iron particles were mixed before casting. The plain specimens without finishing materials (n) were also measured from both inner (nI) and outer (nO) surfaces. As with the carbonation depth, specimens with higher w/c ratio showed deeper corrosion depth than those with lower w/c ratio. This indicates that higher w/c ratio make reinforcing steel more prone to corrosion. The graph also shows that the plain specimens (n) showed deeper corrosion depth, when measured from inner surface (nI) than from outer surface (nO).

Comparing the corrosion depth measured from outer surfaces, multi-layer coating material E (b), waterproof thin coating material E (d), and thick coating material E (g) had a smaller depth of corrosion than that of plain specimen (nO). Multi-layer coating material E (b) and waterproof thin coating material E (d) are considered to have relatively higher water repellent effect than other finishing materials. Though carbon dioxide may have permeated concrete from the delaminated surface, thick coating material E (g) is considered to have been effective in preventing water penetration.

The pre-carbonated specimens tended to have deeper corrosion depth, which was especially true for those with w/c 0.70. This indicates that reinforcing steel is more likely to corrode in carbonated area.

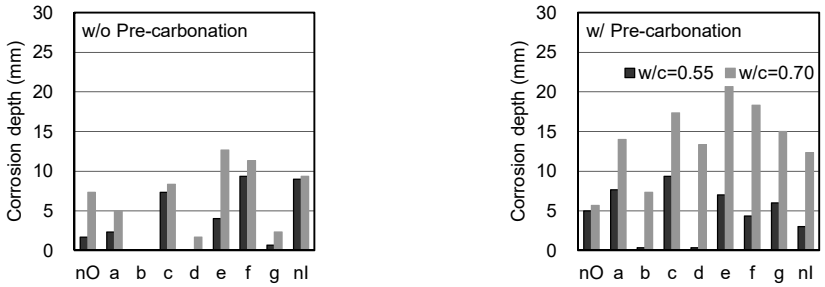

Figure 7. Corrosion depth.

Figure 8 shows the relationship of the corrosion depth to the amount of chloride ions in the specimens of w/c 0.70 (D, E, F, G), in which iron particles and chloride ions had been added before casting. Again, the pre-carbonated specimens tended to have deeper corrosion depth compared to those without pre-carbonation. However, the amount of chloride ions, including its presence or absence, did not show significant effects on the corrosion depth.

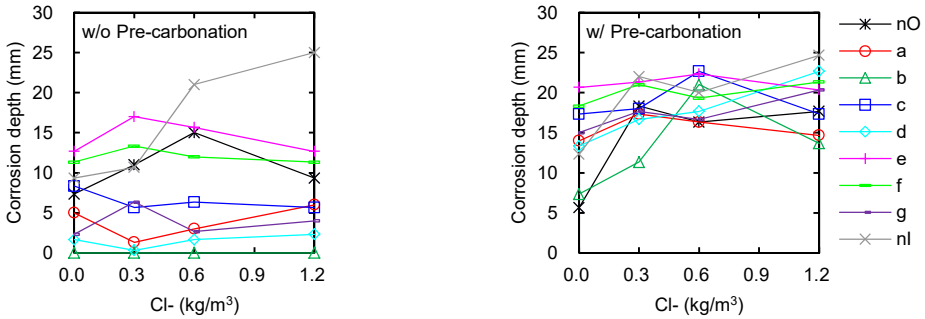

Figure 8. Relationship between corrosion depth and chloride ions.

3.4 Relation between Corrosion Depth and Carbonation Depth

Figure 9 shows the relationship between the corrosion depth and carbonation depth measured from the outer surfaces of the concrete specimens (C, D) in which iron particles had been mixed before casting. The depths measured at 3 points on each finishing material are plotted on the graph. The progress of corrosion is preceded by that of carbonation. This suggests that the corrosion is not initiated immediately after the carbonation front reaches reinforcing steel. It can be assumed that when the concrete surface is properly coated by finishing material, corrosion may not be initiated in non-carbonated area where the pH level is not lowered.

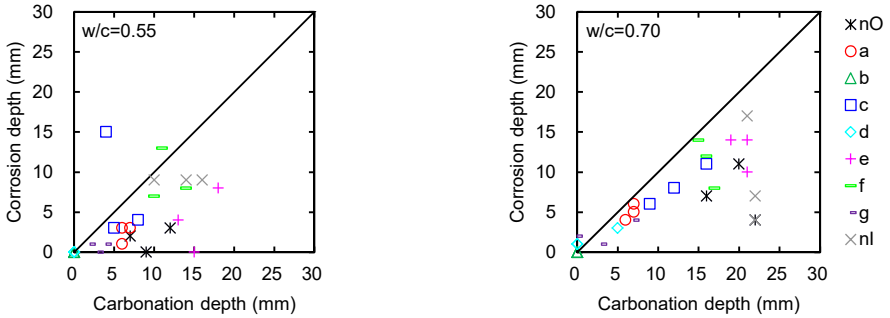

Figure 9. Relationship between corrosion depth and carbonation depth.

4 Conclusion

In this study, a model building made out of concrete block specimens whose surfaces were coated with various finishing materials was constructed for the outdoor exposure test. After 30 years of outdoor exposure, the deterioration of the finishing materials and their carbonation and corrosion inhibition effects were investigated. As a result, the following conclusions were obtained.

- Though the deterioration levels differed depending on their types and thickness, all finishing materials showed some kind of deterioration after 30 years' long-term outdoor exposure.
- The progress of carbonation is prevented when the surface is coated with finishing materials of sufficient thickness or waterproof effect. However, the carbonation inhibition effect cannot be obtained when using air-permeable finishing materials or there is a peeling finish on the surface.
- The progress of corrosion is prevented when the surface is coated with finishing materials of sufficient thickness or waterproof effect.
- Regarding the relationship between corrosion depth and carbonation depth, corrosion is initiated after the carbonation front reaches the area. It usually takes a while to initiate corrosion in the carbonated area, not immediately after the carbonation reaction.
- When the concrete surface is properly coated with finishing material, corrosion may not be initiated in non-carbonated area in concrete where the pH level is not lowered.

Abstract. *Polyurethane composite coatings are frequently applied to strengthen the barrier properties of various construction materials such as wood, metal and concrete. The changes of color and glossiness of the composite coatings for building materials proceeds more slowly than that of polyurethane because of containing fillers and several types of additives. However, the most critical barrier properties have not been studied directly based on the difference from the degradation mechanism of polyurethane coatings. Additionally, the difference in thermal and UV degradation mechanisms of coatings is not clear in the existing studies dealing with conventional accelerated weathering tests and outdoor exposure tests. Therefore, the behavior of the filler contained in the coatings was observed using an oven to accelerate thermal degradation. The chemical analysis of the coating surface by XPS and the analysis of the images and elemental mappings by SEM-EDS were carried out, and the mechanism of degradation progress was investigated. In addition, the temperature dependency of the degradation was studied in changing the heating temperature. It was suggested that polymer and fillers interact in promoting mass transfer at the same time as the thermal degradation reaction consequently.*

1 Introduction

Building material products used for topcoat contain so many chemical materials and consist of chemically complex systems. The products contain polyurethane, polyacrylic, modified silicone, and hybrid polymers. Furthermore, their products contain plasticizers, additives, and inorganic fillers in order to ensure performance and durability (Annamalai Pratheep Kumar *et. al.* (2009), D.K. Chattopadhyay (2006), Ivan S. Stefanović *et. al.* (2019), Jun Liu *et. al.* (2017), Li Bin (2014), M.Sabzi *et. al.* (2008) and S.M. Mirabedini (2013)).

In the present circumstances, the degradation process of coating materials containing polymers and inorganic substances has not been discussed. Even manufacturing companies have difficulty in elucidating their degradation mechanism, because such companies purchase raw materials from other companies and mix them to make products in many cases. In addition, there are few studies that separate thermal degradation from UV degradation through accelerated weathering tests and outdoor exposure tests. Therefore, this paper examines thermal degradation mechanism of coatings based on the result of the chemical analysis of the coating surface by XPS and the analysis of the images and elemental mappings by SEM-EDS.

doi:10.23967/dbmc.2020.100

2 Methods

2.1 Samples

In this study, both thermally-degraded and non thermally-degraded samples were prepared. The Conventional two-component type urethane coating including TiO_2, $CaCO_3$, and $BaSO_4$ as fillers was coated on a slide glass with a spin coater to control film thickness. After the surfaces of the samples were sufficiently dried, they were cured for 120 days at 20°C and 60% relative humidity, and cut to 7mmX7mm for fitting measuring instruments.

Subsequently, the samples after cutting were heat-degraded at 30°C, 50°C, and 70°C. The periods of the degradation are 0, 1, 3, and 7 days, and XPS measurement and SEM-EDS measurement were conducted respectively. The features of the measurements are briefly shown in Table 1.

2.2 XPS Measurement

X-ray photoelectron spectroscopy (XPS) was used to evaluate the chemical properties of urethane resin coatings. This technique is applied to analyze the type, concentration, and chemical state of elements on sample surfaces. Each sample is irradiated with an X-ray source using Mg-Kα rays, and wide spectrums with a binding energy in the range of 10 to 1000 eV and narrow spectrums around the peak of each detected element was obtained at a measurement area of 1.0 mmX1.0mm. The shift of the peak due to charging is corrected by setting the C1s spectrum to 284.0 eV, and correction using a neutralizing electron gun is not performed.

2.3 SEM-EDS Observation

A scanning electron microscope (SEM) equipped with an energy dispersive X-ray analyzer (EDS) was applied due to analyze the elemental information of the cross section of the samples. The samples were preliminary processed with a cross section polisher (CP) using argon ion beam for cross sectional observation.

In addition, the surfaces of the samples were coated with Au by ion sputtering to avoid thermal degradation of the samples.

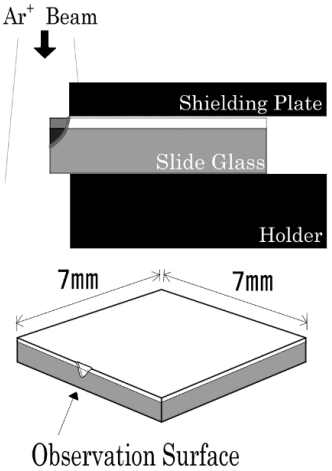

Figure 1. Processing before sample observation.

Table 1. Survey contents in each method.

XPS	・History of elemental type and chemical bonding state of coating surface layer	
SEM-EDS	SEM image	・Cross section thickness of coating ・Filler particle size
	Elemental mapping	・Distribution of elements in the cross section of coating film and its history

3 Results

3.1 XPS Scans

Figure 2 shows XPS narrow scan spectra of the urethane resin coatings that were thermally degraded at 70°C for 0, 1, 3, and 7 days. The peak of O 1s, N 1s, and Si-O increased as thermal degradation treatment continued. This result could be explained that the polymer such as urethane and siloxane was decomposed and appeared on the surface layer of the coatings due to low molecular weight and low density. On the other hand, the Ca peak was hardly detected on the surface layer. This result indicates that the substance in the coating may move up and down dramatically before the surface of the coating is cracked while the coating is thermally degraded. The fillers such as $CaCO_3$ originally floating on the surface of the coating film could be sunk as the polymers were scattered and float by heat.

Figure 3 shows O spectra of the samples that were thermally degraded at 30°C and 50°C for the same period. The graph shows that the peak increase on the 1st to 7th days at 30°C, however at 50°C, it increases on the 1st and 3rd days and decreases on the 7th day. These tendencies suggest the possibility of different thermal oxidation reactions on the coating surface, such as increases in C—O and C═O bonds and a decrease in O due to the progress of C crosslinking. Furthermore, each thermal oxidation reaction takes place at different times during the process of thermal degradation.

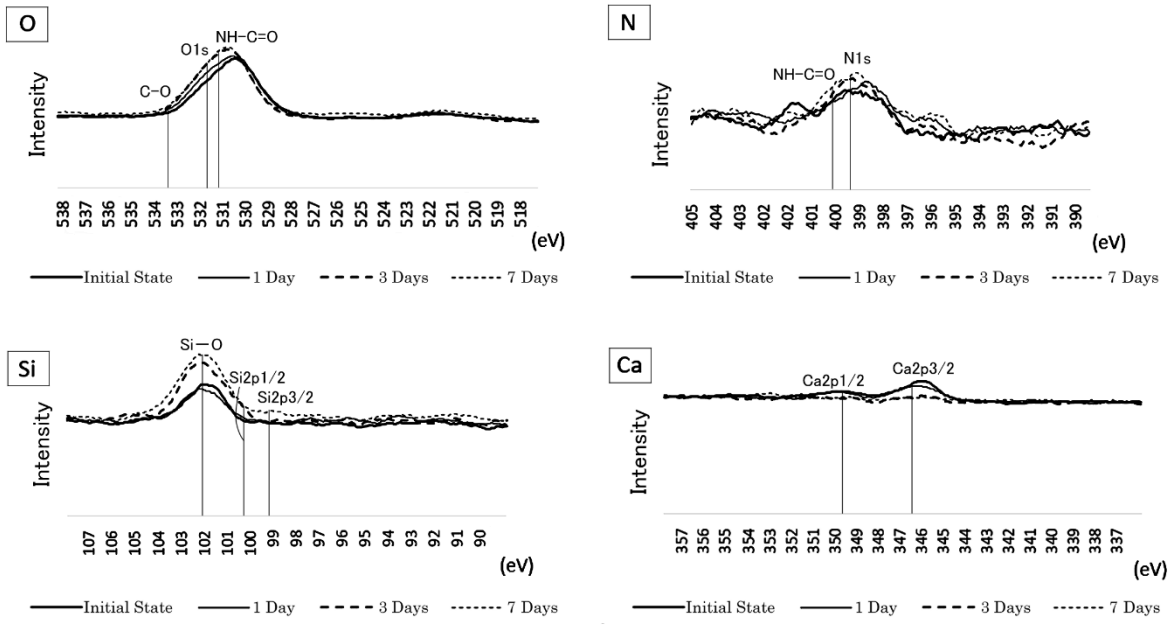

Figure 2. Narrow scan spectra of the urethane resin coatings that were thermally degraded at 70°C.

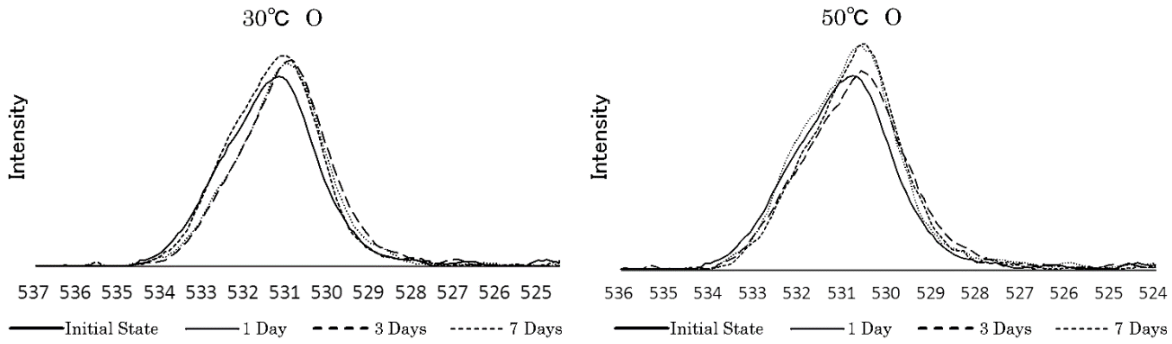

Figure 3. O spectra of the urethane resin coatings that were thermally degraded at 30°C and 50°C.

3.2 SEM Images

Figure 4 shows the film thickness history of each sample obtained from SEM image of the sample thermally degraded for 0, 1, 3, and 7days, respectively, at 30°C, 50°C, and 70°C. However, it should also be noted that samples exposed at 70°C and samples at 30°C or 50°C are different in initial states. In the non thermally-degraded sample, the thickness of the coating was approximately 60 mm. The thickness of coating gradually decreased due to heat degradation at 70°C, and was 38 mm on 1st day, 18 mm on 3rd day, and 10 mm on 7th day. The coating thickness decreased due to thermal decomposition and volatilization of components such as plasticizers in the coating (Wei, X. (2019)). In contrast, at 30°C, the film thickness increased slightly, and at 50°C, it appeared to decrease on the 7th day. The dimensional change of the coating could be caused not only due to reduction of components in coating but also due to changes of gel structure in cross-linking and scission (Petrović *et. al.* (2000) and Y. Nawab, *et. al.* (2017)).

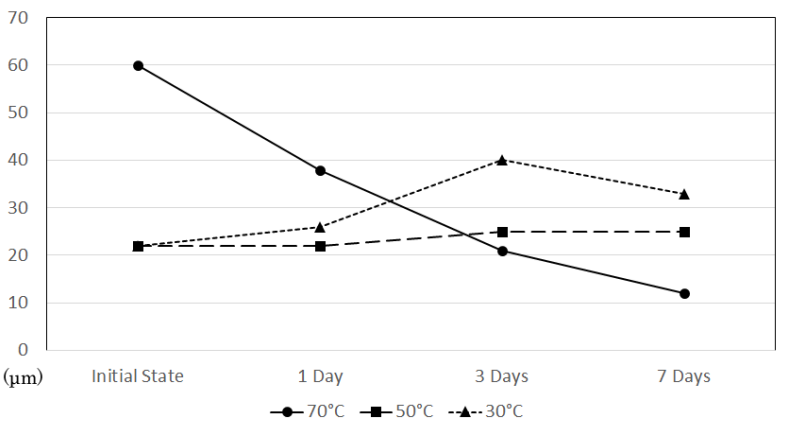

Figure 4. Changes in film thickness of each sample.

3.3 Elemental Mappings

Figure 5 shows the history of element mapping of Ti. Ti was homogeneous in the initial state, increased at the bottom on the first day, and gradually increased on the surface over time by heating at 50°C. On the first day, fillers move to the bottom of the coating as polymers become

smaller and less dense due to thermal decomposition. From the third day, filler have been pushed up from the bottom due to polymer cross-linking and polymerization reaction (Wei, X., *et. al.* (2019)).

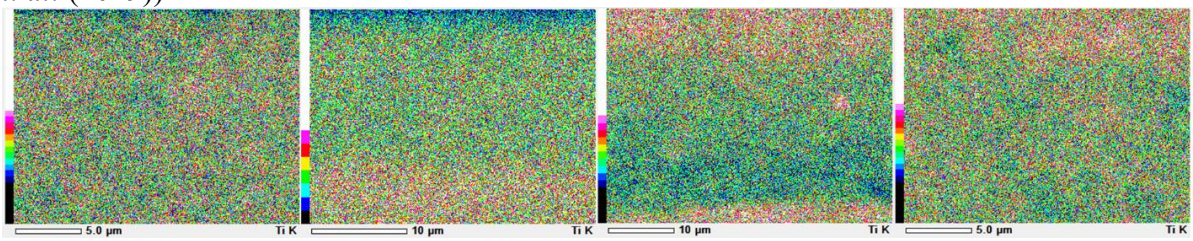

Figure 5. Sectional elemental mapping of Ti in urethane composite coatings at 50°C.

4 Discussion

4.1 Temperature Dependence of Coating Durability

The coating thickness increased initially at lower temperatures and decreased at higher temperatures, accompanied by the movement of the filler. Since fillers such as titanium dioxide have a role to protect the coating from UV degradation, the durability of the construction coating could vary greatly due to differences in temperature history.

4.2 Movement of the Filler

Why does the position of the inorganic filler in the coating fluctuate greatly due to thermal degradation? The movements of each filler of $CaCO_3$, TiO_2, and $BaSO_4$ were analyzed as follows.

4.2.1 $CaCO_3$

In elemental mapping, Ca is always homogeneous, whereas in XPS, the Ca peak increases and decreases depending on the temperature. There was no significant movement of $CaCO_3$ contained in the coating as a filler, and the XPS Ca peak changed due to a change in the state of the surface layer of the coating. The decrease in the Ca peak at 70 ° C could indicate that the surface layer became smoother and covered with polymer as the temperature of the coating approached the glass transition temperature (L.S De Bernarde, *et. al.* (1984)).

4.2.2 TiO_2 and $BaSO_4$

XPS peaks of titanium and barium were not detected, however in elemental mapping by SEM-EDS, there were dramatic movements in the coating as shown in Figure 5. Moreover, the movement tendency of the position of the two elements is very similar and corresponds to the movement of TiO_2 and $BaSO_4$ in the coating as fillers. These fillers could move shrinkage stress due to polymerization, expansion stress due to heating, and stress due to movement of the polymer having a low molecular weight. The positions of these fillers are inhomogeneous unlike CaSO4, because the stress from the polymer may differ depending on the particle size of the filler (Nabil Hayeemasae *et. al.* (2018)). However, understanding these mechanisms require further studies.

5 Conclusions

- The position of the fillers contained in the organic composite coating are inhomogeneous due to thermal degradation.
- Polymerization, scission and cross-linking of the polymers can be accelerated by the action of heat, which can affect the thickness of the coating.
- The cross-sectional morphology of the coating changes depending on the temperature of thermal degradation.
- Changes in thickness and inhomogeneous distribution of materials due to thermal degradation of architectural composite coatings could affect their barrier performance because of the movements of the fillers and changes of the thickness.

Abstract. *In this paper, we discussed the concept for appropriate repair period for finishing materials of reinforced concrete structures. We investigated the actual building repair cycle, the progress of carbonation of concrete, and the adhesion strength of various finishing coating. In addition, we carried out 10-years exposure test of concrete with various finishing to evaluate the progress of carbonation and the degree of deterioration of the finish coating material. From these results, we showed the possibility of extending beyond the current repair cycle.*

Keywords: *Concrete, Finishing Materials, Repair Cycle, Carbonation and Appearance Change.*

1 Introduction

In order to use reinforced concrete buildings for a long term, it is necessary to regularly repair finishing materials in addition to appropriate daily maintenance. Therefore, in Japan, it is required to make a long-term repair plan for condominiums by law, and the repair plan is designed and executed according to the guidelines[1)] issued by the Ministry of Land, Infrastructure, Transport and Tourism. However, repair work, especially the recoating of exterior finish materials, has a uniform repair cycle in any condominiums regardless of their age, surrounding environment or type of finishing materials. Previous studies[2)-4)] pointed out that deterioration speed is different in each material or environment. In other words, in the current repair work may have problems such as deterioration in performance due to leaving the deteriorated part or an increase in extra cost due to the repair of the healthy part. Therefore, in order to efficiently repair work and reduce Life Cycle Cost, it is necessary to set an appropriate repair cycle corresponding to the type of materials, environment and deterioration status.

In this study, we evaluated the current repair cycle by analysing the relationship between the cycle and the deterioration state of existing RC condominiums. Then, we examine the idea of an appropriate repair cycle in terms of performance by verifying the carbonation preventive effects of the finishing materials using the specimen exposed outdoors for 10 years.

2 Materials and Method

2.1 Analysis of Current Repair Cycle and Deterioration State

In this study, we examined the actual status of finishing materials repair cycle and deterioration states before repair in 222 condominiums around Tokyo, Japan. Based on the deterioration

diagnosis report, we focused three deterioration index: carbonation of concrete and decrease in adhesion strength of finishing materials and cracks, and examined the actual deterioration state of exterior walls due to differences in factors affecting deterioration (especially age, repair period and directions). For these deterioration phenomena, we calculated the average value, maximum value and standard deviation for each building. In this report, we will report the results of carbonation and adhesion strength.

As shown in Table 1, we classified the finishing materials into three types: mastic, multi-layer and single-layer coating, and further classified into eight types by kind of materials.

Table 1. The types of finishing materials and number of condominiums.

Type	Number	Materials type	Number
Mastic (without substrate mortar)	53	Cement	39
		Acrylic	14
Multi-layer coating	112	Acrylic	41
		Acrylic Silicon	6
		Silicon	8
		Urethane	10
		Unknown	47
Single-layer coating (with substrate mortar)	57	Cement	50
		Synthetic resin	7

2.2 Performance Evaluation of Various Finishing Materials Using Exposure Specimens

Table 2 shows the Factors and levels of the exposed specimens. The finishing material was applied to the side of a concrete specimen having a water cement ratio of 65% and a size of 100 mm × 100 mm × 400 mm. We experimented six types of coating materials, three types of mortar and three types of tile finishing at exposure test site in Building Research Institute, Tsukuba, Ibaraki, Japan (N36°7’38”, E140°4′39″, sea level +29m).

Exposure environment were three types, indoors, outdoors and outdoors under eaves. We measured the carbonation depth and color difference of finishing materials. The color difference (ΔE) was measured by L*a*b* color coordinates using a colorimeter, and expressed by equation (1) as the difference from the indoor exposure test specimen that seems to be less deteriorated.

$$\Delta E = \sqrt{(L_o - L_i)^2 + (a_o - a_i)^2 + (b_o - b_i)^2} \qquad (1)$$

where L is Lightness, a and b are Chromaticity indicating hue and saturation, Subscript o is Measured value of outdoor exposure test specimen and Subscript i is Measured value of indoor exposure test specimen.

Table 2. Factors and levels of exposure specimens.

Factor	Level	
Exposure environment	Indoors, Outdoors (rain / no rain) Directions (North, East, South and West)	
Finishing material type	Coating	Synthetic resin (Multi / single) Waterproof synthetic resin (multi / single) Gloss paint
	Mortar	Cement mortar t=10 / 20 mm Polymer cement mortar t=10 mm
	Tile	Mortar t=2.0~3.0 / 10mm, Adhesive

3 Results and Analysis

3.1 Analysis of Current Repair Cycle and Deterioration State

3.1.1 Analysis of current repair cycle

Figure 1 shows the cycle and number of exterior walls repair carried out in 222 condominiums that were analyzed in this study. The cycle was an average of 12 years, with a minimum of 9 years and a maximum of 17 years. More than 70% of the first repairs were done by the 12th year. Most of the second repairs were carried out after the 12th year, and the cycle was longer than the first repair. Among the targeted apartment houses, there were only a few them that over 30 years old and the third large-scale repair work was carried out.

Table 4 shows the results of comparing the average repair cycle for each finishing materials. Looking at the types of finishing materials, the repair cycle of thin coating materials was slightly longer. Among them, the single-layer coating had the longest cycle, and the silicon multi-layer coating materials had the shortest cycle. However, although multi-layer coating generally has high durability, repair cycle has almost no change regardless of the difference in finishing materials. Accordingly, it indicates that the repair cycle was not set by the type of finishing materials or the degree of deterioration. In other words, it was set by the uniform repair plan.

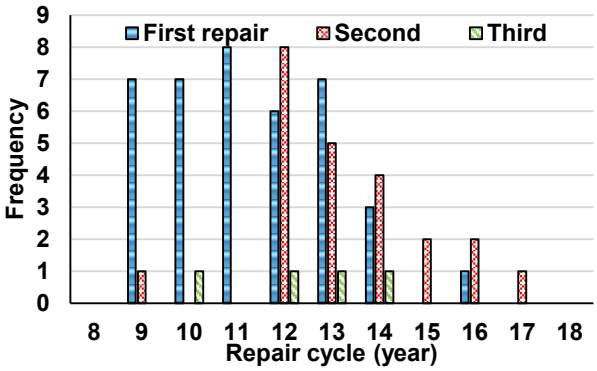

Figure 1. Cycle and number of exterior repairs.

Table 3. Repair cycle for each finishing materials.

Type	Cycle (year)	Materials type	Cycle (year)
Mastic	11.4	Cement	11.3
		Acrylic	12.0
Multi-layer	11.4	Acrylic	11.3
		Acrylic Silicon	11.3
		Silicon	10.5
		Urethane	12.5
Single-layer	12.5	Cement	12.3
		Emulsion	13.0

3.1.2 Analysis of carbonation preventive effect in existing condominiums

The following equation can express carbonation coefficient:

$$A = \frac{C}{\sqrt{t}} \tag{2}$$

where A is the carbonation coefficient (mm/years$^{0.5}$); C is the carbonation depth(mm); t is the time(years). In this study, we used this A as an index of performance against carbonation.

3.1.2.1 Relationship between carbonation and building age (repair cycle)

Figure 2 shows the carbonation coefficient for condominiums with different ages. Although it shows a few relatively large numbers after approximately 10 years, most of numbers are less than 1.50 after 20-30 years. Previous studies have revealed the relationship between carbonation coefficient and compressive strength in unfinished concrete.[5)] Assuming that the carbonation coefficient of targeted condominiums is estimated to be about 3.00 mm/years$^{0.5}$. Therefore, since the carbonation coefficient was kept low, the carbonation preventive effect has been maintained by repair work for more than 30 years.

Figure 3 shows the carbonation coefficient for each time of repair work. The average carbonation coefficient is about 0.5 to 1.0 mm/year$^{0.5}$. On the other hand, the maximum value for the first repair can be confirmed similar value to that of the unfinished concrete. However, in both the second and third repair, the maximum value is significantly lower than the first repair. This is an effect of recoating that the defective part at the time of construction such as pinhole was repaired.

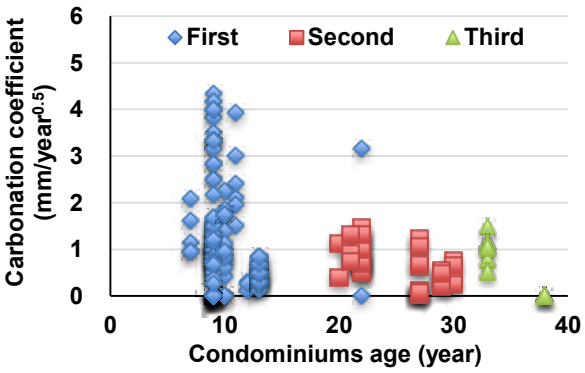

Figure 2. The carbonation speed coefficients for different ages.

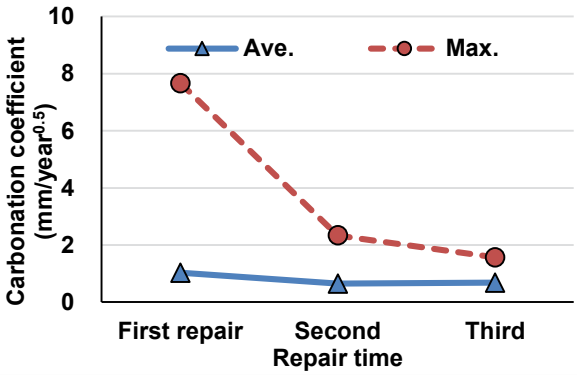

Figure 3. The carbonation coefficients for each repair time.

3.1.2.2 Relationship between carbonation and directions

Figure 4 shows the average of the carbonation speed coefficients for each orientation. The norther and southern sides show slightly larger values than the eastern and western surfaces, especially with thin coating materials. The southern surface has the highest amount of solar radiation, so it is possible that it is more susceptible to UV degradation than other surfaces. In addition, it is known that neutralization is more likely to proceed with dry concrete. In other words, the southern side was in an environment where it was easy to carbonate due to the prolonged dryness caused by solar radiation. According to this result, there is an orientation in

which the deterioration of the finishing material tends to proceed. On the other hand, the reason for the high numerical value on the north surface is unclear, so we analyzed further about relationship between carbonation and orientation in the exposure test conducted in 3.2.

3.1.2.3 Relationship between adhesion strength and repair cycle

Figure 5 shows the average adhesion strength for repair cycle. Mastic and multi-layer adhesion strength almost did not deteriorate. However, single-layer coating strength deteriorate, and seem to decline below 0.3-0.5 N/mm^2 that is established as quality standards of single-layer coating in Japanese Industrial Standards[6] after about 17 years. On the other hand, their strengths were maintained above quality standards in JIS until around 15 years.

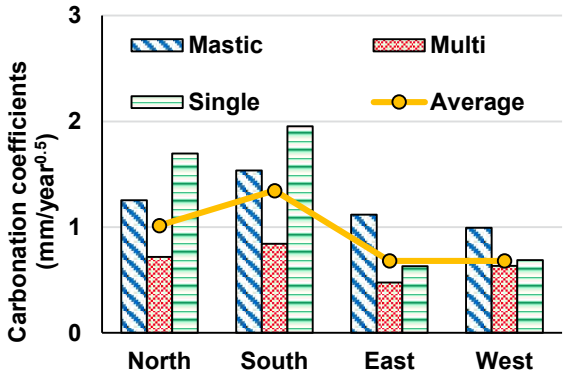

Figure 4. The carbonation coefficients for each direction.

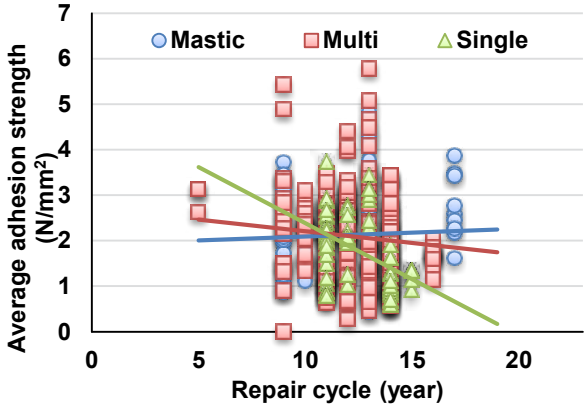

Figure 5. Adhesion strength for each repair times.

3.2 Performance Evaluation of Various Finishing Materials Using Exposure Specimens

3.2.1 Carbonation preventive effect after 10 years of each finishing materials

Figure 6-8 shows the carbonation coefficients for each finishing materials in each environment (left side) and each direction (right side). The carbonation coefficients of None finishing concrete was 4.56 mm/years$^{0.5}$ indoor, 1.95 mm/years$^{0.5}$ outdoor with rain, and 5.00 mm/years$^{0.5}$ outdoor under eaves. Therefore, we considered these values as each evaluation standard for the carbonation preventive effect of the finishing materials.

In the case of outdoors with rain, the single-layer coating is 1.89 mm/years$^{0.5}$, which is almost same value as none finishing one. This is because the single-layer coating has almost no carbonation suppressing effect, rather than due to deterioration. On the other hand, even with the synthetic resin type materials, multi-layer coatings and waterproof ones had a certain preventive effect. Similarly, even in the case of no rain, the single-layer coating shows a higher value than other finishing materials.

In other materials, mortar 10 mm and tile on substrate 2.0-3.0 mm mortar showed relatively high values outdoors without rain. However, the mortar 10 mm has low value outdoors with rain. This is because the specimen outdoor with rain was supplied with water by rain. It caused a high moist state in a specimen and the mortar became denser because the hydration reaction of the cement progressed. Therefore, the high carbonation coefficient of 10 mm mortar outdoors

without rain did not cause by deterioration.

Outdoors with rain, the carbonation preventive effect of most finishing materials was maintained except for the single-layer coating, so they had no deterioration of performance for coating materials, mortars and tiles by 10 years. From these results, it is possible to extend the repair cycle because the current cycle is not at the limit of performance in about 12 years. However, as the data for 10 years cannot mention how long we extend it, further exposure testing is necessary. Moreover, since we handled only synthetic resin type in the coating materials this time, we have to evaluate other coating materials.

Further, although the finishing materials are hardly deteriorated indoors, the tendency that the carbonation of the thin coating E was high, and the others were low is the same in this case.

3.2.2 Relationship between carbonation and orientation

The high values on the northern and southern sides of thin coating material E was similar to the survey results in 3.1. Especially on the northern side, it was much larger than the value of none finishing concrete. On the other hand, other materials had the small variation in each orientation and the deterioration has not been promoted by direction.

3.2.3 Analysis of color difference

Figure 9 shows the color difference of coating material specimens exposed outdoors. In an environment with rain, the color difference is large overall, especially in the single-layer coating. In general, the evaluation standards of color difference, people cannot identify color difference when it is lower than 3.2, can recognize a color difference when it over 6.5 and can recognize as a different color when it over 13.0. In these results, the single and multi-layer in an environment with rain coating have deteriorated in design. On the other hand, all finishing materials under eaves were lower than 13.0. However, because the carbonation of single-layer coating progress in under eaves, the change in appearance did not necessarily match the carbonation preventive effect depending on the type of finishing materials or environment. We need to consider changes in appearance and carbonation preventive effects as separate factors.

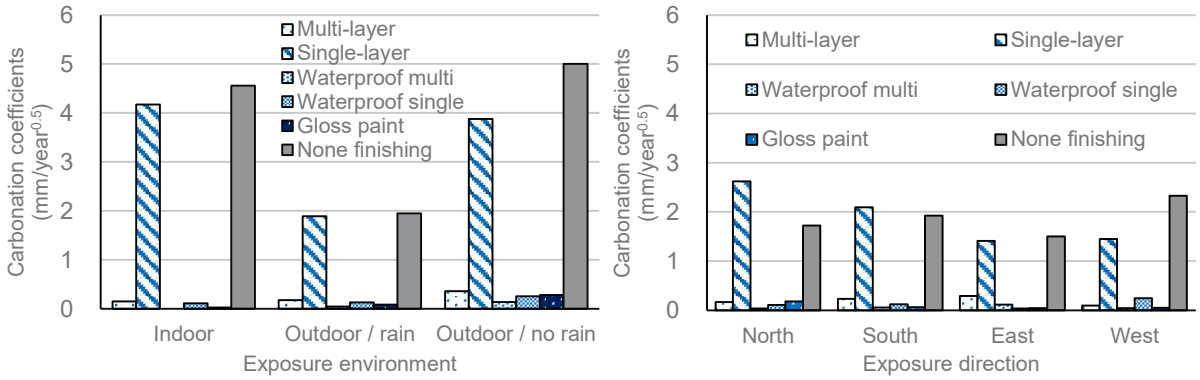

Figure 6. The carbonation coefficients after 10 years (Coating material).

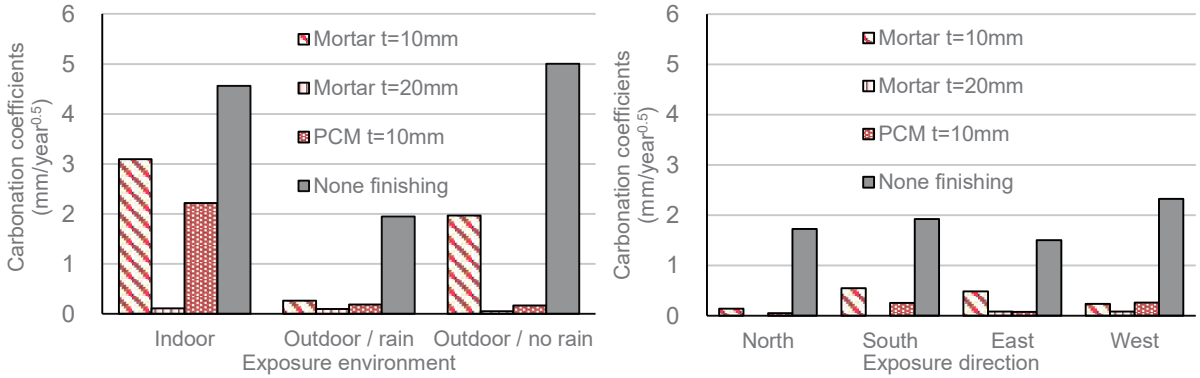

Figure 7. The carbonation coefficients after 10 years (Mortar).

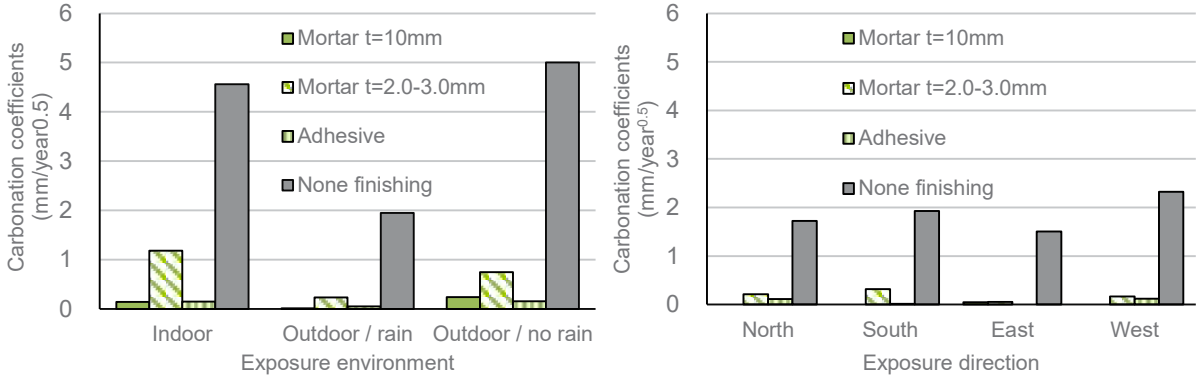

Figure 8. The carbonation coefficients after 10 years (Tile).

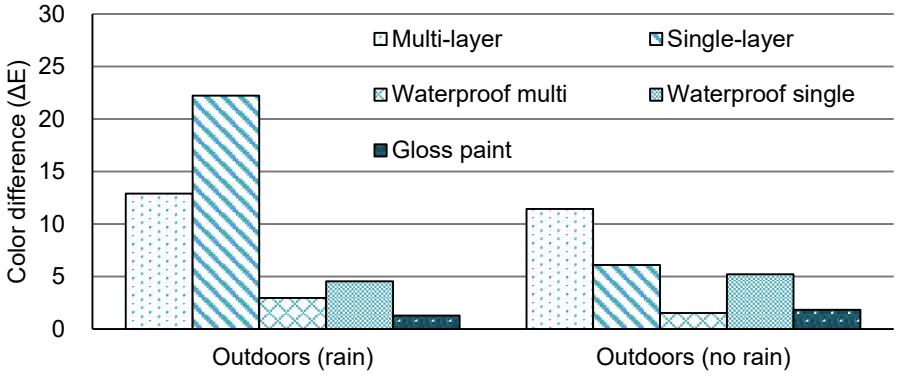

Figure 9. The color difference after 10 years (Coating material).

4 Conclusion

In this study, in order to examine the appropriate repair cycle of exterior finishing materials, we investigated and analyzed the current repair cycle and deterioration state, and second we evaluated the carbonation preventive effect of the finishing materials by using specimens exposed for 10 years. As a result of the survey, the current repair cycle was about 12 years, but since the carbonation preventive effect was sufficiently maintained at the time of repair, the repair cycle may be longer than the current cycle in terms of performance. Furthermore, in the exposed specimens, the single-layer coating had no carbonation preventive effect, but other materials still have the carbonation preventive effects at 10 years, and almost no difference of carbonation in each direction. In the previous study that conducted an outdoor exposure test for 20 years in model building[7)], the multi-layer coating had had the carbonation preventive effect even after 20 years.

While the finishing materials had not reached their performance limit, repairs may be done from an aesthetic point of view. In particular, appearance of coating materials in an environment with rain relatively changed more than under eaves them after 10 years. Therefore, we need to consider changes in appearance and carbonation preventive effects as separate factors. We will continue the exposure test for more long term to confirm the performance (the carbonation preventive effect, deterioration of coating itself and aesthetics) of each material at various environment.

Abstract. *External Thermal Insulation Composite Systems (ETICS) contribute significantly to building energy efficiency by increasing thermal insulation, correcting thermal bridges and reducing interior water condensation. Additionally, these solutions protect the structure and thus enhance the durability of the building. The use of ETICS remarkably increased in the last three decades also due to the introduction of new international and national regulations on building energy efficiency (e.g. EU Directive on the Energy Performance of Buildings). ETICS are constantly exposed to weathering (e.g. wind, rain, sun light) and anthropic factors (e.g. graffiti, environmental pollutants), which can lead to cracks, biocolonization and stains and thus affect ETICS durability. However, international technical documents on the evaluation of the effectiveness and durability of ETICS do not consider the possible synergies between these factors, which can trigger and speed up multiple biological, mechanical and chemical degradation processes. With the aim of filling this gap, this paper focused on the water resistance and surface properties of several ETICS surface coatings, verifying possible connections between these factors. The moisture transport properties (capillary water absorption, water vapour permeability, and drying kinetics) and surface properties (colour, brightness and roughness) of some commercially available ETICS were tested. This study is part of a wider research project (WGB_Shield: resistance for water, graffiti and biocolonization of external thermal insulation systems) that aims at the development of ETICS with improved durability in urban environment.*

Keywords: *ETICS, Durability, Water Behaviour, Surface Properties*.

1 Introduction

The implementation of long-term building renovation strategies is a key challenge in modern society. As a matter of fact, 40% of energy in EU is used for buildings (producing 36% of total CO_2 emission) and 2/3 of this energy consumption is used for heating and cooling. For these reasons, EU has set new rules also for energy efficiency, both in new and retrofitted buildings, with the objective of achieving a nearly zero energy built environment by 2050 (EPBD 2010).

In this context, External Thermal Insulation Composite Systems (ETICS), sometimes also identified as External Wall Insulation (EWI, in UK) or Exterior insulation finishing system (EIFS, in the US), can significantly improve the thermal performance and energetic efficiency of buildings. In fact, these systems can improve thermal insulation, reduce thermal bridges and avoid water

condensation within masonry. Additionally, these systems can increase occupants' health and wellbeing, by improved air quality, and thermal comfort (Barreira and P. de Freitas, 2013).

Hence, ETICS have been established in the last three decades among the most used solution to improve the energy efficiency of buildings, with a wide variety of system configurations and design. It is estimated that more than 2 billion m^2 have already been installed in Europe (Pasker, 2017).

These systems are generally composed of a variety of materials, which include insulation materials (Schiavoni *et al*., 2016), basecoats with mineral binders (*e.g.* air or hydraulic lime, cement), finishing coatings (*e.g.* silicate, acrylates, siloxanes and additives (*e.g.* aggregates, pigments, biocides). The compatibility among these components is a crucial factor to achieve an efficient and durable system.

According to the European Technical Approval Guideline (ETAG 004), which gather the technical approval requirements of ETICS in the EU zone, service life of ETICS should be over 25 years. It is thus necessary to plan a careful maintenance of these systems.

As a matter of fact, ETICS are constantly exposed to weathering agents (*e.g.* wind, rain, sun light, etc.) as well as to direct (*e.g.* vandalism) and indirect (*e.g.* environmental pollutants) anthropic factors. These factors have often a synergic effect on the affected surface, triggering and speeding up multiple biological, mechanical and chemical degradation processes.

Degradation patterns are typically identified in the alteration of the physical-chemical, aesthetical and mechanical properties of ETICS, with formation of *e.g.* cracks and stains.

In this paper, the moisture transport properties (water capillary absorption, drying kinetics, water vapour permeability) and superficial properties (colour, brightness, surface roughness) of several commercially available ETICS were studied. The main aim was the identification of the possible connection between these properties and, ultimately, a deeper comprehension of the dynamics behind the durability of ETICS surface coatings in urban environment.

2 Materials and Methods

2.1 Materials

Several ETICS were analysed, as resumed in Table 1. It has to be pointed out that 3 different ETICS producers were considered (systems 1 to 3; systems 4 to 8; systems 9 to 12). Specimens with 15x15 cm were considered for the absorption and drying kinetics, whereas cylindrical specimens (8 cm diameter) were used for the water vapour permeability test. Specimens 5x5 cm were used for the evaluation of the surface properties (colour, brightness, roughness). The specimens have thickness varying between 3.9 and 6.5 cm.

2.2 Methods

2.2.1 Absorption and drying kinetics

Capillary absorption tests were performed according to ETAG 004 (EOTA, 2013) in a conditioned room (at T=23 ± 2ºC and 65 ± 5% RH). A total of four cycles (with measurements at 3 min, 1h, 4h, 8h and 24h) of capillary absorption were conducted. Capillary water absorption coefficient was obtained by the slope of the initial phase of the curve that expresses the water absorption as a function of the square root of time.

Table 1. ETICS identification and composition (EPS = Expanded polystyrene; ICB: Insulation cork Board; MW = Mineral wool).

Systems	Thermal Insulation	Base Coat	Finishing coat
1	EPS	2 layers of cement-based mortar + mesh	*Primary:* water-based dispersions of acrylic co-polymer *Finishing:* acrylic paint + quartz aggregate
2	EPS	Cement-based mortar + mesh	*Primary:* water-based acrylic dispersion *Finishing:* a) water-based acrylic co-polymer + pigment + marble powder b) water-based acrylic paint
3	EPS		*Primary:* water-based acrylic dispersion *Finishing:* water-based acrylic co-polymer + pigment + marble powder
4	ICB	Hydraulic lime and cement mortar + mesh	*Mortar:* air lime + hydraulic binder + organic additives
5	ICB		*Primary:* acrylic co-polymer + mineral additives *Finishing:* acrylic paint + mineral aggregate + pigments
6	EPS		
7	EPS	Cement-based mortar + mesh	*Primary:* acrylic co-polymer + mineral aggregate *Finishing:* acrylic paint + organic additives + pigments
8	MW		*Primary:* acrylic co-polymer + mineral aggregate *Finishing:* acrylic paint+ mineral aggregate + pigments
9	ICB	Hydraulic lime and cork aggregate mortar + mesh	*Primary:* water-based dispersions of silicate *Finishing:* water-based silicate paint + organic additives + pigments
10	ICB		
11	EPS	Hydraulic lime and cement mortar + mesh	*Primary:* acrylic dispersion + mineral aggregate *Finishing:* acrylic paint + siloxane resin + marble powder
12	MW		

Drying test was performed following the recommendations of EN 16322 (2013) and started immediately after the capillarity test. The test was performed in a conditioned room (23 ± 2ºC and 65 ± 5% RH). Specimens were weighted after determined periods of time until the variation of mass was constant for all specimens. Two drying phases were determined: DR1 – the first drying phase, obtained by the negative slope of the initial linear section of the drying curve plotted with time in abscissa; and DR2 – the second drying phase, calculated by the negative slope of the linear section of the drying curve, plotted against the square root of time in abscissa. Drying index (DI) was obtained by Equation (1), in which M_x is the mass of the specimen registered during the drying process (g), M_1 is the mass of the specimen in a dry state (g), M_3 is the mass of the specimen in a saturated state (this mass corresponds to the mass at the beginning of the drying process (t_0), t_f is the time at the end of the drying process.

$$DI = \frac{\int_{t_0}^{t_f} f\left(\frac{M_x - M_1}{M_1}\right) dt}{\left(\frac{M_3 - M_1}{M_1}\right) \times t_f} \quad (1)$$

2.2.2 Water vapour permeability

Water vapour permeability (WVP) tests were performed according to ETAG 004 (EOTA, 2013), adopting the dry cup method, i.e. sealing the lateral and bottom side of ETICS specimens within a recipient which contains a dryer substance ($CaCl_2$) than the external

conditions. The lateral sides are sealed with paraffin, whereas the superficial finishing of the ETICS is exposed to the external environment. The cup is filled with a dessicant ($CaCl_2$), which keeps the relative humidity (RH) inside the cup fixed at ≈20%. All specimens are then stored within a climatic chamber at T=23 ± 2ºC and 50 ± 5% RH. Hence, water vapour is forced from the external environment (50% RH) to the interior of the cup (≈20% RH), fluxing through the layers of the ETICS. Specimens were weighted over time, till stabilization of the specimens' weights. The change in the mass of the cup's content is used to quantify the water vapour permeability of the ETICS.

Based on the obtained results, the following parameters can be obtained by using the following equations:

$$\Lambda = \frac{m}{A \times \Delta_p} \quad (2)$$

$$\mu = \frac{1.94 \times 10^{-10}}{\Lambda \times e} \quad (3)$$

$$S_d = \mu \times e \quad (4)$$

where Λ is the water vapour permeance (kg/m^2.s.Pa), which defines the Wvp; m is the slope of the linear relation between mass variation and time (kg/s), A the specimen area, Δp is the vapour pressure difference between the exterior and interior (Pa), referred to the thickness of the specimen (m), μ the water vapour diffusion resistance factor, Sd the diffusion-equivalent air-layer thickness (m).

Furthermore, the thermal insulation and complete systems (as in Table 1) were tested separately, in order to verify the requirements of the ETAG004 (EOTA, 2013). In fact, the WVP of the complete system (base and finishing coat) was analysed with the diffusion-equivalent air-layer thickness (S_d), whereas the WVP of the thermal insulation with the water vapour diffusion resistance factor (μ).

2.2.3 Colour and brightness

Colour was assessed with a colorimeter Minolta CR-410 Chroma Meter, by measuring the three colour coordinates (L^*, a^*, b^*) of the CieLAB colour system. L^* is the the lightness, which varies from 0 (black) to 100 (white), whereas a^* and b^* identify the colour, i.e. the chromatic coordinates of red-greed ($+a^*$ refers to red, $-a^*$ to green) and yellow-blue (($+b^*$ refers to yellow, $-b^*$ to blue). The chroma or colour saturation is calculated based on the values of a* and b*:

$$C = \sqrt{a^2 + b^2} \quad (5)$$

The total colour difference (ΔE^*), which takes into account the differences between the L, a, b of the specimens and a standard/reference specimen, can be calculated as follows:

$$\Delta E^* = \sqrt{\Delta L^{*2} + \Delta a^{*2} + \Delta b^{*2}} \quad (6)$$

Each specimen was analysed in 4 different spots, using a standard illuminant D65 (which

corresponds to average daylight, including Uv wavelength region, with a correlated colour temperature of 6504K). The colorimeter was set to measure 3 repeated times in each spot. The relative average values and standard deviations were considered.

Brightness test was performed according to ASTM D6578 (ASTM, 1987). A Rhopoint Novo- Gloss Lite equipment was used, measuring the brightness with a light source angle of 60º (suitable for matte specimens). The brightness (Gloss Unit – GU) was tested in 9 different spots in each specimen, considering the average value and relative standard deviation.

2.2.4 Surface roughness

An Elcometer 223digital surface profile gauge was used to measure the peak-to-valley height (surface roughness) of the specimens. This equipment can measure up to 2mm, with a resolution of 0,001 mm. Surface roughness was tested in 9 different spots in each specimen, considering the average value and relative standard deviation.

3 Results and Discussion

3.1 Capillary Absorption and Drying Tests

Results obtained for capillary absorption and drying kinetics are presented in Figure 1 and Table 2. It can be observed that the systems 4 and 5, from the same producers and both with ICB, have the higher capillary absorption values at 1h, as well as the higher capillarity coefficient (Table 2). However, those values are < 1kg/m^2, thus meeting the requirements of ETAG 004 for the technical approval of ETICS. Systems 7 and 8, which present the same cement-based base coat, present the higher capillary absorption at 24h (respectively, 1.36 and 1.46 kg/m^2). On the other hand, system 2 have the slower capillary absorption at 24h (0.24 kg/m^2). This latter system, similarly to systems 1, 3, 9 and 11, has capillary absorption < 0,5 kg/m^2, and, thus, according to ETAG 004, those systems are resistant to freeze-thaw cycles. It has to be pointed out that system 9, which presents a ICB thermal insulation, a base coat with NHL and cork aggregate and a silicate-based finishing coat, has lower capillary absorption values, when compared to system 10, which differs only for its acrylic-based finishing coat. This confirms that this silicate-based finishing coat has lower capillary absorption, when compared to the referred acrylic-based finishing coat.

Additionally, if comparing systems 2 and 3, which have the same base coat, it can be concluded that the combination of an acrylic-based and co-polymeric acrylic finishing coat (system 2) plays an important role in the reduction of the water absorption, which is considerably lower (44%) compared to system 3, which has only one layer of finishing coat.

Finally, it can be observed a significant difference between the capillary coefficient of systems 6 and 8, which differ only for their thermal insulation material (EPS and MW, respectively), as well as for systems 11 and 12, which again differ only for their thermal insulation materials (EPS and MW).

This can indicate that liquid water reaches the insulation layer and that there is an influence of the thermal insulation material on the capillary absorption, *i.e.* a higher and faster absorption of MW, when compared to EPS.

When observing drying kinetics, it can be noted that system 7 has the highest DR1 (which corresponds to water transport in the liquid phase), DR2 (which corresponds to water vapour

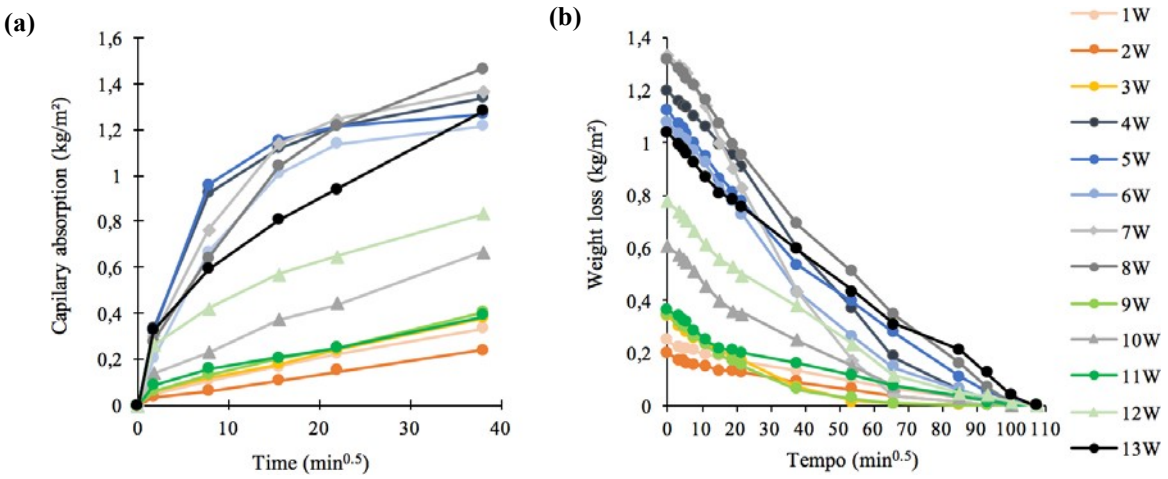

Figure 1. Capillary absorption (a) and drying curves (b) of the ETICS specimens.

diffusion) and drying index (0.94). Similar trends were observed for systems 4, 5, 6 and 8 (all from the same producers), which are also the systems with higher capillary absorption values. Conversely, ETICS 1, 2, 3 and 11 have the highest DR1 and DR2. It can be concluded that, generally, the systems that absorbed more water by capillarity, are those with faster drying, which allows for some compensation and a possible adequate global behaviour.

3.2 Water Vapour Permeability

Results are presented in Table 2. The highest values of water vapour diffusion resistance were registered for ETICS 1 (65.75) and 2 (65.22), followed by systems and 11 (48.94) and 3 (44.27). As a matter of a fact, these systems were those with lower capillary absorption and lower water transport in the liquid phase (DR1).

Conversely, systems 4, 5 and 8, those with higher capillary absorption, present lower values of water vapour diffusion resistance, with higher WVP and thus faster drying. A different trend was observed for systems 6 and 7, which have both a higher water vapour diffusion resistance and water absorption when compared to ETICS 8. This behaviour can hinder a suitable drying of this system.

However, when verifying the diffusion-equivalent air-layer thickness of the base and finishing coat of the systems (by subtracting the S_d of the whole system to that of the thermal insulation), these values are < 2m in all cases. Thus, all systems are in agreement with the requirements of the ETAG 004, which define S_d values limits of 2 m for EPS systems (specimens 1,2,3,6,7,11) and 1m for MW systems (specimens 8,12).

3.3 Colour and Brightness

Results presented in Figure 2 indicate a low chroma for all systems (minimum L* at 71.71, for ETICS 5), with shades of grey and a tendency to yellow (positive b* values). More specifically, systems 8 and 12, those with MW thermal insulation, have the higher b* values. In all systems, the a* values are close to zero, *i.e.* to an ideal white colour.

Table 2. Capillary water absorption, drying and water vapour permeability test results.

Systems	Capillary absorption		Drying				WVP	
	Capillary absorption 1h (kg/m²)	Cc (kg/m².min$^{0.5}$)	DR1 (kg/m².min$^{0.5}$)	DR2 (kg/m².min$^{0.5}$)	DI	μ ETICS	μ Thermal Insulation	Sd finishing (m)
1	0.10	0.027	0.000053	0.0027711	1.05	65.75		1.12

7	0.77	0.172	0.000403	0.019722	0.94	42.20		0.58
8	0.64	0.160	0.000280	0.0146646	0.98	6.73	1.90	0.31
9	0.13	0.034	0.000110	0.0051607	1.03	12.06	14.07	-
10	0.23	0.081	0.000158	0.0079991	1.00	25.49		0.54
11	0.15	0.049	0.000086	0.0043290	1.00	48.94	39.83	0.59
12	0.42	0.151	0.000186	0.0099738	0.98	24.43	2.74	0.99

When comparing the different systems, it can be noted that ETICS 1 and 3 have similar chroma, even if system 1 is closer to an ideal white (lower C*). On the other hand, system 2 have higher L* and lower C*, being thus slightly brighter and more whitish than systems 1 and 3. Those systems are the only ones with –a* values (green component).

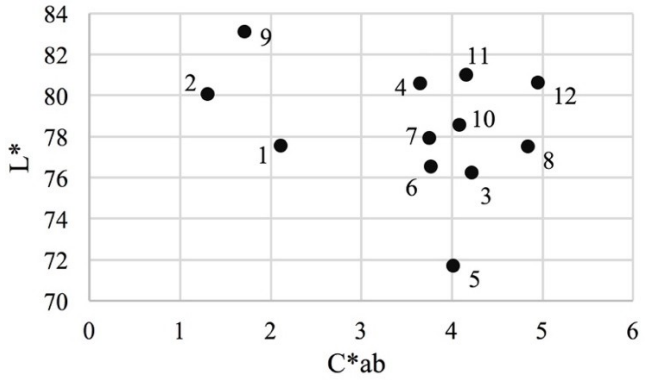

Figure 2. Comparison of the CieLAB values of the different ETICS.

When comparing systems 4 and 5, from the same producers and with the same thermal insulation (ICB), it can be noted a difference in L* and C*, attributed to the difference in their finishing coating (lime-based and acrylic-based, respectively). Systems 6 to 8, although with different compositions, have similar chromatic coordinates. ETICS 10 to 12 (from the same producers, and with the same acrylic-based finishing coat) have similar colour, although system 10 has lower chroma, which might be related to the use of ICB as thermal insulation. On the other hand, system 9 (finished with a silicate- based coating), has even higher L* and lower C*, being thus more close to an ideal white colour.

When considering brightness, it can be noted that those values are in agreement with colour values. In fact, systems 1 and 2 have similar brightness, whereas ETICS 3 (with co-polymeric

acrylic finishing coat) has significantly lower values, when compared to 1 and 2 (both with 100% acrylic- based finishing coat). Systems 6 to 8 have similar GU values, whereas ETICS 5 (which differs for its ICB thermal insulation, when compared to systems 6 to 8) have lower values. Conversely, system 4, finished with a (aerial and hydraulic) lime-based mortar, has brightness value which doubles that of system 5. Ultimately, systems 10 to 13 have similar brightness values, however, system 10 slightly differs from these systems, possibly due to its ICB thermal insulation. In agreement with colour values (Figure 2), system 9, is the only system with a silicate-based finishing coat, that has a considerably higher values when compared to systems 10 to 12 (all with acrylic-based finishing).

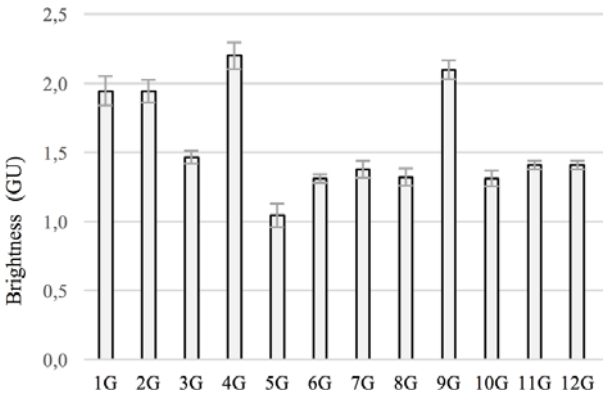

Figure 3. Brightness (average value and standard deviation) of the ETICS specimens**.**

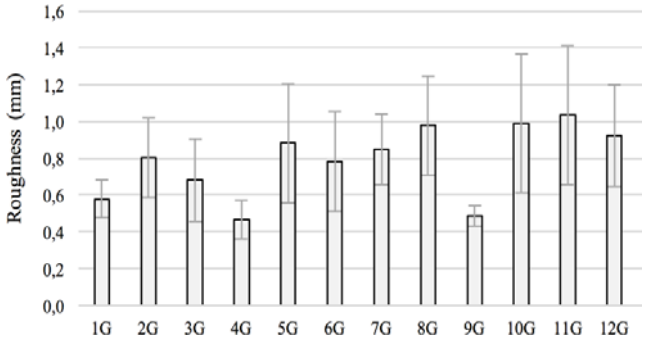

Figure 4. Surface roughness (average value and standard deviation) of the ETICS specimens.

3.4 Surface Roughness

Results show that systems 1, 4 and 9 (one for each producer) present the lower roughness values (467 µm to 580 µm) (Figure 4). When comparing systems 1 to 3, from the same producers, it can be noted that systems 2 and 3 have higher values, when compared to ETICS 1, due to the use of a coarser (co- polymeric-based) finishing coat. Systems 5 to 7, although with different compositions, have similar roughness values, whereas system 8 (with MW thermal insulation) have slightly higher (15%) values. The significant lower values of ETICS 4 can be attributed to the use of a thin lime-based layer as finishing coat, when compared to the systems 5 to 8 (784 µm to 978 µm), which present coarser mineral aggregates in their finishing coat. Ultimately, systems 10 to 12, which have the same acrylic- based finishing coat, have similar roughness (874 µm to 1035 µm), with slightly lower values in system 12. On the

other hand, ETICS 9, which is finished with a silicate-based coat, has remarkably lower surface roughness, comparable to that of systems 1 and 4.

When comparing the moisture transport properties and roughness of the 3 different producers, it is worth highlighting that systems 1 to 3, with relatively low roughness (0,575 μm 0,761 μm), have also low water capillary absorption. Conversely, ETICS 5 to 8 have slightly higher roughness (0,704 μm to 0,978 μm) and significantly higher water capillary absorption. A trend similar to the latter systems is observed with ETICS 10 and 12. Interestingly Systems 4 show both low roughness and capillary absorption, whereas systems 11 have low roughness and considerably high water absorption (and drying rate). This can be explained again by the composition of these systems (lime-based finishing for ETICS 4, silicate-based coating for ETICS 9).

4 Conclusions

The aim of this paper is the evaluation of the moisture transport properties and surface properties of commercially available external thermal insulation composite systems (ETICS).

Results showed that all systems respected the hygric requirements of ETAG for the technical approval of ETICS, *i.e.* all have capillary absorption lower than 1kg/m^2 at 1h and a suitable water vapour permeability (diffusion-equivalent air-layer thickness < 2m). It was observed that, generally, systems that absorb more water are those that have higher dry rates and higher water vapour permeability (as in the case of systems 4 to 8, from the same producer).Conversely, systems 1 to 3 (again, from the same producers) show an opposite behaviour. Furthermore, it can be concluded that the system with silicate-based finishing coat (system 9) has lower absorption and faster drying (however, slightly higher WVP) when compared to other systems (10 to 12) from the same producer. In general, an influence of the thermal insulation on moisture transport properties of the systems can be observed only in systems 11 (EPS) and 12 (MW), i.e. a higher capillary absorption, faster drying and higher WVP of the system with MW, when compared to that with EPS. Moreover, a significant difference in the moisture transport properties is given mostly by the composition of the finishing render (base and finishing coats), rather than the surface properties (*e.g.* roughness).

When observing results of the optical surface tests, it can be seen that the systems with acrylate- based finishing coat are generally less whitish and less bright, when compared to systems finished with silicate-based (ETICS 9) or lime-based (ETICS 4) systems.

Ultimately, it was observed that systems 1, 4 and 9 (one of each producer), the ones with the highest colour and brightness values, have also the lowest roughness values. The higher values of the other systems are attributed to the addition of mineral loads (aggregate) in the finishing coat.

It should be noted that all systems were tested in ideal conditions (no exposure to external weathering). For this reason, further tests are ongoing to assess the moisture transport properties and surface properties of ETICS before and after natural and artificial aging.

Abstract. *A gap in the durability assessment of thermal mortars applied in multi-layer systems was observed. The existing standardisation for the durability assessment of hardened mortars does not include a consistent evaluation of thermal coatings applied in multilayer systems, which motivated the development of a new durability assessment methodology. The determination of the physical, hygrothermal and mechanical properties allowed deepening the knowledge of thermal mortars, contributing to develop more reliable simulations. The existing durability methodologies applicable to one-coat mortars and those applicable to thermal multilayer systems (such as ETICS – External Thermal Insulation Composite Systems) are suitable to be adapted to thermal rendering and plastering systems since they present some similar characteristics. The methodology takes into account the material characteristics and specific requirements, such as the application and climatic conditions. The knowledge of these parameters allows the definition of representative accelerated ageing cycles of the relevant degradation mechanisms. The combination of existing procedures with hygrothermal simulation allowed the development of accelerated ageing cycles, taking into account the European climatic context. The existing procedures allowed analysing several degradation mechanisms, but the fixed parameters are not transversal to different climates. The developed methodology allows a realistic durability evaluation since the ageing cycles are adapted to thermal mortars and real climate conditions, contrary to the existing standardised procedures.*

1 Introduction

One of the seven objectives defined by the European Mortar Industry Organization (EMO) is to "raise awareness for sustainability", emphasizing the ecology of mineral mortars and the need to promote the advantages of using this type of products, their durability and lack of hazardous substances in comparison with other materials on the market (EMO, 2013). However, the concept of eco-design should relate to not only the environmental ecology issue but also the quality of life of the users of such products or services. According to Erhorn, Hansen, Kaan, and Barker (2007), eco-buildings can reduce energy consumption and enhance the use of renewable energies, bio-climatically designed. This reduction could be achieved taking into account sun exposure, architectural requirements, increase of the thermal insulation and tightness of the building, throughout new products, constructive solutions and viable technologies.

The use of thermal mortars in multi-layer façade systems influences several aspects of the sustainability of buildings as the fulfilment of several basic principles stated above. As such,

the continuous interest in the development of sustainable solutions with thermal enhanced properties, incorporating different types of wastes (industrial or plant origin), allows the development of new solutions with less harmful impact to environment than traditional construction materials (Matias, Faria, and Torres, 2014; Skoczylas and Rucińska, 2018; Torres and Matias, 2016). To improve the thermal behaviour of buildings, different products incorporating lightweight aggregates with low density and thermal conductivity have appeared on the market. Thermal renders and plasters continue to awaken the interest of the researchers (Borges, Flores-Colen, and de Brito, 2018; Nosrati and Berardi, 2018; Soares, de Fátima Júlio, Flores-Colen, Ilharco, and Brito, 2018; Westgate, Paine, and Ball, 2018).

Thermal mortars applied in multi-layer systems frequently have at least two different layers: thermal mortar and finishing coating. Thermal mortars are addressed in EN 998-1 (CEN, 2010), which refers to EN 1015-21 for durability test methods in mortars (CEN, 2002). However, this standard is only applicable to one-coat renders, not taking into account the different material layers (i.e. the system as a whole). The durability assessment methodologies preconized in the ETAG 004 (EOTA, 2013), are directly applied to ETICS. Consequently, the existing procedures, such as the ones provided by EN 1015-21 and ETAG 004, do not allow a feasible durability assessment of thermal rendering and plastering systems (see Figure 1).

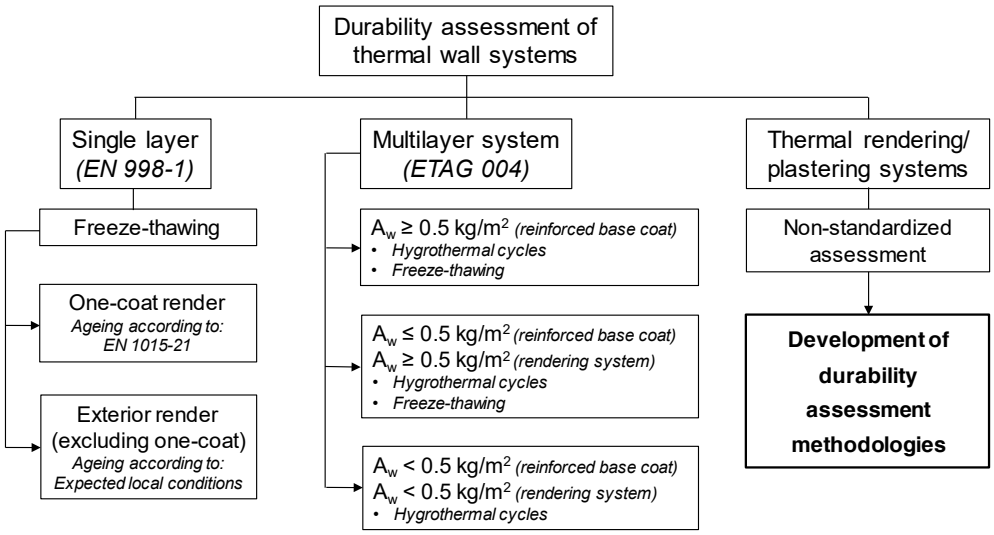

Figure 1. Framework of existing durability assessment methodologies, applicable to renders and thermal multilayer systems.

In order to obtain more durable building envelopes, the durability assessment should focus on the required performance, especially the climatic conditions (Pedro Júlio, Paiva, and Dominguez, 2013). Since construction materials are subjected to several degradation agents, which promote different degradation levels, their selection presents an important role in the durability of the system (ABCB, 2006; Gaspar and Brito, 2008). In that way, the objective of this paper consists of presenting an integrated proposal of a new durability assessment methodology applicable to thermal mortars in multilayer systems.

2 A New Durability Assessment Methodology – Methodological Process

Being the EN 1015-21 and ETAG 004 methodologies applicable to renders and thermal multilayer systems (ETICS), they may be adapted to thermal rendering and plastering systems, since they present some similar characteristics. This adaptation could give reliable data and inputs to the development of durability assessment methodologies directly applicable to thermal rendering and plastering systems. As such, a methodological process for the durability assessment of the systems in study was developed, as explained in Figure 2.

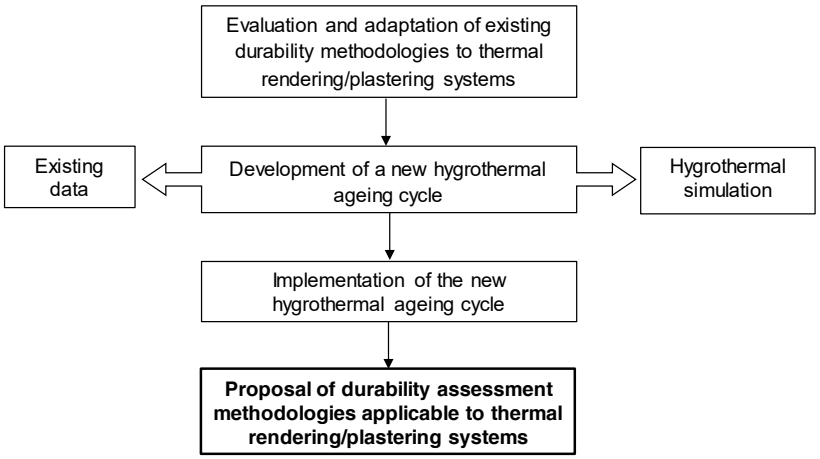

Figure 2. Methodological process for the durability assessment of thermal rendering/plastering systems.

The methodology combines several stages, being the first one the evaluation and adaptation of the referred existing methodologies (EN 1015-21 and ETAG 004). The analysis of existing ageing procedures combined with hygrothermal simulation and existing data resulted in the development of a new hygrothermal accelerated ageing cycle. The development of the hygrothermal cycle focus the South European climate context, using a representative Portuguese climate of the most severe conditions, in terms of temperature fluctuation. After the implementation of the new hygrothermal ageing cycle, it was possible extrapolating this methodology to the development of a theoretical algorithm. The developed algorithm is capable of defining accelerated heat-cold ageing cycles representative of several European climates (Maia, Ramos, and Veiga, 2019).

3 Durability Assessment of Thermal Mortars – Experimental Methodology

Figure 3 presents the adopted experimental methodology to evaluate the durability assessment of thermal rendering and plastering systems. The first step consists in the adaptation of existing methodologies, such as the envisaged in EN 1015-21 and ETAG 004, using small-scale specimens. The EN 1015-21 methodology includes heating-freezing and humidification-freezing ageing cycles and the ETAG 004 freeze-thawing cycles. The evaluation of the existing procedures allowed understanding the gaps, disadvantages and advantages of implementing such methodologies to thermal rendering and plastering systems. The second step consists in the implementation of a new accelerated ageing hygrothermal cycle adapted to thermal rendering systems, through hygrothermal simulation and previous knowledge of the existing

methodologies. Being the location where the system is intended to be applied, one of the main aspects to take into consideration in the durability assessment, the wide range of existing climates should be considered (Juaristi, Gómez-Acebo, and Monge-Barrio, 2018; Perino and Serra, 2015). In the present work, the European climatic context, which combines very different conditions, was analysed. Köppen-Geiger climate classification is one of the most used and well-known and classifies according to the main climate, precipitation and temperature (Kottek, Grieser, Beck, Rudolf, and Rubel, 2006). Focusing on the European context, the EOTA (1999) Guidance Document classifies the climatic zones according to the air temperature and the solar energy intensity. Analysing different European climates, a tendency from the lower to the higher latitudes was observed, being more representative of zones C to A, respectively. In that way, freeze-thaw may have a more relevant impact in northern climates, while thermal shock, originated by the incidence of cold rain in warm surfaces, in southern climates. In terms of internal environment, EOTA (1999) groups four sub-divisions, due to specific conditions to which the buildings are subjected: a) Temperature: heating, non-heating, refrigerating, localised radiation, etc.; b) Humidity: dry or wet conditions; c) Liquid water: permanently wet (*e.g.* bathrooms); and d) Chemicals: cleaning, cooking and special conditions in laboratories, hospitals, etc.. Figure 4 summarises the different stages of the durability assessment methodology and the sequencing between them.

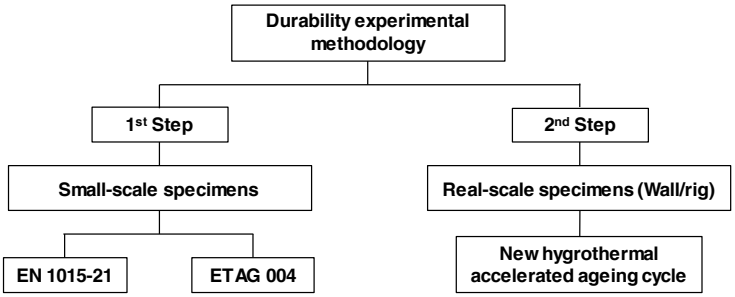

Figure 3. Durability experimental methodology.

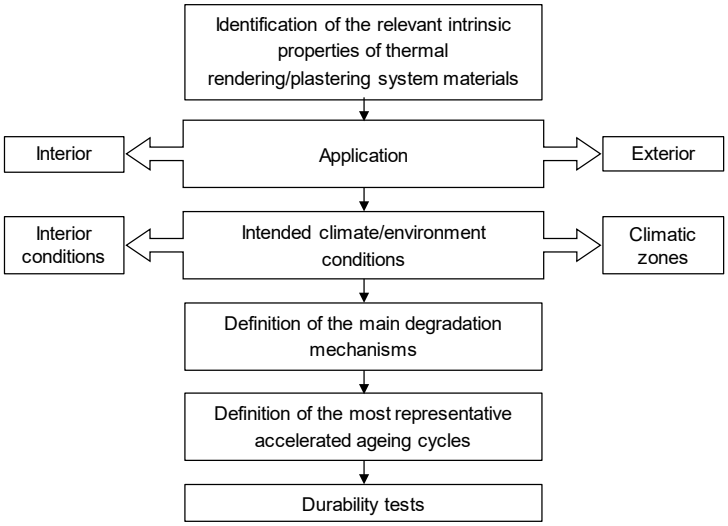

Figure 4. Durability assessment methodology.

4 An Integrated Durability Assessment Methodology Applicable to Thermal Mortars in Multi-layer Systems

4.1 General Methodology

The development of methodologies that reproduce the most relevant degradation mechanisms in thermal rendering and plastering systems were performed. According to the requirements applicable to thermal mortars and considering their relevant properties, a methodology regarding the application of the thermal mortars in multi-layer systems is presented in Figure 5. The knowledge of the physical and hygrothermal behaviour of the referred systems is based on the work developed in Maia, Ramos, and Veiga (2018).

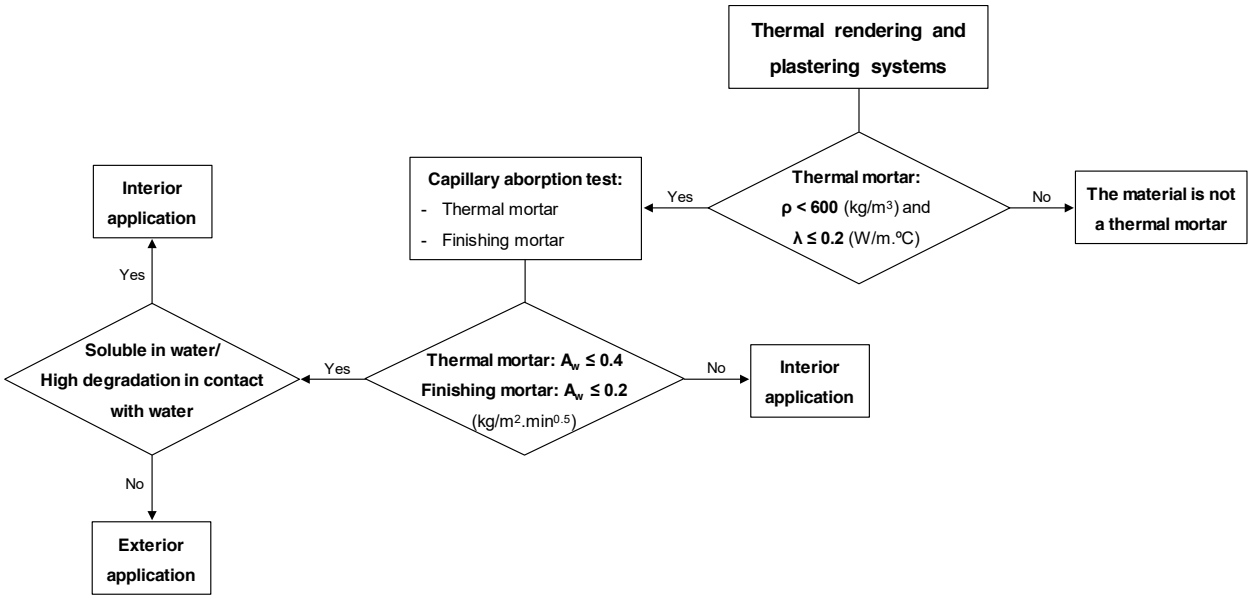

Figure 5. Methodology of application of thermal rendering and plastering systems.

4.2 Durability Assessment Methodology Applicable to Thermal Plastering Systems

Despite the little development of the durability assessment of thermal plastering systems, the implementation of EN 1015-21 ageing cycles allows observing the degradation of the system performance. As such, a preliminary proposal of a durability assessment methodology applicable to thermal plastering systems, regarding the interior application, is presented in Figure 6. The capillary absorption requirement is supported by the capillary classes defined in EN 998-1 (CEN, 2010). The heating (60 ºC)-freezing (-15 ºC) procedure (defined according to EN 1015-21 (CEN 2002a)), allows analysing the effect of the temperature fluctuation, regarding high-temperature variations. The application tof freezing conditions may be too severe for plastering systems applied in interior layers and may therefore be replaced by a higher minimum value adequately justified. However, the effect of humid environments, at high or low temperatures, was not evaluated and is a crucial aspect concerning the durability of plasters. In short, the application of thermal plastering systems requires an accurate analysis, regarding the environmental conditions where the system is intended to be applied, and the definition of the

related ageing cycles (that should represent the environment as accurately as possible).

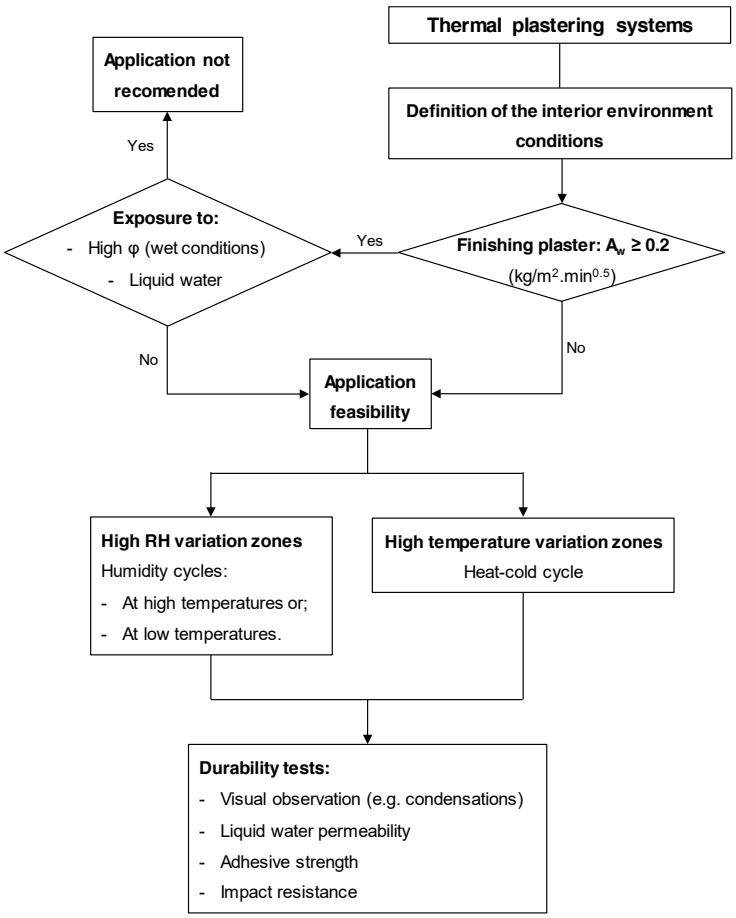

Figure 6. Preliminary durability assessment methodology applicable to thermal plastering systems.

4.3 Durability Assessment Methodology Applicable to Thermal Rendering Systems

The characteristics and durability of thermal rendering systems, suitable for the exterior application, were already presented in the previous work of Maia et al. (2019). The developed methodology, applicable to thermal rendering systems, combines the previous knowledge of the requirements and material properties (obtained by experimental tests and numerical simulation) with a detailed durability experimental campaign. This campaign preconizes the implementation of several accelerated ageing tests, taking into account the relevant degradation mechanisms. To a better adequacy of the durability assessment to thermal rendering systems, a new hygrothermal ageing cycle, which combines heat-cold and heat-rain cycles regarding the Portuguese climatic, was developed through climate analysis and hygrothermal simulation, with WUFI Pro software (IBP, 2018). The heat-cold cycle comprises a cold period (-5 ºC for 11h), a warm period (65 ºC for 7h) and the transitions between the 2 stages, resulting in a 24h cycle. The heat-rain cycle comprises a warm period (70 ºC for 2h), a rain period (15 ºC and 1l/m^2.min. of water spraying, for 1h) and the transitions between the 2 stages, resulting in a 6h cycle, repeated 80 times. This first approach allowed the development of a theoretical

methodology for the definition of heat-cold cycles in the European context (Maia *et al.*, 2019).

5 Conclusions

The existing durability assessment procedures of thermal mortars showed to be insufficient to a precise and realistic evaluation. In that way, the authors developed a new durability assessment methodology, based on real material characteristics and the performance of the system as a whole. The developed methodology highlighted the importance of combining different evaluation methods, such as numerical simulation and experimental tests (existing and new procedures). The previous knowledge of the application requirements allowed the definition of different paths regarding the main degradation mechanisms and, consequently, the most representative accelerated ageing cycles. The main degradation mechanisms include high temperature variations, high relative humidity variations, exposure to high relative humidity, exposure to liquid water and freeze-thaw. The presence of liquid water and high relative humidity is a key factor for the decision on the applicability conditions of thermal mortars. A high water absorption of both the thermal mortar and the finishing layers, in multilayer systems, will define the limitation to interior applications only.

In summary, the implementation of the standard procedures to different thermal rendering and plastering systems allowed understanding the deterioration caused by each degradation mechanism. The acquired knowledge contributed to the development of the hygrothermal ageing cycles since the relevant gaps were identified and bridged. The several experimental tests, performed before and after the different ageing procedures, deepened the knowledge of thermal renders/plasters and the respective systems, giving valuable information about their properties and performance. This knowledge is fundamental to develop the durability assessment methodology, applicable to thermal rendering and plastering systems, together with the developed hygrothermal cycle.

Abstract. *External Thermal Insulation Composite Systems (ETICS) are nowadays often used in new constructions but are also one of the most frequently used thermal retrofitting solutions for buildings. These systems have several advantages such as low installation cost, ease of application and increased thermal efficiency. Nevertheless, a number of questions have been raised on their long-time durability particularly related to biodeterioration. Biological growth is strongly influenced by several parameters, such as water content, temperature, pH but also by the type and hygroscopic properties of the building materials. It is therefore essential to understand and correlate those properties with biological growth. This paper aims at evaluating some ETICS characteristics that might influence surface mould development which is recognized as one of the major groups of deteriorating organisms. The susceptibility of the surface finishing layer and thermal insulation to biological growth was assessed through natural inocula and selected fungi and, whenever possible, correlated with water absorption and drying capacity. This study is part of a wider research project: WGB_Shield (Shielding building' facades on cities revitalization. Triple-resistance for water, graffiti and biocolonization of external thermal insulation systems) that aims at the development of ETICS with improved durability in the urban environment. Further development on this issue are ongoing.*

Keywords: *ETICS, Durability, Mould Growth, Water Performance, ETAG 004.*

1 Introduction

The External Thermal Insulation Composite Systems (ETICS) are nowadays often used in Europe for new constructions and for thermal refurbishment of building facades (Barreira and Freitas, 2013). These systems present several advantages in comparison with other insulation solutions, such as the correction of thermal bridges, reduction of interior water condensation and increase of thermal efficiency, while maintaining the aesthetic appearance of the building, with relatively low installation cost and ease of application (Simona *et al*., 2017). Nevertheless, biological growth has been identified as one of ETICS main disadvantages, with several ETICS facades showing this problem only few years after the building construction/intervention (Johansson *et al*., 2010). Over time, biological growth causes cladding defacement, though it might not have major influence on the thermal performance of the system itself, however,

altering the aesthetic appearance of the building. This situation commonly leads to a disapproval of the building owner, ending up with several economic and social consequences, that limit the full implementation and a wider diffusion of ETICS (Johansson *et al*., 2010).

Factors influencing mould growth on ETICS include nutrient availability, temperature, pH and moisture which seems to be the key factor (Johansson *et al*., 2012). Extensive fungal development is linked to high levels of surface moisture content, resulting from the combined effect of surface condensation, drying process as well as from the finishing render composition. When the drying process is slow, the surface moisture content remains high for long periods, increasing the risk of biocolonization (Barreira and de Freitas, 2013). Thus, the main parameters affecting biological colonization on ETICS are thought to be the composition of the different elements (insulation material, base coat mortar and finishing coat) and the behaviour of the system concerning water absorption and drying. It is therefore essential to understand the hygrometric properties of ETICS and their composition in order to correlate them with biological growth.

2 Materials and Methods

2.1 Materials

Seven different ETICS solutions from three different manufactures were tested for mould growth and water behavior (capillary absorption and drying capacity). Table 1 briefly describes the selected materials. Detailed information about the formulation of each solution is not available due to industrial confidentiality.

Table 1. Characteristics of each system.

System (S) / Manufacturer (M)	Thermal insulation (TI)	Finishing render (FR)*				S thickness (mm) = TI thickness + FR thickness
		Base coat (+ mesh)			Finishing coat	
		Binder	Aggregates	Admixtures and additives	Coating	
S1 / M1	EPS-1	Cement	Mineral fillers and resins	Not identified	Acrylic paint	S: 40.57 TI: 35.29
S2 / M1	EPS-1	Cement				S: 40.44 TI: 35.29
S3 / M2	ICB	Lime + hydraulic binders	Mineral fillers		Acrylic paint + pigment	S: 63.61 TI: 59.73
S4 / M2	EPS-2	Cement	Mineral fillers, resins, and synthetic fibres			S: 65.45 TI: 59.99
S5 / M3	ICB	Natural hydraulic lime +	Acrylic resins and mineral		Acrylic with siloxane resins	S: 41.91 TI: 37.91

		Mixed binders	fillers			
S6 / M3	EPS-2	Cement + Mixed binders				S: 43.30 TI: 38.30
S7 / M3	MW					S: 44.80 TI: 39.80
EPS: expanded polystyrene; ICB: expanded cork; MW: mineral wool. EPS-1 and EPS-2 were produced by different manufactures. *The FR includes a biocide						

Two types of samples were cut from the original ETICS panels of each system: the first was a set of 3 samples of each system with dimensions of 40 mm × 40 mm × S thickness (Tab. 1), which was used to assess mould growth; the other is described in Table 2 and was used to assess capillary absorption and drying capacity of each system. The total thickness of each system ranges between 40.44 mm and 65.45 mm and is presented in Table 1. The thermal insulation materials of each solution were also individually tested for mould growth. There are four types of insulation materials, including mineral wool (MW), expanded polystyrene from two different manufactures (EPS-1 and EPS-2) and expended cork (ICB). The dimensions of these samples are 40 mm × 40 mm × TI thickness (Tab. 1).

Table 2. Materials, samples and laboratory tests for water behavior assessment.

Test	Reference	Sampling [Samples × S]	Dimensions [mm]
Capillary absorption	ETAG 004 (2013)	2 × 7	150 × 150 × TI thickness
Drying	EN 16322 (2013)	2 × 7	150 × 150 × TI thickness

2.2 Mould Growth Tests

The resistance of the different ETICS and insulation materials to mould growth was assessed using a method adapted from ASTM D 5590-17 (2017) and ASTM C1338-19 (2019) and previously described by Santos *et al*. (2017). Three replicates of each ETICS solutions and corresponding thermal insulation were tested.

Three fungal species were used in this study: spore suspensions of *Aspergillus niger and Penicillium funiculosum*, applied together, and *Aureobasidium pullulans*, applied alone. These species were chosen due to their widespread presence in interior and outdoor environments and commonly referenced in the literature and standards (Hoang *et al*., 2010; ASTM D 5590-17, 2017; Verdier *et al*., 2014). A volume of 2 ml of each spore suspension was uniformly distributed on the surface of the previously sterilized specimens and controls and the surrounding culturing media (4% malt, 2% agar). The controls were 3 replicates of Whatman nº 1 filter paper (45 mm diameter) and 3 wood samples (*Pinus pinaster*) with dimensions 40 mm × 40 mm × 10 mm, that allowed the validation of the test (ASTM C1138-19, 2019). After inoculation, the test flasks were incubated at a temperature of 22 ± 1ºC and 70 ± 5% RH for a period of four weeks. A third group of test specimens was exposed in the same conditions but without any sterilization or inoculation thus allowing their natural inocula to potentially develop. Each week, the samples were visually rated for mould growth using the scale defined in Table 3. At the end of the exposure period the samples were removed from the flasks and the final percentage of contaminated surface (Table 3) was evaluated with the help of a stereo microscope.

Table 3. Rate of fungal (mould) development as defined in ASTM D 5590-17 (2017).

Rating	Description	Percentage of contaminated surface
0	None	0%
1	Traces of growth	<10%
2	Light growth	10 to 30%
3	Moderate growth	30 to 60%
4	Heavy growth	>60%

2.3 Capillary Absorption and Drying Tests

Water performance of ETICS was assessed through capillary absorption and drying capacity.

Capillary absorption tests were performed according to ETAG 004 (EOTA, 2013) in a conditioned room (T = 23 ± 2ºC and 65 ± 5% RH). A total of four cycles (each cycle has 24h with measurements at 3 min, 1, 4, 8 and 24h) of capillary absorption were conducted. Capillary water absorption coefficient was obtained by the slope of the initial phase of the curve that expresses the water absorption as a function of square root of time.

Drying test was performed following the recommendations of EN 16322 (2013) and started immediately after the capillarity test. The test was performed in a conditioned room (23 ± 2ºC and 65 ± 5% RH). Samples were weighted after determined periods of time until the variation of mass was constant for all samples. Two drying phases were determined: DR1 – the first drying phase, obtained by the negative slope of the initial linear section of the drying curve plotted with time in abscissa; and DR2 – the second drying phase, calculated by the negative slope of the linear section of the drying curve, plotted against the square root of time in abscissa. Drying index (DI) was obtained by Equation (1), in which M_x is the mass of the sample registered during the drying process (g), M_1 is the mass of the sample in a dry state (g), M_3 is the mass of the sample in a saturated state (this mass corresponds to the mass at the beginning of the drying process (t_0)), t_f is the time at the end of the drying process.

$$DI = \frac{\int_{t_0}^{t_f} f\left(\frac{M_x - M_1}{M_1}\right) dt}{\left(\frac{M_3 - M_1}{M_1}\right) \times t_f} \quad (1)$$

3 Results and Discussion

3.1 Resistance to Mould Growth

The results of the average rate of mould growth for ETICS surface finishing layer considering all type of inoculation were the same during or at the end of the test: zero (no growth). All controls (Whatman nº 1 filter paper and wood) were rated as 4 at the end of the 4-week testing which confirms the validity of the procedure. The fact that no growth occurs for any ETICS surface after 4 weeks of testing can be explained by the presence of biocide on the finishing render. Nevertheless, these are newly produced, unaltered sound systems, which were not subjected to any kind of aging or weathering procedures.

The results of the average rate of mould growth for the insulation materials are shown in Figure 1. After 4 weeks of incubation, significant mould growth was observed on the ICB samples, rated as 2 or more for every type of inocula (natural or artificial). For EPS-1 samples,

no growth was reported at any time during the test, however, for EPS-2, some samples presented traces of growth, especially with natural inocula. MW samples presented no growth for the *A. pullulans* inoculation and traces of growth since the first week of observations for the *A. niger* and *P. funiculosum* inoculation. Only one of the three MW tested samples showed traces of growth (rated as 1) after 4 weeks testing for natural inocula.

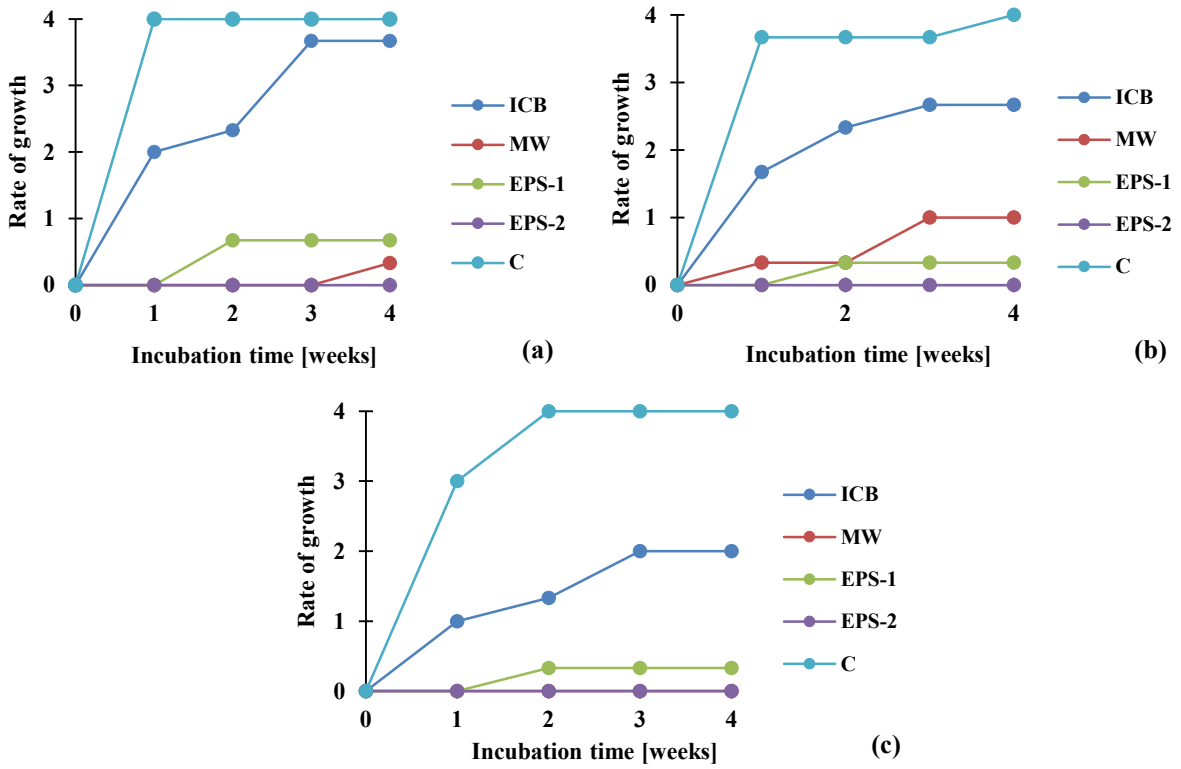

Figure 1. Results of the average rate of mould growth for the insulation materials considering: (a) natural inocula (b) artificial inoculation with *A. niger* and *P. funiculosum* (c) artificial inoculation with *A. pullulans*.

Amongst the insulation materials, ICB samples presented the most intense mould growth. In fact, cork is a natural organic material with suberin, lignin and polysaccharides (cellulose and hemicellulose) in its composition (Knapic *et al*., 2016). Organic or organic-based materials are more vulnerable to fungal deterioration since they provide ample nutrients, through their composition, contributing to fungal growth (Klamer *et al*., 2004; Hoang *et al*., 2010). Additionally, the results of rate of growth for ICB were significantly higher when inoculated with *A. niger* and *P. funiculosum* rather than *A. pullulans*.

In general, MW and EPS samples present a good resistance to mould attack, always presenting a rate of growth lower or equal to 1. Concerning MW, as an inorganic material, the susceptibility to mould growth is naturally lower than that of organic materials. The only sample rated as 1 for natural inocula could have been previously contaminated with some organic dust particles, that contributed to the increase of mould growth susceptibility (Jerábková and Tesarová, 2018). Regarding EPS, the resistance to fungal growth is noteworthy, which is in accordance with the results obtained by Jerábková and Tesarová (2018).

All insulation materials presented higher mould growth for natural inocula than for artificial inoculation. If, on the one hand, natural inocula can be more representative of real conditions (Hoang *et al*., 2010), artificial inoculation significantly accelerates the test while improving repeatability and comparison between materials (Johansson *et al*., 2012, 2014).

3.2 Capillary Water Absorption and Drying

The results obtained for capillary absorption and drying are shown in Table 4 and Figure 2. Sample S3 presents the highest value of capillary absorption at 1h and 24h, whereas sample S1 presents the lowest values. In fact, samples S1 and S2, both with cement-based matrix in the base coat and from the same manufacturer, presented lowest capillary water absorption, and, as a consequence of low water content, also the fastest drying capacity. Sample S1 presented not only the lowest values of capillary absorption at 1h and 24h but also the lowest value of capillary water absorption coefficient.

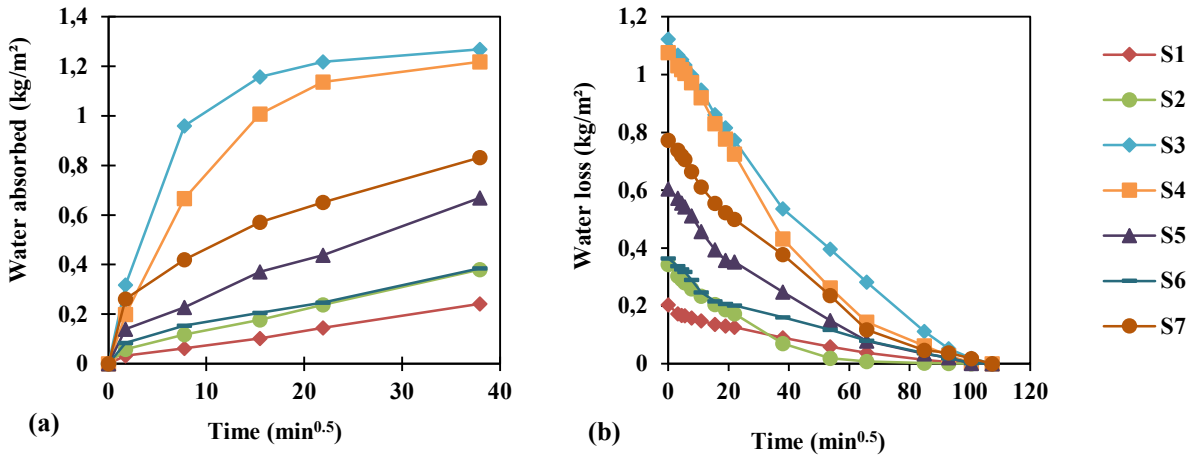

Figure 2. Capillary absorption curves (a) and drying curves (b).

By comparing the capillary water absorption coefficient (C) obtained for sample S5 and S6, it was noticed an increase of 65% of the value of C for S5 in relation to S6. These samples present the same composition of finishing render with exception of the binder (S5 has natural hydraulic lime and mixed binders while S6 is composed of cement and mixed binders).

All samples achieved values of capillary absorption after 1h testing that are lower than 1 kg/m^2, which is the value required by ETAG 004 (EOTA, 2013). In fact, for all tested solutions, the highest level of capillary absorption happens in the first hour of test (even in the first 3 min), followed by a stabilization of the capillary water absorption. Therefore, all solutions have an adequate performance with regards to capillary absorption and drying, presenting low values of capillary absorption.

The results obtained for drying test are in line with those obtained for capillary water absorption, since samples that generally absorb more water are those that present higher drying rates, allowing fast removal of absorbed water. Additionally, a high correlation was obtained between the capillary absorption coefficient and drying rate 2 ($R^2 = 0.77$).

Table 4. Capillary absorption and drying test results.

System (S)	Capillary absorption				Drying		
	Capillary absorption 1h (kg/m^2)	ETAG 004 (≤ 1 kg/m^2 at 1h)	Capillary absorption 24h (kg/m^2)	C ($kg/m^2.min^{0.5}$)	DR1 ($kg/m^2.h$)	DR2 ($kg/m^2.h^{0.5}$)	DI
S1	0.062	√	0.242	0.019	0.0030	0.0197	1.05
S2	0.118	√	0.379	0.034	0.0068	0.0396	1.02
S3	0.959	√	1.268	0.184	0.0151	0.0989	1.01
S4	0.667	√	1.217	0.115	0.0169	0.1099	0.94
S5	0.227	√	0.669	0.081	0.0095	0.0619	1.00

S7	0.419	√	0.832	0.151	0.0111	0.0773	0.98

4 Conclusions

With the aim of evaluating the resistance of different ETICS surface finishing layer and insulation materials to mould growth under laboratory conditions, 7 different ETICS solutions were tested considering three different types of inoculation. The thermal insulation materials of each solution were also individually tested for mould growth. Additionally, capillary water absorption and drying capacity of each ETICS were assessed.

The main conclusions of this study are the following:

- No mould growth was detected on any ETICS surface finishing layer after 4-week testing though it should be noticed that the materials were tested without previous aging or weathering procedures.
- Considering the thermal insulation materials tested individually for mould growth, ICB samples were the ones obtaining the highest level of mould growth after 4-week of incubation. For EPS-1 samples, no growth was reported at any time during the test. However, this is not the case for the EPS-2, where some samples presented traces of growth, especially when considering the natural inocula. MW samples presented no growth for the *A. pullulans* inoculation but traces of growth for the mixed spore suspension. However, as stated in the previous point, these differences in the insulation materials didn't visibly affect the full system behavior.
- All insulation materials presented higher mould growth for natural inocula than for artificial inoculation with either of the spore suspensions.
- All tested ETICS solutions showed good performance regarding capillary water absorption and drying capacity, with all solutions accomplishing the ETAG 004 requirements. Such good characteristics could be one of the reasons why, at this stage, the susceptibility of some insulation materials to mould growth didn't affect the performance of the full system. However, further tests are necessary to assess the moisture transport properties of ETICS after natural and artificial aging and compare those values with the ones presented in this study.

The results obtained in the present study give an overview on ETICS characteristics (capillary absorption, drying capacity and composition of ETICS layers) that might affect surface mould development. The next step in the research will consist on verifying ETICS durability by natural and artificial aging tests, which will affect ETICS finishing coat, possibly

leading to a higher susceptibility of the system to mould growth.

Abstract. *In this paper, two aerogel-based renders are characterized based on in-situ testing of walls prototypes. The in-situ tests to assess the mechanical performance are: pull-off, surface impact tests and compressive strength on collected samples. The physical performance includes the water resistance and thermal conductivity coefficient. The tests carried out to assess water-resistance are: Karsten tube, moisture meter and capillary water absorption of collected samples. The thermal performance was tested based on infrared thermography and thermal conductivity transient method.*
The combination of these in-situ tests allowed a better performance characterization of the aerogel-based renders and characterized the applied renders. These results were carried out under two national research projects (Nanorender and P2020 PEP).

Keywords: *In-Situ Tests, Renders, Aerogel, Walls, Performance.*

1 Introduction

On-site performance testing of renders avoids subjective diagnosis and contribute to a better understanding of render behavior under natural exposure conditions. In-situ techniques on conventional renders have been applied on several studies (Flores-Colen *et al.*, 2011; Duarte *et al.*, 2020; Menezes *et al*., 2015; Santos *et al*., 2013) such as ultra-sound; pull-off; surface impact test; Karsten tube; moisture meter; and infrared thermography. Also, compressive strength and capillary water absorption have been carried out on render samples collected from on-site. The study of aerogel (Garrido *et al.*, 2019) and aerogel-based renders is increasing due to their excellent thermal performance and application on thermal rehabilitation of walls, with decreased thicknesses solutions when compared with other conventional thermal renders. In the literature there are already a few number of studies that focus on in-situ testing of aerogel-based

renders, but mainly on the hygrothermal behavior of these renders based on numerical simulations (Fantucci *et al.*, 2020; Fenoglio *et al.*, 2018; Ibrahim *et al.*, 2014; Stahl *et al.*, 2017).

In this paper, several in-situ techniques are applied on wall prototypes with different formulations of aerogel-based renders, in order to discuss the mechanical, water resistance, and thermal performance. The tested formulations (renders A and B) were developed in two national research projects. In Nanorender project (2012-2015), funded by FCT (Foundation for Science and Technology) PTDC/ECM/118262/2010 ("Nanorender: Performance of nanoaerogel silica-based renders" 2015), a cement-based aerogel render, with fly ash and lightweight co-aggregates was developed reaching a good balance between thermal conductivity (0.088 W/m.K) and compressive strength (1.03 MPa). In PEP project (2016-2019), funded by COMPETE 2020/Portugal P2020-POCI-01-0247-FEDER-017417, a new aerogel-based render was developed (thermal conductivity of 0.028 W/m.K) with compressive strength above 0.2 MPa and water vapour diffusion resistance coefficient below 15. Only some results are discussed for two specific aerogel-based renders formulations in order to discuss the potential of in-situ techniques to assess in-service performance.

2 Experimental Program

2.1 Materials

The render $A^{Aero+EC}$ has in its composition: cement CEM II B/L 32.5 N, 1% of surfactant agent and 0.075 % cellulose ether, in weight relative to the total mixture mass. The mixing procedure was initially manual and with slow rotation at the final part of the mixing procedure, following the EN 1015-11, and the water/binder ratio was 1.25. The aggregates include, in volume, 60% of commercial supercritical hybrid silica aerogel and 40% of expanded clay. The aerogel-based render showed problems in the application of a composition with 100% aerogel in volume of aggregates. Thus, the incorporation of the expanded clay (40% in volume) as a co-aggregate improved the mortar consistency and allowed a quick and easy application of the render. A render with only expanded clay (A^{EC}), with 0.05% of air-entraining agent instead of 1%, and with water/cement ratio of 0.78, was also produced and applied for comparative purpose (Lazera *et al.*, 2016).

The render B^{Aero} is composed by a blend of mineral binders, rheological agents, resins, hydrophobic agents, lightweight fillers, containing a commercial supercritical hydrophobic hybrid silica aerogel as a lightweight and thermal insulation aggregate. The silica aerogel granules represent around 58% in volume or a total of 37 % (m/m) in the weight, both for the mixture powder. The water/binder ratio was 1.33 (Pedroso *et al.*, 2019; Sousa *et al.*, 2019). This render has also a multilayer coating composed by a basecoat layer, fibreglass mesh, key coat, and an acrylic finishing coat (Pedroso *et al.*, 2019).

2.2 Wall Prototypes

The renders $A^{Aero+EC}$ and A^{EC} (Figure 1, a) were manually applied with 4 cm thickness on an opening of a brick wall, with 15 cm of thickness and 40x45 cm^2 dimensions. The curing conditions were at ambient air temperature (average of 15 ºC) during 28 days. The surface of the render was periodically moistened in the first days of curing, a plastic sheet covered the wall (Figure 1, b). The render B^{Aero} was mechanically applied with 5.5 cm of thickness on a lightweight concrete masonry wall with 3 x 3.6 m^2 (Figure 1, c and d). The curing conditions were at ambient air temperature

(average of 20 ºC) during 28 days without any humidification of the render surface.

2.3 Testing Procedures

Several techniques were carried out on the wall prototypes: adhesive strength on substrates (EN 1015-12 - pull-off; water permeability under low pressure (LNEC FE Pa 39.1/RILEM nº II.4) Figure 2 a; pendulum hammer index (RILEM MS-D.7), Figure 2 b; hardness impact (LNEC Fe Pa 25), Figure 2 c; thermal conductivity coefficient (ASTM D5930) and also following the test recommendations by Gomes *et al.* (2018), Figure 2 a; Tramex moisture meter (Figure 2 d), and FLIR infrared camera.

a) b) c) d)

Figure 1. a) Render $A^{Aero+EC}$; b) curing condition at early stages of renders $A^{Aero+EC}$ and A^{EC}; c) lightweight concrete block wall to receive render B^{Aero}; d) render B^{Aero}.

a) b) c) d)

Figure 2. a) Thermal conductivity, Karsten tube in render $A^{Aero+EC}$; b) pendulum hammer, c) impact test with Martinet Baronnie device; d) moisture meter in render B^{Aero}.

The prototypes were installed in climatic chambers with an internal controlled environment. Some samples were collected and prepared for compressive strength and capillary water absorption tests, with and without the multilayer finishing system (when applicable). All the renders were tested at 28 days of curing.

3 Results

Table 1 presents some of the experimental results obtained for aerogel-based renders A and B. These results showed that the applied thermal renders have good thermal performance. The incorporation of aerogel improves the thermal characteristics (for example compare A^{EC} and $A^{Aero+EC}$ with the same formulations, 0.1359 for A^{EC} and 0.1200 for $A^{Aero+EC}$)).

Furthermore, the thin coating of the multilayer coating system misleading the in-situ measurement of the thermal conductivity (0.034 for B^{Aero} and 0.120 W/m.K for the mortar with finish coating, respectively). The latter measurement should not be consider because two requirements of this technique are not accomplished: the measurements on a homogeneous material and the minimum thickness. Aerogel-based renders have low compressive strength values and low compacity. However, they have higher deformability, lower pendulum hammer index and higher notch diameter in the Martinet-Baronnie device. If necessary, depending on the surface requirements, a protective multilayer coating system could improve or maintain acceptable values of surface resistance (*e.g.* B^{Aero} has the same surface resistance than the $A^{Aero+EC}$ without a finish layer).

Table 1. Results aerogel-based renders A and B.

Render	Bulk density (kg/m^3)	R_c (MPa)	IE	$Ø_{notch}$ (mm)	*Pull-Off* (KN/m^2)	$H_{superficial}$ (%)	λ_{Isomet} (W/m.K)	*C* ($kg/m^2.min^{0,5}$)	*Volume of water at 60 min (ml)*	C_A ($kg/m^2.min^{0,5}$)

$$CA = \frac{Q \cdot 10^{-3}}{D^2 \cdot \left(\frac{\pi}{4} 10^{-6} \cdot \sqrt{t}\right)} \qquad (1)$$

The presence of expanded clay guarantees values of mechanical strength above the minimum of 0.4 MPa from EN 998-1, for thermal renders however significantly increases the thermal conductivity coefficient (from 0.034 of B^{Aero} for 0.12 for $A^{Aero+EC}$) (Júlio *et al.*, 2016). Therefore, both lightweight aggregates and paste formulation contribute to the balance between compressive strength and thermal conductivity.

In terms of water resistance, aerogel-based renders tend to have high water absorption (capillary suction or under low pressure) due to their high porosity, despite the hydrophobic nature of the aerogel and the introduction of more entraining agents (from 2.67 to 10.37 ml in $A^{Aero+EC}$ to A^{EC}. The water absorption due to capillary requirements for renders to be applied to external walls is not accomplished (0.85 and 0.62 $kg/m^2.min^{0.5}$, in table 2, for aerogel-based renders) according to EN 998-1 (CEN, 2010). However, a compatible multilayer coating reduces the water absorption of the render system (from 0.85 to 0.02 $kg/m^2.min^{0.5}$ in B^{Aero}).

The experimental results also showed that aerogel-based renders have drawbacks in adhesive strength. The majority of the results were nil, or the values were too low (0.04 MPa with cohesive rupture). Because of the low weight of these renders and low susceptibility to thermal gradients, the low adhesion values can be accepted. However, some admixtures could be added with this purpose). The results also showed that less intrusive pull-off technique should be adapted in the future to have a more reliable test to assess the adhesion of these renders and other lightweight thermal mortars. Furthermore, the moisture meter confirmed the presence of surface moisture on the render $A^{Aero+EC}$ after 28 days of curing in laboratory conditions. In render B^{Aero}, the values were nil due to the multilayer coating system. In addition, in this render, the infrared thermography was used and no significant differences of the superficial temperature was found, therefore concluding that there is a uniformity of the thermal render, without the presence of moist areas.

4 Conclusions and Future Developments

This paper contributes to the discussion of the performance of aerogel-based renders on walls prototypes. The results showed that these renders have excellent thermal behaviour but with specific characteristics in terms of compressive strength and water resistance.

The in-situ testing and lab testing on the collected samples confirm the mechanical, water-resistance and thermal performance of the applied aerogel-based renders. These renders tend to have lower compressive strength, low compactness but high surface deformability. Because of the low weight of these renders and low susceptibility to thermal gradients (lower values of thermal conductivity), the solutions are stable after application, despite of having reduced adhesion values.

The water resistance of these renders depends on the paste formulation notwithstanding the hydrophobic nature of the aerogel. However, the common application of a compatible multilayer coating system improves the water behavior of the complete render system (thermal render + multilayer coating system).

In-situ tests are relevant techniques to monitor the performance of aerogel-based renders and to give additional information to numerical simulations of these renders. However, some drawbacks can be highlighted, specially when multilayers systems are applied. For example, in-situ measurements of thermal conductivity with ISOMET technique are reliable only on aerogel-based renders without thin coating systems. Further research should discuss the thermal performance of these multilayer systems based on the thermal resistance.

Politecnico di Torino - Department of Energy, C.so Duca degli Abruzzi 24 Torino, Italy.
stefano.fantucci@polito.it

Abstract. *Thermal insulating plasters and renders are becoming a popular solution for the energy retrofit of existing and historic buildings because of their suitability/compatibility with the existing masonry supports. However, as for most of the insulating products, the actual performance of these materials might significantly differ from the one determined with simplified methods (EN ISO 6946 standard) that are commonly adopted by the designers. In this study, an overview of the latest Authors researches that involve three different thermal insulating plasters, containing respectively perlite, vegetal and aerogel aggregates, are presented. The developed plasters were characterized in the laboratory and successively applied in three demonstration buildings. From the in-field thermal monitoring activities, all the analysed thermal insulating plasters showed a decrease in the thermal performance between 25 and 30% if compared to the laboratory measurements.*

Keywords: *Plaster, Render, Aerogel, Retrofit, Historical Buildings.*

1 Introduction

In the last years the energy demand reduction, and hence, the reduction of greenhouse gas emission has become a crucial global strategy. Building sector can play a key role in this process. Since the largest part of the EU existing buildings is old and thus weak from the thermal point of view, retrofit strategies should be adopted for improving the thermal insulations level. Nevertheless, a big challenge is to identify suitable insulating solutions able to guarantee the proper compatibility with the existing masonries, considering that ~39% of the EU residential buildings were built before the 1960'. Recently, different retrofit strategies for existing buildings have been developed. Among all the different solutions one of the most promising is represented by the thermal insulating plasters and renders. These materials are similar to the traditional plasters, but the sand is replaced by lightweight thermal insulating aggregates (LWA) to reduce density and thermal conductivity. Key-features of these materials are the ease of application on irregular surface, the higher hygrothermal compatibility, the minimum space reduction (indoor application) and the good thermal performance improvement. Several studies have demonstrated that good thermal performance can nowadays be achieved by using different LWA typologies e.g. vegetal (Cherki A *et al.,* 2014, Mazhoud B. *et al.,* 2016, Brása A. *et al.,* 2013), mineral (Barbero-Barrera M. *et al.,* 2015, Osman G. 2016, Konakova D. *et al.,* 2017), polymeric (Mayor P. *et al.,* 2012, Šeputytė-Jucikė J. *et al.,* 2014) or silica aerogel (Ibrahim M. *et al.,* 2014, Stahl T. *et al.,* 2012, Buratti C. *et al.,* 2014, Fantucci S. *et al.,* 2020).

Nevertheless, despite the interesting potentials of thermal insulating plasters, some aspects are currently under investigation. Actually, during their service life, these materials might be exposed to variable boundary conditions *e.g.* temperature and relative humidity variations,

that can strongly affect the expected thermal performance. It seems evident that, in addition to the laboratory nominal thermal conductivity measurements, an in-field monitoring activity can be useful.

The aim of this paper is to present a comparison between the laboratory performance and the actual in-field monitored performance, in real case studies. For this sake, an overview of the latest Authors researches that involve the monitoring of three different historical case study buildings in northern Italy in which three different thermal insulating plasters containing different LWA were applied (vegetal, mineral and aerogel) is here presented.

1.1 The Developed Materials

The materials hereafter presented were developed adopting different LWA typologies (vegetal, mineral, and aerogel). The plasters were measured in the laboratory to determine the nominal thermal conductivity and then applied and monitored to different case study buildings in north Italy. The first formulation presented (VGT 04) is made by natural hydraulic lime as a binder with addition of vegetal and mineral aggregate, respectively corncobs (33% in weight) and perlite (10% in weight); the product was then applied to a historical building located in Turin (Ex Albergo della Virtù, 1580). The second analysed plaster typology (P_30) is made by mineral LWA. The Natural Hydraulic Lime (NHL2) was mixed with cement (<7.5% in weight) and perlite was used as aggregate (30% in weight); the product was applied to a XIX - XX century rural house located in Dogliani (CN).

The last plaster typology was made by a mineral-based binder with the addition of ~50% in weight of granular aerogel (Sample G). The product after the laboratory test was applied to a 1920 building located in Turin (ATC social house). More exhaustive analyses performed on the different materials were presented in (Bianco L. *et al.,* 2015, Fenoglio E. *et al.,* 2018, Fantucci S. *et al.,* 2019).

2 Laboratory Assessment

Accordingly, to the EN 998-1 standard, the thermal plaster to be classified as "T1" must achieve a λ-value lower than 0.10 W/mK. So for this classification, it is essential to experimentally assess the thermal conductivity in laboratory conditions.

2.1 The Laboratory Analysis

The procedure to perform the thermal conductivity measurement is reported in EN 12667:2001. The apparatus adopted for the plaster samples presented in this paper is the Heat Flux Meter (HFM Figure 1a). It is made by two flat parallel plates in which the plaster specimen is placed in between. It is possible to set different temperatures of the plates to establish a constant temperature difference ΔT, then the generated specific heat flux φ is measured. In this case, a temperature difference between the plates of 10°C was set. The HFM collects the surface temperature difference and the heat fluxes until constant conditions are reached, then for known specimen thickness t it is possible to determine the thermal conductivity as follow:

$$\lambda_{eq} = t \cdot \frac{\varphi}{\Delta T} \; [W \cdot m^{-1} K^{-1}] \tag{1}$$

The tested samples are characterized by a size of 60 x 60 x 10 cm (VGT 04) and of 40 x 40 x 5 cm (P_30 and G). Before to start the test, the samples were dried in a climatic chamber (ACS DM 340 Figure 1b) until a constant mass was reached. Then to avoid any vapour migration between the samples and the environment, they were sealed in a vapour-tight envelope.

b)

Figure 1. a) the heat flux meter adopted for the measurements (picture from Fantucci et al. 2020); b) the climatic chamber adopted for the material drying.

2.2 Results

The thermal conductivity of the thermal plaster formulations is reported in Table 1. Results show that the lower is the thermal conductivity of the LWA added in the formulations, the lower is the density of plaster, and hence, their thermal conductivity. Nevertheless, adopting non super-insulating LWA (perlite and corncob), a quite low thermal conductivity (below 0.1 W/mK) can be achieved to be classified as T1 plaster according to the EN 998-1 standard.

Table 1. Thermal conductivity results of the thermal plasters.

Code	Sample	ρ [kg/m^3]	$\lambda_{10,dry}$ [W/mK]	Results from
A	VGT_04 (vegetal)	400	0.090	Bianco L. et al., 2015
B	P_30 (perlite)	394	0.084	Fenoglio E. et al., 2018
C	Sample G (aerogel)	134	0.027	Fantucci S. et al., 2020

3 In-situ Monitoring

In addition to the laboratory thermal conductivity measurement, an in-field monitoring campaign was carried out for the three different thermal plaster formulations.

3.1 Demonstration Buildings

For each formulation, a different case study building was selected for the material installation. The monitoring phase aims at analysing the actual in-field thermal performance and to compare it with the laboratory measurements. For each case study, two identical walls with the same orientation were selected: one was kept as reference wall while the other was retrofitted with the thermal insulating plasters applied on the internal side of the wall.

The plaster A (vegetal-based) was applied at “Ex Albergo di Virtù” (1580), a historic

building located in Turin (Figure 2a). The south-east oriented external wall was selected for the application of 6 cm thick layer of thermal plaster from the interior side. The existing walls are made of a ~50 cm thick layer of stones and bricks.
The plaster B (perlite-based) was applied in a 5 cm thick layer for the energy retrofit of a rural building located in Dogliani (CN) (Figure 2b). The selected walls are north-east oriented, and the structure is made up of about 50 cm layer of solid bricks with an external lime plaster layer.

Finally, a 1920 social house building, located in Turin, and managed by ATC (Agenzia Territoriale Per La Casa del Piemonte Centrale) was chosen as reference building for the application and monitoring of the plaster C (aerogel-based) (Figure 2c). Two identical solid brick cavity walls south-east oriented were selected, the retrofitted one was coated with ~4.5 cm plaster layer.

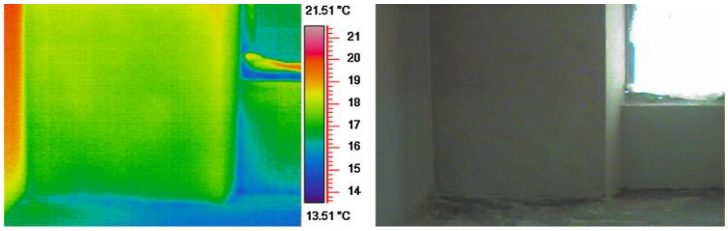
3.2 Monitoring Procedures

The standard procedure for the in-field measurement of the thermal transmittance (U-value) and thermal resistance is reported in the ISO 9896:2014. In order to compare the U-values of the retrofitted and the non-retrofitted walls, the measurements were carried out simultaneously. A preliminary thermographic survey was performed to assure that the wall portion selected for the monitoring was sufficiently uniform and not affected by thermal bridges (Figure 3a). The internal and external air temperature values were measured by means of Type-T thermocouples. Moreover, heat flux plates (HFP01), glued on the inner side of the walls,were used to measure the heat flux densities and then, after at least 72 h of measurements, to assess the U-value by using the average method described in the ISO 9869 standard. The comparison of the U-values measured in the reference and in the retrofitted walls allowed determining the thermal performance improvement achievable by adopting the thermal insulating plaster. Furthermore, the equivalent thermal conductivity of the thermal insulating plaster layer was calculated according to Eq. (1).

$$\lambda_{eq} = t/\left(\frac{1}{U_{plt}} - \frac{1}{U_{ref}}\right) \left[{}^{W}/_{mK}\right] \quad (1)$$

Where: t is the plaster layer thickness [m]; U_{plt} is the thermal transmittance of the plastered wall [W/m^{2}K]; U_{ref} is the thermal transmittance of the reference wall [W/m^{2}K];

In the different case studies, the measurements were carried out for a period longer than those required by the standard. Moreover, since some façades are south-east oriented, the data adopted for the calculation correspond to the period with low solar radiation and external temperature.



a)

Figure 3. a) a thermographic survey carried out on the Ex Albergo di Virtù (picture from Bianco et al. 2015).

3.3 Results

3.3.1 Results of Plaster A

Figure 4 report the data of the U-value for the wall retrofitted with the plaster A (vegetal-based). The measurement was performed for 19 consecutive days. The thermal transmittance value achieved at the end of the monitoring period was 0.56 W/m^{2}K. Considering a U-value of about 0.8 W/m^{2}K (estimated by EN ISO 6946 standard) for the reference wall, a reduction of about 30% can be underlined. Moreover, the equivalent thermal conductivity of the thermal plaster layer was determined according to eq. (1), so the estimated in-field actual conductivity (~0.116 W/mK) showed an increase of ~30% if compared to the laboratory value (0.09 W/mK). This thermal performance reduction can due to higher moisture content in the installed plaster compared to the one tested in the laboratory. Indeed, for this case study, it is worth to be highlighted that the drying process was still in progress during the testing phase and the wall U-value was slightly still decreasing.

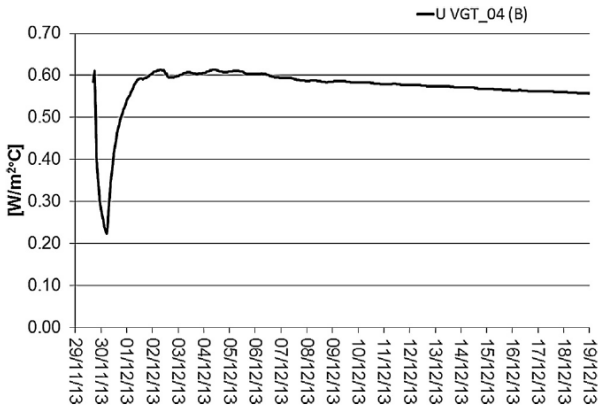


Figure 4. Thermal transmittance measured for the wall retrofitted with the plaster A.

3.3.2 Results of plaster B

The plastered and bare walls used for the thermal transmittance assessment of plaster B were monitored for 4 days and the results of the monitoring campaign are reported in Figure 5.

The plastered wall reached a U-value of ~0.80 W/m^{2}K that is the 45% lower than the value achieved by the bare wall (~1.43 W/m^{2}K).

The equivalent thermal conductivity calculated for the perlite-based thermal plaster reached a value ~0.092 W/mK that is ~10% higher than the values measured in the laboratory.

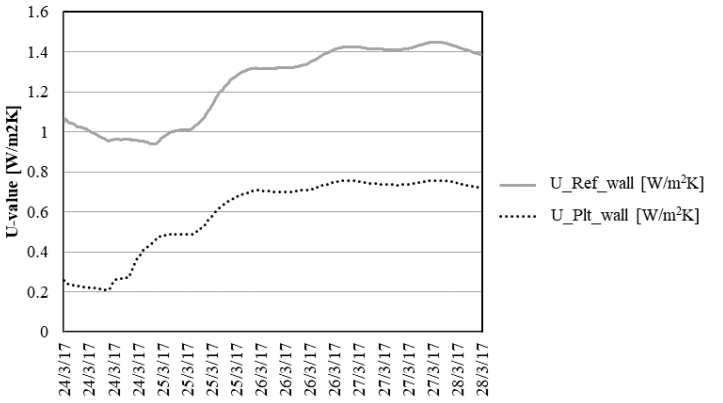

Figure 5. Thermal transmittance measured for the wall retrofitted with the plaster B.

3.3.3 Results of Plaster C

The aerogel-based plaster was monitored for more than one month. However, only one reference week was selected for the analysis because of the more suitable boundary conditions. Thermal transmittance values for both the bare and retrofitted wall were measured and reported in Figure 6. It is noticeable a thermal transmittance reduction of ~60%, indeed the reference wall shows a U-value of ~0.99 W/m^{2}K while the retrofitted wall reached a U-value of 0.42 W/m^{2}K. The thermal conductivity of the plaster layer that was calculated from the U-values of the two walls, was ~0.033 W/mK, that was about 17% higher than the value measured in laboratory conditions.

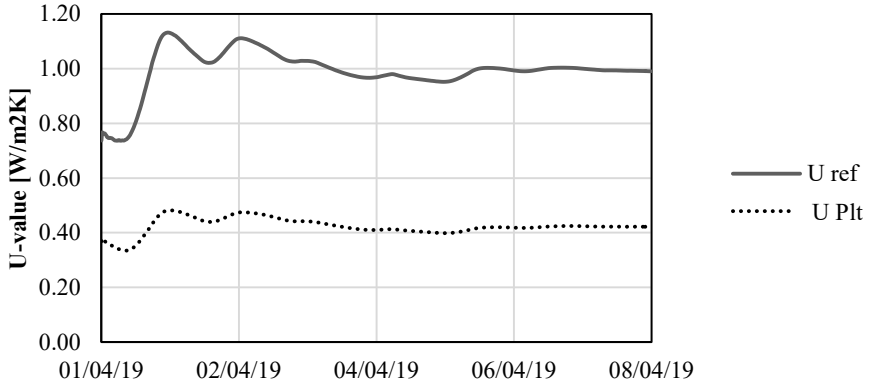

Figure 6. Thermal transmittance measured for the wall retrofitted with the plaster C.

4 Discussion

The laboratory tests performed on different thermal insulating plaster samples highlighted, as expected, a decrease of the thermal conductivity due to the addition of lightweight (vegetal, perlite and aerogel) aggregates in the formulations.

The in-situ measurements performed for the vegetal based plaster (~60 mm thick layer) have shown a decreasing of the U-value of about 30% respect to the non-retrofitted wall. Nevertheless, for this case study, it should be highlighted that the measurement was carried out when the material was still losing moisture. The perlite-based plaster shows a reduction of the U-value of about 45% (~50 mm thick layer). As expected, the plasters with a lower thermal conductivity (aerogel-based) allowed the achievement of the higher thermal transmittance reduction, up to 60% with a thinner layer (~45 mm). Comparing the nominal thermal conductivity values measured in the laboratory with the actual equivalent thermal conductivity determined through the monitoring campaign, an increment between 10% and 30% was highlighted a slight decrease in the thermal performance.

This performance decrease can be mainly related to different reasons: i) the high in-field measurement uncertainty; ii) the different drying stage of the three analysed plasters; iii) the different temperature and the higher moisture content of the in-field monitored plaster compared to the laboratory measurements. The latter reason can be explained since the material tested in the laboratory were dried before the test and the measurements were carried out at 10°C (mean temperature). Nevertheless, the results demonstrate that the adoption of the thermal insulating plasters are a suitable solution for the energy retrofit of existing buildings.

5 Conclusions

The thermal plaster formulations tested in this study were made up of different mineral (perlite), vegetal and super-insulating (aerogel) lightweight aggregates. The thermal conductivity measurements carried out in the laboratory have shown a significant decrease in the thermal conductivity by adding these LWA. Thermal conductivity values between 0.09 W/mK to 0.027 W/mK were achieved; as expected the lower is the thermal conductivity of the LWA adopted, the lower is the final thermal conductivity of the plaster.

The in-field applications and measurements, on three demonstration buildings, were performed for each plaster formulations to determine the benefit achievable in terms of thermal transmittance reduction. The promising results, that were achieved in the laboratory, were confirmed by the monitoring campaign: a reduction of thermal transmittance between 30% to 60% was measured for the different plaster.

Comparing the nominal thermal conductivity values measured in the laboratory with the actual equivalent thermal conductivity determined through the monitoring campaign, an increment between 10% and 30% were highlighted. This decrease of performance was mainly due to higher moisture content and different temperature at which the plasters were exposed.

From these analyses, it is possible to underline that the characterisation of the thermal conductivity at different temperatures and moisture content are necessary to properly evaluate the actual thermal performance and allow more conscious evaluation among different retrofit alternatives.

Abstract. *Within the framework of the European project Wall-ACE a large-scale laboratory test (EOTA-Wall Test) was performed. Additional a test field in Switzerland was equipped with six different aerogel renders by the project partner AGITEC. Laboratory walls and test field were equipped with sensors to monitor in real-time climate, heat flux, temperature, relative humidity, and at the laboratory tests additional material moisture. The data allow calculating U-values and material parameters as well as drying behaviour of render and substrate. During and after the artificial weathering in laboratory the renders were subjected to visual inspection and mechanical adhesion tests. The performance of the aerogel renders will be assessed and compared with results on conventional insulation renders.*

1 Introduction

As the European Union (EU) requires an improvement of 27% regarding the buildings energy efficiency by 2030 (European Commission), the development of innovative technologies to improve the performance levels of the building envelop is encouraged. In this sense, the Horizon 2020 project (Wall-ACE, 2016) aimed to develop a package of new advanced aerogel-based insulation products and systems that could be used to strengthen the competitiveness of Europe through innovation and excellence. Among the developed products was an external high performance insulating render, which had as goals providing a long lasting, breathable continuous insulation layer where its thickness could be adjusted depending on the climate, on the geographic orientation of the wall and on architectural or specific local needs (thermal bridges, uneven walls, windows reveals, architectural constraints such as in semidetached housing, etc.).

Within the framework of the project there were included tests to assess the efficiency and behaviour of the different insulation systems in extreme conditions in large-scale tests and real conditions on building scale.

2 Experimental

2.1 EOTA-Wall Test

To assess the durability of the external insulation render developed by the Wall-ACE project partner Quick-Mix, a large-scale laboratory test (EOTA-Wall test) was performed according to (EN 16383:2016).

doi:10.23967/dbmc.2020.089

2.1.1 Test set-up

The test chamber consists of two opposing walls spaced one meter apart, with the render system facing each other, forming an inner room that characterizes the outside conditions. On one of the chamber sidewalls, the Quick-mix external render, an aerogel-based exterior insulation render was applied, while on the other side a commercially available, regular perlite-based insulation render, TRI-O-THERM, was used as a reference material. Each wall was split vertically and was made up of bricks on one side and concrete blocks on the other, measuring in total 4.0 x 2.1 m (length x high). Therefore, it can be considered that four walls were under investigation, named here from A to D, see Figure 1.

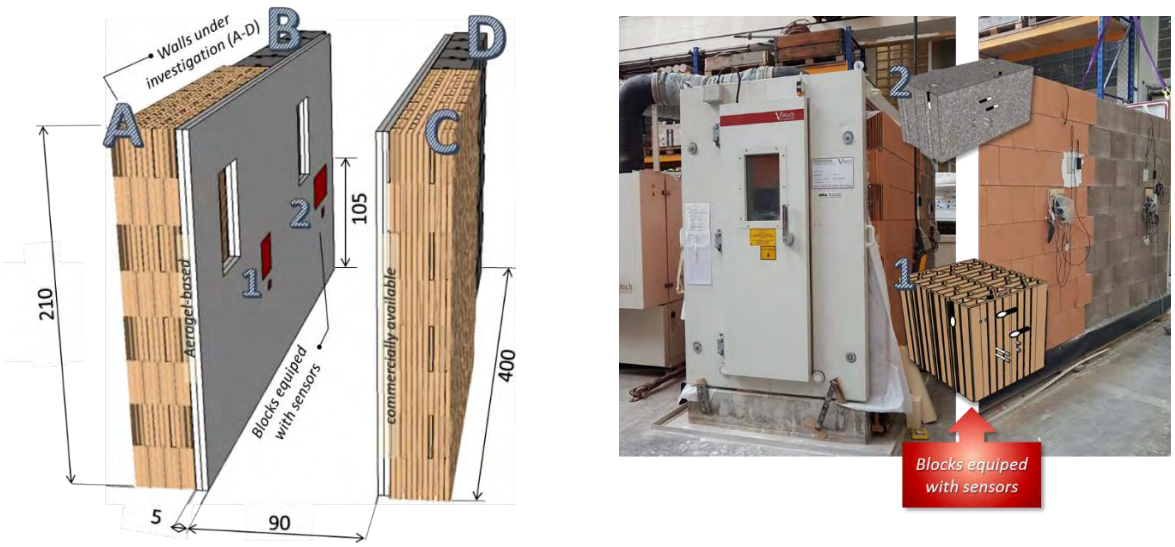

Figure 1. Left: Aerogel render wall (A, B), perlite render wall (C, D). Right: EOTA test rig and monitoring system.

The set-up of both walls are as following: 1 Substrate: bricks or concrete blocks, 2 adhesion layer (concrete blocks), 3 exterior insulation render: two layers of around 3 cm of aerogel or perlite render, 4 two layers of supporting plaster together with a reinforced mesh in the first layer, 5 hydrophobic final coting. Such solution is necessary to ensure both mechanically stability and protection from weathering and mechanical impact.

2.1.2 Durability test – weathering cycles

The large-scale test walls were exposed to weathering cycles according to (EN 16383:2016), which are grouped into heat-rain, heat-cold and heat-rain-cold cycles, see Figure 2. Lasting on average 84 days, the ageing test offers harsh conditions with a 90°C temperature range and 1.5 l/m²min amount of water during the rain cycles.

2.1.3 Material moisture and temperature monitoring

On each of the four monitored walls, one concrete or brick block equipped with impedance and hygro-thermal sensors was placed among the layered blocks (Figure 1). Impedance sensors, which consist of two probes (screws or thread rod) surrounded with a conduction rubber at a

proximity distance of 1.5 cm were incorporated in the bricks, joints and exterior render layers. Additional, hygro-thermal sensors were installed as well and covered with a porous tube or with a glass fibre tape. The used hygro-thermal sensors (Sensirion SHT25) have a small size (3x3x1.1 mm) and a resolution of ±0.2 K and ±1.8% RH.

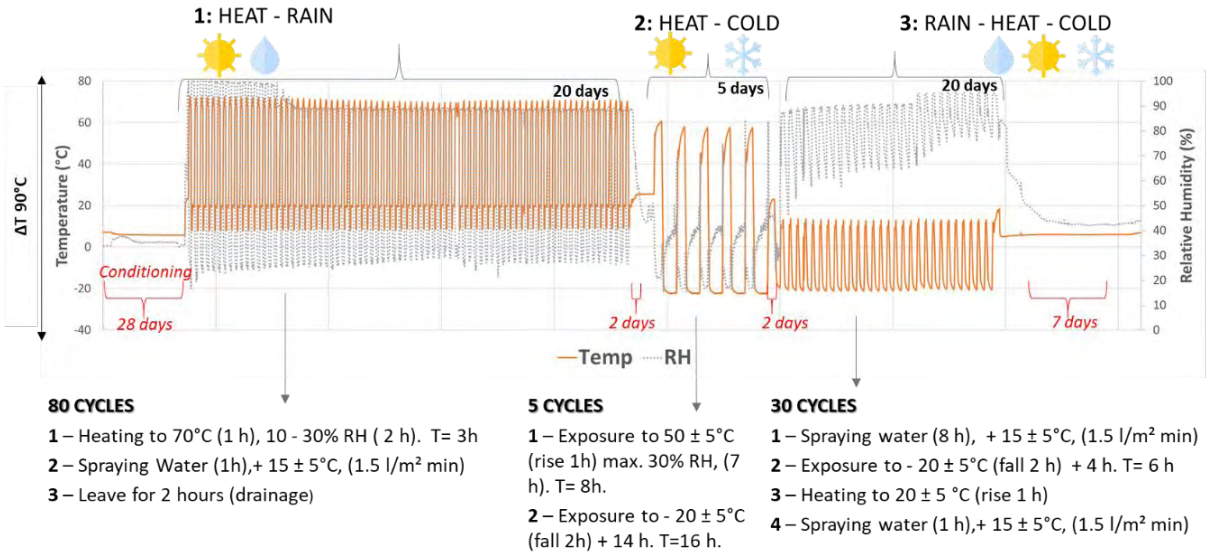

Figure 2. EOTA weathering cycles.

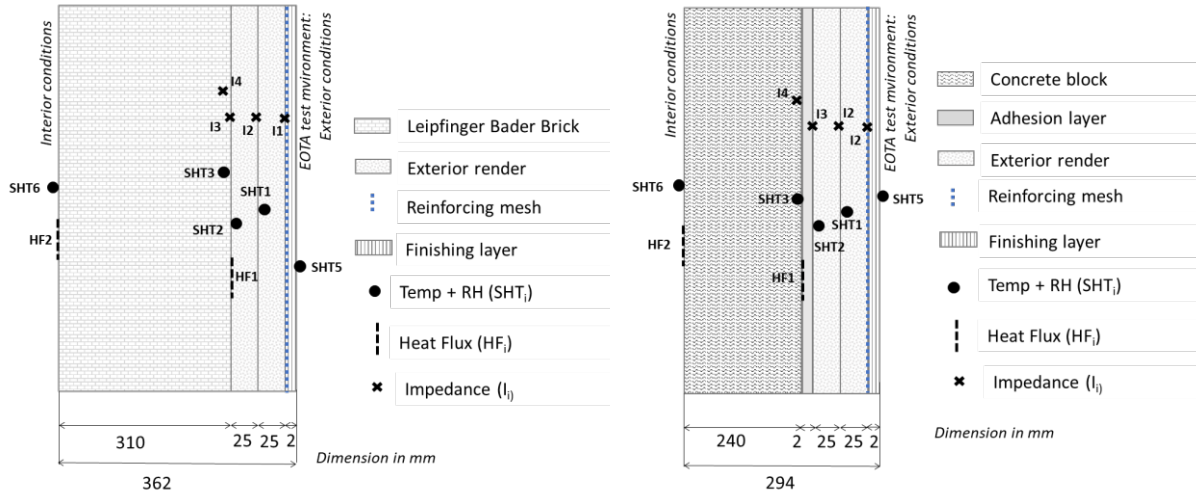
A cross-section of the walls with their corresponding materials and thickness as well as the positioning of the different sensors is shown in Figure 3. Furthermore, heat flux sensors (Ahlborn, FQA018C, type 118) were added at the tested walls. Together with the surface temperature measurements, the wall thermal resistance or U-value, according to (ISO 9869-1:2014) was determined before and after the weathering cycles.



a) Brick walls (A and C) b) Concrete block walls (B and D)

Figure 3. EOTA test – walls sections (A-D).

2.1.4 Adhesive strength

Adhesive strength between insulation render and substrate was tested according to (ETAG 004:2013, Section 5.1.4.1.1, Paragraph 2). Adhesive strength was tested after the weathering cycles for both renders: developed aerogel-based and commercially available TRI-O-THERM.

Results of adhesive strength before weathering cycles represent initial adhesive strength. For testing of adhesive strength, square test surfaces with 50 mm edge length was chosen. The edges of the test surfaces (50 mm edge length) were dry-cut through the insulation render until substrate surface. A metal plate with an edge length of 50 mm was glued to each test surface using a 2-component adhesive based on epoxy resin. After sufficient hardening of the adhesive, the metal plate was pulled off using a pull-out testing device, see Figure 4.

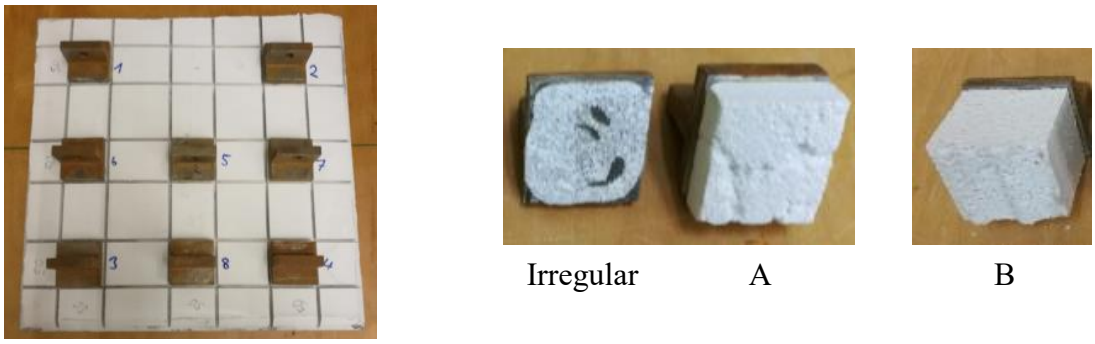


Figure 4. Testing of adhesion to the substrate: Glued tension plates on specimen surface and possible failure modes (from left to right): (Irregular) failure along glued Surface, (B) specimen failure, (A) adhesion failure.

2.2 Test Field

2.2.1 Case description

Different aerogel based exterior renders were spread over a south-oriented wall at storage and office building to both monitor their behaviour at a real building site and to pursue a comparison study to evaluate its performance. The wall under investigation stand to the left of the main entrance of AGITEC industrial shed building, located in Dällikon - Switzerland, close to the Zurich (47°26'44.3"N 8°26'26.2"E).

In details, the industrial shed area is the ground floor of the building with a total height of 7.07 m, and gross external dimensions of 15.20 m x 39.32 m. It has a prefabricated concrete structure, composed of pillars spaced every 6.5 m. Moreover, the warehouse has MDF and plasterboard partitions, both vertical (internal walls) and horizontal (floor slabs), thus creating small deposits in its interior space. These deposits have an average height of 3.10 m.

Regarding the analysed materials, four commercially available aerogel renders (anonymized data: A to D), and Quick-Mix Wall-ACE renders 1&2 (Figure 6) are studied. Firstly, the four commercially available aerogel renders (A-D) were applied to the industrial shed south façade with an area of 5.5 m² each. Later on, Quick-Mix Wall-ACE renders 1&2 were applied alongside the others, having an area of respectively 23 m² and 10 m². The application followed the following scheme: 1 cleaning, primer and roughcast for adhesion, 2 two layers of aerogel insulation render by machine spraying, 3 two layers of supporting plaster (the same for all walls) together with a reinforced mesh in the first layer, 4 final coting.

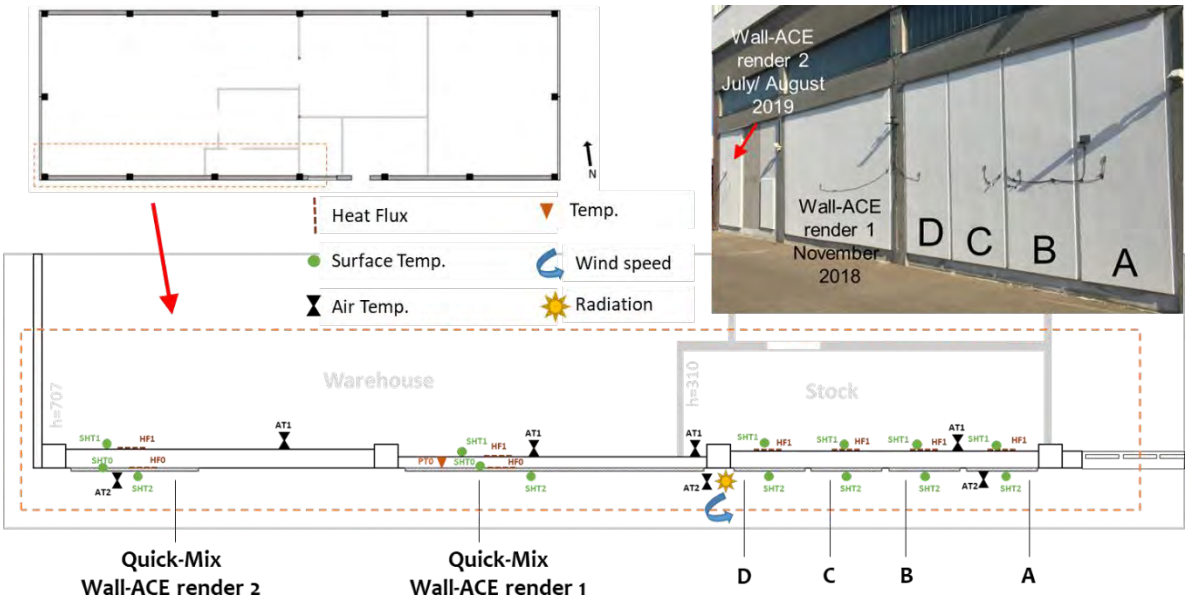

Figure 5. Floor plan: AGITEC storehouse. Feature test walls, sensors and installation.

2.2.2 Monitoring

Both environment/boundary conditions and walls elements were equipped with sensors to allow, through on-site measurements, an in situ thermal characterization and consequently, a performance analysis of the different aerogel render products under investigation.

For this, air temperature and relative humidity sensors were installed outside, inside the warehouse and stock (Sensirion STH25), and at both interior and exterior wall surfaces (Sensirion SHT31). Heat flux sensors (Ahlborn, FQA018C, type 118) were also installed at the inner side for all tested materials, and additionally between the Quick-Mix Wall-Ace exterior renders and the substrate wall. Besides that, sensors to measure global solar radiation (W/m²) and wind speed (m/s) were installed to assess the outside weather conditions. All sensors were placed approximately at 1.5m high (see Figure 6). However, the presence of outdoor weather conditions configures a challenge to estimate a stationary parameter such as thermal resistance. Moreover, the average method, described in ISO 9869-1:2014, requires walls not exposed to direct solar radiation, which is not the case here.

Furthermore, it is emphasized that the composition of the storehouse walls differ from each other, presenting distinct thicknesses and materials, according to their location (Figure 1), which also has different heights (warehouse= 7.07 m and stock=3.10 m). All these factors make an instant comparison between the renders difficult.

3 Results and Discussion

3.1 EOTA-Wall Test

3.1.1 Material moisture and temperature monitoring

The temperature difference across the brick and concrete block walls (ΔT=°C), as well as both heat flux (W/m²) and Impedance (MΩ) measured at the exterior insulation render layer are

shown in Figure 6. After certain weathering cycles the plasters showed a moisture uptake in the impedance measurements. Such behaviour should be omitted in the final product development due to the risk of frost cracking.

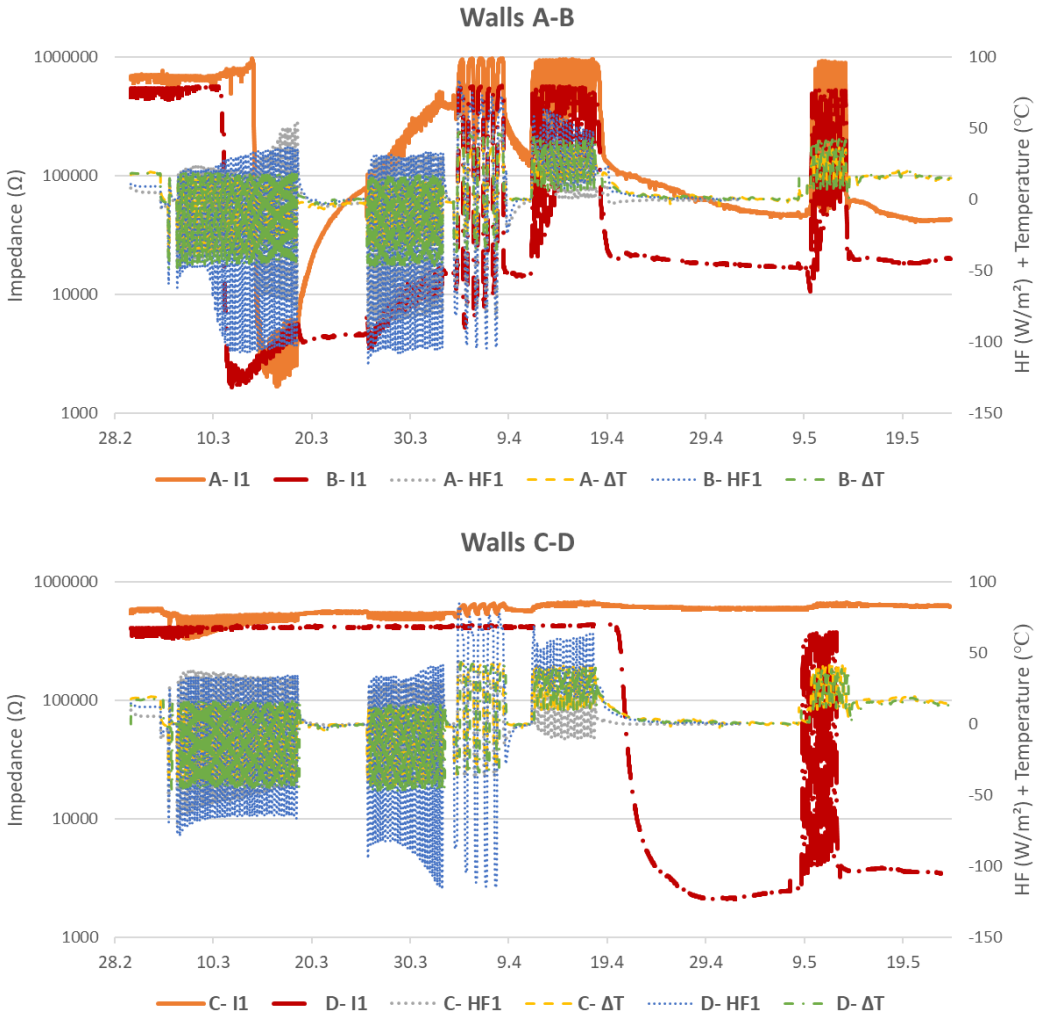

Figure 6. Temperature difference (°C), heat flux (W/m²) and Impedance (MΩ) measured during the EOTA test: (a) Wall A and B (Wall-ACE Quick-Mix Aerogel render); (b) Wall C and D (TRI-O-THERM render).

3.1.2 Adhesive strength

Results of adhesive strength (determined from the maximum load and the area of 2500 mm² subjected to tensile stress) are given in Table 1. It can be seen that average adhesive tensile strength of aerogel-based exterior insulation render was 33-60% lower after ageing compared to initial adhesive strength. These values (strength after ageing) are comparable with adhesive strength of TRI-O-THERM after ageing. The failure was 100% in the insulation render in all tests.

Before the start of the EOTA-Wall Test, the test wall was checked for its initial condition. No defects were found during the initial inspection.

Table 1. Results of adhesive strength

Substrate	Render type	Testing time	Adhesive strength [N/mm²]	Failure mode
Hollow brick	QUICK-MIX WALL-ACE	Before ageing	0.009	Specimen failure
Light weight concrete		Before ageing	0.005	Specimen failure
Hollow brick		After ageing	0.003	Specimen failure
Light weight concrete		After ageing	0.003	Specimen failure
Hollow brick	TRI-O-THERM	After ageing	0.004	Specimen failure
Light weight concrete		After ageing	0.004	Specimen failure

The test wall surface was observed during the EOTA test for changes such as cracks, chipping of surface, etc. Only minor chipping of surface was present after EOTA test. Furthermore, crack propagation (crack length/crack width) was observed for each window. Crack propagation is similar for both renders. Crack width is never bigger than 0.15 mm which is a sign for positive behaviour of tested systems.

3.2 Test Field

The weather data obtained from the experimental campaign (20/05/19 – 20/09/19) are shown in Figure 6. External conditions or outside environment measured by the sensors presented an average 26.5°C of air temperature, 52% of air relative humidity and 743 W/m² of global radiation since the analysed walls face south.

The completion of the Quick-Mix Wall-ACE render 2 applications is highlighted in the chart. Furthermore, in Figure 8 it is possible to follow the drying process of the material by reading the humidity between the brick and the render layer. By mid-September it is clear that the material is still damp. A U-value estimation is foreseen for the winter season 2019/2020.

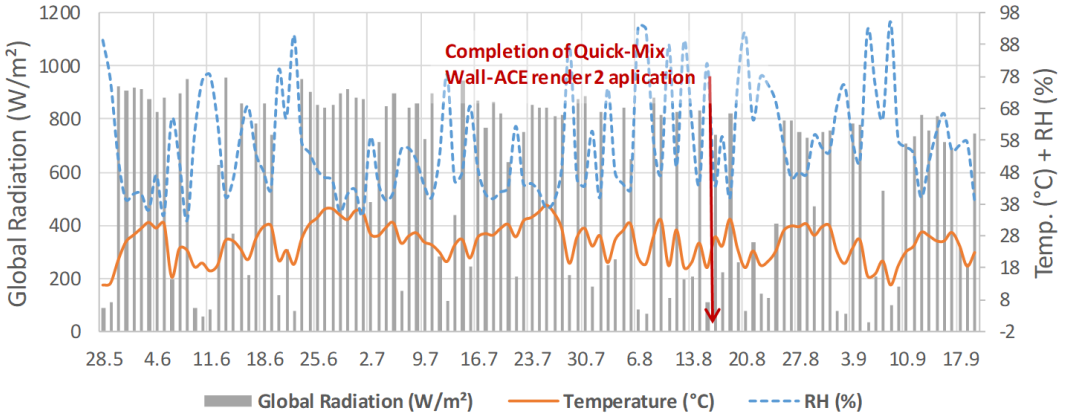

Figure 7. Environmental data at test side.

4 Conclusions

The large scale EOTA-Wall Test, originally developed for ETICS systems, is a valuable method to assess new developed insulation render systems. It provides a harsh environment and acts therefore as acceleration benchmark. Additional monitoring of certain parameters (moisture,

climate, heat flux) within the material helps to assess energy performance under such conditions. First experiences (Frick *et al.*, 2016) were further developed.

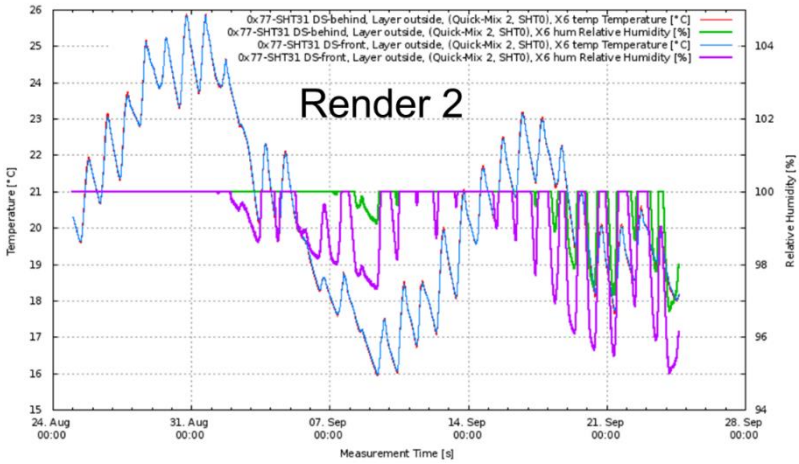

Figure 8. Temperature and relative humidity measured in the Quick-Mix render 2.

The field tests serve as benchmark in real conditions. The installation at the south side results in harsher conditions with higher temperature gradients. On the other side the estimation on energy performance parameters like U-values will be more difficult. Certain methodologies will be tested with the monitoring data from the upcoming winter season (Nocentini *et al.*, 2018).

Acknowledgements

The research project Wall-ACE has received funding from the EU Horizon 2020 research and innovation programme under the Grant Agreement No. 723574. The authors wish to thank the project partner AGITEC that installed the different aerogel materials and made available the building for the field tests, and Quick-mix that provided/installed the developed material in the experimental chamber.

Abstract. *Bio-based materials are gaining importance in the building industry, as the focus on sustainability and life-cycle-assessment has increased substantially over the last decade. Wood and wood-engineered products as well as insulation materials made from cellulose, wood, flax, hemp, etc. are increasingly used. These materials are made from renewable resources and with considerably lower energy consumption than various other building materials, such as insulation polymers, steel and concrete. As steel can corrode and concrete can rot, so can bio-based building materials degrade over time when exposed to those conditions that favour decay. Since fungi cause not only aesthetical degradation, but can also severely compromise the structural integrity of a building component this is critical for any service life approach. Consequently, a proper understanding of the fungal susceptibility of bio-based materials is needed, both for optimal application of bio-based materials as for the design of new materials. Based on a combination of tests we try to unravel the role of the material's chemical components, structure and moisture dynamics on its fungal susceptibility, as well as the interaction between those material characteristics. In a first test set-up, the 'paste test', the material's structure is removed and fungal growth is assessed over time in 2D, with only the material's chemical components playing a role. In the second test set-up, the 'X-ray CT test', fungal development is assessed non-destructively in 3D with X-ray CT, giving an indication of moisture production and distribution over time, in relation to the material's structure. By comparing the results, we have a better idea of how much each material characteristic influences fungal susceptibility. This knowledge can then be used for optimising fungal testing of bio-based materials, ensuring optimal application and providing the building industry with the confidence they need to pave the way to a more sustainable future.*

Keywords: *Bio-Based Building Materials, Material Characteristics, Fungal Degradation, X-Ray CT.*

1 Introduction

The construction sector has a considerable impact on the environment as it consumes large quantities of energy, water and raw materials (Melchert, 2007). In Europe, around 65% of all aggregates (sand, gravel and crushed rock) and approximately 20% of all metals are used in this sector (Herczeg *et al.*, 2014). There is, however, a clear trend towards sustainable building projects, both in the residential and industrial construction sector (Jones and Brischke, 2017). Bio-based materials, *in casu* wood, wood-engineered products and insulation materials made from cellulose, wood, flax, hemp, etc. are key in the sustainable building context. These materials originate from renewable resources and hence have several advantages. They constitute a significant carbon sink when managed sustainably and are produced by consuming considerable less energy than aluminium, steel and concrete (Sathre and O'Connor, 2008; Jones

and Brischke, 2017). As they are often biodegradable, they are easy to process at the end of their service life (Ganotopoulou, 2014). The latter characteristic is, however, most unwanted while in service. When an organic material is exposed to favourable moisture and temperature conditions as well as to degrading organisms, its functional and aesthetic service life can decrease. Fungi can also cause structural damage and lead to degradation of building materials (Bertron, 2014; Dedesko and Siegel, 2015). It is, for example, well known that most wood products used in outdoor environments must be protected against deterioration by decay fungi (Goodell *et al.*, 2003).

It is widely agreed that the proliferation and growth of fungi on building materials are controlled by the presence of nutrients and sufficiently available water. Moisture problems in buildings can for instance occur when building materials get moist during the construction phase, due to infiltration of rain water or because of condensation (Adan and Samson, 2011). When the environment provides a high relative humidity, porous materials can become sources of water for microorganisms (Hoang et al, 2010; Verdier *et al.*, 2014). Next to spatial structure and the closely related moisture dynamics (Verdier *et al.*, 2014), the chemical composition of a material plays an important role in fungal susceptibility as well. For example, there are several wood species of which the heartwood contains natural fungicidal extractives (Jebrane, 2014; Goodell, 2003). Other less durable materials are either modified or treated with protection products to increase their durability. For instance, solid wood and fibre products are subjected to heat treatment, hydrophobation with oils or resins and chemical modification such as acetylation and furfurylation to increase durability (Homan and Jorissen, 2004).

There is little detailed data available on the fungal susceptibility of bio-based materials, except for solid wood (CEN EN 350: 2016). The most widely used laboratory method for determining the natural durability of solid wood against wood-destroying fungi is the CEN TS 15083-1 test method (CEN TS 15083-1: 2015). Resistance of preservative-treated wood against basidiomycetes is assessed according to the standard EN 113 (CEN EN 113: 1996). Both tests subject wood samples (5 x 2.5 x 1.5 cm^3) for 16 weeks to pure cultures of white rot and brown rot fungi selected for their strong ability to degrade wood (CEN TS 15083-1: 2015). The samples are weighed before and after exposure to the test fungus and the amount of mass loss due to degradation is calculated. These standards for the assessment of the efficacy of wood preservatives and of the inherent resistance of wood species are generally regarded to be sufficient and adequate (Kutnik, 2013). However, these standards are typically inadequate for the qualification of new wood products, whose durability is not enhanced with biocides but by new technologies, such as chemically modified wood (acetylation, furfurylation, etc.), thermally treated wood, glue-laminated wood, wood-based panels and wood treated with water repellents (Candelier *et al.*, 2016; Jones and Brischke, 2017; Kutnik *et al.*, 2014; Ringman *et al.*, 2014; Ormondroyd *et al.*, 2015). For example, laboratory tests are performed using conditions optimal for the test fungus. A growth medium is used and serves two purposes: one being nutritional support for the fungus, the other to maintain a high enough moisture content for fungal activity. If the wood does not reach the required moisture content, the test may be declared invalid according to the strict interpretation of the standard (CEN EN 113: 1996, CEN TS 15083-1: 2015). However, thermal and chemical modifications change the wood-water interactions in such a way that the resulting equilibrium moisture content (EMC) of modified woods is lower than the equivalent non-modified wood (Candelier *et al.*, 2016; Mai *et al.*, 2010; Ormondroyd *et al.*, 2015; Ringman *et al.*, 2014). The modified wood samples might not moisten

fast enough during the 16 weeks testing period for the fungus to reach significant degradation. It does not mean, however, that these materials cannot eventually become wet enough for degradation. Kamden *et al.* (2002), confirmed that after a period of six weeks exposure, the modified wood samples did become wet and noted moisture contents varying between 72% and 156%. We therefore need to contemplate whether the set-up of the standard needs to be adapted, for instance by prolonging the test duration or increasing the initial moisture content of the modified wood, or whether fungal degradation of modified wood needs to be observed under the same humidity conditions as for the non-modified wood (Ormondroyd *et al.*,2015). This example illustrates the importance of understanding certain material characteristics and their influence on fungal resistance as well as the test methodology, in order to properly interpret experimental data derived from standard tests. Consequently, further research is needed on the intricate material-fungal relationship to gain the necessary insights for adequate adaptation of the standard tests, both for optimal application of bio-based materials as for the design of new materials. This is especially pressing given the lack of experience with these new materials compared to the traditional building practice.

In this paper, we propose two tests to unravel the role of the material's chemical components, structure and moisture dynamics on its fungal susceptibility, as well as the interaction between those material characteristics. In a first test set-up, the 'paste test', the material structure is removed and fungal growth is assessed over time in 2D, with only the material's chemical components playing a role. In the second test set-up, the 'X-ray CT test', fungal development is assessed non-destructively in 3D with X-ray CT, giving an indication of moisture production and distribution over time, in relation to the material's structure. By comparing the results, we have a better idea of how much each material characteristic influences the fungal susceptibility.

2 Assessing the Role of Material Chemistry on Fungal Susceptibility

In the paste test, a bio-based material is grinded to a fine powder with a particle size smaller than 0.1 mm, thus eliminating the influence of the material's structure on fungal growth. By mixing the powder with agar and water, we ensure that the powder is water saturated, thereby also limiting the influence of hydrophobic components. The resulting paste is inoculated with a wood degrading fungus and mycelial growth is assessed over time with a flatbed scanner. The paste test thus gives an indication of how the overall chemistry, consisting of the nutritional value and the presence of toxic components, influences the fungal susceptibility of a bio-based material.

Figure 1 shows the mycelial development of *Coniophora puteana,* a common wood-rotting basidiomycete, on four bio-based materials. A material with a low natural durability, such as untreated beech wood, does not inhibit mycelial growth (Fig. 1 a). In contrast, a wood species containing toxic components typically limits fungal growth, as is the case for the heartwood of European cherry (Fig. 1 b). The paste test provides additional insights when combined with other tests, for instance assessing the degradation of the material with the structure still intact or of the material with its toxic components removed. In that way, we can find out the influence of the chemistry, and to what extent the durability is due to the material's density or hygroscopic properties. An interesting example is thermally modified wood and derived products, which have been chemically changed because of the wood being heated at high temperatures (Homan

and Jorissen, 2004). Thermal modification reduces the amount of hydroxyl groups in the wood cellulose and hemicellulose (Mazela *et al.*, 2004). The wood-water interactions of thermally modified wood therefore change in such a way that the resulting EMC is lower than that of the equivalent non-modified wood (Candelier *et al.*, 2016; Mai *et al.*, 2010; Ormondroyd *et al.*, 2015; Ringman *et al.*, 2014). Mazela *et al.* (2004) determined the fungal resistance of blocks of Scots pine sapwood (*Pinus sylvestris* L.) subjected to different thermal and hydrothermal treatments. They found that wood blocks exposed to thermal treatments of 190°C and 220°C were resistant to the test fungi. They hypothesized that besides the thermal effects on wood hygroscopicity, thermal treatment also generates toxins that could affect fungal growth. With the paste test, we can easily verify whether the amount of toxins that are possibly formed, such as furfural or trace quantities of lignin phenol derivates (Mazela *et al.*, 2004), are sufficiently present to inhibit or slow down fungal growth. Figure 1 shows an example of the paste test performed on non-modified (c) and thermally modified (d) three-layer-plywood of spruce. In this case, we can state that the applied modification process did not generate meaningful amounts of toxins, as the mycelial development is not inhibited. The fungal resistance of this particular product therefore stems from its acquired hygroscopic properties.

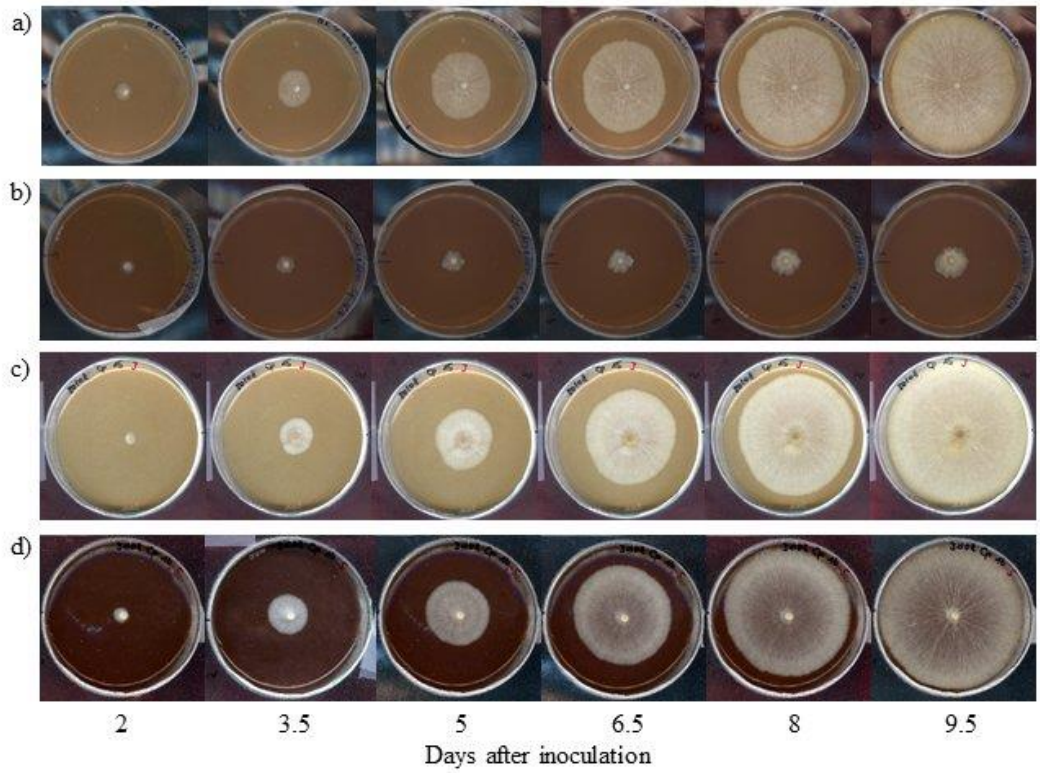

Figure 1. *C. puteana* growing on a paste of a) beech heartwood b) heartwood of European cherry c) three-layer-plywood of spruce and d) thermally modified three-layer-plywood of spruce.

3 Assessing the Role of the Material's Structure and Moisture Dynamics on Fungal Susceptibility

Degradation of (treated) solid wood is usually assessed by measuring the mass loss caused by decay fungi after sixteen weeks (CEN EN 113: 1996, CEN TS 15083-1: 2015). This is an excellent method for testing the durability of a certain wood species or the efficacy of a preservation product, but does not offer much information on what is going on inside the wood structure during degradation. To gain more insight into how the material's structure and moisture properties affect the degradation process, we propose X-ray CT to provide additional information. X-ray CT scanning is a technology that uses X-ray projections to produce tomographic images (slices) of specific areas of a scanned object, allowing the user to inspect the inside of the scanned object in a non-destructive way (Li, 2016). Due to the different attenuation coefficients between material and air, X-ray CT scanning can reveal the internal spatial structure and density distribution of a material (Bergsten *et al.*, 2001; Chen *et al.*, 2010; Freyburger *et al.*, 2009). It therefore enables us to obtain localized information inside wood during degradation, without disrupting the degradation process. The set-up we designed is able to automatically scan a stack of Petri dishes, one after the other, allowing extensive testing of the degradation process (Fig. 2).

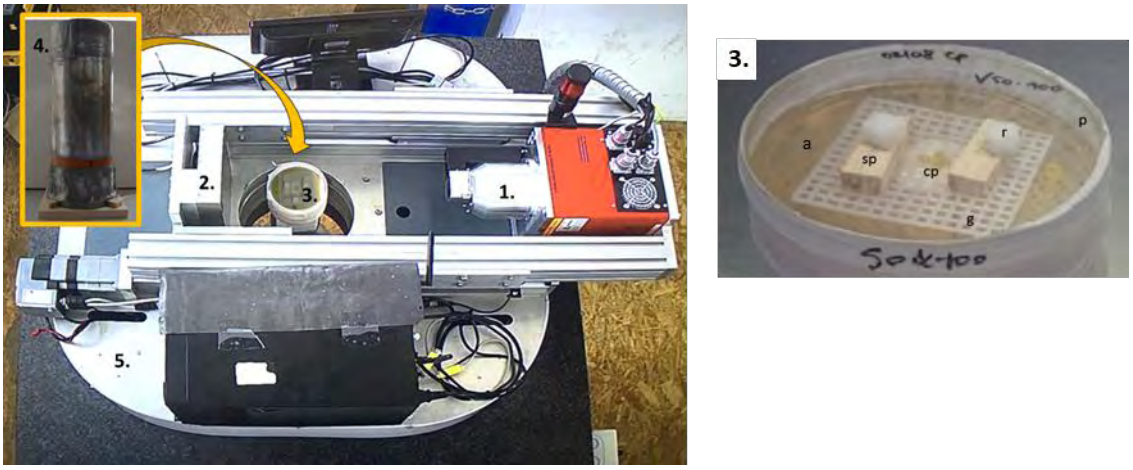

Figure 2: X-ray CT set-up. 1) X-ray source 2) Detector 3) Stack of Petri dishes 4) PVC tube with lead cladding 5) Rotation table. a= agar medium, cp= *C. puteana,* p = Petri dish, g = plastic grid, r = reference material, sp = Scots pine

A first test was performed on mini-blocks of Scots pine sapwood under degradation by *C. puteana*, scanned at weekly intervals with X-ray micro CT (De Ligne *et al.*, 2019). We were able to assess the weekly change in density for each wood block. The results are not straightforward to interpret as a consequence of confounding effects, as several factors affect the assessed density: moisture uptake from the agar medium and moisture production by the fungus increase the average density profile, while water evaporation and mass loss due to degradation decrease it. However, we were able to link increasing density to increasing moisture content, which in turn is linked to increasing fungal activity, as fungi metabolise sugars into carbon dioxide and water (Schmidt, 2006). To assess how the material's structure and density influence the fungal degradation process, we are currently performing a test on

mini-blocks (0.5 x 1 x 3 cm³) of four wood species with differing densities: beech (*Fagus sylvatica* L.) (a), gaboon (*Aucoumea klaineana* Pierre) (b), Scots pine sapwood (*Pinus sylvestris* L.) (c) and Norway spruce (*Picea abies* (L.) Karst) (d). Figure 3 gives a snapshot of the degradation process over time. Darker pixels indicate regions with low density, such as air. White pixels show regions with high density. The white stripes in beech (a), Scots pine sapwood (c) and spruce (d) indicate the latewood zones of the growth rings, which are denser than the earlywood. At the start of the experiment (week 0), no degradation had taken place. White blotches start appearing as degradation progresses over time. These regions with high density are an indication of liquid water production by the fungus, and demonstrate an increasing fungal activity. For Scots pine (c) and spruce (d), degradation is clearly starting from the sides of the mini-blocks (week 1) and progressing towards the center of the mini-blocks (week 4 to 8). This is to be expected, since the mini-blocks were cut in such a way that the transverse plane is one the side, providing ample tracheid openings through which hyphae and water can enter the wood.

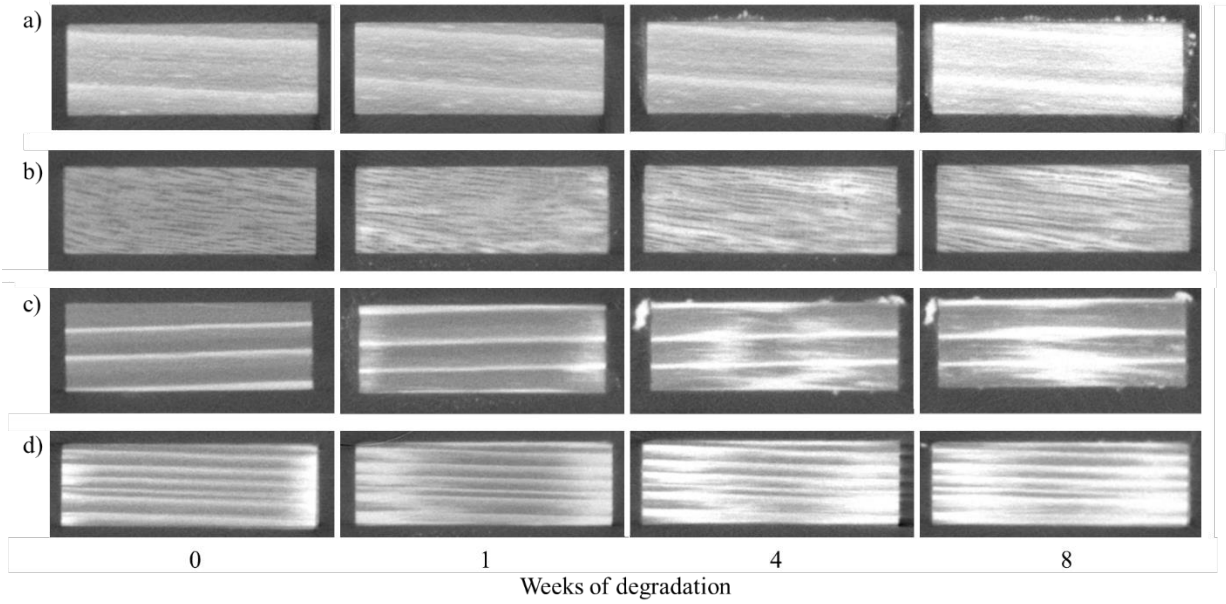

Figure 3. CT slices showing the fungal degradation of beech (*Fagus sylvatica* L.) (a), gaboon (*Aucoumea klaineana* Pierre) (b), Scots pine sapwood (*Pinus sylvestris* L.) (c) and Norway spruce (*Picea abies* (L.) Karst) (d) mini-blocks over time by *C. puteana.* The whiter the pixels, the higher the density.

4 Conclusions and Future Perspectives

- In the paste test, the influence of the material's structure and hygroscopic components on fungal growth is eliminated. It thus provides insight into the role of only the material chemistry on the overall fungal susceptibility of a material. It is currently being applied to a wide range of bio-based materials and will provide useful insights, especially in combination with other test methods.
- The X-ray CT test is useful to gain insight into the influence of material's structure and moisture dynamics on its fungal susceptibility. It allows us to gather localized

information on fungal activity during the entire degradation process, without disrupting it.

Abstract. *New technical solutions are introduced at a fast pace in the Swedish construction industry, mainly driven by issues concerning costs and productivity. These new technical solutions can comprise new materials, new goods, new designs but also new processes. The record of accomplishment when introducing new technical solutions in the industry is not unproblematic and serial failures of different new technical solution have occurred. In an earlier interview study exploring introduction of new technical solutions in the Swedish construction industry, a common lack of thorough methods for evaluation of new solutions was identified. To address this issue, a case study was performed, exploring a method of evaluation with respect to building physics while implementing a cross laminated timber frame in a multifamily building. The case study uses a framework of assessment with focus on building physics. This paper presents the findings from the case study focusing on how evaluation of a new technical solution with respect to building physics is performed, together with an evaluation of the method, using the experiences of the participants in the case study.*

Keywords: *Serial Failure, Hygrothermal Performance, New Technical Solutions, Risk Assessment.*

1 Introduction

Introducing new technical solutions in the construction industry is a challenge. Examples exist in the Swedish construction industry of both too slow adaptation of new technical solutions, i.e. loss of competitiveness or not reducing emissions of greenhouse gases, and too fast adaptation, i.e. poor quality and failure as the functional requirements are not sustained. Building physics failures, mainly moisture related, have been reported as a significant contributor to poor quality and related costs in the Swedish construction industry (Boverket, 2018). To systematically address the specific problems related to introduction of new technical solutions, the term *Serial failures* has been introduced defined as "Multiple cases of failure where a specific technical solution fails to sustain the functional requirement due to reasons in the design or production phases that could have been predicted by calculations or other assessment in the design stage." (Svensson Tengberg and Hagentoft, 2019)

In an interview study exploring introduction of new technical solutions in the Swedish construction industry, a common lack of (use of) thorough methods for evaluation of new solutions was identified (Svensson Tengberg and Hagentoft, 2019). It was also noted new technical solutions are usually introduced and evaluated at construction project level, with the supplier as a strong actor, providing the solution as well as related documentation.

Risk can be defined as the effect of uncertainty on objectives. Risk can be described by risk sources and potential events as well as consequences and likelihood (ISO 31000:2018, 2018).

Risk management in the construction industry typically focuses on risks in the specific construction project. Although risk management in the construction industry complies with relevant standards (ISO 31000:2018, 2018) (ISO Guide 73:2009, 2009) (Project Management Institute, 2017), there is a lack of guidelines and systematic approach for selecting appropriate risk identification techniques according to (Siraj and Robinson Fayek, 2019). In a construction project there is a wide array of risks handled, *e.g.* risks related to management, commercial or technical issues. Specifically to address risks related to building physics/moisture performance, there is an Industry Standard, ByggaF (Mjörnell, Arfvidsson and Sikander, 2012), suggesting a common risk identification in the design stage where all actors in the design group should conduct a moisture risk analysis based on a checklist for each building part as a starting point. The checklist starts from applying relevant moisture sources to the designs and assess the (unwanted) effects on the design. A more elaborate framework for testing, evaluating and documenting variations in performance of building envelopes was suggested in a research project focusing on reliability through probability assessment of performance and cost (Bednar and Hagentoft, 2015) and (Sasic Kalagasidis and Rode , 2015), see Figure 1.

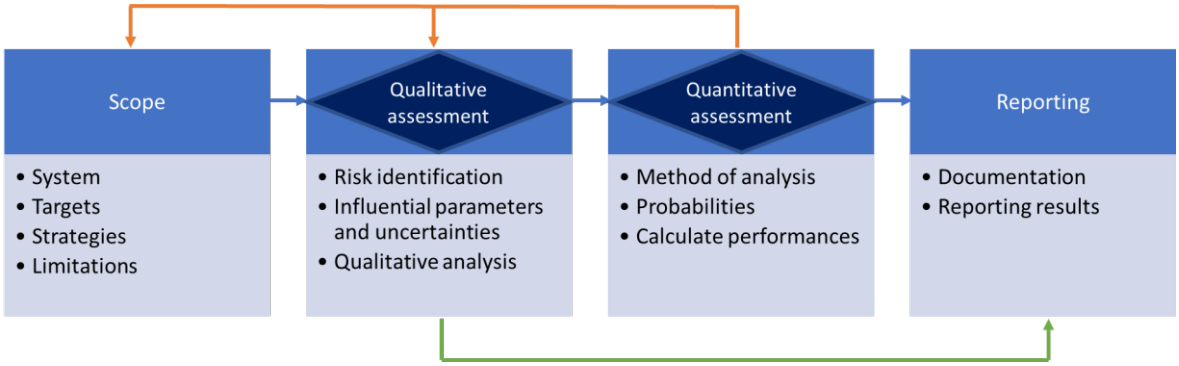

Figure 1. Work Flow adapted from Annex 55 (Bednar and Hagentoft, 2015).

This framework suggests involving a team of experts, not exclusively the project team, to perform the risk assessment and to perform the assessment methodically and transparently i.e. well documented. In (Pallin, 2013) it is suggested to perform the risk identification using common tools, *e.g.* ETA, FTA or VMEA. However, although there are suggestions of the format of the workshop and possible risk identification tool this is not further defined.

The objective of this paper is twofold, firstly to investigate the potential of the framework for qualitative assessment in a case study and secondly to collect data on risks associated to the case study. This paper is a part of a research project initiated with the aim of reducing risk of serial failure related to building physics when introducing new technical solutions in the construction industry.

2 A Case Study

To investigate the potential of the framework for qualitative assessment, a case study was designed. The case chosen for investigating the framework was *Fulfilment of functional requirements related to building physics using a technical solution of cross-laminated timber in a multi-dwelling building*. Cross-laminated timber was chosen as it is a relatively new technical solution, based on a material, wood, that historically has been associated with moisture issues. (Svenskt Trä, 2017) (Olsson, 2019). The outline of the work was performed

according to the first two parts of the framework in **Figure *1***: The scope and the Qualitative risk assessment including an expert workshop. :

- **Defining the scope.** The scope is described by *The system*, *The targets*, *The strategies* as well as *The limitations*. As the case study is not a retrofit, the existing conditions are not relevant and therefore omitted. This material was prepared before the workshop.
- **Qualitative assessment, Risk identification. Preparing the expert workshop.** To prepare for the expert workshop, a three-hour pre-workshop was performed with six participants representing the competences project management, designing engineer, moisture expert, and building physics. The objective of the pre-workshop was to try out the format and classifications before preparing material to the final workshop. The agenda was divided into Introduction, Theory and objectives, followed by Risk identification firstly on a general level and then in more detail, while discussing likelihood and consequences. As a result, a preparation material for the expert workshop was compiled and distributed.
- **Qualitative assessment, Risk identification. Expert workshop.** An expert workshop constituted the core of the qualitative risk assessment, as suggested in the framework. A four-hour expert workshop was designed , with the scope to identify and assess risks related to building physics for the technical solution. More specific, the focus was on “Not to exceed the critical moisture condition in the CLT structure” during production or operation of the building. The workshop started with a presentation of the participants, introduction to the background including an overview on risk management and objectives of the workshop. The risk assessment was divided into two sub workshops: risk identification (risk sources and potential events) and risk analysis (focus on uncertainties) respectively. The two parts were summarised at the end of the day. The participants were selected to represent key actors with different perspectives of the building process, Table 1. As researchers, the two authors took the part of workshop leaders.

Table 1. Workshop participants.

Profession	Gender	Profession	Gender
Project manager	M	Supplier, CLT	M
Design manager	F	Supplier, CLT	M
Construction manager	M	Supplier, CLT	M
Architect	F	Estimator	M
Designing engineer	M	Academia	M
Designing engineer	M	Academia	F
Building physics	M		

- **Evaluating the framework.** After the workshop, notes from the workshop were sent out to the participants together with a questionnaire with a few questions concerning their experience of the workshop, including the preparations, the different sections of the workshop and new insights.

3 Results and Discussion

3.1 Defining the Scope

One of the results was the scope definition according to the framework. It was summarised before the workshop and presented to the participants.

System. The system is defined as a five-storey multi-dwelling building with 18 apartments in a point block, using a cross-laminated timber structure situated in the metropolitan area of Stockholm. The building was chosen to be representative in size and type for a new Swedish multi-dwelling building. Point blocks represents more than a third of new built multi-dwelling buildings and four to six storeys are most common (SCB, 2019).

Targets. The target of the case study was defined as fulfilment of the building physics requirements described as "Not to exceed critical moisture condition in the CLT structure", addressing both construction phase and operation of the building. Other functional requirements according to building regulations (Boverket, 2018) should also be met.

Strategies. The anticipated design of the building is a cross laminated timber structure, including a timber structure in exterior walls and intermediate floors as well as balconies. The roof is assumed to be a timber frame construction. Energy performance of the building is assumed to be according to Swedish Building Regulations with U-values for walls, roof and windows in the range of 0.14/0.13/0.8 W/m^2/K respectively (average U-value of 0.34 W/m^2/K). A wooden façade is chosen. The building is heated to 22°C. The building is heated by district heating and an exhaust air heat pump. Air tightness of the building is expected to be 0.3 l/s/m^2 at 50 Pa.

Limitations. The assessment is made on basis of the prerequisites above. If changes are made, an update of the assessment should be performed.

3.2 Risk Identification During Expert Workshop

One of the results from the workshop was the thorough risk identification concerning building physics. At the workshop, the main risk categories as compiled from the hand-ins were presented and the participants were asked to supplement and adjust the risk list. In a summary of the risk identification, the participants were asked to vote on top-5 risks of interest. The issue that was given far most relevance was moisture during the construction phase, specifically

Precipitation during construction. Other risks of high relevance were noted: *Hygrothermal performance of external wall (including façade)*, *Window connections*, *Balconies* and *Walls with membranes on both sides*. It can also be noted, *Water leakage from pipes* was lifted as the effects were considered highly unknown. The results from the risk identification and the voting are shown in Table 2.

Table 2. Risk identification "To exceed critical moisture conditions in the CLT structure". Phase and location in the building are used as categories. Constr= Construction phase, Op= Operation phase.

Phase/location	General description	Votes
Constr/General	Precipitation during construction	18
Constr/General	Material moist/damaged by other materials/construction at site	4
Constr/General	Material moist/damaged before construction	1
Constr/General	Inferior air and moisture tightness between elements	8
Op/Wall	Hygrothermal performance of external wall design (incl. facade)	6
Op/Roof	Hygrothermal performance of external roof design	n.a.*
Op/Details	Bushings in wall	1
Op/Details	Connection wall/base	1
Op/Details	Connection wall/window	4
Op/Details	Balconies and connection wall/balcony	5
Op/Details	Connection wall/roof	0
Op/Details	Bushings in roof	n.a.*
Op/Details	Fastenings in roof	n.a.*
Op/Wet room	Walls with membranes on two sides	3
Op/Wet room	Bushings in wet room walls	0
Op/Wet room	Fastenings in wet room walls	0
Op/Wet room	Indoor climate exceeds critical conditions	0
Op/HVAC	Condensation at pipes	0
Op/HVAC	Leakage through deformations	0
Op/HVAC	Unknows effects of water leakage	1

* The roof in the case study is assumed to be a timber frame construction, not a CLT construction.

3.3 Risk Assessment During Expert Workshop: Precipitation During Production

Another result from the workshop was the risk assessment of a selected risk: *Precipitation during the production phase*. This risk was chosen as the participants identified it by far the most relevant risk. For the assessment, the participants were asked to identify relevant influential parameters and related available data/documentation as well as different types of uncertainties. The identified influencing parameters referred to *Design and material*, *Loads*, *Production methods* or to *Organisational issues* and were compiled in a table together with relevant influential parameters, uncertainties and correlations. An illustrated summary of the table with influencing parameters and a suggestion of which type of uncertainty associated with them is shown in Figure 2. Similar tables and illustrations were also developed for the other top-3 risks: *Hygrothermal performance of exterior wall* and *Balconies.* However, these are not presented in this paper.

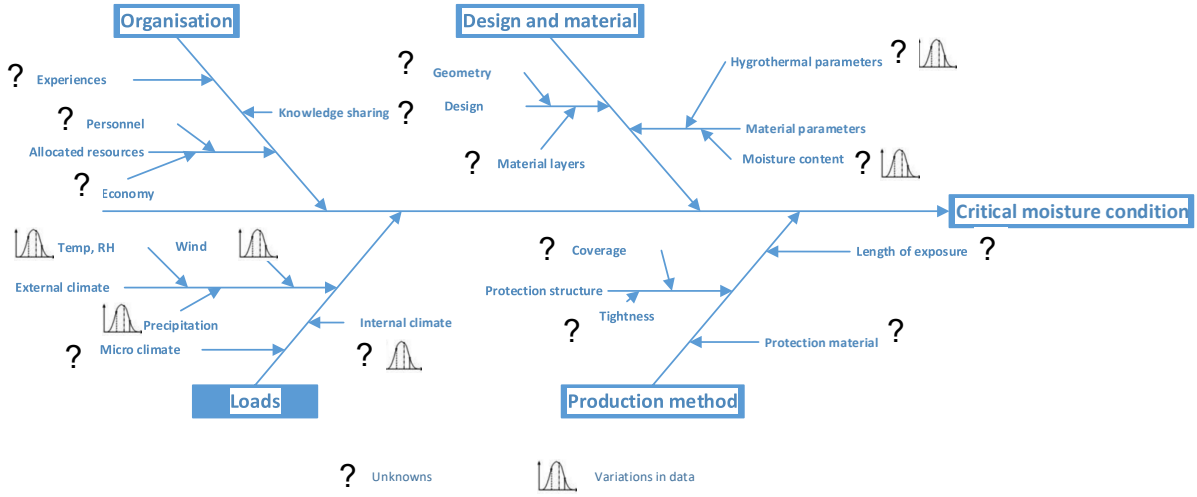

Figure 2. Precipitation during the production phase: Ishikawa graph showing identified influencing parameters for the risk of exceeding the critical moisture conditions. Also, anticipated type of uncertainties, unknowns and variations in data, are noted.

3.4 Risk Assessment During Expert Workshop: Important Uncertainties/Unknowns

The third result of the workshop is the identification of important uncertainties/unknowns for the case. After the top-3 risks with relevant influential parameters, uncertainties and correlations had been presented, the uncertainties perceived to have the most importance were identified by the participants:

- Unknown hygrothermal behaviour of wall (lack of data/variations)
- Unknown performance of material (lack of data/variations)
- Unknown moisture exposure and loads during construction (lack of data/variations)
- Unknown effects of water leakage during construction phase (lack of data/variations)
- Compliance to design and moisture routines (lack of data)
- Knowledge in the organisation (lack of data)
- Responsibility of different actors (lack of data)

3.5 Workshop Experiences

In the pre-workshop, valuable reflections were made. The suggested agenda was slightly changed, as the introduction was extended to create common understanding. The grouping of risks was added as an activity and thus, the continued risk description was left with less time for estimation of likelihood and consequences of identified risks. Also, the participants perceived the ranking of likeliness and consequences as difficult. Another experience was that several issues were lifted by the participants, where the level of uncertainty was low, but solutions had impact on other objectives (primarily costs but also other functional requirements). The insights from the pre-workshop resulted in a more thorough preparation material including a hand-in of three to five risks. The material was distributed to the participants two weeks in advance. The objective of the preparation material was to reduce time spent on these issues at the workshop.

At the main workshop the participant expressed their expectations. More than half of the expectations were oriented towards possibilities and finding solutions in general or to find a solution for a specific issue, i.e. the issue of moisture during the construction phase: “Is there need for weather protection?”. Other expectations on the workshop were to know more about the uncertainties of the technical solution in general or to be able to quantify the costs related to risks. One of the participants expressed a wish to be able to “…follow the risks from design to production.” At the end of the workshop, the participants agreed on that many of the expectations were met and that the workshop had provided a greater understanding and awareness of risks in general, and of the three selected risks specifically.

Eight out of eleven answered the survey after the workshop. The answers indicate a strongly positive experience of the workshop. The participants valued the overall experience of the workshop as good or very good (3 and 5 respectively), and most participants indicated that the workshop gave a lot of new insights in the subject. There were different opinions on the length of different parts of the workshop, with a slight tendency to experiencing the risk assessment and the summary as too short. The preparation material was perceived as helpful or very helpful, but a few of the participants had not had the time to use it.

4 Conclusions

The general perception of the workshop format was positive, and the expert workshop was perceived to give a lot of new insights to the participants.

Setting up appropriate boundary conditions of the workshop is important. The scope of the initiated workshop was broad, aiming at identifying relevant issues for multi-dwelling buildings using a cross-laminated timber structure. A broad topic will give results on a “landscape level”, while a targeted topic will give more developed and detailed results. In our case, we only analysed part of the material at the workshop, leaving part of the material for later analysis. Preferably, the workshop is repeated on increasingly more detailed level throughout the process.

A well-prepared workshop with preparation material and hand-ins will help the process, starting from a more advanced level, spending less time on background or trivia.

Likeliness and consequences of different events are perceived difficult when introducing new technical solutions. This was handled at the workshop with focusing on establishing a thorough list of relevant uncertainties.

The different competences at the workshop were perceived as a prerequisite to enable a fruitful risk identification.

4.1 Future Work

Future work will take two main paths:

- Continued analysis of the case study. Analysis of the data collected will result in a thorough qualitative assessment and in a quantitative assessment in line with the qualitative assessment, with the aim to address and reduce risks in multi-dwelling buildings with CLT.
- Continue to the adaption of the framework to the scope of introducing new technical solutions in the Swedish construction industry, by continuing the case study of multi-dwelling buildings with CLT and possibly extend with other case studies.

Abstract. *The most commonly used wall coverings are still, undoubtedly, plasters and renders, whether lime-based or cement-based, whether traditional and prepared in-situ or pre-dosed. In accordance with the available standards, the characterization of these mortars is made on laboratory test specimens, with dimensions, curing conditions and test procedures according to the prescribed. However, when applying these mortars to the real substrates, their behaviour will not be the same. After application of the mortar to the substrate, an interface will be formed, and the interactions that occur after the contact of the mortar, still in the plastic state, with the substrate will change over time due to the hydration kinetics and absorption of the substrate. It is very important to know the real behaviour of mortars after application, in order to ensure their durability. A research project is being developed to analyse the proper behaviour of mortars after application to the substrates. In order to characterize a mortar after application to a substrate, it is necessary to detach it. The introduction of a fiberglass grid in the mortar-substrate interface makes the detachment easier. The purpose of this study is to determine if the placement of this grid will influence the characteristics of the applied mortar. For this, an experimental campaign was carried out, comparing the characteristics of two mortar formulations, applied to different types of substrate (without introduction of the fiberglass grid), with the characteristics of these mortars applied to the same substrates, but with the introduction of a fiberglass grid at the interface mortar-substrate. In this paper, we present the results obtained for some of the physical and mechanical characteristics of cement and hydraulic lime mortars.*

Keywords: *Mortars, Substrates, Interface, Durability, Fiberglass Grid.*

1 Introduction

Mortar based coverings are widely used in all types of constructions, whether new or old, in need of rehabilitation or requalification. When we talk about exterior coverings, we are talking about the outermost layer of protection of these constructions, i.e. the layer that will contribute most strongly to their durability. There is an increasing variety of available solutions, and it is very important to ensure the quality of the applied mortars, since they must contribute to the habitability, comfort and durability of buildings. In recent years, much research has been conducted to increase knowledge on the behaviour of different types of mortars and to develop new formulations incorporating new products, so that one can always make the best choices, regarding the type of mortar to be used, its composition and characteristics.

The choice of the mortar that is best suited to the real situation is based on its various properties, which are determined in laboratory, following all applicable standards, particularly with respect to the dimensions of the test specimens, curing conditions and test methodology.

After the mortar has been selected, it is applied to the real substrate — and there are various

types of substrates, such as hollow brick, solid brick, pre-cast concrete, concrete blocks, natural stone, among others. It is known that inter-layer adhesion is one of the key performance indicators of multi-layer systems. The behaviour of mortars depends on the adhesion between the substrate and the mortar itself. This is one of the characteristics that will influence the properties and behaviour of the mortar (Moropoulou *et al*., 2000).

When applying a mortar to a real substrate, which will always have some porosity — unlike the laboratory moulds where the specimens that are used to characterize mortars are made, which have virtually no porosity —, an interaction will occur between the two surfaces. The contact between these two elements occurs with the mortar still in the plastic state. When this contact occurs, part of the mixing water, containing dissolved components of the binder, is absorbed by the substrate and penetrates its pores and/or discontinuities. Inside the pores of the substrate, hydration phenomena of cement/lime occur. After this penetration into the substrate and during the subsequent mortar hardening phases, the mortar is subjected to real climatic conditions, which may be quite different from the curing conditions recommended by the mortar characterization standards.

From the foregoing, it can be concluded that the same mortar moulded into specimens and hardened in the laboratory, under standard curing conditions, when applied to real substrates subjected to real climatic conditions, will not acquire equal characteristics. Thus, in order to choose a mortar more rigorously, it is very important to predict the behaviour of the mortar after application to the substrate.

With the objective of being able to estimate the characteristics of the mortars applied to a substrate, using the mortar characteristics determined in laboratory conditions, a research project funded is under development: IF MORTAR.

The aim is to compare, for the same mortar, the characteristics analysed in laboratory specimens with the characteristics determined after application to the substrates. For this, it is necessary to apply the mortars to the substrates and, after hardening, to detach and analyse them. To facilitate the detachment of these mortars, a fiberglass grid has been introduced between the mortar and the substrate. However, a question arises: will the introduction of the grid change the characteristics of the applied mortars? To answer this question, a preliminary experimental campaign was carried out, comparing the characteristics of the mortars applied to the substrates, with and without the application of the grid. Until now only two prescribe mortars were analysed, but the intention is to also analyse design mortars.

2 Experimental Campaign

2.1 Introduction

The experimental campaign developed aimed to analyse the behaviour of cement and hydraulic lime mortars applied to hollow ceramic brick substrates, in two different conditions: with and without the introduction of a fiberglass grid between the mortar and the substrate.

For this, a fiberglass grid was applied to half of the hollow brick substrates. Then, all the brick substrates were moistened and a 1.5 cm mortar layer was applied (Figure 1).

The following mortars were selected for the experimental campaign:

- Cement mortar, with a 1:4 cement to sand ratio, by volume;
- Hydraulic lime mortar, with a 1:3 lime to sand ratio, by volume.

Both mortars were formulated in the laboratory.

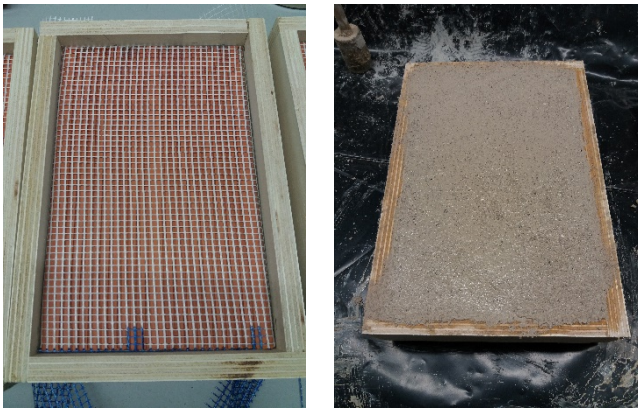

Figure 1. Application of the mortar to the substrate.

2.2 Specimens and Tests

The experimental campaign began with the execution of 40x40x160 mm3 prismatic specimens, for the determination of the bulk density, open porosity (NP EN 1936:2008), capillary water absorption (ISO 15148:2002) and compressive strength (EN 1015-11:1999), and cylindrical specimens (100 mm diameter and 15 mm thickness) for the determination of water vapour permeability (NP EN 1015-19:2008 and ISO 12572:2016) (Figure 2).

After the detachment of all mortars from the substrates, specimens of appropriate dimensions for the respective tests were cut. Given the thickness of the applied mortars (1.5 cm), it was not possible to obtain specimens with the exact dimensions indicated in the standards. Therefore, instead of 40x40x160 mm3 specimens, 40x40x15 mm3 specimens were used for the determination of bulk density, open porosity, capillary water absorption and compressive strength. For the determination of water vapour permeability, cylindrical specimens with 100 mm diameter and 15 mm thickness were used.

After the execution of the laboratory specimens and application of the mortar layer on the substrates, all specimens were subjected to the following standard curing conditions: 20ºC and 95% RH, for 7 days, and 20ºC and 65% RH, for another 21 days.

Figure 2. Test specimens.

The results of the tests carried out are presented and commented in the following section. Even though the main objective is to compare the behaviour of the mortars applied to the substrate, the results obtained for the mortars hardened in the laboratory moulds are also presented.

2.3 Presentation and Analysis of Results

2.3.1 Bulk density and open porosity

The determination of the bulk density by the geometric method, which translates the simple direct relationship between the dry mass of a specimen and its apparent volume (volume limited by the outer surface of the specimens, including all voids) and the determination of the open porosity, which represents the relationship between the open pores volume and the apparent volume of the specimen, was conducted according to the standard. Figures 3 and 4 show the medium values and standard deviation obtained for bulk density and open porosity, respectively, for the specimens hardened in the moulds and for the specimens hardened on the substrates (with and without grid). It can be seen that the open porosity of the mortars decreased and the bulk density increased, after application to the substrates, as was expected.

When comparing the results of the mortars applied with the grid with those of the mortars applied without grid, it can be seen that they are very similar, i.e. the presence of the grid does not affect the results obtained.

2.3.2 Capillary water absorption

The water absorption coefficient gives an indication of the water absorption capacity of a mortar when placed in contact with a water film. The results obtained for the water absorption coefficient, for all the mortars, are presented in Figure 5. Once again, it can be seen that the application of the mortars to the substrate changed this parameter, causing it to decrease. It is also possible to observe that the difference between the results corresponding to the two conditions of application (with and without grid) is small.

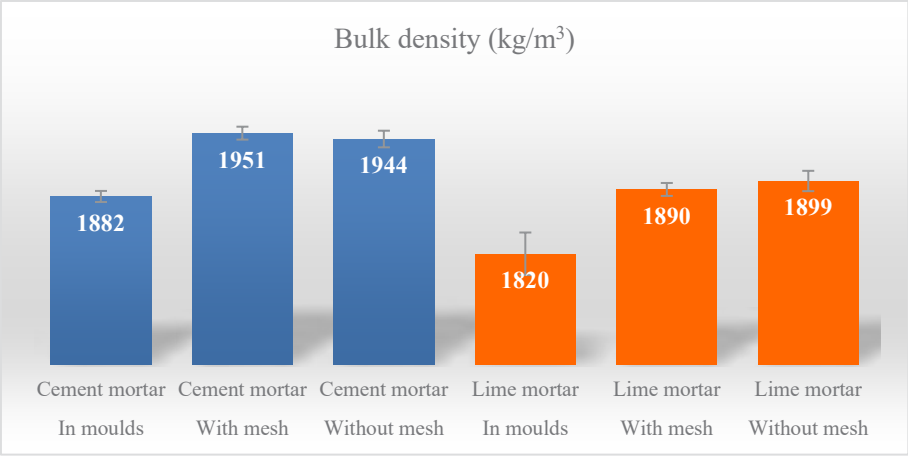

Figure 3. Bulk density.

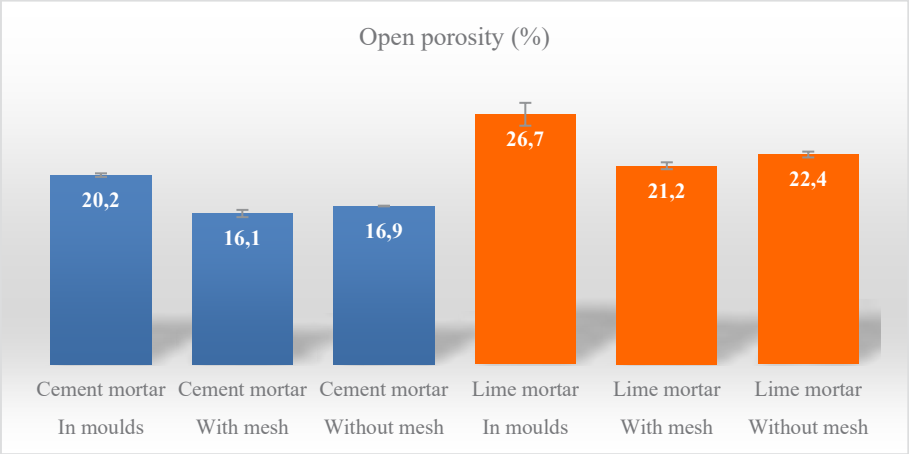

Figure 4. Open porosity.

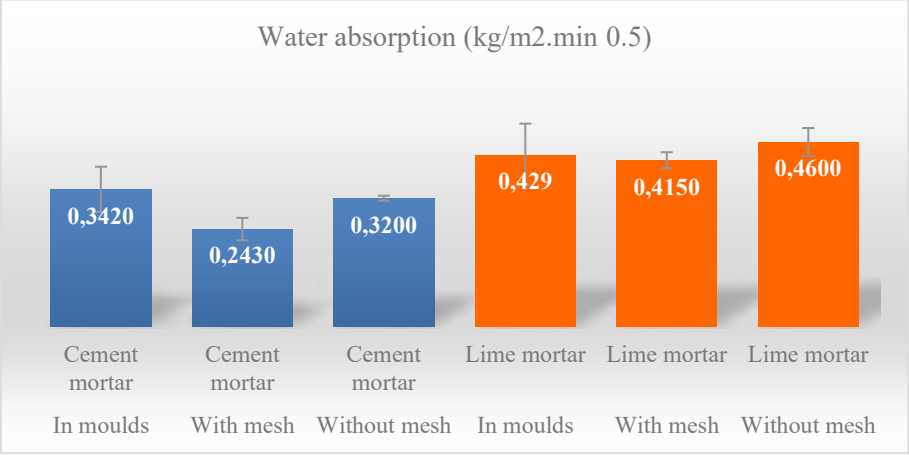

Figure 5. Water absorption coefficient.

2.3.3 Water vapour permeability

The water vapour permeability coefficient, which reflects the ability of a material to be traversed by water vapour, was determined using the wet cup method.

Figure 6 shows the water vapour permeability coefficient results obtained for all the mortars.

The application of the cement mortar to the substrate led to a decrease in its water vapour permeability, while the application of the hydraulic lime mortar led to an increase of this parameter. In the case of the cement mortar applied to the substrate without grid, it was not possible to detach specimens for this test due to the high cohesion of the mortar to the substrate. For the hydraulic lime mortar, it was verified, once again, that the difference between the results of the detached specimens with and without grid were not significant.

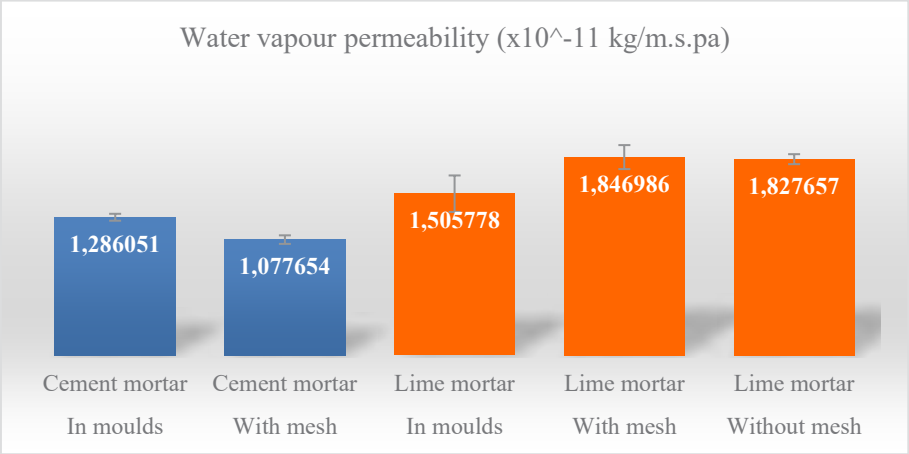

Figure 6. Water vapour permeability.

2.3.4 Compressive strength

As it is not possible to cut specimens of sufficient size for the flexural test from the mortar layer applied to the substrates, only the results obtained for the compressive strength are presented here. The compressive strength is obtained by applying a compressive force (until failure) centred on the application area of 40x40 mm^2.

The compressive strength was determined on specimens measuring 40x40x15 mm^3, both for the mortars hardened in the laboratory moulds and for the mortars applied to the substrates. Figure 7 presents the results obtained. It can be seen that the application to the substrates increased this property and that the introduction of the grid does not have great influence on the results.

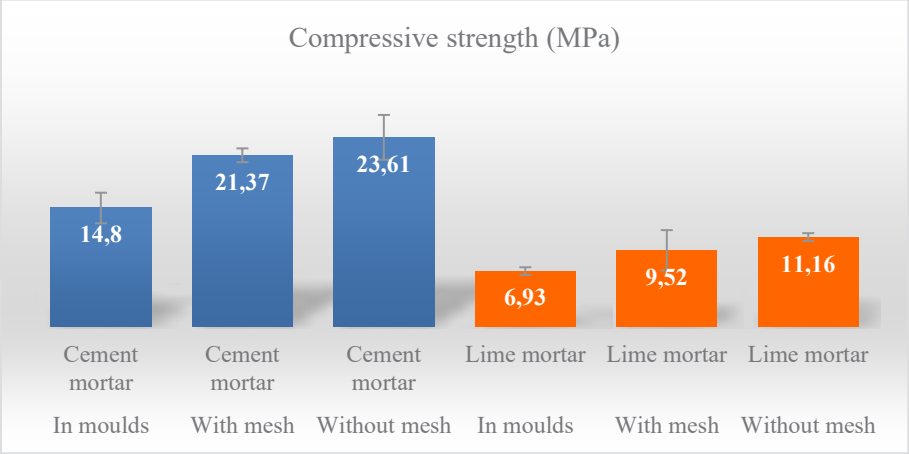

Figure 7. Compressive strength.

3 Conclusions

In order to choose a mortar in a more sustained way, regardless of its intended purpose, it is essential to know its behaviour, *i.e.* to know all its properties. These properties are determined

on mortars hardened in moulds, in the laboratory, in accordance with the applicable standards.

The mortar in service, i.e. after application to the substrate, will acquire different properties from those determined in the laboratory, because the application conditions, interface characteristics, curing conditions, etc., are different from those considered in the laboratory.

To have knowledge of the in-service characteristics of mortars, it is necessary to apply them to the substrates, wait for them to harden, detach them from the substrates and, finally, analyse them.

Mortars are applied to the substrate in the plastic state and, when hardened, will adhere to it. The greater their adherence to the substrate, the more difficult their detachment will be. To facilitate this detachment, a grid can be introduced between the substrate and the mortar, but it is important to know whether this grid will affect the final properties of the mortar. The main objective of this work was thus to analyse the influence of the presence of a fiberglass grid, placed between the mortar and the substrate, on the properties of the applied mortars.

The experimental campaign conducted, which included the analysis of the influence of the presence of the fiberglass grid in the behaviour of cement and hydraulic lime mortars, concluded that the properties of the mortars do not change significantly due to the presence of this grid.

In fact, it was observed that the presence of the gird caused a slight increase in open porosity which also slightly increased water absorption and vapour permeability.

Although it was not the main objective of this work, the behaviour of the two mortars moulded in the laboratory moulds was also analysed and compared with the behaviour of the mortars applied to the brick support. Observing the obtained results, it was possible to conclude that the application of the mortars in the support caused the increase of the bulk density and the decrease of the open porosity. The behaviour face to the presence of water was also affected. The water absorption coefficient also decreased. This behaviour is in line with what was expected because when the mortar of the fluid state comes into contact with the brick support, which is a porous material, part of its mixing water with the finer particles dissolved are absorbed and penetrate into its pores. This decrease in the amount of water causes lower porosity with the consequent increase in bulk density and decrease in water absorption.

Abstract. *The objective of the present work is to analyze the influence of the lightweight concrete block support on the physical and mechanical characteristics of the applied mortar. This work aims to understand how the physical and mechanical properties of the mortar are modified by the support. The methodology used consisted of conducting laboratory experimental tests to compare the behavior of mortar molded in standard moulds with the behavior of mortar applied to lightweight concrete block supports. Open porosity, bulk density, capillary water absorption, water vapor permeability and compressive strength were studied. These results have shown how the support influences the characteristics of the mortar, improving the understanding of the performance of the applied mortar. This study provides a global approach to the assessment of mortar characteristics, considering the analysis and comparison of mortar applied to the support and molded in the laboratory, according to current standards. Such understanding may contribute to the reassessment of the way mortars are produced, seeking to optimize their characteristics and compatibility with the support.*

1 Introduction

Coating mortars have an important role in protecting buildings from degradation agents (Flores-Colen, 2016). One of the most important in-service degradation agents is water, which can lead to physical, chemical and, in some cases, mechanical deterioration (Addleson, 1991). Thus, the performance of coating mortars is influenced by water capillary absorption, hygroscopic moisture content, water permeability, diffusion of water vapor, porosity, soluble salts content and propensity for the growth of microorganisms (Flores-Colen, 2013).

Therefore, it is very important to ensure the quality of the applied mortars, as they contribute significantly to the durability of buildings. For this, it is important to use mortars that are compatible with the supports and that will ensure adequate protection to the building. Thus, low water permeability, good water vapor permeability, good adhesion to the substrate, deformation capacity, among others, are sought (LNEC, 1968; Flores-Colen, 2009; Martins, 2008; Arromba, 2011).

The influence of different factors on the behavior of mortars, such as the quality of the binder, aggregate particle size, water-binder ratio, application conditions, and dosage, have been extensively studied (Torres, 2014; Veiga, 2005; Veiga, 1998; Valente, 1996). However, there are still few studies on the influence of the support on mortar characteristics (Torres, 2014). This work aims to contribute to this knowledge.

doi:10.23967/dbmc.2020.083

This research intends to identify how the lightweight concrete block support influences the performance of the applied mortar, considering that the applied mortar is in different conditions than those of mortars hardened in laboratory molds. Thus, the understanding of the characteristics of the applied mortar and the possibility of creating a correlation with the characteristics of the mortar hardened in laboratory molds, may enable a greater compatibility of the mortar with the support and provide data for the optimization of mortar composition. Such understanding may help to increase the in-service durability of mortars.

2 Materials and Methods

2.1 Materials

In this experimental campaign, the following materials were used: lightweight concrete blocks, with Leca expanded clay aggregates, with dimensions of 50 x 20 x 10 cm³, CEM II / BL 32.5N cement and sand with well-distributed granulometry. For the cement mortar preparation, a cement/sand ratio of 1:4, in volume, and a water/cement ratio of 1:1, in weight, were used.

2.2 Methodology

A laboratory experimental campaign was carried out, for the comparison of the characteristics of the cement mortar hardened in standard laboratory metallic molds and the characteristics of the cement mortar applied to (and later detached from) lightweight concrete block supports.

For the execution of the tests and comparison of the results, the mortars hardened in the standard molds (with dimensions of 40 x 40 x 160 mm³) were cut into slices of 40 x 40 x 15 mm³, thus having the same dimensions of the mortar samples applied to the support and later detached.

To prepare the applied mortars, wooden molds were made in order to ensure a constant thickness (1.5 cm) of the mortar applied to the lightweight concrete block support, according to figure 1.

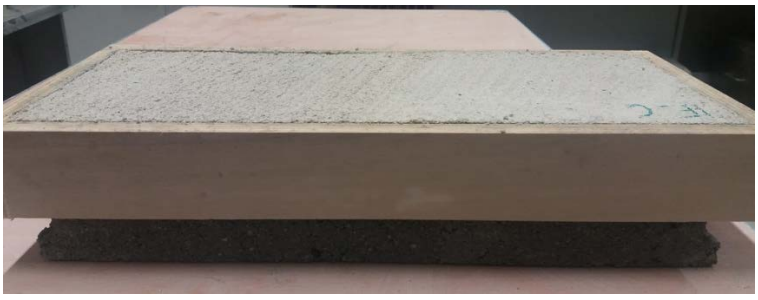

Figure 1. Lightweight concrete block with wooden frame and applied mortar.

As an initial step, the bricks were dried until mass stabilization, and, before applying the cement mortar, each support was wetted by spraying 100 ml of water.

The tests were performed after 28 days of curing. The curing was carried out according to the indications of EN 1015-11: 1999, both for the mortar hardened in the molds and for the mortar applied to the supports. The curing conditions were as follows:

• First 2 days: temperature of 20ºC +/- 2ºC, inside of a polyethylene bag (in the mold);
• Next 5 days: temperature of 20ºC +/- 2ºC, inside of a polyethylene bag (demolded);
• 21 days remaining: temperature of 20ºC +/- 2ºC, relative humidity of 65% +/- 5% (without the mold).

The tests carried out in this experimental campaign are listed in table 1. The results presented in the following sections refer to the average of results obtained in tests carried out on three specimens.

Table 1. Tests conducted and standards followed.

Test	Standard
Water absorption by capillarity	ISO 15148:2002
Open porosity	NP EN 1936:2008
Bulk density	NP EN 1936:2008
Water vapor permeability	ISO 12572:2016
Mechanical strengths	EN 1015-11:1999

3 Results and Discussion

3.1 Open Porosity

Open porosity represents the relationship between the volume of open pores and the apparent volume of the sample. Figure 2 presents the mean open porosity results and indicates a slight reduction in the open porosity of the detached mortar in relation to the mortar hardened in the mold. This can demonstrate a greater compactness of the applied mortar. In fact, when a mortar in the fresh state comes into contact with a porous support as is the case with lightweight concrete blocks, its mixing water together with the smaller particles is absorbed and as a consequence there will be a decrease in its pores and its open porosity.

3.2 Bulk Density

The determination of bulk density by the geometric method reflects the simple relationship between the dry mass and the apparent volume (including all voids) of a sample. Figure 3 shows a slight increase in the mean density of the mortar detached from the support in relation to the mortar hardened in the mold, which is consistent with the reduction of the open porosity.

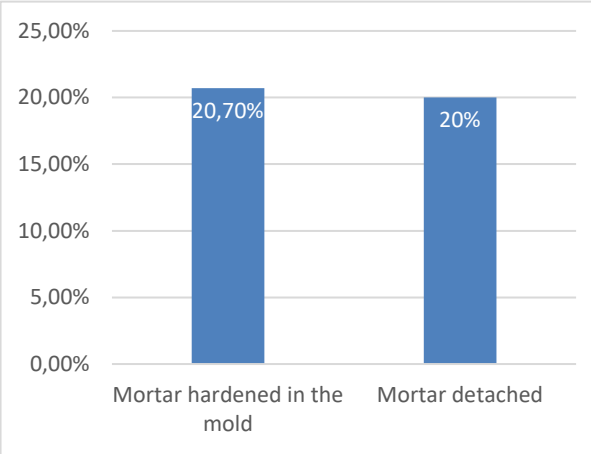

Figure 2. Open porosity.

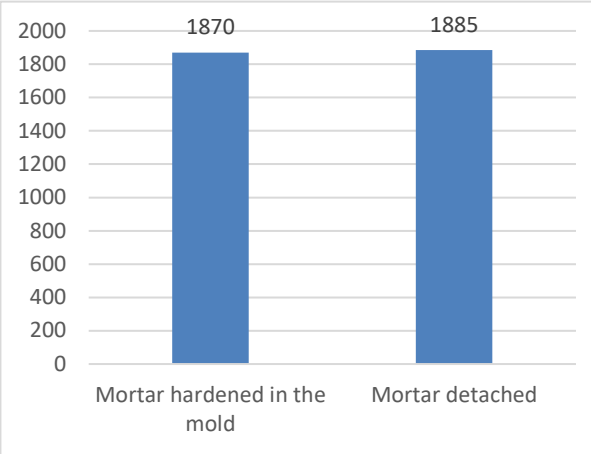

Figure 3. Bulk density (kg/m³).

3.3 Capillary Water Absorption

The water absorption coefficient provides an indication of the water-absorbing capacity of a mortar when placed in contact with a water film.

It can be seen, in figure 4, that the mortar hardened in the mold has a higher coefficient than the mortar detached from the lightweight concrete block support. These results confirm a slight increase in the compactness of the mortar applied to the lightweight concrete block, as mentioned in the discussion of the open porosity results.

3.4 Water Vapor Permeability

The water vapor permeability coefficient reflects the ability of a material to be traversed by water vapor. It can be seen, in Figure 5, that the mean water vapor permeability coefficient of the detached mortar is lower than that of the mortar hardened in the mold — such a result demonstrates a greater resistance to the passage of water vapor by the detached mortar in relation to the mortar hardened in the mold.

3.5 Compressive Strength

Figure 5 shows the mean results obtained in the compression test and indicates that the mortar hardened in the mold presented a slightly higher compressive strength in relation to the detached mortar. Although the decrease in open porosity could lead one to think that the mechanical strength would increase, it is possible that this decrease may be due to some weakening that may have occurred when detaching the mortar from the substrate.

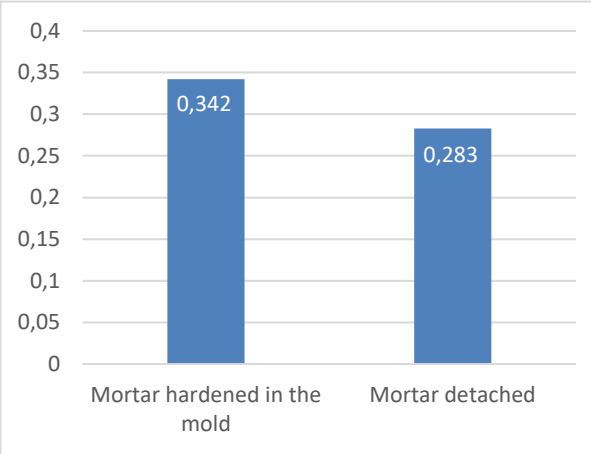

Figure 4. Capillary water absorption coefficient (kg / ($m^2.s^{0.5}$).

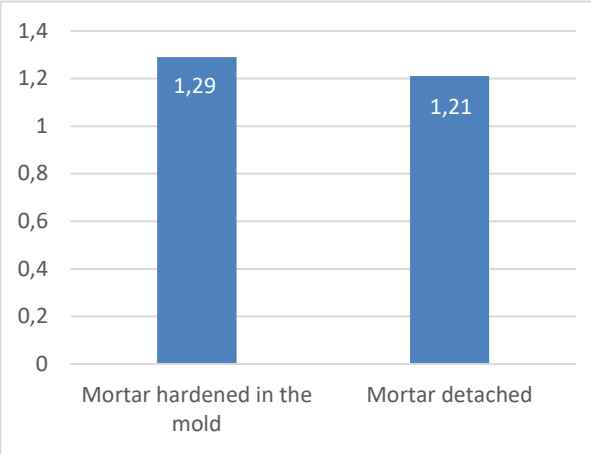

Figure 5. Water vapor permeability coefficient [(kg/(m.s.Pa).10^{-11}].

An expected result face to the obtained results for the characteristics already mentioned.

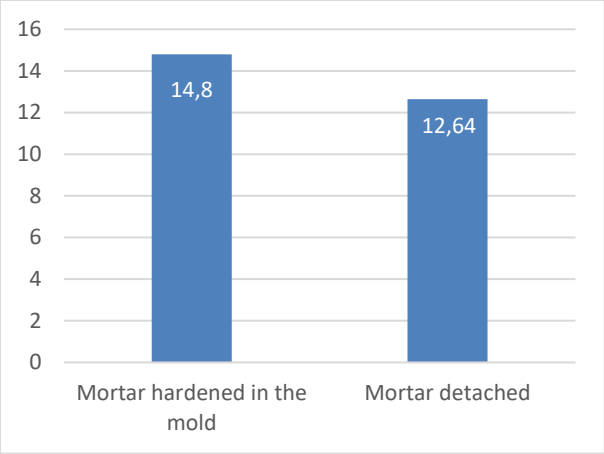

Figure 6. Compressive strength (MPa).

4 Conclusions

As a conclusion, it can be observed that the mortar detached from the support has slightly different characteristics in relation to the mortar hardened in the molds; however, it is not clear that these differences are due to the support. The support can influence the characteristics of the applied mortar, as already seen in previous works using the ceramic brick support (e.g. Torres, 2014), however this influence was not significant for the lightweight concrete block.

It can be seen that the mortar applied to the lightweight concrete block is slightly more compact, with less open porosity. Consistently, the lower water absorption and lower water vapor permeability occurred for the mortar applied to the support. Conversely, the compressive strength of the applied mortar is lower than that of the mortar hardened in the mold.

The influence of the support on the physical and mechanical characteristics of the applied mortar is a relevant issue in relation to performance and durability, and extensive studies on different types of supports and different types of mortar may increase the compatibility of the mortar/support interface.

Performance and Durability of Adhesive Tapes for Building Applications. From Product Documentation to Scientific Knowledge (and Back Again)

Malin Sletnes[1] **and Susanne Frank**[2]

Abstract. *Adhesive tapes are used extensively in both new buildings and renovation projects in order to achieve airtight building envelopes and energy efficient buildings. It is important to be able to reliably predict whether these adhesive solutions are durable. In our roles as both a research institute and a national approval body for building materials, SINTEF have been performing product evaluations and testing of adhesive tapes for 10 years. During this time, we have tested the durability of more than 30 different tapes on a variety of substrates commonly used in the building industry. After systemising and analysing this data, we have gained valuable insight into the factors governing the durability of adhesive tapes for the construction market. In this paper we share our findings and discuss how we intend to utilise the new knowledge in the design of further scientific experiments in the field.*

Keywords: *Adhesive Tape, Construction, Durability, Accelerated Ageing.*

1 Introduction

Air-tightening systems, such as vapour barriers and wind barriers are essential for energy efficient buildings. In order to achieve high air-tightness performance, the overlaps and connections of the air-tightening systems to other building components like foundations, roof constructions, windows, and air and electric ducts, are today frequently sealed by self-adhesive tapes. However, there is little knowledge on the durability of the adhesive tapes used in construction, partly because it is a relatively new application, and partly because it is a very complex system to study systematically in laboratory conditions (Leprince *et al.*, 2017) due to the many variables in the properties of adhesives and substrates, as well as the effect of initial conditions of the bond formation and climatic exposure.

In response to this knowledge gap several research groups have recently studied the durability of air-tightness systems including adhesive products. (Antonsen, 2017; Fufa *et al.*, 2018; Langmans *et al.*, 2017; Litvak *et al.*, 2019) The referenced papers all include well-defined, systematic studies, many of them focusing on full- or reduced-scale airtightness system testing before and after artificial ageing. However, the small number of adhesive tapes included in each study restricts the possibility to draw general conclusions. Often no more than two tapes are tested per system. This is a necessary limitation, due to the extensive experimental matrix that would otherwise arise if tapes should also be tested on several different substrates and under different exposure conditions.

The main objective of the research project TightEN (2019 – 2023) is to develop robust test and evaluation methodology for ensuring durable adhesive airtight solutions for energy efficient building envelopes. The experimental design at the starting phase of a project will be

important for the outcome, and prior knowledge of important parameters can result in a better design of the experimental matrix. Thus, we have systemised and analysed our existing data on adhesive tape durability in order to gain a better understanding of the importance of different parameters. In our roles as both a research institute and a national approval body for building materials, SINTEF have been performing product evaluations and testing of adhesive tapes for 10 years, testing more than 30 tapes. The data we have available is mostly from small-scale adhesive bond testing, such as peel and shear resistance of the joint. The correlation of these properties with the actual air-tightness performance is not well established and will be investigated more thoroughly in the TightEN project. Nevertheless, we believe that adhesive joint testing will in all probability still have a role in the evaluation of adhesive tapes for airtightness application because it is simple, cost-effective and standardised.

2 Data and Methodology

The data subject to analysis was collected from standardised peel and shear resistance testing of adhesive joints before and after artificial ageing, over a course of 10 years. Data from both product certification and previous research projects have been included. Some tapes have been tested several times, as a part of the control procedures for product certifications. An overview of the test methods, number of tapes and associated data points included in the study are given in Table 1.

Material testing and sample preparation was performed according to the European test standards for peel and shear resistance of joints for plastic and rubber sheets for roof waterproofing, EN 12316-2 and EN 12317-2. The joints were created by manually sticking the materials together and applying hand force. The resulting joint area was 50 x 100 mm. (This is not specified in the test standards and may have varied for the testing performed at the earliest dates in the 10-year time period.) Peel resistance was tested in the configuration of 180° peel for tapes adhered to rigid substrates, whereas a T-peel configuration was used for flexible substrates, such as vapour and wind barrier membranes. The test configurations for the two peel tests, as well as the shear test are shown in Figure 1.

The test specimens were exposed to artificial ageing according to one of the three different ageing programs shown in Table 1. The climate carousel refers to ageing in a vertical climate simulator according to NT Build 495. In the climate carousel, the samples are subjected in turn to four different climate exposure conditions; ultraviolet (UV) and infrared irradiation (black panel temperature of 63 °C), water spray, freezing (-20 °C) and ambient laboratory conditions. The exposure time is 1 h for each climate condition.

Table 1. Key information on the dataset subject to analysis.

Evaluation parameter	Test method	No. of unique tapes	No. of data points*
Average peel resistance	EN 12316-2	37 (30 acrylic, 7 butyl)	143
Shear resistance	EN 12317-2	38 (30 acrylic, 8 butyl)	132

* One data point includes the measurement values from both aged and non-aged samples. Each value represents the average of measurements on 5 individual samples (excluding outliers).

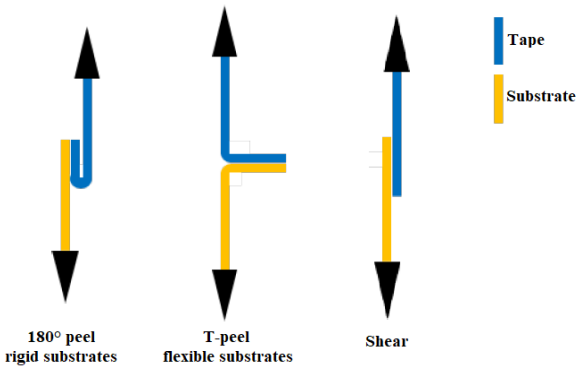

Figure 1. Configurations for testing peel and shear resistance.

Table 2. Ageing programs.

Ageing program	Climate carousel	UV light	Heat chamber at 70 °C
Climate simulator + heat	2 or 4 weeks	-	12, 22 or 24 weeks
UV fluorescent lamps + heat		2 days	12 weeks
Only heat ageing	-	-	24 weeks

The tapes have been anonymised and categorised based on adhesive type, backing material, intended application temperature range etc. whereas the different substrates have been broadly grouped into different material classes. Standardised substrates have not been used, and in general the choice of substrates have been individually chosen in each case, based on the intended application range of the tapes in question. If an adhesive tape was a part of a specific product range, for instance as part of an airtightness system, it would typically have been tested against a wind barrier in the same product range, as well as rigid substrates of typical construction materials, such as wood or steel. Therefore, we do not have a complete experimental matrix to analyse, and any attempts at performing rigid statistical analysis have been hampered by confounding variables and missing data points. Hence, the analysis is based on plotting and visualisation techniques.

3 Results and Discussion

3.1 Repeatability of the Data

The European test methods do not specify how the joint should be made, other than stating that the pieces should be joined by the methods to be used for installation in the end use application. *I.e.* application pressure and speed were not controlled. Nevertheless, the repeatability of the measurements was generally acceptable. The pooled standard deviation of measurement values within one test series (5 measurements on test specimens prepared from the same tape and substrates, undergoing identical ageing programs and conditioning, tested on the same day) was 2 N/50 mm before ageing and 4 N/50 mm after ageing for peel resistance, and 19 N/50 mm before ageing and 23 N/mm after ageing for shear resistance.

3.2 Correlation Between Measurements on Aged and Non-Aged Specimens

Peel resistance for aged specimens are plotted as a function of the peel resistance for the corresponding non-aged specimens in Figure 2a. The equivalent plot for shear resistance is shown in 2b. The light grey fields mark the regions where the peel or shear resistance decreased with ageing, whereas the darker grey fields mark the region where the said properties decreased more than 50 % relative to non-aged samples.

The purpose of the plots was to see if a correlation could be found between measurement values before and after ageing, *i.e.* if a high measurement value before ageing increased the probability of getting a high measurement value after aging. To some extent, this correlation is present, because large increases in joint strength after ageing were rarely observed. However, it is clear from Figure 2a, that peel resistance for non-aged samples is a poor predictor of peel resistance after ageing. In comparison, a much stronger correlation is observed for shear resistance (2b). In fact, shear resistance appears to have changed very little with ageing for a large portion of the test specimens.

The peel resistance is often seen as a measurement of the adhesion force between the adhesive and the substrate (presuming the failure mode is interfacial), whereas the shear resistance is considered to to a larger degree reflect the cohesive strength of the adhesive. Although this is a great simplification, the results can nevertheless be an indication that the degradation caused by the artificial ageing is more detrimental to the interfacial bond than to the bulk properties of the adhesive.

Another observation worthy of mention is that the lowest peel resistance values after ageing were from tapes adhered to flexible membranes, such as vapour or wind barriers, rather than rigid substrates. This could be due to interaction effects between the adhesive and substrate, but more likely it is an indication that it is also important to consider the effect of the ageing of the substrate as well as the adhesive tape.

For the design of experiments to investigate the durability of adhesive bonds, these findings highlight that peel resistance is a much more sensitive evaluation parameter than shear strength to assess changes caused by artificial ageing. However, more knowledge is needed on both correlation between natural and artificial ageing for adhesive tapes, as well as the acting forces in in-use condition to assess whether peel or shear resistance are good indicators for long-term performance.

3.3 Difference in Ageing Properties Across Adhesive Tape Products

Several attempts were made to group the available test results based on substrate types and surface materials, properties of the adhesive tape products (e.g. adhesive, backing material etc.) and investigate the effect on adhesive properties, however the result was always that the range of measurement values within the groups was considerably larger than the observed difference between the groups. The difference from one unique tape to another proved to be a confounding variable for all other attempted groupings. Thus, the conclusion was drawn that the effect of ageing and substrates had to be analysed on an individual tape basis. Because this could not easily and clearly be presented for all tapes in the dataset, a selection was done according to the following criteria:

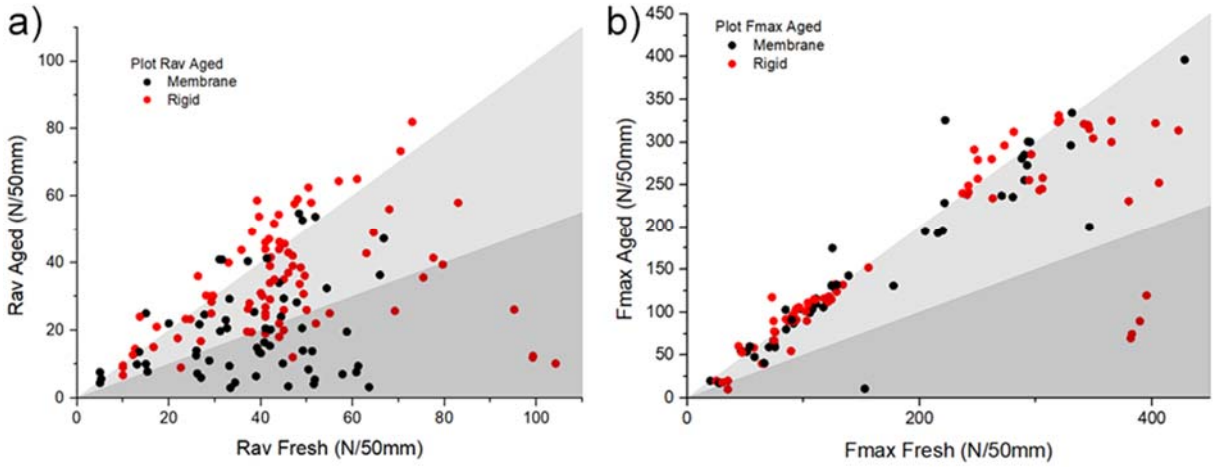

Figure 2. a) Peel resistance for aged specimens as a function of peel resistance for non-aged specimens b) Shear resistance for aged specimens as a function of shear resistance for non-aged specimens. The light and dark grey fields mark the regions where the shear resistance decreased 0 – 50 % and 50 – 100 %, respectively

- Only specimens subjected to 2 weeks climate carousel + 24 weeks heat ageing
- Only single-sided tapes
- Only tapes tested on at least two different substrates
- Excluding data points from substrates that could not be confidently categorized

The resulting plots are presented in Figures 3 and 4 for peel and shear resistance, respectively. In the plots, each row contains data points from one tape product, labelled A1 – A8 for acrylic tapes and B1 – B3 for butyl rubber tapes. The height of each row represents the full range of values for the peel/shear resistance in the dataset (0 – 110 N/50mm for peel and 0 – 450 N/50mm for shear resistance). A more detailed view of the data points for tapes A2, A3 and A4 are presented in Figure 5. Some important observations are:

- Both initial values and change with ageing differ greatly between tapes. This can be exemplified by studying the peel resistance of tapes A2, A3 and A4. Both A2 and A3 start out at medium peel resistance for all tested substrates before ageing. After ageing, the peel resistance for A2 is largely unchanged for all substrates, wheras the values for A3 drop somewhat for all substrates, and the drop is distinctly larger for the joint to the vapour barrier than to the other substrates. A4, on the other hand starts out with peel values at the very top of the range, but degrade dramatically upon ageing for all substrates.
- The trends in initial values and degradation upon ageing are in many cases similar for peel and shear resistance. For instance A4 displays a similar drop in shear resistance upon ageing as in peel resistance.
- The effect from testing on different substrates is less pronounced. With few exceptions, all values from one tape on different substrates are in the same range. This applies to both peel and shear resistance, and both before and after ageing, however the variation from substrate to substrate appears to be slightly higher after ageing.

All these tapes have been subjected to the same ageing program, yet they display completely different responses to the accelerated ageing. Thus, when designing experiments to learn more about the ageing mechanisms of adhesive tapes it is important to include enough different tape products to get the full picture. Furthermore, it is necessary to gain a better understanding of the differences between the tapes, and what properties are significant for the durability.

The number of substrates may be kept smaller to limit the size of the experimental matrix. However, it is important to do the ageing on stable, rigid substrates as well as membranes to account for the fact that membranes themselves are also subject to changing properties during the ageing process. If fact, membrane properties should possibly also be checked seperately, in order to correct for this.

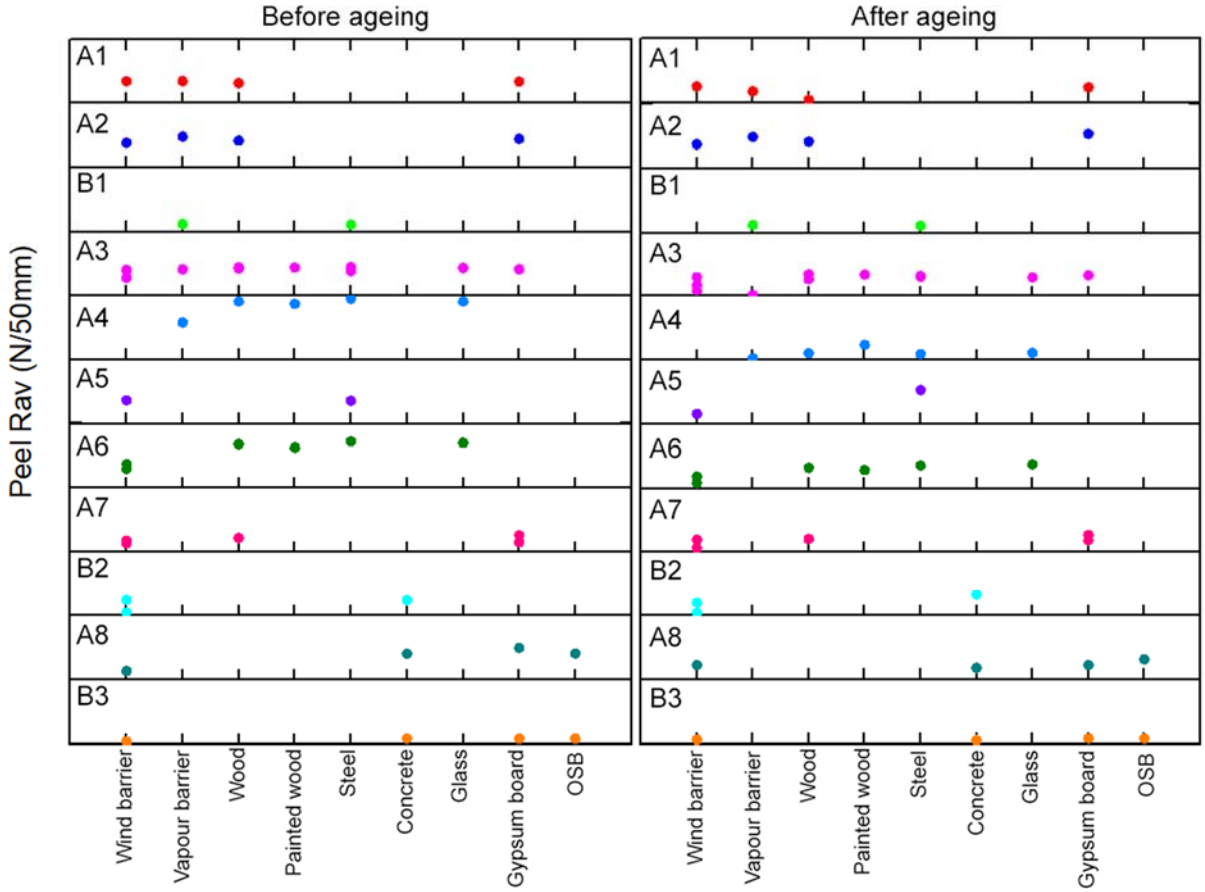

Figure 3. Stacked plot of peel resistance for 11 different adhesive tapes on various substrates. Each row contains data points from one tape product, labelled A1 – A8 for acrylic tapes and B1 – B3 for butyl rubber tapes. The y-axis for each row starts at 0 N/50mm and ends at 110 N/50 mm.

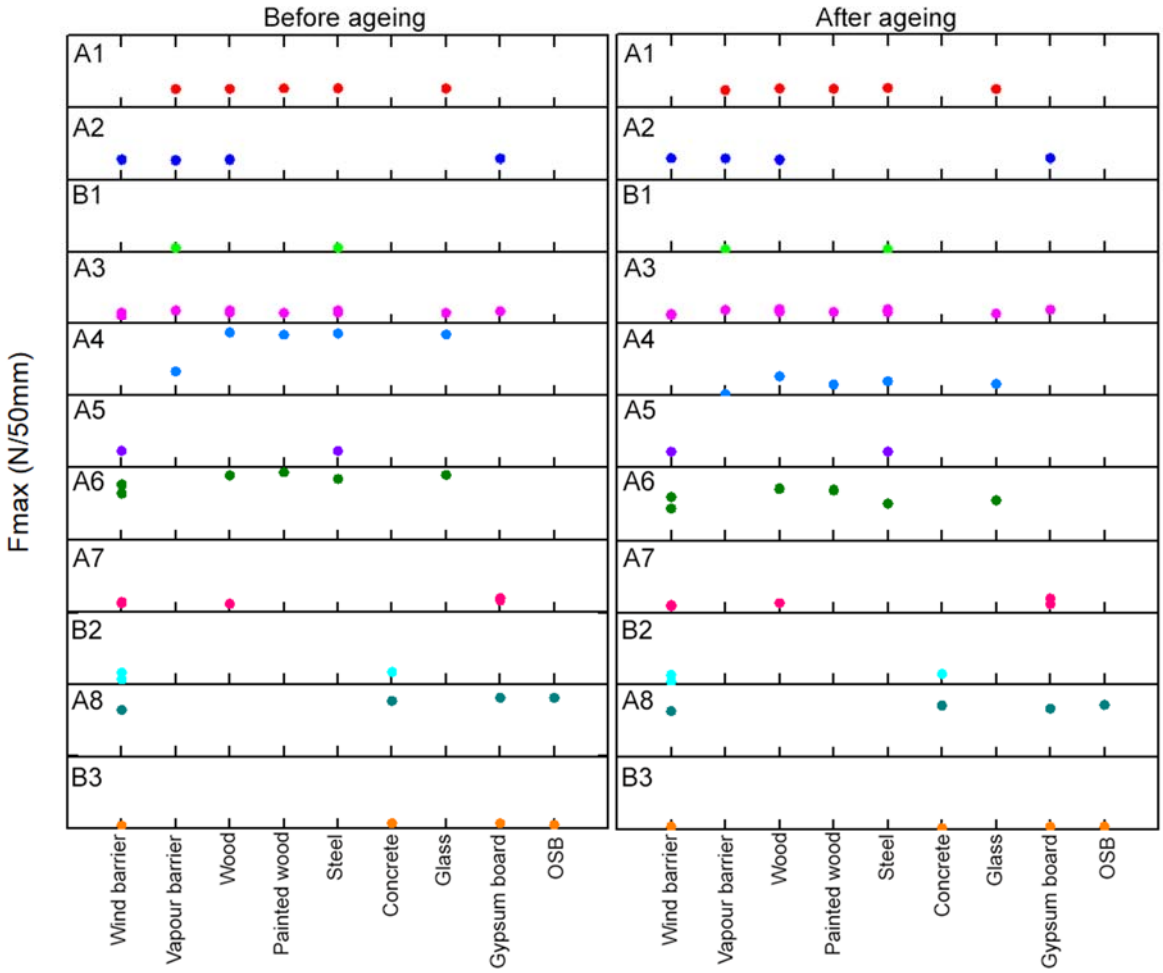

Figure 4. Stacked plot of shear resistance for 11 different adhesive tapes on various substrates. Each row contains data points from one tape product, labelled A1 – A8 for acrylic tapes and B1 – B3 for butyl rubber tapes. The y-axis for each row starts at 0 N/50mm and ends at 450 N/50 mm.

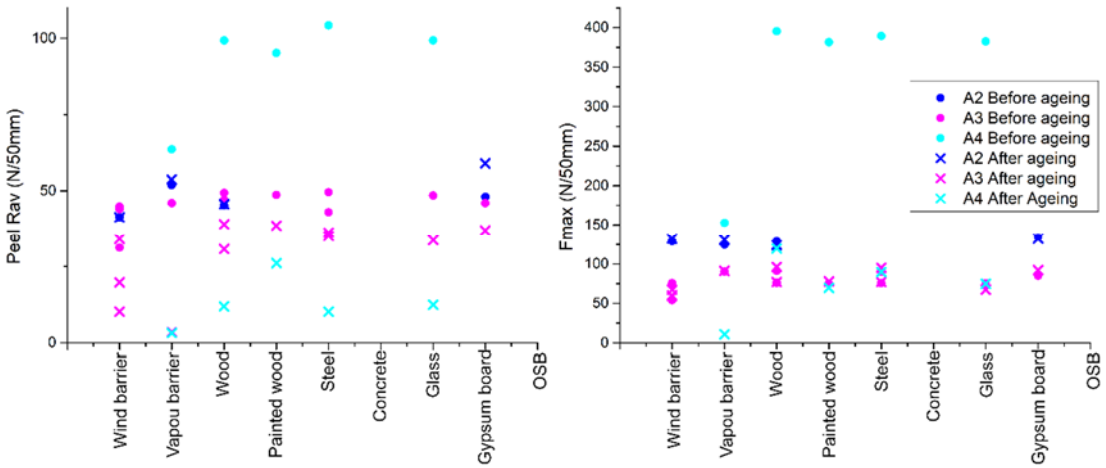

Figure 5. Peel and shear resistance before and after ageing for tapes A2, A3 and A4.

4 Conclusions

- Peel resistance for non-aged samples was a poor predictor of peel resistance after ageing.
- There was a clear correlation between shear resistance for aged and non-aged samples.
- Peel resistance was a more sensitive evaluation parameter than shear strength to assess changes caused by artificial ageing.
- The measurement values for peel and shear resistance varied considerably more between different tapes than between different substrates. This was true for both non-aged and aged test specimens.
- More consideration should be made to include several different tapes in the experimental matrix when planning experiments to study the durability of adhesive tapes for building air-tightness systems.

Predominant Climate Exposure Strains - Thermal Degradation Testing Compared to Historical and Future Climate Scenarios

Petra Rüther, Klodian Gradeci and Malin Sletnes

SINTEF Community. Department for architecture, building materials and constructions, Høgskoleringen 7A, 7461 Trondheim, Norway, petra.ruther@sintef.no

Abstract. *The service life of a building or structure is often presumed to be 60 years. Products used in the building envelope are often covered by a facade material on the exterior side. Hence, the failure of these products is not easily observable, and the repair or replacement is normally not technically nor economically feasible. Thus, these products are expected to endure the entire estimated lifetime of the building. Service life prediction of these products is based on accelerated ageing tests, whose aim is to measure future possibilities of materials' durability under their expected service life. Preliminary calculations of acceleration factors are discussed and related to historical and future climate scenarios for a dataset from Calgary, Canada. The changes in temperature threshold values for this dataset is significant. Relating the measured values to a duration of a typical accelerated durability test indicates that the test duration is sufficient for a service life of 102 years according to historical climate, but only 52 years taking into account an assumed climate change.*

Keywords: *Durability Testing, Accelerated Ageing, Future Climate Scenarios, Exterior Applications.*

1 Introduction

The service life of buildings and building products is presumed to be 60 years. Wall membrane and roofing products, including adhesive products, are widely used in modern building assemblies and the service life of these products that play an important role in ensuring the air and rain tightness of the buildings has to reach 60 years. Furthermore, the inspection of these products, that are often hidden from visual inspection by cladding material mounted on the outermost layer of a building, is difficult.

Wall membrane and roofing products are usually subjected to an accelerated ageing procedure (see Table 1), depending on the use of the product in question. The test standards are designed with regards to the product in question and the prevailing climate condition in the use area of the product.

The ageing procedures are often, but not always a combination of what is believed to be a realistic climatic condition: elevated temperatures, (UV) radiation, water spray, freeze-thaw cycles, to mention the most common ones. Studies on material degradation usually involve a very detailed study of the degradation mechanism. The common ground for building products is usually their application area and not the type of material. Hence, test procedures should preferably account for the climatic strains, and attempt to reproduce the climatic conditions in service (Riahinezhad *et al.,* 2019) as correctly as possible.

While many test procedures are cycling several climatic agents, *e.g.* solar radiation and humidity, or humidity and elevated temperatures, this study will discuss implications for the testing in elevated temperatures, and discuss whether the effects of climate change, hence increased temperatures, need to be taken into account when designing accelerated ageing procedures.

doi:10.23967/dbmc.2020.226

2 Brief Review of Accelerated Weathering Methods

In order to be able to link the weather conditions to accelerated ageing methods, the temperatures are compared to the elevated temperatures of some European and international test standards for products used on the exterior of wall and roof assemblies.

Table 1. Summary of the most relevant ageing procedures for building envelope materials.

Standard	Temperature	RH	Test duration	Acceleration	Application
EN 1296:2000	70 ^{O}C	Not stated	24 weeks	not stated	Roofing membranes
EN 1297:2004	60 ^{O}C	10 ±5 %[1]	not stated	not stated	Roofing membranes [2]
NT BUILD 495	63 ±5 ^{O}C	not stated	not stated	not stated	Materials and components used in the building envelope [3]
NS 8140:1985	75 ±5 ^{O}C BPT	not stated	not stated	not stated	See footnote [4]
ETAG 004	(1) 70 ^{O}C (2) 50 ^{O}C /-20 ^{O}C	(1) 10-30% (2) 30%	(1) 80 cycles, 3h+1h spray and 2h rest (2) 7 h/16 h	not stated	External Thermal Insulation Composite Systems (Etics) with Rendering[5]
EOTA TR 010: 2004	M[6] 60 ± ^{O}C (BST) S[6] 70 ±3 ^{O}C	65 ± 5% (drying conditions)	5000 hours	5000 h = 5 years[7]	Liquid applied waterproofing kit
CAN/ULC – S741 (2008)	50ºC		32 days	not stated	Air barrier materials[8]

1 The relative humidity shall be (10 ±-5) % after 30 min of the dry period.
2 In addition to heat and humidity the standard requires UV radiation and cyclic water spraying
3 The test method is based on cycling radiation, water spray, frost and laboratory climate.
4 The test method resembles the Nordtest NT Build 495 method with minor adjustments.
5 The systems must pass a series of tests regarding the performance of the rendering after the cycles
6 Distinguishes between M (moderate climate) and S (severe climate). Weathering cycles include water spray. Focus on radiation exposure.
7 The AF refers to the radiation exposure.
8 CAN/ULC-S741 conditioning includes UV exposure followed by extended heat exposure. UV exposure includes 210 hours (10 hr for 21 days) of UV radiation according to ASTM G154. Heat exposure includes placing the specimens in an air circulation oven for either 772 hours at 50±2°C for non-accessible air barrier material or 336 hours at 50±2°C for accessible air barrier materials.

The above summary shows that most products for exterior applications in the building envelope are tested under elevated temperatures between 50°C and 70°C for between 32 days and 24 weeks. The acceleration factors stated are usually connected to the radiation exposure and not the thermal degradation.

3 Historical and Future Temperature Values

The selected location is Calgary, Canada. Two sets of climate data generated in Gaur *et.al.* (2019) that include the following:

- 15 historical climate data set, and
- 15 climate data set for a climate change scenario in which the global climate temperature change is forecast to be 3.5ºC.

The reader is referred to Gaur *et al.* (2019) for more in-depth understanding of the methodology used, while a short description follows. A merged observational climate time-series (1986–2016) for the city of Calgary was prepared from the hourly observations (surface global horizontal irradiance, total cloud cover, rainfall, relative humidity, air temperature, station pressure, 10 m wind-speed and wind-direction), and daily observations of the snow-depth from the collection of all of the Environment and Climate Change Canada (ECCC) climate gauging stations located within the domains of Calgary and containing more than one year of data between the time-period: 1986–2016. The database of climatic projections from

CanRCM4 LE, Global Climate Model (GCM), was used to extract climatic projections for Calgary spanning the historical and future time-periods. In total, 15 members of the hourly CanESM2 LE projections covering the historical and the future time-periods were extracted for the grids covering the Calgary for the generation of 15 historical and 15 projected time-series of the climate variables.

Data was analysed to find the time periods where temperatures lie above a distinct temperature threshold. Temperature steps of 10°C between a range of -45°C and +45°C. Results are presented below for historical data and for the chosen climate scenario, together with averages, standard deviations and differences.

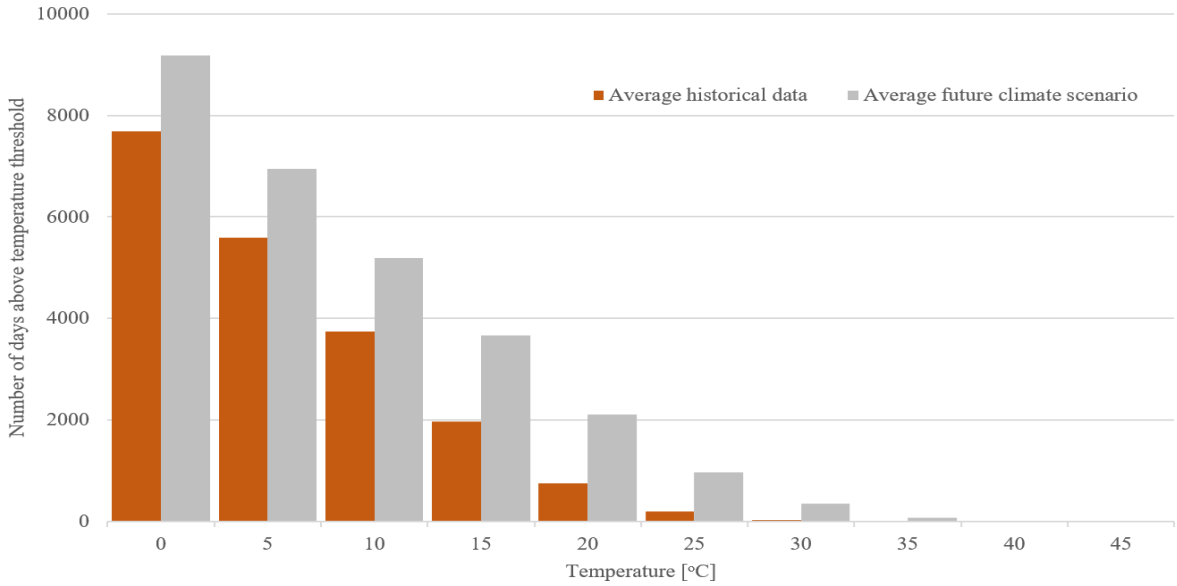

Figure 1. Number of days above temperature threshold for historical and future climate, temperatures above 0°C.

The analysis of the climate data presented in Figure 1 shows a significant deferral of the average temperatures towards higher temperature levels. The number of days where the temperature exceeds 0°C increases for example by 1490 in the course of a 30-year period, or by an average of 50 days per year. For elevated temperatures the relative increase in days above the threshold value is significant: The accumulated period where the average temperature exceeds 30°C increased 3.52 times from 30 days to 352 days in a 30-year period. Correspondingly, the amount of time accumulated at lower temperatures decrease

4 Investigation of Acceleration Factors

In order to ensure that building materials exposed to outdoor conditions have the quality to endure the desired service life, accelerated laboratory testing is conducted. A brief review of some common test methods is presented in Table 1. The tests commonly include amongst others solar radiation and elevated temperatures between 50°C and 70°C, for some test methods the temperatures are cycled and/or alternated with water spray.

The service life of buildings and building parts that are not to be replaced is often set to between 50 and 60 years (Byggforsk, 2017), for materials and components in the building envelope that are accessible for replacement between 25 and 30 years.

Hence, the durability test should aim for testing a service life of 25-30 years or 50-60 years, respectively. The common dilemma with durability testing is to keep the test duration as short

as possible, *i.e.* to accelerate the test as much as possible, without generating degradation effects caused by elevated temperatures not present in a real application.

The following sections explore and discuss acceleration factors along with respective test durations for thermal degradation processes based on the above presented historical and future climate scenarios.

4.1 Methodology

Polymeric materials used in building materials are subject to degradation mainly caused by photoirradiation and thermal degradation. The dependence of the rate of thermal degradation on the temperature can be described by the Arrhenius law:

$$\boldsymbol{k = A \cdot e^{\left(\frac{-E_a}{R \cdot T}\right)}} \tag{1}$$

where A is a pre-exponential factor, E_a [J/(mol K)] is the activation energy, R = 8.314 J/mol is the gas constant, and T [K] is the temperature. A temperature acceleration factor AF_{temp} may then be calculated as the ratio between the reaction rate in the accelerated weathering test k_1 and the natural outdoor weathering k_2, leading to the following equation for the acceleration factor AF_{temp}:

$$\boldsymbol{AF_{temp} = \frac{k_1}{k_2} = e^{\left(\left(\frac{E_a}{R}\right)\left(\frac{1}{T_1} - \frac{1}{T_2}\right)\right)}} \tag{2}$$

where T_1 and T_2 denote the temperature in the accelerated weathering test and the natural outdoor weathering, respectively. Given that the pre-exponential factor A is temperature independent, the calculation of the acceleration factor is only dependent on the value of the activation energy E_a and the two temperatures T_1 and T_2 (Meeker et al). The activation energy is strongly dependent on the material composition, the interaction between different chemical agents, the presence of catalysts, and hence very challenging to estimate for a complex material. However, for the purpose of this study four different activation energies have been used for the calculations: 72 kJ/(mol K) (as suggested by Riahinezhad *et al.,* 2019), 90 kJ/(mol K), 60 kJ/(mol K) and 50 kJ/(mol K).

The following assumptions and approximations are taken in the investigation of the acceleration factor:

- The pre-exponential factor A in Equation 1 does not vary during the degradation process.
- The calculations are solely based on thermal degradation.
- The reaction mechanism, and hence the activation energy, does not vary during the degradation process.
- The chosen values for E_a are either chosen from literature (72 kJ/(mol K) from Riahinezhad *et al.,* 2019) or parametrically assumed in order to explore the influence of the activation energy on the overall result.
- The temperature values for the outdoor exposure is based on average hourly values.

Acceleration factors are calculated based on Equation 2 for four different laboratory test temperatures T_1= 60°C, 70°C and 80°C and an effective outdoor temperature T_2, where the lowest included temperature is 0ºC, assuming that thermal degradation processes below 0ºC might be neglected for the purpose of this study.

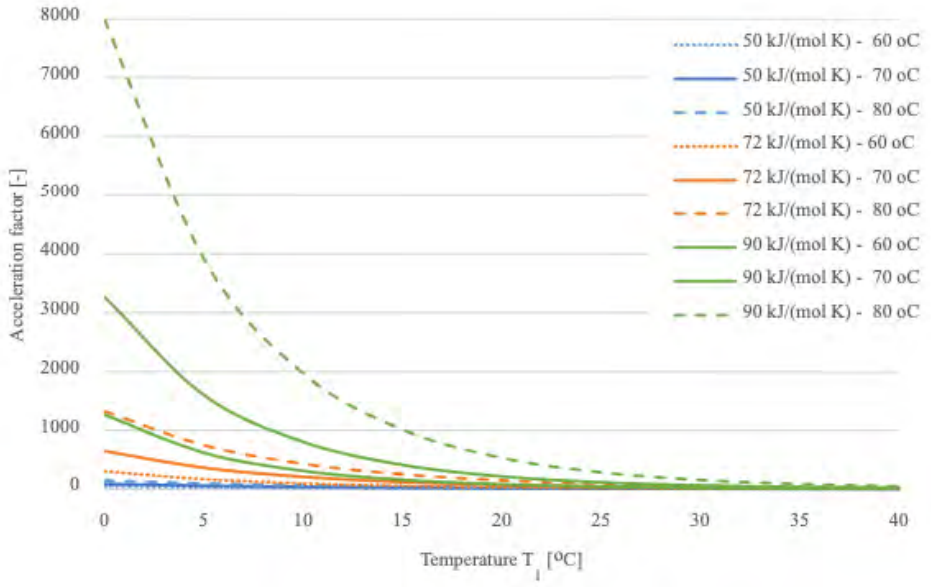

Figure 2. Acceleration factors plotted against average outdoor temperature for 80°C (dashed line), 70°C (solid line) and 60°C (dotted line) laboratory test temperature for different activation energies.

The value of the acceleration factor AF depends (given the assumptions and approximations stated in section 4.1) solely on the activation energy E_a and the two temperatures T_1 and T_2. Table 2 shows the acceleration factors calculated for an activation energy of 72 J/(mol K) for different temperatures T_1 and T_2. Figure 2 shows acceleration factors AF for different values of E_a.

In the further course of the calculations the focus will be on an activation energy of E_a= 72 kJ/(mol K), as shown in Figure 3 with a more detailed plot. With all assumptions considered, the acceleration factor varies between 23 and 1325 for a test temperature of 80°C, 11 and 648 for a test temperature of 70°C and between 5 and 304 for a test temperature of 60°C. Basing the calculation of the test duration on annual average values leads to an acceleration factor of 379 for historic (T_2 = 4,7°C) and 225 (T_2 = 9,4°C) for future climate scenarios (for E_a=72 kJ/(mol K) and 70°C test temperature), leading again to a laboratory test duration of 28 days and 48 days.

Table 2. Acceleration factors AF for E_a = 72 J/(mol K).

T_2 [°C]	**T_1** [°C]		
	60	**70**	**80**
0	304	648	1325
5	172	366	749
10	99	211	432
15	58	124	254
20	35	74	152
25	21	45	93
30	13	28	57
35	8	18	36
40	5	11	23

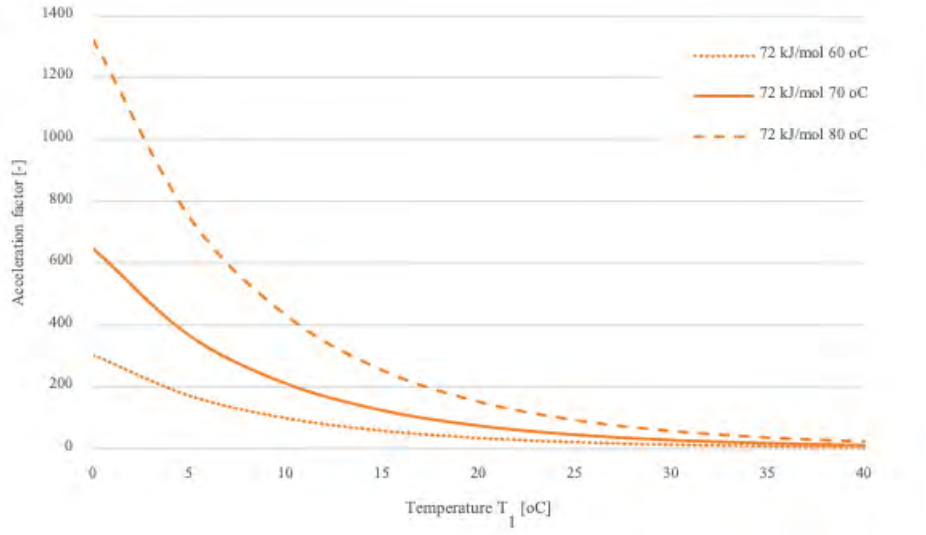

Figure 3. Acceleration factor plotted for E_a = 72 kJ/(mol K) for three different laboratory test temperatures for average outdoor temperatures between 0ºC and 40ºC.

5 Laboratory Test Duration

In order to estimate a laboratory test duration, an average temperature representing the outdoor temperature during the test period is to be calculated. The temperature data is divided into temperature ranges of 5ºC between 0ºC and 40ºC (assuming that the thermal degradation processes below 0ºC might be neglected). Further, the average temperature for each interval and the according duration is derived from the climate data. For the calculation of the acceleration factor for the respective temperature range, T_2 is set to the average temperature of the respective interval.

The results of the calculation are shown in Figure 5 for three different laboratory test temperatures for historical and future climate. For a laboratory test temperature T_1 the laboratory test duration (for a simulation of a 30-year outdoor test period) is 49 days based in historical climate scenarios and increased to 94 days based on future climate scenarios.

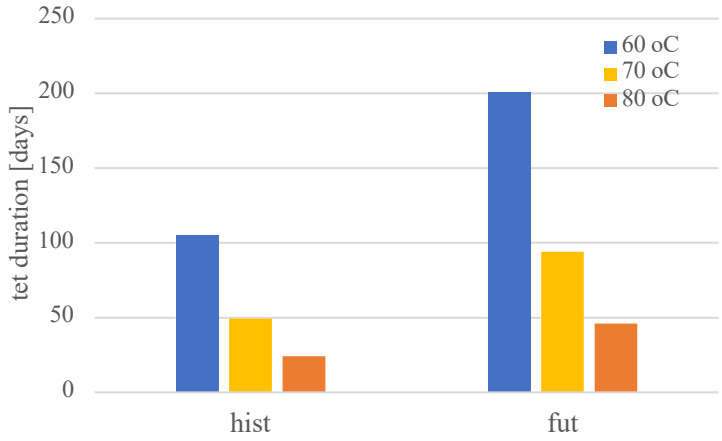

Figure 4. Laboratory test duration [days] for three different laboratory test temperatures T_1 based on historic and future climate scenarios.

With a calculation of the outdoor temperature T_2 in the above described way, the duration of the accelerated test is based on shorter time intervals with their respective duration based on hourly mean values. This contributes to a more accurate calculation, compared to *e.g.* using and average monthly or annual values, where the calculated test duration is considerably shorter (see section 4.1).

Due to the uncertainty in estimations of acceleration factors, test procedures for durability evaluation in product standards or for certification purposes normally specify longer test periods than those calculated from the Arrhenius equation. Thus, these tests have an inherent error margin to be on the safe side with regards to durability. This is known as stress testing, and the goal of the test is to assess whether it is probable that a product will have sufficient durability in the end use environment rather than specifying a particular service life. The error margin of durability testing may become smaller in the future due to climate change. For instance, in a common test method for roofing membranes (EN 1296, 2000), the temperature during the laboratory test is set to 70°C and the test duration is 24 weeks (168 days). Assuming an activation energy of 72 kJ/(mol K) this test roughly corresponds to an outdoor exposure period of 102 years based on historical climate data. Based on the future climate scenario, however, the laboratory testing would only correspond to 53 years of outdoor exposure.

6 Conclusions

The results show a significant influence of the increasing temperature on the accumulated amount of time where certain temperature threshold values are exceeded. For the Calgary data, where the historic average temperature is 4.7°C and the future average temperature over a 30-year time period is 9.4°C, the increase in amount of days where the threshold value exceeds 30°C is from 30 to 352.

In a durability test, based on the calculated acceleration factors, given a number of assumptions, based on thermal degradation and on historic climate data for Calgary, 49 days account for an outdoor test period of 30 years. Based on future climate data, the test duration must be increased to 94 days.

Compared to a commonly used laboratory durability test for roofing membranes (EN 1296, 2000), the test duration of 24 weeks (168 days) accounts for an outdoor test period of 102 years for historical climate and 53 years for future climate.

This calculation shows that future climate scenarios should be considered when designing laboratory experiments.

7 Future Work

This work is based on temperature data measured at a meteorological station. In order to account for microclimate at the exact location where the material in question is applied, it would be interesting to study the differences for temperature values. Also, different geographical locations and their future climate scenarios need to be explored to take into account different climate zones. The further exploration of degradation processes in order to deepen the understanding of thermal degradation and possible interactions between thermal degradation and other climatic strains needs to be further explored.

Abstract: *Due to climate change, higher temperatures and rainfalls are expected to happen in some areas of Canada, which might increase the climate loads on buildings and lead to premature degradation of moisture-sensitive materials in wall assemblies. To investigate potential durability issues in three cities across Canada (Ottawa, Vancouver and Calgary), code-compliant wood-frame walls with two types of claddings, stucco and brick, were simulated using Delphin 5.9. Two different climate data sets, historical and future when a global warming of 3.5ºC is expected to be reached were used. The hygrothermal performance in terms of mold growth risk was analysed with respect to cladding types, considering air leakage. All the three cities are similarly warmer in the future. However, wind-driven rain (WDR) is higher in Vancouver than in Ottawa and Calgary. With brick cladding the relative humidity is kept below the threshold for mould development only in Ottawa and Calgary. With stucco in future, while Ottawa shows greater mould indices than historical, Calgary shows opposite behavior. The results suggest that the risk of mould growth due to air leakage may decrease in the future.*

1 Introduction

Climate change has received increasing attention globally due to many possible consequences, including building long-term performance issues from temperature increases and more severe and frequent rainfall events. The Intergovernmental Panel on Climate Change (IPCC, 2014) has indicated that climate changes has resulted from anthropogenic action and, whereas temperature changes arising from human influence is indeed a global concern, it is known that in Canada annual average temperatures will rise about twice the global average.

It is also expected that weather extremes will intensify in the future from a warming climate and, even though rainfall events might decrease in some areas, these are likely to increase for over most of Canada (Bush and Lemmen, 2019). In some regions, increases in precipitation as high as 40% are expected and this will have significant effects on buildings: water infiltration, related mostly to wind-driven rain, will increase accordingly and might pose a higher risk to the premature degradation of moisture-sensitive materials in wall assemblies (Lacasse, Defo, *et al*., 2018).

To address these issues of moisture accumulation in wall assemblies due to condensation or

water ingress, the National Building Code (NRC, 2015) set prescriptive requirements for all the walls separating conditioned from unconditioned spaces. These include: i) minimum thermal insulation according to the climate zone; ii) an air barrier system with an air leakage rate not greater than 0.1 L/(s.m^2) at 75 Pa; iii) a vapor barrier with permeance not greater than 60 ng/(Pa.s.m^2); and iv) position of low permeance material in the wall. As well, in case where an exterior insulation is added, NBC might also require a minimum ratio between outboard and inboard thermal resistance (NRC, 2015, p. B-9.159). All these technical requirements are intended to minimize the chance of moisture accumulation in wall assemblies, which can lead to deterioration of wood and wood-based building products.

Although the requirements were set based on historical climate loads, item 5.1.4.2 of NBC says that "… assemblies exposed to the exterior shall be resistant to any mechanism of deterioration that may reasonably be expected". As such, the impacts of climate change on moisture performance of code-compliant walls need to be assessed.

The primary objective of this study is to evaluate the moisture performance of code-compliant wall assemblies in both historical and future climate. The approach followed is the one provided in the "Guideline for the Design for Durability of the Building Envelope" (Lacasse *et al*., 2018).

2 Methods

The methodology for the assessment of moisture performance of code-compliant wall assemblies as described in this paper follows the approach given in the "Guideline for the Design for Durability of the Building Envelope" (Lacasse, Ge, *et al*., 2018). This approach essentially uses hygrothermal modelling as means to assess the response of wall components to climate loads acting on the exterior and environmental conditions on the interior of the assembly; so, the moisture performance of the wall can be determined on the basis of the risk of mould growth or wood decay in wood based components.

The simulation tool is first described and, thereafter, details in respect to input data for simulation are provided: wall configuration, which is dependent on the geographic location for which simulations will be completed; weather data, and the reference years to be used in simulations; boundary conditions, in which boundary parameters are defined; air leakage; and material properties.

2.1 Geographic Location

Three cities were selected across Canada: Calgary (AB), Ottawa (ON) and Vancouver (BC), with low, medium and high moisture indices respectively. The main characteristics of the cities are shown in Table 1.

Table 1. Geographic location and climate details about the cities.

City (Province)	Latitude (°)	Longitude (°)	HDD	Zone	RSI_{min} (W/m^{2}K)	MI	Annual rain (mm)
Ottawa (ON)	45.25	-75.42	4440	6	2.97	0.84	750
Vancouver (BC)	49.28	-123.12	3100	4	2.78	1.93	1850
Calgary (AB)	51.05	-114.07	5000	7A	2.97	0.37	325

HDD - heating degree days below 18ºC
RSI - Effective thermal resistance
Zone - climatic zone
MI - moisture index

2.2 Simulation Tool

A state-of-the-art hygrothermal modelling software, Delphin 5.9, was used to undertake the hygrothermal simulations. The solver parameters were adjusted to 0.01 s initial time step, 60 s maximum time step, 10^{-6} relative tolerance and 10^{-7} moisture mass balance.

2.3 Wall Configuration

A wood frame wall of a 3.5-storey (10-m high) residential building located in suburban areas was considered. For each city, two cladding types were simulated: brick and stucco. Figure 1 shows the composition of the brick wall.

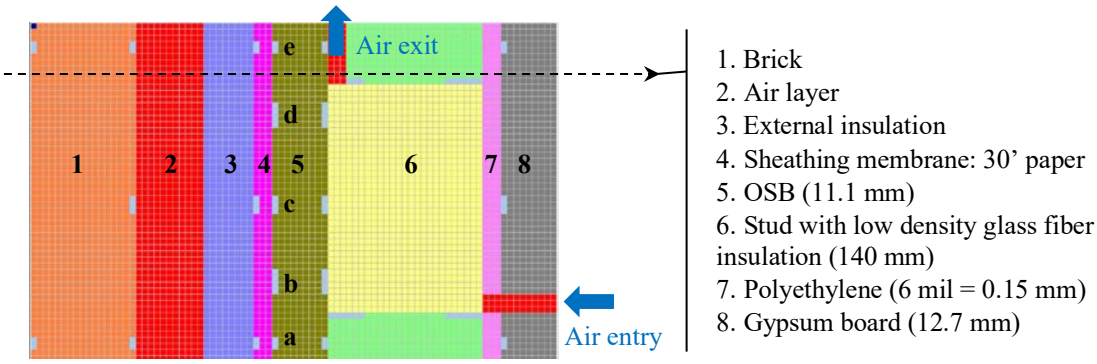

Figure 1. Layers of the brick wall and the locations for reading Relative Humidity and Temperature.

From the sheathing membrane to the interior side of the wall (from layer 4 to layer 8), all the layers are the same for all walls. The height of the wall was 2440 mm: 36 mm for the single bottom plate (spruce), 2332 mm for the insulation (low density glass fiber insulation) placed within the vertical wood studs, and 72 mm for the double top plate (spruce). For the outer part of the walls, complete details for each city are given in Table 2.

Table 2. Cladding details.

City	Cladding		Drainage cavity (mm)	External insulation	Air change (/h)	Air leakage
	Type	Thick (mm)				
Ottawa	Brick; Stucco	90; 19	25; None	EPS (6.5; 12.7 mm)	10; None	With and Without
Vancouver	Brick; Stucco	90; 19	25; 10	None; None	10; 10	
Calgary	Brick; Stucco	90; 19	25; None	EPS (6.5; 12.7 mm)	10; None	

In Calgary and Ottawa it was necessary to incorporate an external insulation to reach the minimum energy requirement (RSI ≥ 2.97 W/m^{2}K) whereas in the warmer climate of Vancouver (RSI ≥ 2.78 W/m^{2}K) the stud cavity insulation alone was enough.

2.4 Weather Data

Two sets of climate data were used: historical and future (when a global warming of 3.5ºC is expected to be reached). Both sets were prepared according to Gaur *et al*. (2019) and encompass a 31-year time period, from 1986 to 2016 and from 2062 to 2092. From each set, the median and the wettest years were selected based on the moisture index (Cornick *et al*., 2003) and were used as moisture reference years for simulations. Those years and the wall orientation with the

highest wind-driven rain load are summarized in Table 3. In all cases there is an increase in the temperature in the future; RH levels vary quite the same way in Calgary and Vancouver, but are higher in the future climate for Ottawa.

Table 3. Moisture reference years and wall orientation for each city.

City	H - Historical data (year)			Wall orientation (°)	F - Future data (year)			Wall orientation (°)
	Period	Median	Wet		Period	Median	Wet	
Ottawa	1986 to 2016	1989	1991	180	2062 to 2092	2074	2070	180
Vancouver		1988	1994	145		2091	2066	180
Calgary		2015	2016	292		2069	2063	315

2.5 Boundary conditions

2.5.1 Air Leakage

All the walls were simulated with and without air leakage and the exfiltration path (Figure 1) is one of the worst cases in terms of moisture accumulation suggested by Ojanen and Kumaran (1992; 1996). This path is also the same as the one used by Saber (2014). An air leakage rate of 0.1 L/(s.m^2) at 75 Pa was tested, which is the maximum rate prescribed by the NBC (NRC, 2015, p. B-5.27) when the indoor relative humidity ranges between 27 and 55%. An equivalent air leakage area was computed assuming a discharge coefficient of 0.6 and air density of 1.2 kg/m^3. For a 2.4 m high wall, the area of the orifice is around 35mm^2 at 75Pa, but since the real pressure difference between outdoors and indoors is roughly 10 Pa, this area was converted to 26 mm^2 (ASHRAE, 2017, p. 16.16). Indoor and outdoor air pressures were derived from the combination of wind and stack pressures and applied to the bottom and top openings of the wall respectively (Figure 1). Since the simulation was run in 2D, the opening was assumed to have a circular shape and its diameter was used as the width of the opening.

2.5.2 Wind-driven rain

Wind-driven rain (WDR), used as an imposed moisture flux on the exterior surface of the wall, was calculated according to ASHRAE 160 (ASHRAE, 2016, p. 6,7), assuming a 3.5 storey building (10-m high) located in a suburban area. The exposure (FE) and deposition (FD) factors were set to 1.0 and 0.5 respectively. Figure 2 shows the accumulated wind-driven rain for all cities, historical and future.

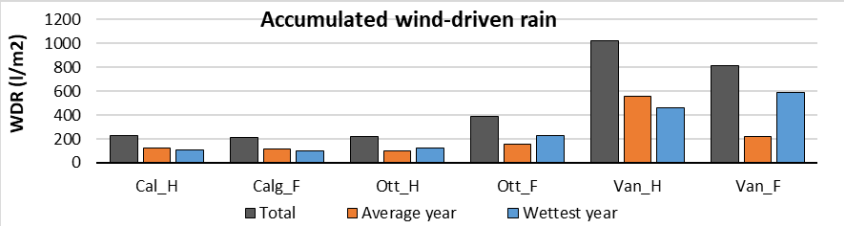

Figure 2. Accumulated wind-driven rain (ASHRAE) for all cities, historical and future.

Calgary has quite the same amount of rain in both scenarios for the two years together; Ottawa shows an increase in the rain in the future for both average and wettest years; Vancouver is less rainy in the future, but there is an important difference between the two years: in the

future, the average year is about 65% dryer and the wettest year is about 30% rainier.

2.5.3 Other parameters and conditions

Initial conditions for all layers were set to 21°C and 50%, respectively for temperature (T) and relative humidity (RH).

Indoor conditions were calculated using the ASHRAE method, heating only (ASHRAE, 2016, p. 4), which means $T \geq 21.1$°C (no upper limit) and $40\% \leq RH \leq 70\%$.

Other coefficients were adopted as follows: outdoor heat transfer coefficient: 4+4v W/m^{2}K (v is wind speed) (ISO, 2017); indoor heat transfer coefficient: 8 W/m^{2}K; outdoor vapor transfer coefficient: $2.44*10^{-8} + 2.44*10^{-8}$v s/m; indoor vapor transfer coefficient: $1.52*10^{-8}$ s/m; ground shortwave reflection = 0.1; shortwave surface absorption = 0.6; ground longwave emission coefficient = 0.9; surface longwave emission coefficient = 0.9.

For wall assemblies having a drainage cavity, the air change per hour (ACH) was set to 10.

2.6 Discretization of the Walls

Preliminary tests simulations with different number of elements were undertaken to select the optimal scheme in terms of accuracy and simulation time. The final mesh used in this paper was composed of 3465 elements for stucco and 4345 for brick.

2.7 Material Properties

Table 4 shows some basic properties of the materials for each of the two wall assemblies.

Table 4. Properties of the main materials according to Kumaran *et al*. (2002).

Material	Thickness (mm)	Dry density (kg/m^3)	Specific heat capacity (J/kg.K)	Thermal conductivity (W/m.K)	Vapor permeance[1] (ng/m^2.s.Pa)
Brick (Br)	90	1900	800	0.500	19
Stucco (Stu)	19	1960	840	0.407	94
OSB	11	600	1880	0.094	101
Glass fiber batt	140	11.5	840	0.043	990
Vapor barrier[2]	0.15	1256	840	0.159	60
Sheathing membrane[3]	0.22	909	1256	0.159	907

1. Values at 50% RH **2**. 0.15 mm polyethylene **3**. 30' asphalt impregnated paper

2.8 Performance Assessment

The performance assessment focused on the mould index calculated according to the VTT model described in Ojanen *et al.* (2010). It is known that mould growth is a highly complex mechanism which is mostly influenced by relative humidity, temperature, material susceptibility, surface quality (Vereecken and Roels, 2012). Different models use different parameters, and not necessarily the same way and, then, distinct outcomes are expected; a deeper discussion about this is out of the scope of this paper and can be found elsewhere, as in Sedlbauer (2001), Vereecken *et al*. (2011), Viitanen *et al*. (2015), Gradeci *et al*. (2017). In this study, the VTT model was adopted because it is recognized by ASHRAE 160 (ASHRAE, 2016, p. 7).

The index was calculated for many different locations of OSB, bottom plate and top plate,

assuming a sensitive class for both material and surface, and 0.1 as decline factor (there is no suggestion in ASHRAE for OSB and then 0.1 was adopted as a conservative value). The highlighted squares in Figure 1 show all the locations in the assembly where values of RH and T were acquired. However, the focus of this paper is in the worst position, identified with the letter "c" in Figure 1 (exterior layer of OSB at mid-height); RH and T values used to compute mould index were acquired on a portion with the dimensions of 0.5 mm x 500 mm.

3 Results and Discussion

Figure 3 shows the mould index profiles for stucco and brick claddings. Solid lines represent situations with no air leakage and dashed lines with air leakage.

Brick cladding in Vancouver (Figure 3a) develops mould, while in Ottawa and Calgary there is no mould growth. This may be explained by the higher amount of WDR in Vancouver compared to Ottawa and Calgary (Figure 2). In Vancouver, mould index profile is consistently greater for historical than future. In fact, the first year (average year) in the future has a lower amount of WDR, which may explain the fact that there is no mould growth, while the second year has more WDR in future than in historical.

In the case of stucco, mould index profiles were quite similar in Vancouver for both climate scenarios (Figure 3b), which is different to the observations for brick. This may be explained by the fact that stucco cladding has higher liquid diffusivity, smaller thickness, and a drainage cavity of only 10 mm. As such, the liquid water reaches the drainage cavity quickly and maintains high RH levels. These factors together with higher temperatures along the year led to high mould indices. Ottawa (Figure 3c) shows higher mould index profile in the future than historical. This may be explained by the fact that WDR is higher in future than historical; in the historical climate, however, the first year is dry and there is no mold growth. Unlike Ottawa, Calgary (Figure 3d) shows lower mould index profile in the future than historical. As shown in Figure 3, the WDR in Calgary is quite similar for historical and future climates, but the temperature is higher and therefore might have increased the drying potential of the whole assembly, decreasing the mould indices.

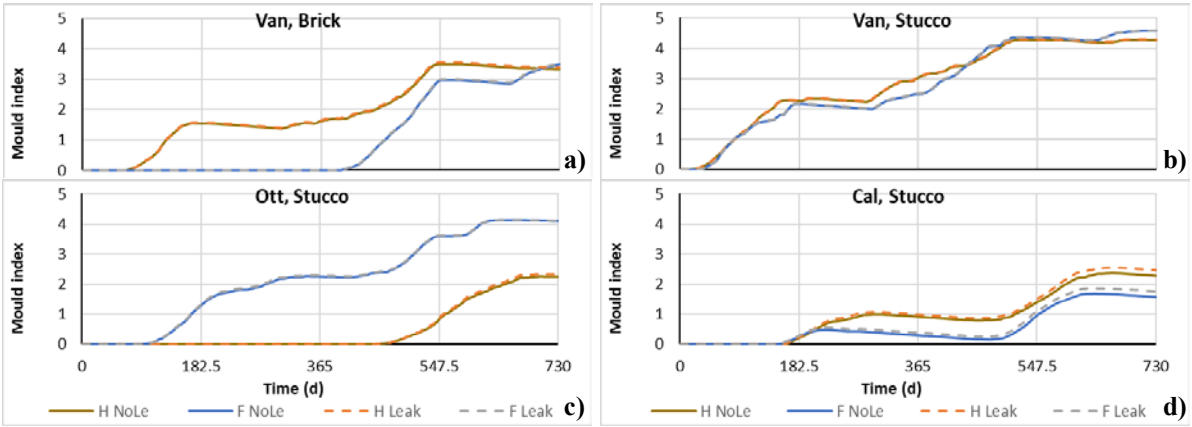

Figure 3. Mould index profiles in the worst position of OSB for both claddings, historical (H) and future (F) scenarios, with (Leak) and without (NoLe) air leakage.

In an attempt to assess the effect of future climate on the risk of mould growth, the difference between the maximum mould index for the cases with and without air leakage was calculated

for both historical and future periods. Table 5 shows the maximum mould values and the difference between historical and future scenarios, with and without air leakage. Those values are labeled as “Leak - NoLe” in the shaded columns.

Table 5. Maximum mould index in the worst position of OSB for each case.

City	Brick						Stucco					
	NoLe		Leak		Leak - NoLe		NoLe		Leak		Leak - NoLe	
	H	F	H	F	H	F	H	F	H	F	H	F
Ottawa	0	0	0	0	0	0	2.25	4.13	2.57	4.13	0.32	0
Vancouver	3.49	3.49	3.56	3.52	0.07	0.03	4.28	4.48	4.40	4.59	0.12	0.11
Calgary	0	0	0	0	0	0	2.36	1.68	2.55	1.86	0.19	0.18
H - Historical			F - Future				Leak - air leakage			NoLe - no air leakage		

Although this calculation is not exactly true because hygrothermal behavior is a combination of all the factors, it gives an idea of the influence of the air leakage itself. It can be seen that air leakage led to higher mould indices in all cases since the exfiltration process brings more humid air to the cavity. Also, the lower values of “Leak - NoLe” in the future suggest that there might be a decrease in the risk of mould growth due to air leakage in the future.

As a general observation of Figure 3 and Table 5, air leakage has a greater impact when the mould index is low, since the major factor responsible for mould growth is the moisture coming from brick and stucco layers. If this amount of moisture is already high, the contribution of the moisture brought to the cavity by the air leakage is very low when compared to the total, which means low impact over the mould indices.

4 Conclusions

Hygrothermal performance of two wall assemblies, stucco and brick cladding, has been assessed in three cities under historical and future climate with and without air leakage to see their response to a possible climate change. Mould index was used as a measurement of performance and the main findings for the cities and the wall configuration considered are:

- Future climate in Ottawa presents higher amount of WDR when comparing with historical, which means the moisture content of the assembly is higher and so is the risk of mould growth. In Calgary, the amount of rain is similar in both climates but the temperature is higher in the future, which means more drying potential and less mould development. Vancouver is rainy in both scenarios and the mould indices are similarly high.
- Brick cladding is safer than stucco in any case in future climate. The higher moisture capacity of the brick, the wider drainage cavity and the higher air temperature all together increase the drying capacity of the assembly, which helps on keeping lower levels of relative humidity and lower mould indices. This situation is more evident in Ottawa and Calgary, which have no mould with this cladding.
- Air leakage increases the mould development in all cases, but the differences are small and cannot be blamed for major changes in the indices. The results suggest risk to mould growth may decrease in the future climate.

Assessment of Moisture Response and Expected Durability of a Heritage Masonry Building Subjected to Projected Future Climate Loads of Ottawa, Canada

John A. Wells[1], Michael A. Lacasse[2] and Gary Sturgeon[3]

Abstract. *As part of the Canadian government's recent drive to the "on Greening Government initiative, heritage buildings forming part of the parliamentary precinct in Ottawa, Canada are to be retrofitted in the coming years to help reduce energy usage and decrease greenhouse gas emissions associated with heating and cooling. Increasing levels of GHG concentrations over time has the potential to raise the mean global temperature by +3.5 degrees. The predicted impact on Ottawa's climate will be significant, increasing precipitation annually by 14.4% and decreasing the January winter design temperature from -25°C to -11.7°C or 53%. In this paper, the moisture response of a heritage building located in Ottawa, Canada is determined from results of numerical simulations when subjected to both historical and projected future climate loads. Various insulation strategies for masonry wall systems were assessed. The objective was to decrease the energy demand associated with heating and cooling by applying insulation on the interior face of the masonry. Using future climate loads, results from hygrothermal modeling showed that although the climate change model produces higher volumes of annual precipitation, no deleterious levels of moisture build-up were observed in the wall system. In fact, moisture levels remained relatively consistent, irrespective of the insulation type applied to the interior face of the walls. Moisture content for all scenarios was well below critical saturation of the masonry materials. The warming climate has a dramatic effect by reducing the number of hours below freezing experienced by the interior brick wythe when interior insulation is applied. From the hygrothermal analysis, it was concluded that the warming temperatures will substantially reduce the number of hours the interior wythe of masonry experiences freezing temperatures which in turn, reduces the potential for freeze-thaw damage to the masonry. The interior application of moderate levels of insulation should therefore be considered for retrofit measures for this heritage building, located in Ottawa, Canada, without increasing the risk of damage to the wall.*

1 Introduction

There is overwhelming evidence that continued increases in world greenhouse gas (GHG) generation is impacting climate change on a global scale. Although Canada's contribution to world GHG's has been trending downward from 1.8% to 1.6% over the last 10 years, it remains 9th overall in contribution to world GHG generation. Buildings in Canada contribute 12% of its overall GHG annual total and this number has remained relatively unchanged between 1990 and 2017[2]. Thus, significant room for improvement exists in Canada to decrease GHG's for both new and existing building stock.

The introduction of the National Energy Code of Canada for Buildings has initiated significant enhancements to reducing the GHG's of new buildings and additions to existing buildings; however, many existing buildings, and particularly heritage buildings are presently exempt from implementing the Code required changes to the building envelope to reduce the contribution of greenhouse gas generation associated with heating and cooling loads.

As part of the Canadian government's recent drive to the "Greening Government" initiative, heritage buildings forming part of the parliamentary precinct district in Ottawa are to be retrofitted in the coming years to help reduce energy use for heating and cooling loads and ultimately decrease greenhouse gas emissions. Such measures may require intensive remediation and for heritage restoration projects may also involve changes to the building envelope, including but not limited to, increased thermal resistance of the wall system, enhanced precipitation managements strategies, and introduction of an air barrier. However, sufficient number of case studies exist to conclude that caution is required when introducing insulation to masonry wall systems on heritage buildings because of the changes in thermal and moisture loads can induce damage, (Wilkenson, De Rose; Wojcik, Bomberg) principally by freeze-thaw degradation.

Hygrothermal modeling is often used to assess the impact changes to materials and assemblies in the building envelope may have on the durability of the exterior walls, primarily due to cumulative moisture effects and the associated degradation actions. Hygrothermal modeling for heritage buildings present a unique challenge for analysis, primarily because owners of these buildings understandably have an entrenched expectation of a long Design Service Life for mass masonry wall systems. The impact of climate change creates a potential confounding error in the analysis if historical weather databases are used in the hygrothermal model rather than databases for the predicted future climate.

The purpose of this paper is to present the results of the predicted durability analysis of one of the several Parliamentary precinct buildings, specifically, the Wellington Building located at 180 Wellington Street in downtown Ottawa, Canada. A comparative study is completed on the hygrothermal analysis for the typical masonry wall system of the building using both the present climatic data and a revised climatic data base that incorporates changes to climate associated with increasing levels of GHG's. The impact of various insulation strategies on cumulative moisture within wall materials and assemblies is also presented for discussion for both the existing and predicted changes in climatic load files.

2 Problem Background

Many historical buildings have performed well for decades (Mario D. Gonçalves 2007) when perimeter steam was used to heat the building and no forced air ventilation systems, or humidification were implemented. The warmer masonry increased the moisture storage capacity of the masonry, reducing condensation potential. Unfortunately, many multi-wythe clay brick buildings have experienced significant degradation after the introduction of interior insulation, forced air ventilation, and humidification (Mario D. Gonçalves 2007).

The presence of exterior Character Defining Elements in historical buildings prohibits the introduction of exterior insulation; thus, insulation is typically applied over the interior surfaces of the masonry to increase the thermal resistance of the wall section and decrease conductive heat loss. However, during the heating season, the low temperatures on the interior face of the brick masonry fluctuates in cold exterior temperatures and when combined with higher moisture levels in the air promote the formation of condensation within the wall system. In order to rationalize the introduction, location, and type of insulation to heritage buildings, a systematic approach is needed, as for example that provided in NRC's "Guideline for design for durability of building envelopes" (Lacasse, *et al.*).

Ottawa is qualitatively considered to have a cold, wet winter. However, climate change associated with increases in GHG's is expected to create overall higher ambient temperatures and rain fall. The Ottawa, Ontario historical (current) climate design values from Appendix C of the National Building Code of Canada are summarized in Table 1, and changes in the design parameters associated with global mean temperature increases of +2.0^{o} C and +3.5^{o}C are also provided for comparison purposes (source ECCC).

Table 1. Current National Building Code environmental loads and predicted loads based on mean global temperature increases of +2.0C and +3.5C. (Gaur, Lacasse, Armstrong)

Scenario	2.5% Jan. Degrees C	2.5% July Degrees C	Degree Days below 18C	Annual Rain mm	Snow Load kPa	Hourly Wind Press., kPa
Current	-25.0	+30.0	4440	750	2.4	0.41
@ +2.0ºC	-17.4	32.7	3609	857	1.66	0.41
@+3.5ºC	-11.7	34.4	3097	933	1.23	0.41

Current models suggest that in addition to rising mean temperatures, the climate will become wetter with estimated increases in annual precipitation of 8.1% and 14.4% for global temperature increases of 2.0º and 3.5ºC, respectively.

The primary goal of the broader investigation is to reduce the heating and cooling loads for heritage buildings and thus, decrease the contribution of building operations to global GHG's. The application of insulation to increase the thermal resistance of exterior walls was therefore analyzed using hygrothermal modeling to reveal deleterious moisture build-up, based on both the existing historical climate loads and predicted changes in climate from increases in GHG's.

3 Methodology

The commercial hygrothermal modeling program, WUFI6.3Pro was utilized for the analysis. The material property input data for WUFI requires the bulk density, porosity, heat capacity, thermal conductivity, and Water Vapour Resistance Factor. Bulk density, porosity, specific heat capacity, and heat conductivity value approximations do not significantly influence the hygrothermal analysis and estimates are generally sufficient (WUFI User Manual). A common problem when undertaking hygrothermal modeling is obtaining the necessary material properties for each of the components in the wall system (Wells, *et al.*). Material testing for all parameters is time consuming and expensive and thus, alternative techniques have been utilized to permit estimating the material properties required for the analysis, including the process of clustering (de Place Hansen and Moller). The following summarizes the known properties and assumptions made determining the material properties used in the present study while Figure 1 shows the plane of each material in the wall system.

- Indiana Limestone (exterior): Quarrier provided data on all properties with the exception of Water Vapour Resistance Factor. WUFI Data base on Krensheimer Shelly Limestone has similar properties; therefore, the vapour resistance for Krensheimer Limestone provided by the WUFI data base was used
- Clay brick (e): Brick hygrothermal data available for red clay brick from Ottawa, tested at NRC. Comparative analysis made to WUFI's material data base on Red Matt Clay Brick.
- Parging(d): Historic Lime and Pozzolana from WUFI data base; largely based on permeability.
- Cork(c), Plaster (a), Paint, etc. from North American WUFI Data base

The Wellington Building was designed and substantially complete in 1927. Figure 1 shows the existing building and interior cross-section; the painted plaster, air space, parging over two wythes of red clay brick, faced by exterior Indiana Limestone veneer. The black spots on the parging are the remnants of mastic that was used to bond one-inch cork insulation to the interior face of the parging.

Figure 1. General elevation view and cross section of exterior wall showing parging and interior red brick behind Indiana limestone veneer. Black spots are mastic used to bond one-inch cork insulation (Interior photo courtesy of JM Carriere of Adjeleian Allen Rubeli Ltd.).

For the hygrothermal analysis, the National Research Council of Canada created WUFI compatible hourly climate data files with assistance from Environment and Climate Change Canada (ECCC). Access to both historical and future projected climate data permits, on the basis of results derived from simulation, estimating the durability response for the exterior walls due to changing climatic exposure conditions. Two climate files were provided; NRC1989, representative of the historical climate loads over 31 years (1985-2016), and NRC2074, characteristic of the predicted climate loads associated with global mean temperature increase of +3.5C due to increasing levels of GHG's. A second set of runs were completed as the base case using the WUFI embedded ASHRAE RP1325 climatic data file for Ottawa.

A primary component of the overall investigation concerns the reduction in GHG generation associated with heating and cooling loads and thus, we assessed the impact on the application of insulation to the interior face of the parging (Figure 1 d.) which is bonded to the inner wythe of brick.The assumption was that the existing interior plaster and cork insulation would be removed to accommodate the new insulation. In total, three insulations were evaluated; open cell polyurethane foam, closed-cell polyurethane foam, and mineral wool insulation. Open cell was chosen to provide air leakage control, and thus an air barrier component on the interior face to reduce interstitial condensation due to its air permeance well below 0.02l/(s-m^2). Closed-cell foam was chosen to provide both air and vapour diffusion control. Finally, mineral wool was also evaluated because of its reversibility and non-combustibility. Each insulation was covered with painted drywall.

With respect to the level of thermal resistance considered for the retrofit, the energy consultant to the project suggested that economics would likely negate a cost-benefit ratio if more than RSI 1.75 to 2.11 were applied. Thus, the hygrothermal models were based on 75 mm of open-cell foam, 50 mm closed-cell foam, and 65 mm of mineral wool such that all levels of thermal resistance were within close agreement.

4 Results

To rationalize the number of hygrothermal model runs to be completed, the existing wall performance, without added insulation was examined based on the climatic data file for ASHRAE 160 embedded into the WUFI program. The ASHRAE 160 - RP1325 historical climate file was found to be generally colder and wetter than that provided in the NRC1989 data and was therefore used as the base or existing case. Four models were run, one for each face of the building, upper elevation to establish the governing case with respect to the largest

moisture build-up. Based on the building's size and geometry, it was confirmed that the upper north face of the building produced the greatest moisture accumulation for both the existing and projected climate change models, NRC2074. Thus, the focus of the investigation centred on the north face. In total, 24 individual hygrothermal model runs were completed for the analysis using an exposure period of five years. Model results were based on with and without the 1% retained moisture, as specified in the ASHRAE 160. In addition to modelling the performance of the existing wall cross-section, the impact of introducing three types of insulation was examined, each applied to the thickness required to increase the thermal resistance of the wall section to approximately RSI2.5.

The following table summarizes the results obtained for the existing ASHRAE Year 1 historical climatic load file, and the predicted performance, based on the 3.5°C mean increase in global temperature, NRC2074. The results show that conditions tend to stabilize seasonally in years three to five; thus, where relevant, the minimum and maximum moisture content is provided. Where moisture levels continue to increase over time, a "∧" has been added to show that the moisture content is generally increasing and not remaining stable over time.

Table 2. Five- year moisture content layer based on existing historical climatic data file and projected climate change model (NRC2074) for base case and insulated wall options.

Scenario	Total Water Content (kg/m^3)	Limestone M.C. (%)		Brick Layer M.C. (%)	Parging M.C. (%)	
		Max.	Min.		Max.	Min.
Exist. Wall	6.0 ∧	0.37	0.24	2.7	0.63	0.45
Exist. + NRC2074	6.0	0.37	0.25	2.90	0.55	0.38
Mineral Wool	6.5 ∧	0.36	0.23	2.80	1.8	0.40
M.W. + NRC2074	6.5	0.39	0.25	2.90	1.5	0.32
Open Cell Foam	6.5 ∧	0.36	0.22	2.80	1.8	0.40
OCF+ NRC2074	6.5	0.42	0.26	2.90	1.4	0.32
Closed Cell Foam	6.2 ∧	0.36	0.22	2.80	0.85	0.50
CCF+ NRC2074	6.5	0.42	0.26	2.90	0.77	0.40
M.W.+Infilt + NRC2074	6.5	0.37	0.23	2.90	2.3	0.40

From the information provided in Table 2, it may be seen that although the climate change model produces higher volumes of annual precipitation, no deleterious levels of moisture build-up were observed in the wall system. In fact, moisture levels remained relatively consistent, irrespective of the insulation type applied to the interior face of the walls. Moisture content for all scenarios is well below critical saturation of the masonry materials as the moisture storage capacity for the limestone, brick, and parging is over 70 kg/m^3, 50 kg/m^3, and 30 kg/m^3, respectively (WUFI Material Data Base).

The ASHRAE 160 recommendation of 1% retained moisture is observed to be the primary driver for increasing moisture content in the walls and based on the results for the existing, wall section (with and without insulation), the model results are indicative of continuing increases in moisture with time of exposure. The climate change model, NRC2074 appears however, to stabilize the moisture accumulation in the walls, regardless of the insulation type applied. The information provided in Figures 2 and 3 show the total water content for the mineral wool insulated wall section based on the current historical ASHRAE 160 climate data file, and the predicted climatic file based on the 3.5°C mean increase in global temperatures, NRC2074.

From the figures, the total moisture content quickly reaches a semi-asymptotic value for the climate change model whereas the historical data file creates a continuing increase in moisture within the wall system. We postulate that the increasing temperatures, as projected in the future under a warming climate, are facilitating a drying process of the walls.

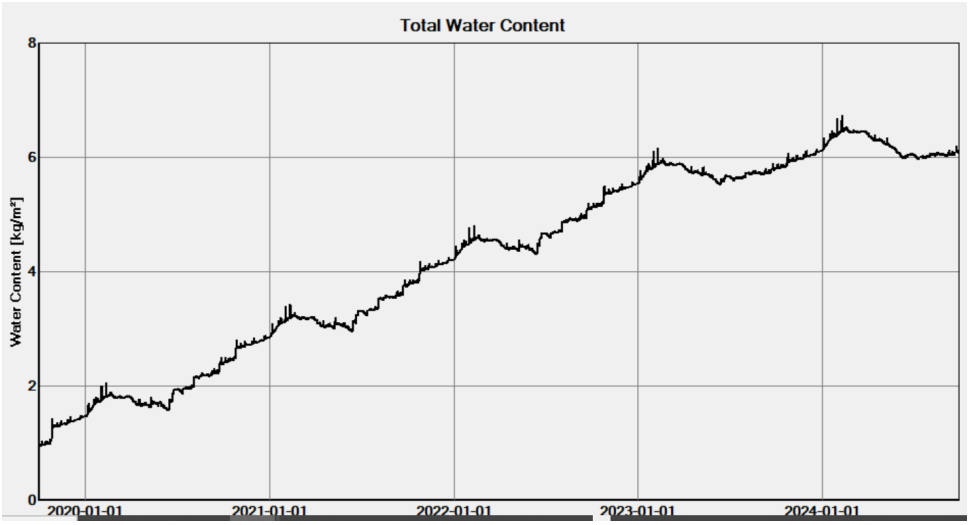

Figure 2. Total moisture content for mineral wool case based on historical ASHRAE 160 climatic data file.

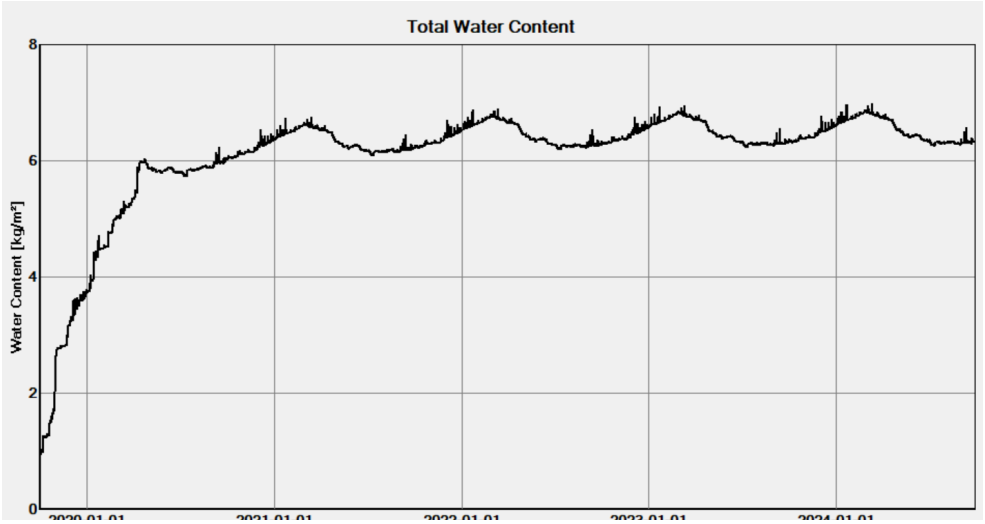

Figure 3. Total moisture content for mineral wool case based on NRC 2074 climate change data file.

One of the principal concerns about the durability of heritage buildings with the inclusion of interior insulation is the potential to reduce masonry wall temperatures below freezing, and to increase the likelihood of freeze-thaw degradation. For the NRC2074 climate file, we introduced air infiltration as a moisture source through the mineral wool insulation model to enable assessing the impact that condensation may have on increasing wall moisture levels. From Table 2, the simulation scenario labelled "M.W. +Infilt. + NRC2074" shows that the moisture levels of the parging and inner wythe of brick predictably increase; however, moisture content remains well below any reasonable limit that might initiate freeze-thaw degradation.

The number of hours per year that the interior face of the parging is below freezing was also found as a simple comparison to evaluate the impact that the different types of insulation have on keeping the interior parging below freezing. A summary of the results of the analysis are given in Table 3; these have been extracted from the WUFI data file in which the mean number of hours per year are provided for the interior parging. It shows the number of hours that the interior parging will be below freezing based on the future projected data (NRC2074) and the same for the historical climate data.

Table 3. Mean number of hours per year interior parging (bonded to inner brick) is below freezing based on existing and projected climate temperatures for existing wall and insulation options.

Climate File	Existing Wall	Mineral Wool	Open Cell Foam	Closed Cell Foam
Historic Climate	718 hrs	1514 hrs	1640 hrs	1733 hrs
Predicted Climate, NRC 2074	0 hrs	604 hrs	740 hrs	830 hrs

The differences in the number of hours per year below freezing amongst the different types of insulation used to retrofit the walls is a function of the type of material and minor differences in the thermal resistances provided by the various insulation types. Regardless, from the information provided in Table 3, the warming climate predicted with the 3.5°C mean global temperature increase will have a dramatic effect by reducing the number of hours the interior parging and inner wythe of brick experiences temperatures below freezing. The warming temperatures may therefore reduce the concern of installing insulation on the interior face of the masonry.

5 Summary and Conclusion

Hygrothermal modeling was utilized to establish if projected changes in temperature and precipitation loads predicted by climate change models from a warming climate will impact the durability of a masonry heritage building, located in Ottawa, Canada having insulation introduced on its interior wall face. The significant findings are summarized below.

- Increasing levels of GHG concentrations has the potential to raise the mean global temperature by +3.5°C degrees. The predicted impact on Ottawa's climate will be significant, increasing precipitation annually by 14.4% and decreasing the January winter design temperature from -25.0°C to -11.7°C or by 53%.
- Results show that although the climate change model produces higher volumes of annual precipitation, no deleterious levels of moisture build-up were observed in the masonry wall systems studied. In fact, moisture levels remained relatively consistent, irrespective of the insulation type applied to the interior face of the walls. Accumulated moisture content for all scenarios is well below critical saturation of the masonry materials.
- Total predicted moisture content in the wall system quickly reaches a semi-asymptotic value for the climate change model whereas the historical data file creates a continuing increase in moisture within the wall system. The increasing temperatures appear to facilitate drying of the walls.
- The warming climate has a dramatic effect by reducing the number of hours below freezing experienced by the interior parging and wythe of brick. The existing wall section, without insulation was predicted to have no hours below freezing along the interior wythe under future climate change loads versus 718 hours under historic loads. With the inclusion of insulation, the reduction in hours below freezing varies from 60%, 55%, and 52% for mineral wool, open-cell foam, and closed-cell foam, respectively, under exposure to future climate loads versus historic climate loads.

The placement of insulation on the interior face of masonry walls in heritage buildings is a proposed solution to reducing heating and cooling loads, and thus, to reducing GHG generation. Using hygrothermal analysis, the study shows that the warming temperatures resulting from climate change potentially will substantially reduce the number hours of freezing temperatures experienced by the interior wythe of masonry, maintain the moisture content of the masonry below a damage threshold, and therefore may reduce the potential for freeze-thaw damage to the masonry. The interior application of moderate levels of insulation should therefore be considered for retrofit measures for this heritage building, located in Ottawa, Canada, without increasing the

risk of damage to the wall. Future studies are proposed which will include a comparative analysis of the hygrothermal results based on testing the actual masonry materials in the Wellington Building in order to validate the material assumptions made in the present study.

Acknowledgements

The authors sincerely appreciate the contribution of Environment and Climate Change Canada (ECCC) for their contribution to the climate data files, Adjeleian Allen Rubeli for the Wellington Building interior photograph, and Mr. Brennan Sperl, E.I.T. of Crosier Kilgour & Partners Ltd. for running of the WUFI models.

Abstract. *The Danish Building regulations are function based and describe in broad terms which requirements must be fulfilled. The main message is that buildings and their structures must be built in such a way that they have a satisfactory functionality and durability i.e. that materials and constructions used can resist the stresses they are exposed to under use. However, there are no Danish guidelines on how to document fulfillment of the requirements. Durability largely depends on moisture related problems, and many failure modes/mechanisms are linked to moisture conditions. It is a prerequisite that the hygrothermal performance of a building component is satisfactory if a long service life shall be obtained. The paper will demonstrate how the risk of moisture problems is assessed in Denmark by using a stud wall as an example. However, simulations can be used for documenting the expected performance of wall assemblies, under in use conditions, however is not a conditional necessity. Even though an evaluation or simulation of moisture conditions show satisfactory results problems can occur e.g. if unsuited materials are used or if materials or building elements are used in another way than foreseen. A few examples are shown how simulations could and could not be used to determine whether a structure would have a long service life or not. Finally, a comparison of simulations, calculations and measurements are performed to illustrate the difference in results from moisture assessment that can be achieved based on assessment methodology.*

Keywords: *Performance Criteria, Assessment of Durability, Documentation, Function-Based, Moisture Simulation.*

1 Introduction

Durability of building materials, components or elements is a crucial parameter in the design of buildings with a long service life. To design for durability, it is necessary to consider which environment the building element is located in, the agents that can degrade the materials and in case of degradation how to maintain or repair the building element (ISO, 2008; Morelli and Lacasse, 2019). Moisture damage is perhaps one of the most critical agents limiting the building's service life causing premature degradation of building elements (Nevalainen *et al.*, 2010; Becher *et al.*, 2017) and contamination of indoor environment (Hägerhed-Engman, Bornehag and Sundell, 2009). A too high moisture content for too long can cause degradation of components inside building elements and/or biological growth of *e.g.* mould. Consequently, studying the coupled heat and moisture transport in structures is essential to improve or document the performance of the building envelope.

This paper presents a number of methods that might be applicable to document the service life as required in the Danish Building regulations (BR, 2019) related to moisture problems.

Furthermore, the paper will discuss if hygrothermal simulations are needed for evaluating the durability of the design of structures. Using an exterior wooden-stud wall as example, the paper discusses how the risk of moisture problems can be assessed applying different methodologies. Furthermore, calculations/simulations are compared to measurements conducted in the stud wall, to illustrate how the documentation of the expected performance can be conducted. Finally, two examples are presented on failure mechanisms, where unsuited materials or design is used for a given outdoor climate.

1.1 Prescriptive or Performance-Based Building Regulations

During the past decades, the Danish building regulations have amended from prescriptive building regulations towards performance-based regulations. Gottlieb and Frederiksen (2019) mention the accelerating development of new products and materials as contributing to change the building regulations towards performance-based requirements. The development from prescriptive to performance-based regulations are seen in the building style of older apartment buildings in Copenhagen. Many old buildings constructed around 1900 have similar façade appearance because the building regulations had prescriptive requirements related to the building design; whereas the appearance of today's building stock is more varying. The performance-based regulations describe the functional attributes that *e.g.* building components must fulfill. These requirements can be achieved with several designs; *i.e.* the regulations do not any more describe how to build but rather what performance the finished buildings shall have.

The chapter of the building regulations related to energy consumption set out a maximum allowable energy consumption for the entire building (BR, 2019, §259-260) and an upper threshold for the U-values of the structures (BR, 2019, §257). In the chapter related to moisture, the regulations only describe that buildings and their structures must be built in such a way that they have a satisfactory functionality and durability, and that materials used can resist the environment they are exposed to (BR, 2019, §334). The energy and moisture examples illustrate the variation in details of the Danish building regulations, that consulting engineers and architects faces (hereafter referred to as designers). On the one hand, exact energy requirements are given (and there exist a tool to use for documentation); however, on the other hand there is no methodology to document that moisture will not result in moisture problems in the structure or indoor climate. Regarding documentation of moisture related properties, the designer can perform, *e.g.* Glaser method calculation (Glaser, 1958) or detailed hygrothermal simulations in 1D or 2D; however, it is up to the designers to decide on the level of documentation for whether the structures comply with the building regulations. A random check is performed in 10% of building projects with occupation permit, however, the random check does not necessary include an evaluation of the moisture documentation.

2 Methods for Assessing Moisture Problems

Designers of structures can use a variety of methods to support or document that the structure is durable regarding moisture exposure under in use conditions. However, the different methods all have limitations. The authors understand that the methods described below are those most commonly used in Denmark. The approaches are ranked from simple to complex, and can be used to evaluate the risk of moisture problems, where mould growth is considered the first

indication of a mediocre structure design, which can contribute to health problems indoors.

1. *"Common best practice" or learn from experience.* This is normally supported by guidelines (*e.g.* www.anvisninger.dk) and experience documents (*e.g.* Building defect sheets, www.byg-erfa.dk) made on basis of experience from the use in practice. Normally, materials and building elements described in this literature function satisfactory under the given climate condition etc. No calculations or further documentation for properties is needed.
2. *Simulation of isotherms combined with determination of the point where the relative humidity exceed 75% or condensation.* This is used in more complex structures of 2D problems. Combined with considerations of the indoor environment and temperatures in the construction this is a simple evaluation method. The designer has to decide on the evaluation criteria of a given relative humidity, which normally is set to 75%.
3. *Glaser calculation according to EN 13788 (EN ISO, 2012).* This includes calculation of surface and interstitial condensation including drying out of the structure or evaluation of critical points exceeding 75% relative humidity. Glaser is used on 1D problems.
4. *Hygrothermal simulations in 1D or 2D.* In more complex structures simulation programs can be used to determine the conditions in the structure and on all internal surfaces. This method is the most comprehensive approach for assessing moisture conditions in building elements. However, the results are to be post-processed with another evaluation tool.

Depending on the chosen approach (1-4), the simplest evaluation is to check if the relative humidity exceed a threshold value of 75%. Post-processing methods that are more sophisticated are developed to evaluate for example the performance of exterior walls with respect to exposure of high moisture load for too long. In these methods both time, temperature, moisture level and material are considered. For organic materials, this would especially be with respect to evaluating the risk of mould growth and/or wood rot, whereas for inorganic porous materials it could be evaluating the risk for freeze-thaw damages. Other types of environmental actions could be subterranean termites, drying and shrinkage as well as alkali-aggregate reactions.

3 Example of Measurements, Calculation and Simulation

In this example, we consider an exterior wood-stud wall constructed with 465 mm glass-fiber insulation as shown in Figure 1 and installed in a single-family house. The vapour barrier was mounted behind the first inside insulation layer. In the wall, measuring devices were installed to measure temperature and relative humidity. The measuring points were located in the interior insulation against the vapour barrier and in the exterior insulation against the plywood board. The measurements were conducted from October 2013 to March 2014.

3.1 Boundary Conditions

The Glaser calculation used boundary conditions from October to March; *i.e.* monthly average values of temperature and relative humidity for Denmark and internal humidity class 2 (EN ISO, 2012) for the interior climate, see Table 1.

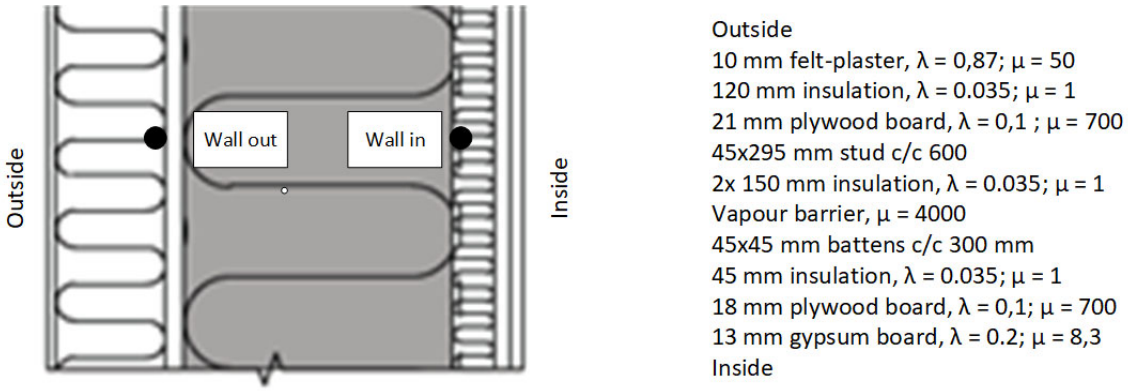

Figure 1. Exterior wood-stud wall with 465 mm insulation.

Table 1. Climate data for Glaser calculation. Temperature in ºC and relative humidity in %.

	October	November	December	January	February	March
T_{in}	20	20	20	20	20	20
RH_{in}	57	53	49	46	46	49
T_{out}	9.2	5.0	1.6	-0.6	-1.1	2.6
RH_{out}	87	91	88	94	91	91

In the hygrothermal simulations, weather data from Lund in southern Sweden (close to Denmark) was used as exterior boundary conditions, and the indoor climate was set according to the internal humidity class 2. Based on the results from the simulations the risk of mould growth was evaluated on the outside of the plywood and the inside of the vapour barrier, which then are comparable with the measurements and Glaser calculation.

3.2 Results from Measurements, Calculations and Simulations

Figure 2 show the results from WUFI simulations (Künzel, 1995), Glaser calculations and measurements for the period October to March. The results are not a validation of the three methods but only a way of illustrating how different approaches can bring different results.

4 Discussion

Designing for durability requires that designers consider several aspects where some information is difficult to predict *e.g.* climate changes and some are unknown *e.g.* material properties of new products. de Place Hansen *et al.* (2020) present a systematic review of new products used in building envelope structures, aiming at reducing the risk of using unsuited materials.

Using common best practice documents for design is based on many years of experience. However, the conditions under which the building elements perform is retrospective and the used materials and components are well known. Therefore, one might question how these structures will perform in the future with expected climate changes. These common best practice designs of the building envelope, further presume that built-in moisture is very limited, and that eaves protect the walls. The common best practice designs do not require documentation of the long-term performance, as this is implicit in the documents published.

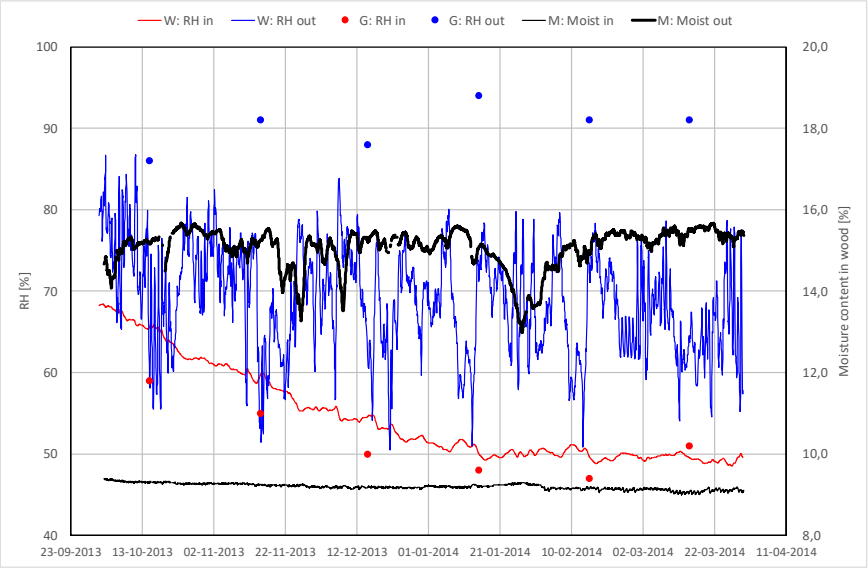

Figure 2. Results from WUFI simulations, Glaser calculations and Measurements from October to March.

Considering the other three methods (isotherm -, Glaser calculations and hygrothermal simulations) presented for assessing moisture problems in structures, all take into account interior and exterior boundary conditions differently. In a Danish context, the different methods are challenged by the different outdoor climate used, *e.g.*, that Glaser calculation uses monthly average values of temperature for a Danish reference year. Danish weather data does not exist for hygrothermal simulations where rain data are included. Therefore, weather data for either Sweden or Germany are used, as these are the closest data that is available. Finally, isotherm calculations only consider temperature.

The climate that the building envelope is exposed to – and especially moisture as an agent that might reduce the durability – is perhaps the most important. Therefore, moisture exposure during the construction phase should be limited as far as possible, thus increasing the durability.

The application of the four approaches are presented as methodologies for assessing the moisture durability of building envelope structure. Depending on the complexity of the structure or (un)known materials, one of the four approaches could be used for documenting the moisture durability, see Figure 3.

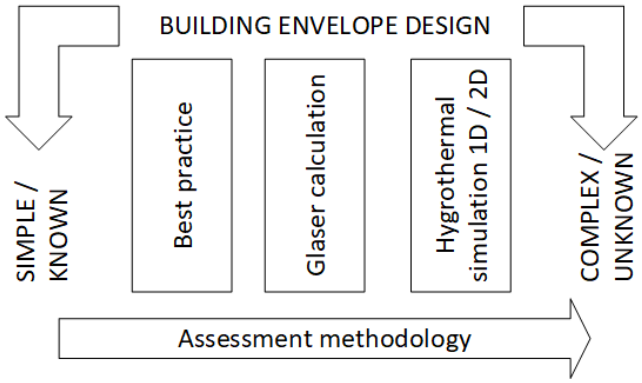

Figure 3. Example of an approach on how to document the moisture durability depending on complexity or (un)known materials.

Hygrothermal simulations are highly relevant in the toolbox of the designer when assessing the durability of building envelope structures. Therefore, it is important to investigate how the building envelope perform under future climate conditions. Performing simulations with a varying climate *e.g.*, as in Canada using cycles of wet-wet-dry years, future climates as can be found under Climate for Culture (a project that investigating the potential impact of climate change on Europe's cultural heritage assets) or weather data with 50 years of occurrence might be needed. Nevertheless, investigating the structure with a retrospective outdoor climate file for several continuous years seems to be insufficient.

In Denmark, the use of hygrothermal simulations become more popular in the design of new structures. However, there exist no guidelines on how to approach such a task and how to assess the output from the simulations. Therefore, the documentation of the requirements in the building regulations depends on the individual designer. The authors suggest that a guideline for design for durability is developed in Denmark. Such a guideline could be inspired by the "Guideline on design for durability of building envelopes" (Lacasse *et al.*, 2018) that is suggested to be implemented in the Canadian building codes. The guideline seems to be reasonable when having known materials that are built together in a different way as described in the common best practice documents. However, the application of the methodology is a challenge when new products are brought to the market that are not already incorporated in hygrothermal simulation programs or for which relevant material properties are not available – here a best estimation must be performed based on the known properties. New materials could be developed for a specific function in a stud wall, however the designer or contractor might suggest to use this new product instead of another product. In such cases, the product might be misused leading to major problems for the building owner. Such cases do not seem to be able to detect using hygrothermal simulation programs.

Performing assessment of the building envelope design also requires post-processing that are anchored in the national building regulations, thus a uniform assessment of the building envelope design for durability can be performed by different designers across the country, such an approach was presented by Overton (2019) for New Zealand.

4.1 Example of Problems Despite Good Results of Moisture Assessment

Even though an evaluation or simulation of moisture conditions show satisfactory results problems can occur e.g. if unsuited materials are used or if materials or building elements are used in another way than foreseen. A couple of examples are given below to illustrate the problems that may be encountered.

4.1.1 Use of MgO boards as wind barrier

MgO boards were introduced in Denmark for use as wind barriers in facades etc. around 2009-2010. Several different suppliers described the material as well suited for the use. The boards had many good properties including permeability, strength, weight, fire properties, workability and price. Due to the price and workability, the boards quickly became popular and gained a good market share even though there was not sufficient impartial documentation. After about five years problems started to occur. The use of boards as wind barrier meant that the boards were exposed to high relative humidity in longer periods of the year. This caused problems as the boards contains salt, which absorbs moisture until the boards start to "cry", *i.e.* salty water

was running from the boards. This caused problems with increased moisture levels in the neighboring materials, corrosion of fastener, screws etc. and mould growth.

The main problem here was that the degradation mechanisms for the material were not identified before the products was used. In this case, an identification of the properties of the board could have revealed that it was not able to withstand the environment in which it was envisaged to be used. A simulation of the moisture content on the wind barrier could have been used to identify the conditions the product would be exposed to.

4.1.2 Use of building elements in harsher environment

In Denmark moisture simulations and full scale tests have shown that wooden facades under certain conditions may be used without ventilation behind the outer cladding.

Recently, the Danish Building Research Institute was asked if the construction also were suited for use in a summer cottage near a coastline exposed to a lot of severe wind (and consequently a lot of driving rain). In this case, a construction tested under conditions simulating a heated house exposed to "normal" wind was proposed to be used under quite different conditions, *i.e.* no heating in winter time and therefore no vapour pressure to remove moisture from the wall, and at the same time risk of more water penetrating through the cladding due to the increased driving rain exposure.

The main problem here is that a correct assessment or simulation is not used – the result of the assessment might be quite different in the less favourable environment. Of importance is that one must understand the context of simulation results and the assumptions/limitations on those results before applying to new scenarios.

4.1.3 Degradation mechanisms must be identified

In order to make a good overall evaluation of the durability of a product it is a necessary condition that an assessment/simulation of the hygrothermal conditions is performed.

However, this is not a sufficient condition as it is also necessary to identify the degradation mechanism of the material or building component and the anticipated assemblies these are envisioned to be used in. The degradation mechanism may be identified partly based on knowledge about the material(s) used. Further, it should be investigated what the functions are of the product, which environment it will be used in (what is the product exposed to) and which properties are necessary.

To ensure long service life materials or building elements should be chosen so they have the sufficient properties. Proof of this should be documented by testing/evaluation of an impartial body.

In case the use conditions are changed as mentioned in the above example (4.1.2) or if the product is envisaged to be used for quite other purposes – *i.e.* with new functions – a new investigation of degradation mechanisms has to be performed as, exposure to another environment must be expected and the necessary properties therefore may be different.

5 Conclusion

To conclude, the authors do not believe that hygrothermal simulations always is the way of documenting building envelope design for its durability. However, the simulations are a strong tool to support the documentation and investigation of new structures that consist of known

materials and components. In any case, the designer must first determine the agents effecting the durability, and then decide how this can be documented *e.g.* applying hygrothermal simulations. Using new materials, the authors do not believe that environmental actions such as agents causing corrosion or decay always are identified as this depends on the designer knowledge. Furthermore, action effects are not necessary made visible through the simulations as new materials are not tested and available in hygrothermal simulation programs. In such cases, the simulations can be used to determine the microclimate that the new product is placed in and its required properties to secure a long service life.

The authors suggest, that in the Danish context, a Guideline on design for durability of building envelope is developed and guidelines for assessing results from hygrothermal simulations. Such two guidelines will be a valuable support for designers when they have to document the durability of structures according to the requirements in the performance-based building regulation. The authors outlined a framework for an approach on how to combine moisture assessment methodologies to the complexity of building envelope structures.

Abstract. *Internal insulation of masonry walls may significantly increase the decay risk of embedded wooden beams due to lower temperature and consequently lower drying potential in the existing wall. Since high moisture contents will affect the performance and service life of wood, the study of moisture-related damage problems in wooden beam-ends in internally insulated masonry walls is of great importance. In the previous studies, the numerical study of hygrothermal performance of wooden beam-ends is performed only with 2D models. In this paper, we study whether a 2D numerical model can represent accurately the 3D hygrothermal behavior of wooden beam-ends. Therefore, the difference between 2D and 3D model results of the hygrothermal performance of wooden beam-ends embedded in an internally insulated masonry wall is analyzed. The difference of temperature and relative humidity in wooden beam-end between 2D and 3D models is in general small. However, 2D hygrothermal models show much lower relative humidities and thus lower moisture risk at some locations in the wooden beam-end. We find that a 3D hygrothermal model more accurately simulates the hygrothermal behavior.*

Keywords: *Interior Thermal Insulation, Wooden Beam, 2D Modeling, 3D Modeling.*

1 Introduction

Many historical buildings are built with solid brick walls and wooden beam constructions. These buildings are mostly not energy efficient and represent a significant energy-saving potential. For some historical buildings with a worth-preserving facade, the only possible energy renovation measure is internal wall insulation. Internal insulation of masonry walls may significantly increase the moisture-related damage risk of building materials and components due to lower temperature and consequently lower drying potential in the existing wall (Morelli and Svendsen, 2013; Harrestrup and Svendsen, 2016; Zhou *et al.*, 2017; Zhou *et al.*, 2018). The floors in old masonry buildings are often carried by wooden beams embedded in the brick. The study of moisture-related problems in wooden beam-ends in internally insulated masonry walls is of high practical and scientific importance (Kehl *et al.*, 2013).

Field investigation and numerical study both indicate that exterior render affects water uptake by external walls during wind driving rain events (Künzel *et al.*, 2004; Pazera and Bomberg, 2010; Guizzardi *et al.*, 2015; Zhou *et al.*, 2018). Exterior renders with high liquid water permeability tend to lead to high moisture contents in the masonry. It is important to study the hygrothermal behavior and durability risk of wooden beam-ends after internal

insulation for renders with different rain protection.

Moisture and heat transport in masonry wall with wooden beam is in reality a three-dimensional problem. However, many studies use only 2D hygrothermal models to study the moisture risk of wooden beam-ends in internally insulated masonry (Johansson *et al.*, 2014; Guizzardi *et al.*, 2015; Harrestrup and Svendsen, 2016). In a 2D model, wooden beam is assumed to have the same width as the wall envelope. However, in reality, the width of wooden beam is much smaller compared to that of wall envelope. It is still an open question whether a simplified 2D numerical model can represent accurately the hygrothermal conditions as modelled in 3D. The aim of this paper is to compare 2D and 3D hygrothermal modelling of the hygrothermal performance of wooden beam-ends embedded in an internally insulated masonry wall.

2 Modelling

2.1 Methodology

Because of modelling restriction, it is hardly feasible to model all bricks and mortar joints of a masonry wall in 3D, since it would lead to very large meshes and high computational costs. Therefore, some simplifications are needed to model the masonry wall in 3D. First, a 2D model with a detailed distribution of bricks and mortar joints is built. Then a 2D model with simplified distribution of bricks and mortar joints is built and compared with the detailed 2D model. The simulated results from these two 2D models are compared and discussed. Finally, based on results of the simplified 2D model, a simplified 3D model is developed.

A typical masonry wall structure of Switzerland is considered for this analysis. The geometry of the 2D model with detailed distribution of bricks and mortar joints is shown in Figure 1. The 2D model comprises from exterior to interior in an exterior render, a masonry wall (three wythes of brick), an original interior plaster, an aerogel-based insulation layer and a new interior plaster layer. In the geometry, there is a 1-cm thick air gap at the wooden beam-end, which prevents direct contact between the wooden beam and the masonry and functions capillary break. A simplified 2D model of this wall is shown in Fig. 2, where the horizontal mortar joints are neglected. The horizontal mortar joints have much smaller liquid permeability compared to brick. Liquid water bypasses the horizontal mortar joints and transports to the inside mainly through brick. The vertical joints are however barriers to liquid transport and have to be considered. The 3D model follows the geometry of the simplified 2D model (Figure 3). In 3D, the width of masonry wall is 100 cm and the width of wooden beam is 20 cm.

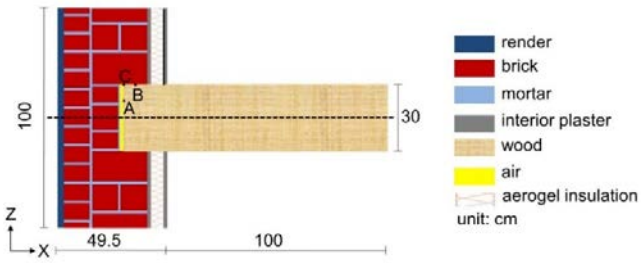

Figure 1. A detailed 2D schematic representation of wooden beam in an internally insulated masonry wall.

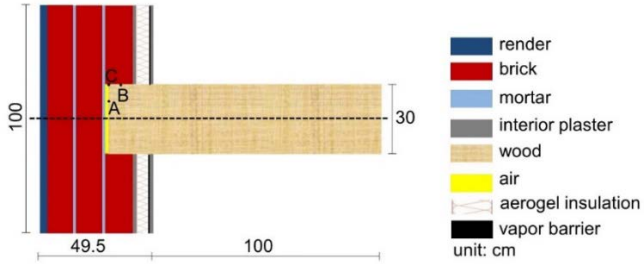

Figure 2. A simplified 2D schematic representation of wooden beam in an internally insulated masonry wall.

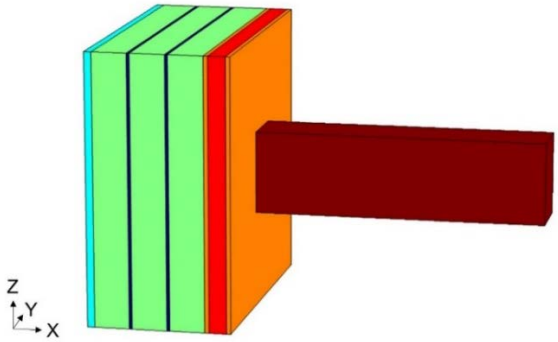

Figure 3. A 3D schematic representation of wooden beam in an internally insulated masonry wall.

2.2 Material Properties

Three types of exterior render are considered: cement lime plaster, lime cement plaster and mineral plaster, which are used to study the influence of the rain protection by the render on moisture-related damage risk of wooden beam-ends embedded in an internally insulated masonry wall. The properties of renders are taken from the WUFI material database (Künzel, 1995). The cement lime plaster shows the highest liquid permeability, followed by the lime cement plaster and the mineral plaster shows the lowest liquid permeability and thus the highest rain protection. No hydraulic interface resistance is considered between brick and mortar. The material properties of brick and interior plaster is from Hagentoft *et al.*, 2004. The material properties of mortar and aerogel plaster are from Guizzardi *et al.*, 2015. The wood of the beam is spruce. Its material properties are obtained from the WUFI database (Künzel, 1995). The wood is considered anisotropic, with longitudinal direction along the beam orientation. Vapor permeability, liquid permeability and thermal conductivity along longitudinal direction are different from those of radial and tangential directions.

2.3 Initial and Boundary Conditions

The hygrothermal performance analysis is based on the moisture reference year of 1999 for Zurich (Zhou *et al.*, 2016). This year is a wet year with a return period of 10 years. The selected wall orientation is 240 degrees from north (WSW), which shows the highest risk for moisture-related problems. This orientation is selected based on the procedure proposed in Zhou *et al.,* 2016. The exterior conditions consists in hourly values of meteorological data from the MeteoSwiss meteorological station. The exterior convective heat transfer coefficient

is calculated according to European standard EN15026. The exterior mass transfer coefficient is related to the exterior convective heat transfer by use of the Lewis analogy. The wind-driven rain load on wall surface is calculated according to ASHRAE Standard 160 - Criteria for Moisture Control Design Analysis in Buildings (TenWolde, 2008). According to Künzel and Kiessl (1996), 70% of the wind-driven rain hitting the façade stays there; the rest splashes off the surface and falls to the ground. The interior conditions are determined according to the European standard EN15026, in which the indoor air temperature and relative humidity depend linearly on the outdoor temperature. The building components have an initial temperature of 20.0 °C and relative humidity of 60%. The simulation is started from October 1st, and repeated for 8 years. The results of the 8th year, which are found to be independent from the initial conditions, are used for further analysis.

2.4 Governing Equation for Moisture and Heat Transport

The three-dimensional governing equations for coupled moisture and heat transport in the building wall envelopes are the following [17]:

$$\frac{\partial w}{\partial p_c}\frac{\partial p_c}{\partial t} + \nabla \cdot (\mathrm{g}_l + \mathrm{g}_v) = 0 \tag{1}$$

with

$$\text{liquid flow: } g_l = -K_{lx} \cdot \nabla p_c - K_{ly} \cdot \nabla p_c - K_{lz} \cdot \nabla p_c \tag{2}$$

Vapor flow:

$$\begin{aligned} g_v = &-\delta_{vx} \cdot \frac{p_v}{\rho_l \cdot R_v \cdot T} \cdot \nabla p_c - \delta_{vy} \cdot \frac{p_v}{\rho_l \cdot R_v \cdot T} \cdot \nabla p_c - \delta_{vz} \cdot \frac{p_v}{\rho_l \cdot R_v \cdot T} \cdot \nabla p_c \\ &-\delta_{vx} \cdot \frac{p_v}{\rho_l \cdot R_v \cdot T^2}(\rho_l \cdot L_v) \cdot \nabla T - \delta_{vy} \cdot \frac{p_v}{\rho_l \cdot R_v \cdot T^2}(\rho_l \cdot L_v) \cdot \nabla T - \delta_{vz} \cdot \frac{p_v}{\rho_l \cdot R_v \cdot T^2}(\rho_l \cdot L_v) \cdot \nabla T \end{aligned} \tag{3}$$

$$(c_0 \cdot \rho_0 + c_l \cdot w) \cdot \frac{\partial T}{\partial t} + \nabla \cdot (c_l \cdot (\mathrm{T} - \mathrm{T}_{ref}) \cdot g_l + (c_v \cdot (\mathrm{T} - \mathrm{T}_{ref}) + L_v) \cdot g_v = -\nabla(\lambda_x \nabla T + \lambda_y \nabla T + \lambda_z \nabla T) \tag{4}$$

where w is the moisture content (kg/m^3), p_c is the capillary pressure (Pa), g_l and g_v are the liquid and vapor flow (kg/m^{2}s), K_{lx}, K_{ly} and K_{lz} are the liquid permeability in the x, y and z direction (s), δ_{vx}, δ_{vy} and δ_{vz} are the water vapor permeability in the x, y and z direction (s), p_v is the vapor pressure (Pa), ρ_l is the density of water (kg/m^3), R_v is the gas constant of water (J/kg K), T is the temperature (K), c_0 is the specific heat capacity of solids (J/kg K), c_l is the specific heat capacity of water (J/kg K), c_v is the specific heat capacity of vapor (J/kg K), ρ_0 is the density of solids (kg/m^3), T_{ref} is the reference temperature (273.15 K), L_v is the latent heat of vaporization (J/kg), λ_x, λ_y and λ_z are the thermal conductivity in the x, y and z direction (W/mK). For two-dimensional model, the variables in the Y direction is neglected.

3 Results

3.1 Comparison of Results Between Detailed and Simplified 2D Model

The simulated results are given for three selected positions at the wooden beam of the 2D detailed and simplified models. The three positions are points A, B and C shown in Fig. 1 and 2. Point A is located next to the air gap in front of the wooden beam. Points B and C are located on the top of the wooden beam in contact with the masonry wall. Point B is located slightly more to the inside compared to Point C. Although the distribution of bricks and mortar joints is different between the detailed and simplified 2D models, the relative humidities are very close between these two models (Figure 4). For render of cement lime plaster and mineral plaster, the largest difference in relative humidity between the two models is less than 0.01. For render of lime cement plaster, the largest difference of relative humidity is less than 0.02. For all the three renders, the relative humidities are almost the same between the two models at Point C. In general, the relative humidity from the simplified 2D model is slightly higher during the cold period, whereas it is slightly lower during the warm period. As the moisture-related damage such as mould growth occurs in the cold period, the result from simplified 2D model will be slightly conservative compared to the detailed model. The difference of temperature between different points is very small. The largest difference in temperature is less than 0.1 K. Considering the small difference of relative humidity and temperature between the simplified and detailed 2D model, simplification of the detailed distribution of brick and mortar joint is reasonable and justified and the simplified 2D model can well represent the detailed 2D model.

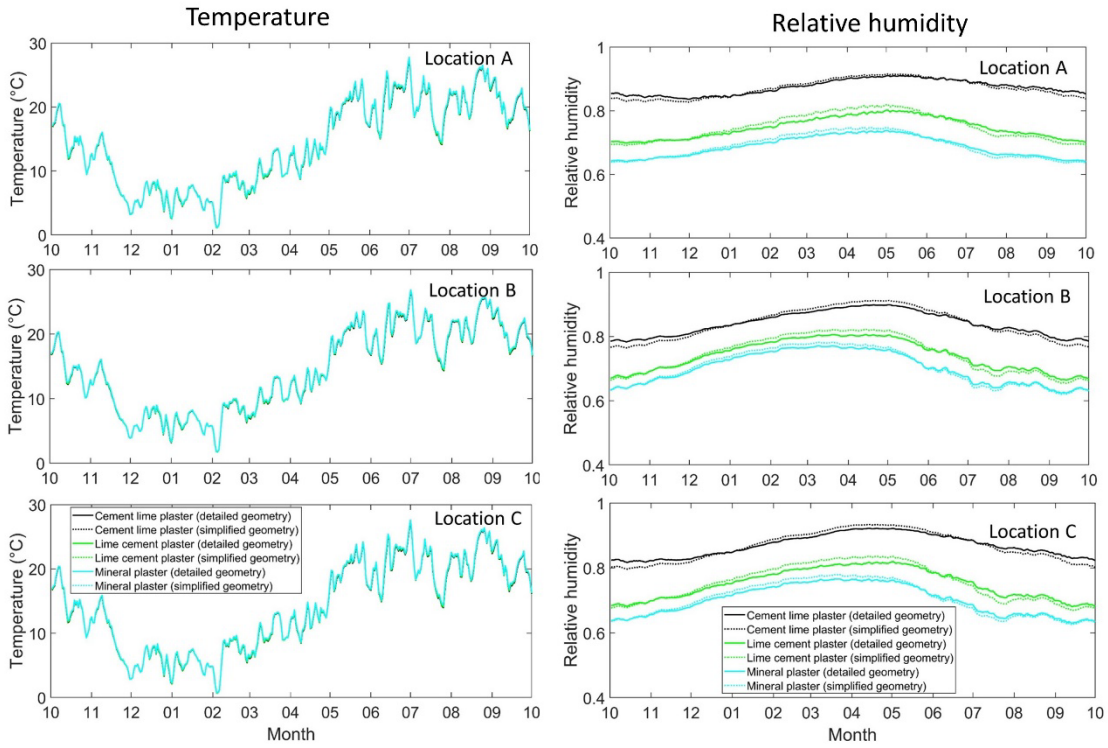

Figure 4. Temperature and relative humidity at Point A, B and C in detailed and simplified 2D model.

3.2 Comparison of Results Between 2D and 3D Model

3.2.1 Comparison of Temperature

In 3D we consider the real width of the wooden beam of 20 cm, while in 2D the wooden beam covers the total width of the wall. Although wood has rather low thermal conductivity, it is still much larger than that of aerogel plaster. Therefore, the wooden beam works as a kind of thermal bridge in the internally insulated masonry wall. Due to the higher heat flux in the beam, the middle cross section of the wooden beam embedded in masonry wall will be warmest cross section of the wooden beam during winter period, while the outermost surface in contact with masonry wall will be the coldest one. So, we consider the temperature in the points A, B and C in the middle section and in the surface in contact with the masonry (called outermost cross section). In general, there are some differences of temperature between the 2D and 3D models (Fig. 5). The temperature in the 2D cross section is the highest. The higher temperature in the 2D cross section is due to larger width of wooden beam and thus larger thermal bridge effect in the 2D model. The largest temperature difference at points A, B and C between the 2D and 3D cross sections is 1.08 K, while the smallest one is 0.02 K. In the 3D model, the temperature from the center cross section is higher than that in the outermost cross section. The largest temperature difference at points A, B and C between the 3D middle and 3D outermost cross sections is 0.46 K, while the smallest one is 0.02 K.

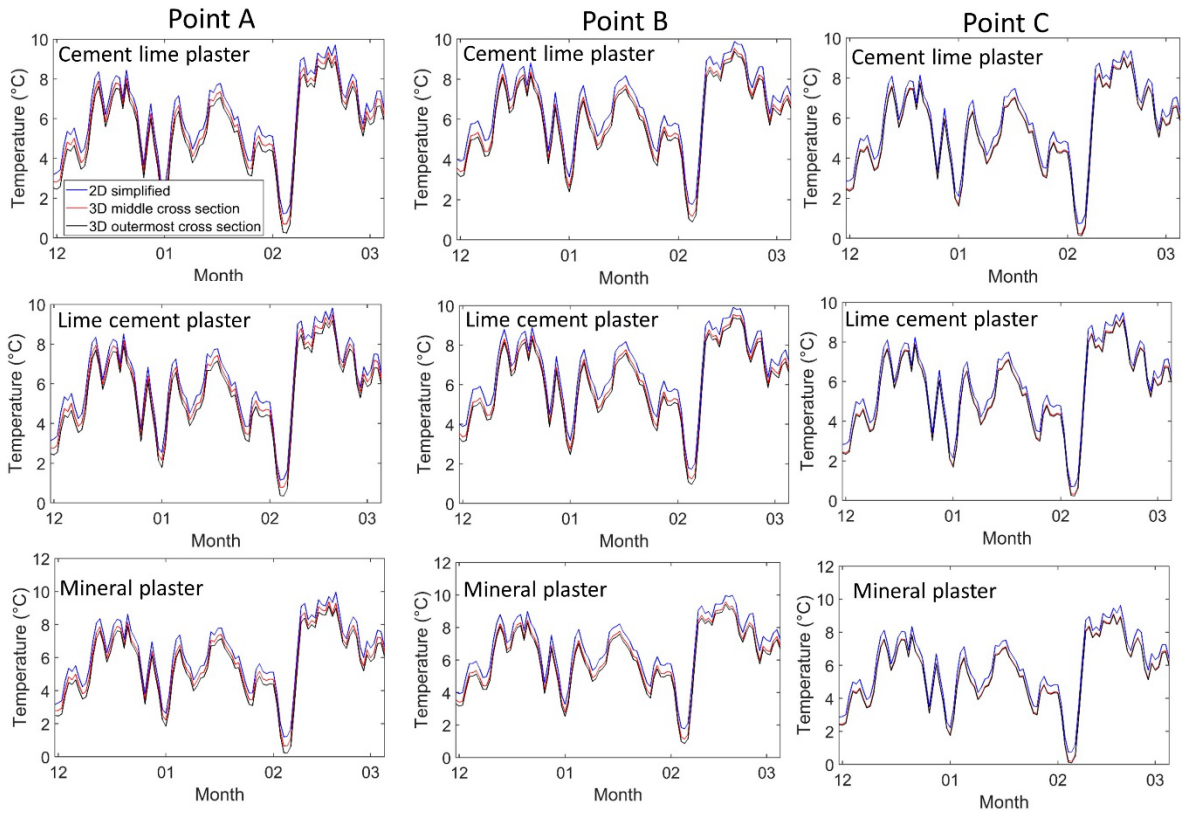

Figure 5. Temperature at Points A, B and C in simplified 2D model and middle and outermost cross section of the 3D model in winter period.

3.2.2 Comparison of relative humidity

The differences in relative humidity among different cross sections is large at point A (Figure 6). The largest difference is in the wall envelope with mineral plaster (low liquid permeability), which can reach 0.06. In general, the fluctuation of relative humidity at the outermost cross section of the 3D model is larger than at the central cross sections, especially during the cold periods. Relative humidity at point A at the central and outermost cross sections is quite different whereas relative humidity at points B and C at the central and outermost cross sections is very close. For the wall envelope with mineral plaster, relative humidity at point A is continuously below 0.8 in the 2D model while it can be above 0.8 continuously from February to June at the outermost cross section in the 3D model. The 2D model will in general underestimate to some extent the moisture risk compared to 3D model. If the study is to have accurate relative humidity in the wooden beam-end, it is not appropriate to replace a 3D model with a 2D one.

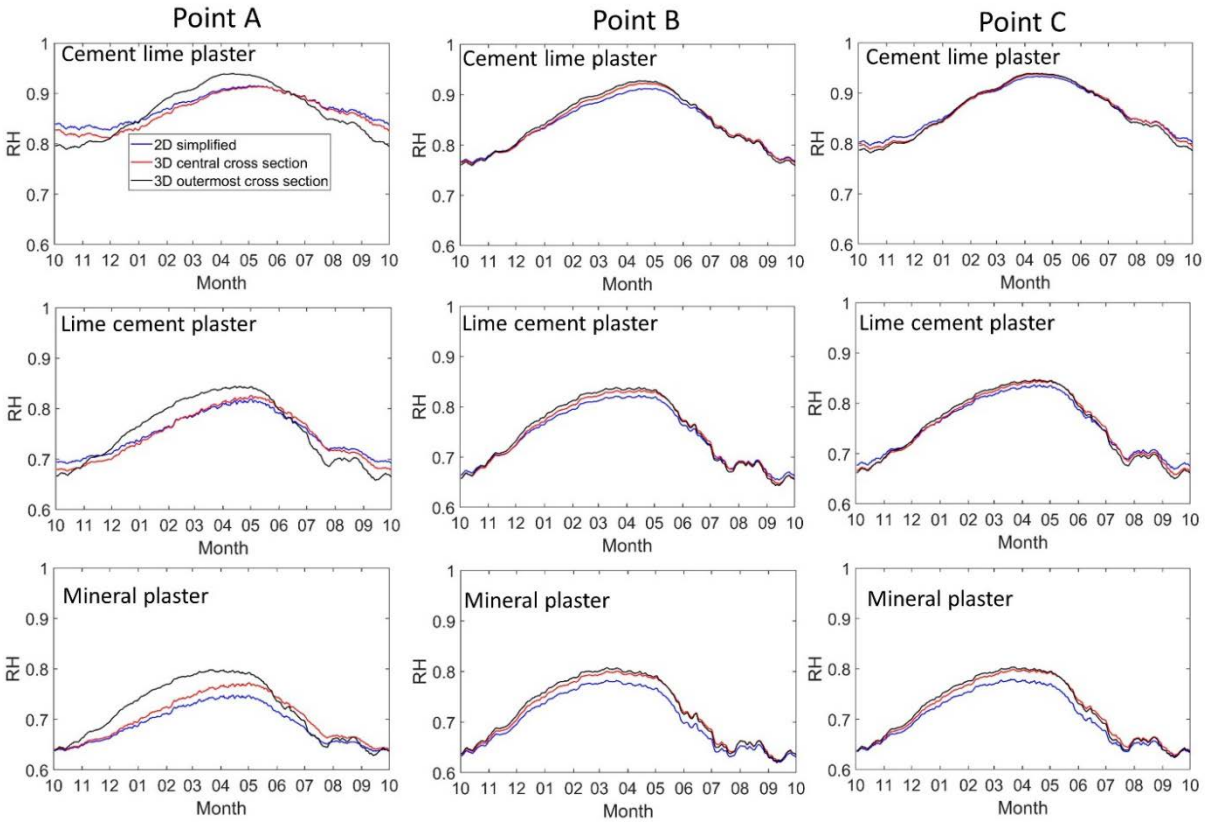

Figure 6. Relative humidity at Points A, B and C in simplified 2D model and central and outermost cross section of the 3D model.

13 Conclusions

- The hygrothermal performance of a wooden beam-end embedded in an internally insulated masonry wall is analyzed using 2D and 3D hygrothermal models.
- The difference of temperature and relative humidity in wooden beam-end between 2D

and 3D models is in general small. However, 2D hygrothermal models show much lower relative humidities and thus lower moisture risk at some locations in the wooden beam-end. In general, a 3D hygrothermal model can more accurately represent the hygrothermal condition than the 2D one.

Preventing Damage by Updating Moisture Control Standards

Hartwig M. Künzel

Fraunhofer Institute for Building Physics, 83626 Valley, Germany,
Hartwig.Kuenzel@ibp.fraunhofer.de

Abstract. *Despite progress in moisture control analysis, repairing moisture damage is still a considerable cost factor in the building sector. While there are many reasons for the lack of improvement during the last decades, inadequate moisture control standards are certainly also to blame. In many countries, interstitial condensation calculations according to Glaser are the sole means for assessing moisture control design, neglecting other important moisture loads such as driving rain, construction moisture and air infiltration. To overcome this lopsided focus on vapour diffusion, the update of the German moisture control standard has restricted the applicability of the Glaser method and introduced a normative Annex on performance evaluation by hygrothermal simulation. Recently, a new project has started to develop advanced models helping to evaluate the simulation results. Currently, it is already possible to assess the risk of mould growth, rot, and critical moisture accumulation by methods referred to in this standards. Also addressed in the standard is the selection of critical indoor and outdoor boundary conditions. Thus, it is officially encouraged to perform hygrothermal simulation, giving architects and engineers the chance to design more moisture tolerant and ultimately more durable constructions. Considering the necessity to reduce the carbon footprint of buildings, the application of hygrothermal simulation provides the opportunity to use more innovative renewable and recycled materials that could not adequately be judged by the Glaser method. Another benefit presents the analysis of construction resilience in case of natural disaster such as flooding or extreme rain events.*

Keywords: *Moisture Control Standard, Hygrothermal Simulation, Moisture Tolerance, Building Resilience, Damage Prevention.*

1 Introduction

Moisture in the building structure impairs thermal performance and accelerates ageing and degradation. Therefore, moisture control has always been an issue for architects and engineers. Despite an improvement in construction quality, moisture problems have not diminished accordingly. This may partly be due to increasing energy savings requirements. More insulation and better air-tightness have resulted in lower temperatures at the exterior layers of the building envelope and higher indoor humidity. This increases the risk of interstitial condensation and reduces the drying potential. The high number of moisture related building failure also demonstrates that traditional condensation control and the steady-state tools to evaluate vapour diffusion are not sufficient to account for all relevant moisture loads. Additionally, natural disaster with torrential rain and flooding will become more frequent which means more risk for moisture susceptible but environmental friendly renewable materials. However, adequate moisture control design can help to prevent problems even in the most energy efficient structures. The necessary design tools are there, but they have to be applied the right way. While it is fair to assume that a building has been erected according to best practice, a perfect seal against water, vapour or air entry is difficult to achieve. Therefore, the consideration of

imperfections should be part of moisture control assessments.

Hygrothermal simulation offers an opportunity to meet the current challenges if the underlying models allow for the fact that no building component is perfectly sealed and envelope leaks and other flaws are always built-in or may eventually occur during the building's service life. New approaches have been developed to account for rainwater penetration and indoor air infiltration. This paper summarizes these approaches and shows examples of standards and guidelines that have started to integrate them into the moisture control assessment process.

2 Moisture Control Design Standards and Guidelines

In the past, moisture control meant for most practitioners steady state vapour diffusion calculations – often called dew-point or "Glaser" calculations – that were performed to determine whether there is a risk of harmful interstitial condensation in the building assembly during the heating season. However, due to numerous simplifications the results of these calculations may be misleading especially when short-term loads such as solar vapour drive or rainwater absorption may have an impact. A steady-state calculation also means that all storage effects are neglected. This penalizes materials with moisture storage capacity, such as renewable insulation materials, because it assumes the formation of condensation where in real life only the sorption moisture content is slightly increased. There are actually many more drawbacks of employing dew-point calculations for moisture control design which lead to the following statement in the ASHRAE Handbook of Fundamentals (2017): *"The dew-point method is not recommended as a sole basis for hygrothermal design of building envelope assemblies. ASHRAE Standard 160 is recommended to assist in hygrothermal analysis for design purposes."* ASHRAE Standard 160 (2016) specifies the application of hygrothermal simulation tools.

To arrive at comparable results pertinent application standards for hygrothermal simulations have been developed which are under continuous revision in order to accommodate new approaches and feed-back from users. The first guideline on moisture control analysis by hygrothermal simulation was issued in 2002 by the WTA, an association dealing with preservation and renovation of heritage constructions and rehabilitation of the building stock (WTA 6-2 2002). Five years later the European Standard EN 15026 (2007) which is largely based on the WTA guideline was published. However, both documents did not contain any information on how to deal with small defects in the building envelope. Parallel to the standard work in Europe a slightly more comprehensive standard on moisture control design has been developed in North-America (ANSI/ASHRAE Standard 160 from 2009). As a result of numerous damage cases linked to rainwater penetration into constructions with rendered facades (Cheple and Huelman 2000), this standard has been the first that proposed the consideration of the effects of small leaks in the exterior finish of exposed walls.

2.1 Updated Version of the Hygrothermal Simulation Guideline WTA 6-2

Since the original version of the WTA 6-2 guideline served as blueprint for the European Standard 15026 (2007) and the updated version from 2014 has been referenced by the German Standard on moisture control design DIN 4108-3 (2018), the new items in this guideline will be described here briefly. Compared to the version from 2002 the WTA 6-2 (2014) allows the

consideration of imperfections in the building envelope by simplified models. It also shows a way of dealing with ventilated cavities in a one-dimensional way and contains some new information concerning boundary conditions. The new version recognizes the problem of determining the material properties as accurately as possible for the intended use by a chart that recommends the test method as function of moisture range. This issue has come up in the context of capillary active insulation materials. These materials are rather vapour permeable, however, they are supposed to prevent condensation at the cold side by compensating the diffusion flux with an opposed liquid flux. This means, liquid transport in capillary active insulation materials has to achieve a considerable magnitude well below 100% RH. Most of the currently employed methods have been designed to determine liquid transport properties in the high moisture range, i.e. when the majority of capillaries are filled with water. However, these methods turned out to be inappropriate for the accurate determination of liquid transport in the hygroscopic range. Therefore, a new method has been developed by Binder *et al.* (2013) that determines the properties of interior insulation materials under the boundary conditions close to the real situation in practice application.

From a moisture safety point of view, however, the most important improvement is the introduction of simplified models to account for unavoidable rainwater and indoor air leakage into the building assembly. These models have been designed for one-dimensional simulations with the aim to quantify the moisture impacts of imperfections in the building envelope without dealing with the complex 3D phenomena that are assumed to happen in reality. Thus, these models are of limited validity and may work well for some construction types but may not be transferable to others. This may seem unfortunate; however, not employing the models described below, may be even more risky. Numerous failures have proven that perfectly installed building assemblies without any leaks belongs to the realm of fiction. Nevertheless, it is absolutely feasible to reduce the potential leaks to a level that will not do any harm to a moisture tolerant construction. The application of the following model assumptions will help to design such moisture tolerant building assemblies.

2.1.1 Rainwater penetration through imperfection in the exterior finish

As already mentioned the American moisture control standard ANSI/ASHRAE 160 (2016) proposes the consideration of small rainwater leaks through the exterior finish which may result from gaps or cracks at joints and connections. It states: *"In the absence of specific fullscale test methods and data for the as-built exterior wall system being considered, the default value for water penetration through the exterior surface shall be 1% of the water reaching that exterior surface. The deposit site for the water shall be the exterior surface of the water-resistive barrier. If a water-resistive barrier is not provided, then the deposit site shall be described and a technical rationale for its selection shall be provided."* In the case of ETICS (external wall insulation systems) on load bearing masonry walls the rainwater deposit site is likely to be the surface of the masonry beneath the insulation (see Figure 1).

It is obvious that neither the leaks nor the wind driven rain exposure are evenly distributed over the building envelope. But the standard committee chose this simple one-dimensional approach as a method to consider the effects of complex bulk water penetration phenomena observed in practice. The rainwater leakage rate proposed in the standard is not meant to be a worst case scenario. It is not based on field test results but on hygrothermal simulations

(Desjarlais *et al.* 2001) that showed that more than 1% of rainwater penetration may be detrimental for a large portion of existing wooden wall structures. A recent literature review (Van Den Bossche *et al.* 2011), analysing data of leakage rates measured on different wall structures, confirmed the appropriateness of the "1% leakage" in ANSI/ASHRAE Standard 160. Therefore the rationale of this standard was also adopted for the new WTA 6-2 (2014) guideline.

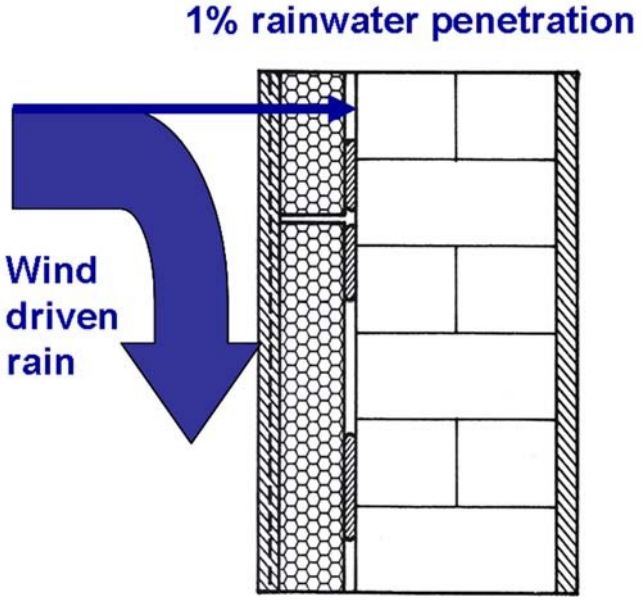

Figure 1. Exposed wall example showing the most likely deposit location for rainwater penetrating through leaks at joints and connections of masonry with external insulation system.

2.1.2 Moisture sources due to air flow through the building envelope

The convective moisture entry due to defects in the vapour respectively air control layer is a multidimensional effect, which cannot be captured directly by one-dimensional calculation. However, also the application of multidimensional simulation tools hardly solves the problem, because the exact configuration of leakages is generally unknown and the complexity of relevant flow paths is exceeding the capacity of most models. Therefore it has been decided to choose an approach that doesn't simulate the flow itself, but concentrates on the effects of vapour convection and subsequent condensation by introducing a moisture source inside the construction.

Based on experimental results from TenWolde *et al.* (1989), a simplified model to quantify the moisture sources due to vapour flow through the building envelope has been developed and checked for plausibility (*e.g.* Künzel *et al.* 2011). The model assumes that vapour contained in the indoor air, penetrating the envelope via so-called moisture leaks, condenses at the cold side of the insulation (see Figure 2). In contrast to energy leaks where the air remains warm because it flows in a short way from the room towards the outside, moisture leaks are small and tortuous channels where the air flow is slow and cools down within the flow path. These "moisture leaks" probably represent less than 10% of all leaks in the building envelope. The position of the condensation plane has to be selected by the user. Its temperature, governed by the transient

boundary conditions, is simulated without taking the latent heat of condensation into account. The right choice of this position depends on the construction. It must be cold enough for condensation to occur and it must be easily accessible for the indoor air that has penetrated the interior lining or air barrier. Examples are the exterior sheathing of wood frame walls or roofs and the interface between the interior insulation and the original wall after thermal retrofits of plastered masonry structures. The convective moisture source is equal to the amount of condensate that forms when the indoor air temperature is cooled down to the temperature of the selected condensation plane in the building assembly. Any increase in sorption water content that could occur in reality by the temperature drop is neglected. In order to remain on the safe side convective drying is excluded, i.e. the moisture accumulated by air convection can only dry out by vapour diffusion or liquid transport.

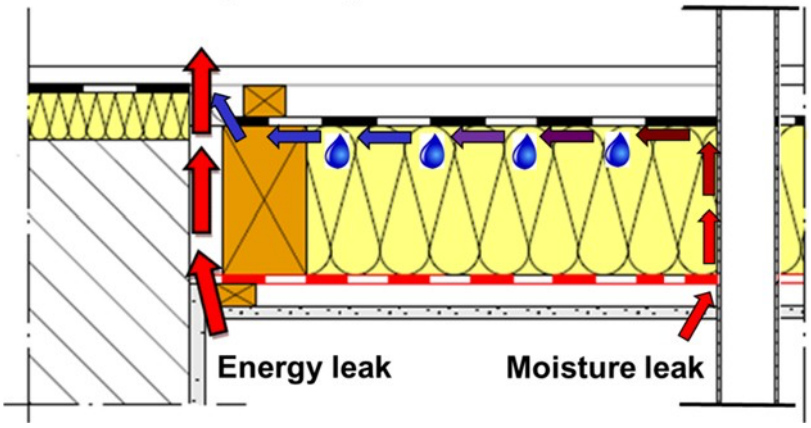

Figure 2. Indoor air leaking through a roof at joints and connections. If the flow path is short, it will be heated up by the air flow and only energy is lost. If the air flow creeps along the cold side of the structure before it finds its way out, its temperature may drop below the dew-point of the indoor air and cause condensation.

Thus the amount of condensation (moisture source S_{CL}), which results from vapour convection at the selected condensation plane p, is determined for each time step according to the following equation:

$$S_{CL} = k_{CL} \cdot \left(c_i - c_{sat,p}\right) \cdot (P_i - P_e) \tag{1}$$

where
S_{CL} moisture source due to vapour convection through the component (kg/(m²h))
k_{CL} air permeance of the "moisture leaks" of the component (m³/(m²·h·Pa))
c_i water vapour concentration of the indoor air (kg/m³)
$c_{sat,p}$ water vapour saturation concentration at predefined plane p (kg/m³)
$P_i - P_e$ air pressure difference over the considered envelope component (Pa)

The air pressure difference is assumed to be due to buoyancy effects and pressure differentials generated by ventilation systems. Wind pressure effects are disregarded because they are difficult to determine and do not act on the building envelope in a continuous manner. Based on investigations in Künzel *et al.* (2011) the air permeance of the moisture leaks is set to 1,9·10-6 m³/(m²s·Pa) [0,007 m³/(m²h·Pa)] for envelope components installed according to best practice. Buildings with higher k_{CL} would represent malpractice. Building components that can handle the moisture loads due to air convection are well-designed. Those that fail under these

circumstances should either be redesigned or special care must be taken during installation which may include continuous moisture monitoring.

2.2 New German Moisture Control Standard DIN 4108-3

The current German moisture control standard for building envelope components DIN 4108-3 (2018) includes three assessment options. As first option, a designer may select a wall or roof assembly from a list of deemed to satisfy (DTS) constructions included in the standard. The second option, which may be applied, if the assembly to be designed, is not part of the DTS list represents the assessment by a steady-state dew-point calculation with fixed boundary conditions. However, there are a number of restrictions that have to be observed, *e.g.* green roofs, unvented metal roofs, capillary active interior insulation systems or basement assemblies must not be assessed.

Most importantly, options one and two may only be applied for envelope components of residential buildings or those that have a similar indoor climate (*e.g.* offices) without air-conditioning. In all other cases option three applies, *i.e.* the designer has to perform a hygrothermal simulation according to appendix D of the standard. This appendix references EN 15026 and WTA 6-2 mentioned above as well as some other standards and guidelines dealing with the evaluation of hygrothermal simulation results, *e.g.* mould risk evaluation. A detailed flow chart showing the preconditions for selecting one of the options is depicted in figure 3.

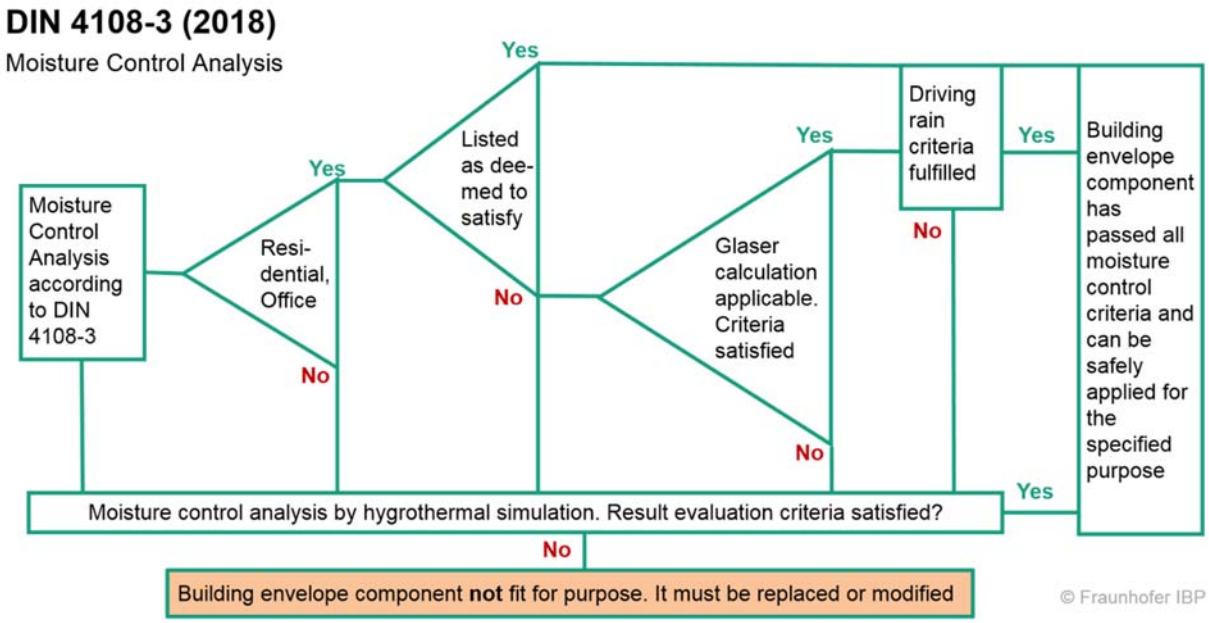

Figure 3. Flow chart explaining the preconditions for the moisture control assessment options in DIN 4108-3.

3 Conclusions and Outlook

Hygrothermal simulation models have become essential to advance our skills in sustainable and resilient building design. Practical experience has proven repeatedly that imperfections and small leakages in the building envelope are unavoidable and have to be accounted for. The same is true for material ageing and unexpected loads due to extreme weather conditions which will

probably occur more frequently in the wake of climate change. The development of hygrothermal design models has to respond to these factors by searching for new approaches that are able to represent real life impacts and effects. This won't be possible without increased research efforts looking at the effects of leaks and other imperfections with the aim to quantify them for different construction types. Most importantly however, there has to be widespread discussions on what kind of flaws are acceptable in order to define what best practice workmanship actually means. Ultimately, the definition of unavoidable moisture sources will result in a clear discrimination between design and installation failures.

This task is far from being easy and may be very controversial because there is a lot of money involved in litigation cases. However, it also represents a great opportunity to arrive at better and more durable constructions and it is preferable, as well as much more sustainable to spend money on improving design instead of wasting money and resources on repair and excessive maintenance. International moisture control standards are slowly moving in the right direction by emphasizing the importance of hygrothermal simulation for realistic building component assessments. However, the next important step represents the integration of moisture control considerations already at the beginning of the design process. Until now, this is mostly done in the end when all components and HVAC systems are already specified leaving only minor options for modifications – *e.g.* selecting the permeance of vapour control or insulation layers.

In the future, the building dynamics (hygrothermal storage capacities of envelope components including HVAC systems) will become quintessential because of the more fluctuating renewable energy supply. This requires new building operation concepts and more integral design of the interdependent building envelope and HVAC systems. Combinations of both, such as thermally activated components or radiant interior surface heating and cooling systems may be part of the response to the new challenges (see figure 4). Moisture control design of such systems is way beyond simple dew-point calculations and may even require new approaches for hygrothermal simulation models.

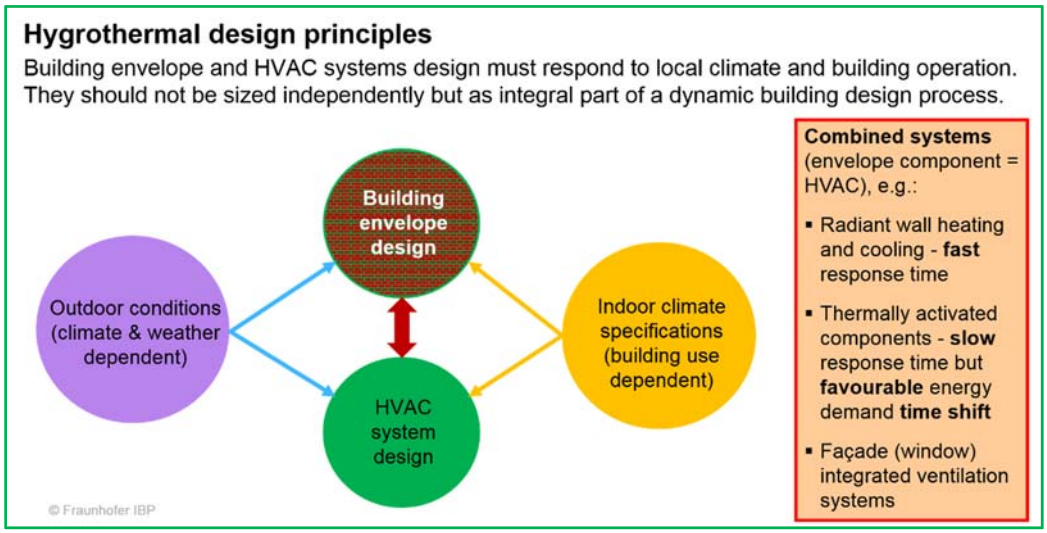

Figure 4. Appropriate design of building envelope and HVAC depends heavily on outdoor and indoor climate. Their performance is interdependent and increasingly both functions are combined in one system.

The Impact of Climate Change on Material Degradation: Finding a Feasible Approach for Climate Model Evaluation

Hamed Hedayatnia and Nathan Van Den Bossche

Building physics Group, Faculty of Engineering and Architecture Ghent University, 9000-Gent, Belgium,
hamed.hedayatnia@ugent.be

Abstract. *Understanding how climate change accelerates or slows down the process of material deterioration is the first step towards assessing adaptive approaches for the preservation of historical heritage. Analysis of the climate change effects on the degradation risk assessment parameters like freeze-thaw cycles and salt crystallization is also a key parameter when considering mitigating actions. Due to the vulnerability of cultural heritage in Iran to climate change, the impact of this phenomenon on basic parameters like temperature was analyzed. Choosing an appropriate regional climate model is the first and most crucial step in the analysis of climate change effects on heritage. The outputs of two different regional climate models: the ALARO-0-SURFEX model (Ghent University, Belgium) and the REMO model (HZG-GERICS, Germany) were analyzed to find out which model is more adapted to the region. So the focus of this research is mainly on the evaluation process to find a feasible approach for validation study to determine the reliability of each model. For model validation, a comparison between model data and observations was performed for 30 yearsfrom 1980-2017. Besides, some climatic parameters which are likely critical for heritage like freeze-thaw cycles were studied to find out how reliable these models are in the field of building pathology.*

1 Introduction

The Iranian plateau hosts one of the world's oldest civilizations. The country's rich cultural heritage is reflected in part by its 22 UNESCO world heritage sites. The Iranian Plateau is one of the world's most mountainous countries, with a landscape dominated by rugged mountain ranges.

Having 11 climates (Figure 1) out of the world's 13, Iran's climate is diverse, ranging from arid and semi-arid, to subtropical along the Caspian coast and the northern forests.

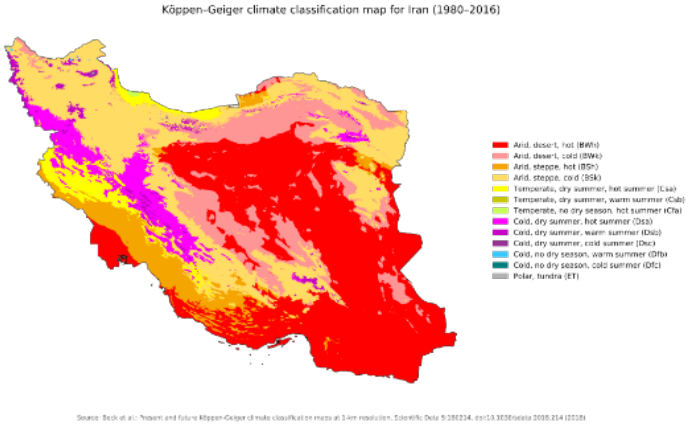

Figure 1.Climate map of Iran (Köppen-Geiger).

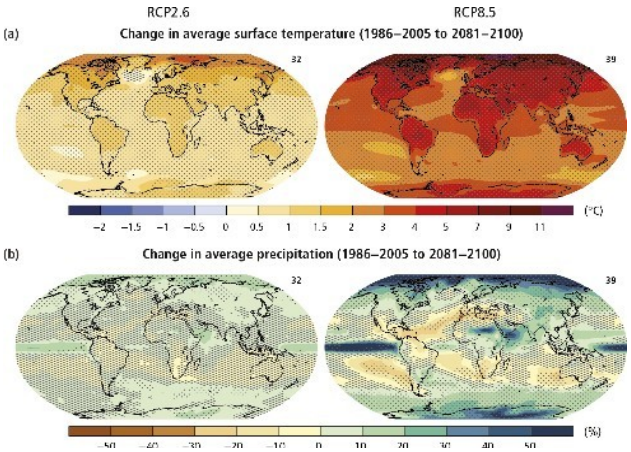

Figure 2.Change map during 1986-2100.

The Fifth Assessment Report of the Intergovernmental Panel on Climate Change suggests significant changes in climate conditions during the twenty-first century, such as drier and hotter summers over the middle East. Moreover, studies with different scenarios show that climate changes in Mediterranean Bassin are anticipated to exceed global mean values significantly (Giorgi 2006), and Iran is located in this region (Figure 2). Climate models are typically based on a top-down approach as a function of spatial and temporal resolution (Termonia, Schaeybroeck, De Cruz and De Troch *et al*. 2018). Therefore High-resolution regional climate models are needed to provide accurate climate change scenarios accounting for this region.

Today there are only low-resolution data available over this domain. Thus in this paper, high-resolution (*e.g*. 25 km) regional climate projections over Central Asia, including Iran, have been analyzed. For more accuracy, two different climate models have been evaluated to find a feasible approach for validating climate models as a non-meteorologist researcher. ALARO-0 model (Ghent University, Belgium) and REMO (HZG-GERICS, Germany). Both models provide climate projections for the "21st" century following different RCP scenarios. These models need to be evaluated first. The RCM data in this analysis originates from the ALARO-0 and REMO models at a spatial resolution of 25 km across the central Asia domain and time-frequency of 1-hour. The analyzed type of model run for both models is the evaluation run. This means that the lateral boundary conditions of the model*, i.e.* the Asian boundaries, are forced by reanalysis data. The evaluation run enables the possibility to evaluate whether the model is able to reproduce the weather conditions within the imposed boundaries conditions at given grid points.

To analyze the evaluation run of the models over the domain, four grid points located in different climate zones, were studied. A comparison is made with historical observations at the same locations using MATLAB. The discussed parameters are outdoor air temperature and relative humidity and precipitation. For each parameter, scatterplots of the observations and modelled data are produced, as well as distribution functions both based on hourly, daily, and monthly values. Through the validation study, some climatic parameters which are likely critical for heritage like freeze-thaw cycles and salt crystallization index were evaluated for both models in comparison with the historical data to find out how reliable these models are in the field of building pathology.

In the case of temperature, relative humidity, and wind velocity, daily values represent daily averages, whereas, for precipitation, total daily values are considered. Furthermore, the root means square error (RMSE), correlations, adjusted R-squared, and regression are computed to find out the reliability of the models. The studied grid points are listed below:

Mashhad**,** which is located in the northeastern corner of Iran, features a steppe climate (Köppen*/BSk*) with hot summers and cold winters.

Shiraz is located in the south of Iran. Shiraz's climate is overall classified as a hot semi-arid climate (Köppen climate classification *BSh*).

Tabriz is located in the northwest of Iran has a humid continental climate with regular seasons (Köppen *Dsa*) bordering Cold semi-arid climate (Köppen *BSk).*

Rasht is located on Iran's Caspian Sea coast, depending on the precipitation, Rasht either has a humid subtropical climate (*Cfa*) or a Mediterranean climate (*Csa*).

2 Methodology

2.1 Model Analysis

Given that Iran has an extended range of climate regions, and models are not often used for such a climatic zone, these models need to be evaluated first. The RCM data in this analysis originates from the ALARO-0 and REMO models at a spatial resolution of 25 km across the central Asia domain and time-frequency of 1-hour. The analyzed type of model run for both models is the evaluation run. This means that the lateral boundary conditions of the model, i.e., the Asian boundaries, are forced by reanalysis data. The evaluation run enables the possibility to evaluate whether the model can reproduce the weather conditions within the imposed boundaries conditions at given grid points.

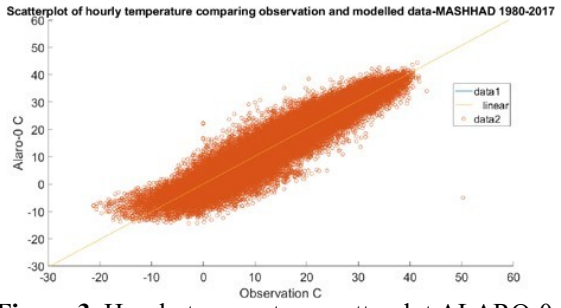
To analyze the evaluation run of the models over the domain, Mashhad which is located in the northeastern corner of Iran and features a steppe climate (Köppen*/BSk*) with hot summers and cold winters were picked.

A comparison is made with historical observations at this location employing MATLAB. Since there is no full overlap between datasets, only the period 1980-2017 is analyzed. Tofind out which approach should be followed, temperature parameter was picked, and scatterplotsof the observations and modelled data are produced, as well as distribution functions both based on hourly, daily, and monthly values plus comparison plots based on daily, monthly and yearly values. Through the validation study, some climatic parameters which are likely critical for heritage like freeze-thaw cycles were evaluated for both models in comparison with the historical data to find out how reliable these models are in the field of buildingpathology.

In the case of temperature, daily values represent daily averages. Furthermore, the evaluation metrics comprise of correlations, adjusted R-squared, and regression are computed to find out the reliability of the models. In this paper, climate models have been evaluated.

2.1.1 Temperature Analysis

The scatterplot of both models during the studied period (Figure 3 and 4) indicates that there is a good overall representation of the observed hourly outdoor air temperature (T) by both models. The linear fit (red) of the hourly temperature almost follows the diagonal (perfect fit). The hourly temperature distribution of both datasets, i.e., the observations and the modeled data, confirms this statement. However, there is a slight bias towards colder temperatures by the ALARO-0 modelled data, and almost the same bias towards warmer temperatures by the REMO modelled data (Figure 5 and 6). In mid-range temperatures, models have different behaviours where ALARO-0 has an underestimation of mid-range temperatures, and REMO has an overestimation.



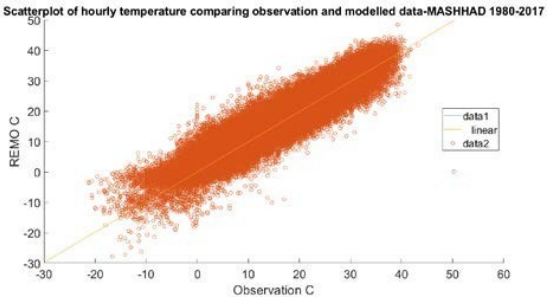


Figure 3. Hourly temperature scatterplot ALARO-0 model. **Figure 4**. scatterplot -Remo model(1980-2017).

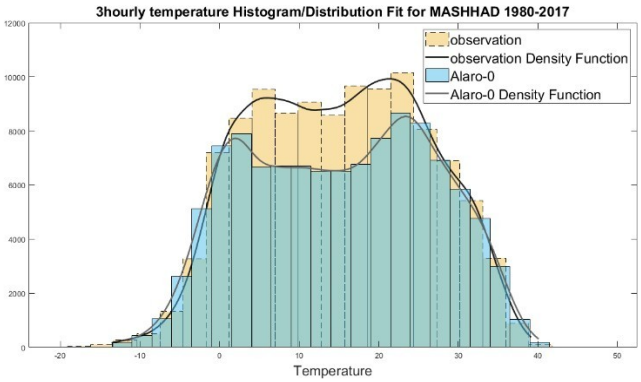
In extreme maximum temperatures, both models follow a similar pattern. A small overestimation of extreme maximum temperatures where REMO has a bigger overestimation. In extreme minimum temperatures, REMO has a slight underestimation, and ALARO-0 has a slight overestimation. Please note that missing values in the observations are removed before calculating the distribution and statistics of the temperature dataset.

The observed T_{mean} over the whole dataset is 15.03° C. For the ALARO-0, the T_{mean} is 15.1°C, and for REMO is 15.6°C. There is a 0.6°C bias in T_{mean} across the entire 36 years dataset for REMO. T_{min} and T_{max} for the observations and modelled data are respectively -21.2°C and 43.2°C, and -14.5°C and 44.5°C (ALARO-0) and -28.8°C and 48.5°C(REMO). These values are not in line with the conclusions based on the distribution, i.e., the underestimation of extreme minimum temperatures by REMO modelled data towards colder temperatures. However, as these values are outliers, they are not expected to represent the temperature distribution.



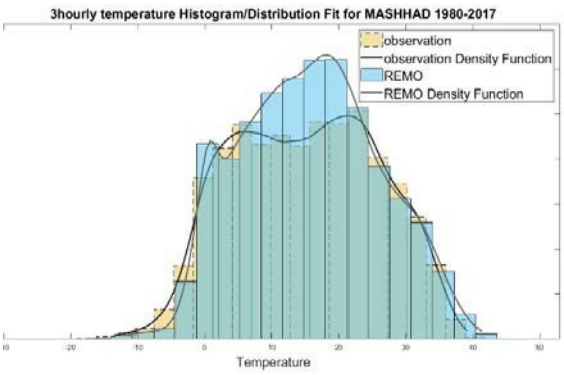


Figure 5.Hourly temperature Histogram ALARO-0. **Figure 6**.Hourly temperature Histogram REMO.

By analysis of the monthly statistics (Figure 7), it can be observed that the monthly T_{mean}, except the observation of summer months (higher temperatures), is lower than the REMO T_{mean} in all months. On the other hand, except winter months, the monthly T_{mean} of the observations is lower than the T_{mean} of the ALARO-0 model. Moreover, the absolute T_{max} of the observations, every month except for August is lower than T_{max} of the REMO. Whereas the observations and ALARO-0 model in this value are very consistent almost every month, the observed absolute T_{min} is lower than the ALARO-0 modeled temperature when the T_{min} is below 0^{o} C.

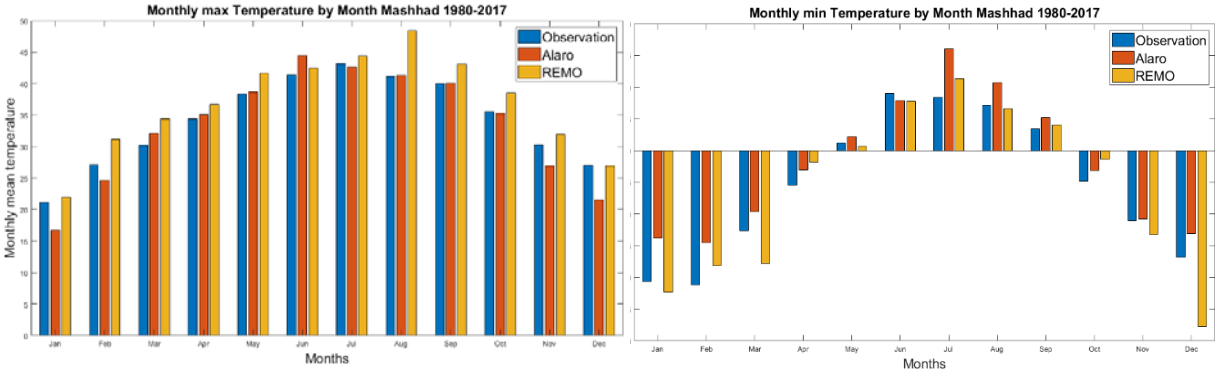

Figure 7. Comparison between monthly min and max temperature of observation and model data.

Figure 8 illustrates the average daily temperature across the entire period based on hourly data and the difference in temperature between the observed and modeled dataset. Note that the ALARO-0 modelled average day is significantly consistent with the observation. The bias range

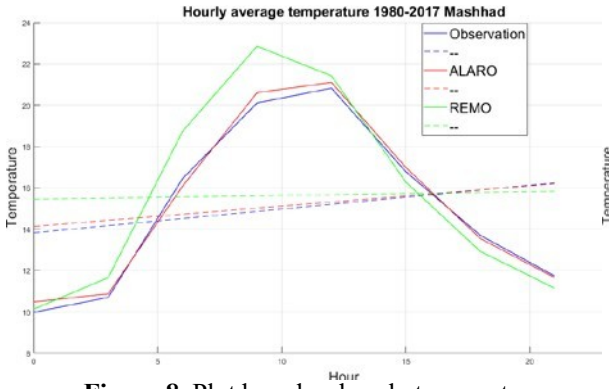

Figure 8. Plot based on hourly temperature.

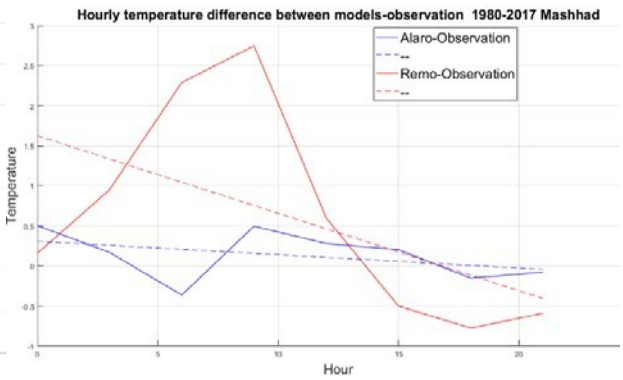

Figure 9. Difference between the datasets temperature.

is between -0.3 and +0.5 °C(Figure 9), respectively, at 6 am, and 9 am, whereas, in the REMO model, more bias is observed mainly during the first hours of the day before 10 am. Biased for every hour, ranging between -0.7 and +2.7 °C, respectively, at 6 pm and 9 am. The most substantial temperature difference is observed in the morning for both models. This could be related to the location of the station, which is located in a semi-arid area, and an essential specification of this climate area is a vast difference between temperature in day and night, and perhaps the REMO model does not capture this effect accurately.

The distributions of daily T_{mean} is provided per season (Figure10). Interestingly, both models show the same results. The most significant difference in distribution between the observations and both models is found in summer, whereas smaller differences characterize spring.

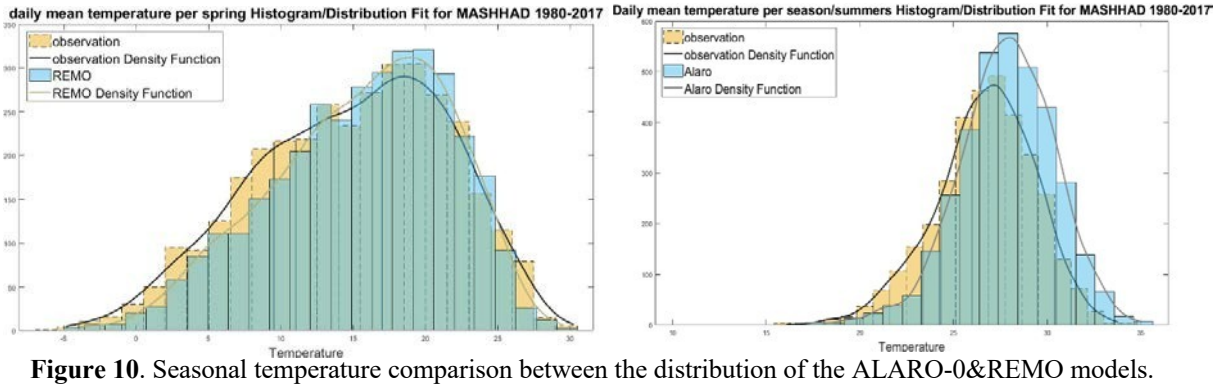

Figure 10. Seasonal temperature comparison between the distribution of the ALARO-0&REMO models.

Besides statistics on hourly and daily T_{mean}, some unusual indices are useful in the field of building physics, such as indices on frost. The first discussed index is the number of freeze-thaw cycles (FTC) as described by Grossi *et al*. (2007), referred to as criterion 1.

Based on daily T_{mean}, one cycle is counted each time the temperature drops below 0°C, given that the previous day was a non-freezing day. Following, the difference in the annual number of FTC between the observations and the modeled data is computed. It can be noted that unlike the observations, both models follow an increasing trend (Figure 11).

The hours of frost index, illustrated in Figure 12, indicate the annual duration of freezing temperatures. The REMO model has predicted considerably fewer frost hours in comparison with the ALARO-0 model and observations. Please note that unlike the observation, both models follow an increasing trend.

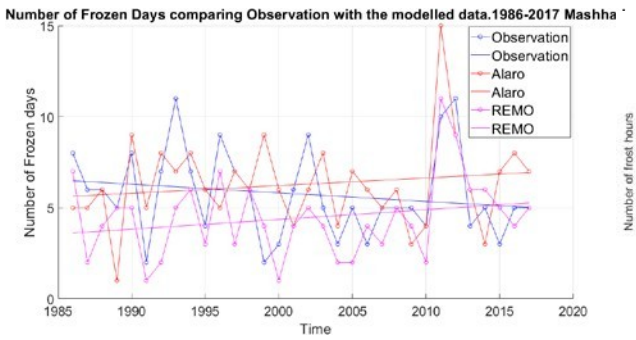

Figure 11. Number of FTC in models and observation.

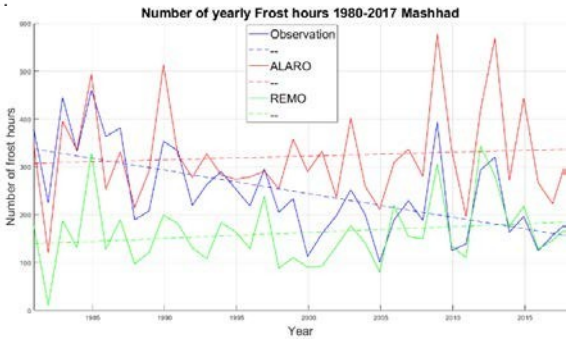

Figure 12. The number of frost hours per year.

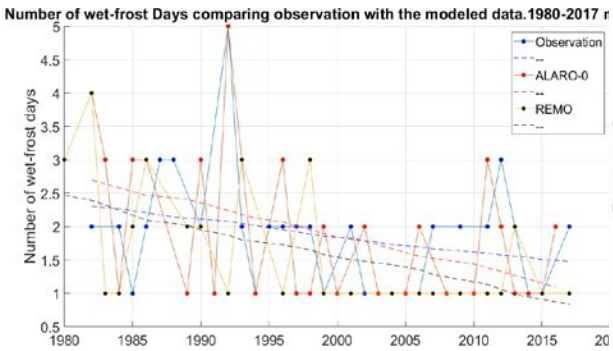

Figure 13. The number of wet-frost cycles. Mashhad.

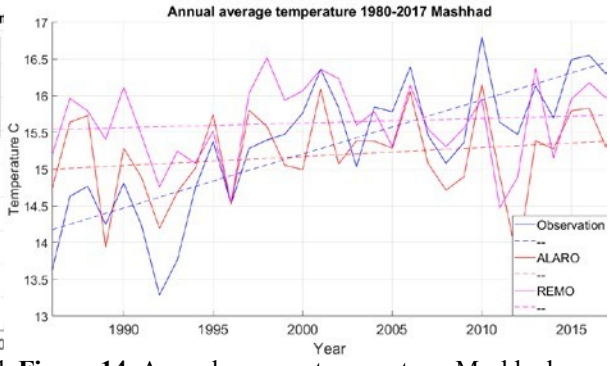

Figure 14. Annual average temperature, Mashhad.

Previous indices are only based on temperature. However, frost damage in building envelopes is highly related to the moisture content in the porous media. The wet frost index considers the annual number of rainy days, i.e., the total daily precipitation exceeding 2 mm and temperatures higher than 0°C, immediately followed by days having a T_{mean} below -1°C (Brimblecombe *et al*. 2006).

The wet frost index is generally higher for the ALARO-0 model compared to the REMO model and more consistent with the observation (Figure 13).

During the analysis of timetables, based on the yearly T_{mean} (Figure 14) regarding the trendlines, it can be observed that the slope of both models similar to observation is incremental, but the real temperature rises at a higher rate. The studied city is the second biggest city in Iran, a dense metropolitan area. Given the existence of the well-known urban heat island phenomenon(UHI), this strong urbanization might Contribute to additional warming at this location, and models cannot catch it.

The evaluation metrics, which are essential in the model validation analysis, are computed (Table.1) and explained in the final part. The adjusted R-squared is a modified version of R-squared that has been adjusted for the number of predictors in the model. An adjusted R-squared of 1 means that the model ultimately predicts the studied parameter. Based on the above descriptions, the correlation, RMSE, and Adjusted R-Squared coefficient of both models indicate high accuracy, but the ALARO-0 model seems more reliable.

Table 1. Validation metrics computed for the temperature parameter.

Mashhad						
Interval/Metrics	Correlation	Adjusted R-Squared	Regression	Correlation	Adjusted R-Squared	Regression
3hourly Temperature	0.9588	0.919	0.9554	0.9386	0.881	0.9674
Daily mean Temperature	0.9676	0.936	0.9558	0.9596	0.921	0.9848
Monthlymean Temperature	0.9882	0.977	0.9600	0.9886	0.977	0.9961

3 Conclusions

Regarding previous analysis and construing the figures and table of statistics, there can be concluded that the best approach for model validation is using the evaluation run of the model and comparing the model dataset with the historical observations in different parametersbased on hourly, daily and yearly time interval. Another critical issue that should be analyzed in each model validation study is considering relevant indexes to the research, i.e., freeze-thaw cycles, which are detrimental in building pathology in the current paper, should be analyzed. This method for our case study proved that both models based on temperature parameter are surprisingly accurate. Based on graphs construing and computed coefficients like correlation and adjusted R-squared, ALARO-0 model is a little more realistic and is suitable to use it as a reliable regional climate model over the target area.

Acknowledgement

The RCM runs used in this paper have performed in the context of the AFTER project, which is granted by the ERA.Net RUS Plus Initiative, ID 166. The computational resources and services for the ALARO-0-0 regional climate simulations were provided by the Flemish Supercomputer Center (VSC), funded by the Research Foundation-Flanders(FWO) and the Flemish Government department EWI. The CORDEX-CORE REMO simulations were performed under the GERICS/HZG share at the German Climate Computing Centre (DKRZ). We would like to thank Steven Caluwaerts (UGent), Lola Kotova (GERICS), and Sara Top (UGent) for providing climate data.

Abstract. *Rainwater entry and penetration through a waterproofing layer, such as external finishing and sheathing membrane, should be avoided to prevent moisture damage to a wooden wall assembly. However, housing warranty insurance organizations in Japan have reported that deterioration in some wall assemblies was caused by rain penetration, and severely damaged walls were detected in airtight and insulated building envelopes. This paper presents various factors of water entry and penetration of the waterproofing layers in wooden wall assemblies in terms of practical situations, as a part of a research project to reveal the risk of water and moisture accumulation in collaboration with government and industries in Japan. Several experimental works using mock-up specimens replicating a part of the wall assembly were carried out. As for external finishing, the water intrusion was observed not only at the joints but also at the bottom of vented cavities. Although these minor defects must be prevented by proper design and site work, it is difficult to avoid them completely through the construction process and period of use. Indeed, the extent of water entry was affected by various factors such as wall configuration, exposure conditions and so on. Experimental results suggested that various factors, including detail of interface and quality of materials, should be considered to assess service life prediction by hygrothermal analysis.*

1 Introduction

Global warming has a significant impact on exposure conditions related to the long-term durability of building envelopes. In humid climate regions, such as coastal areas in East Asia, the frequency of heavy rain tends to increase in recent years. Based on the trends in meteorological data issued by Japan Meteorological Agency, the annual number of days with heavy rain of more than 200 mm per day increased by 1.5 times in the past decade in comparison with the rate of increase 40 years ago (Japan Meteorological Agency, 2019).

Although the energy-efficient house has recently been required to reduce CO_2 emissions even in humid climate regions, a building envelope with higher insulation performance is potentially a concern for a decrease in drying performance (CMHC, 1996; Finch, 2007). An increase in heavy precipitation events might give excessive moisture load to wall and roof assemblies. The housing warranty insurance organizations (HWIO) in Japan reported that more than 90% in 550,000 cases of insurable contingencies was water leakage and its total number has gradually increased (HWIO, 2017). This investigation for the insurable contingency indicated that 80% of water leakage occurred in the wall and wall-roof interface (Figure 1a), and that 44% of it was detected in houses with a shedroof (Figure 1b). Additionally, the percentage of shedroofs

doi:10.23967/dbmc.2020.147

with short eaves and verges is higher than other types of roof in the insurable contingencies. This finding suggests that short eaves and verges are among the factors causing rain penetration through the waterproofing layer, and this phenomenon should be clarified and also quantified to assess the service life of building envelopes.

With these points in mind, this paper describes an experimental study regarding water penetration through primary and secondary waterproofing layers in wooden wall assemblies in consideration of practical situations. Water spray tests for several types of siding panels and wall-roof interfaces were implemented, and their details were selected from the insurable contingencies in HWIO. Water penetration through the fastener interface of the secondary waterproofing layer was also examined. Based on these results, the importance of the clarification of the water penetration rate as a boundary condition for hygrothermal analysis was discussed.

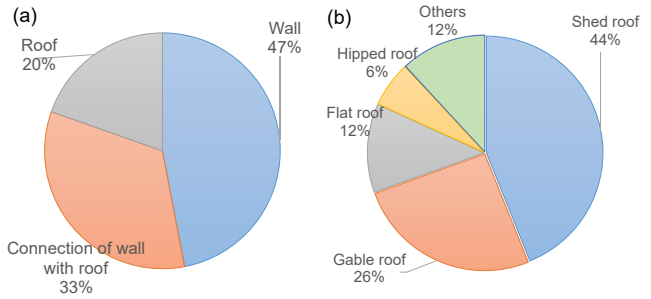

Figure 1. Percentage of water leakage location (a) and type of roof (b).

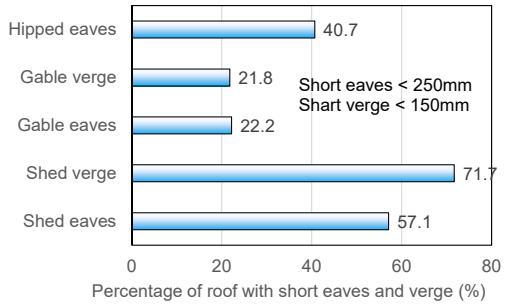

Figure 2. Percentage of roof with short eaves and verge.

2 Water Penetration Through Siding Joints

2.1 Outline of Water Spray Test

To compare watertightness of exterior systems using ceramic sidings, water spray tests (JIS A 1517: Watertightness test under dynamic pressure) with static and dynamic loading were implemented. The ceramic sidings of six products (Sp1 ~Sp6) were selected to understand the performance of representative products in the siding industry of Japan. All sidings employed a two-way shiplap joint between the top and the bottom, and a metal panel clip to fasten it to the substrate of the wall. The thickness and width of the panel were between 15 and 18 mm and 300 and 450 mm, respectively. The heights of the shiplap were between 11 and 15 mm.

Since the outside dimensions of the opening of an airtight box with water spray nozzles were 1.98 m by 1.98 m, two types of siding panel measuring 0.91 m by 1.98 m were fixed to a wood frame, side by side, as specimens (Figure 3). The sprayed water was uniformly applied at a rate of 4 L/[m^2min] across the exterior of the specimens in Case 1 and Case 2, as shown in Figure 4. A rate of 0.3 L/[m^2min] of the sprayed water was applied in Case 3. Static pressure differences through the siding panel were increased stepwise by 150 Pa, 240 Pa, 350 Pa, and 470 Pa with static loading. In addition, dynamic loading tests were implemented in Case 2 and Case 3. Water penetrating the inner plane through the shiplap joints was collected at the bottom of the specimen, and weighed to quantify the overall penetration rate.

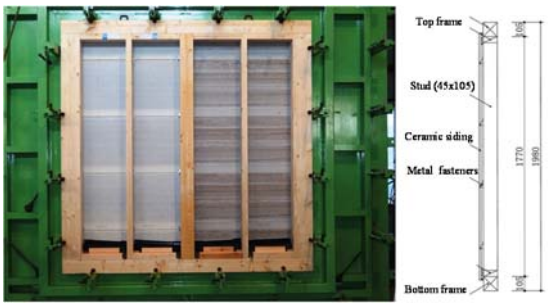

Figure 3. Specimens fixed to airtight box.

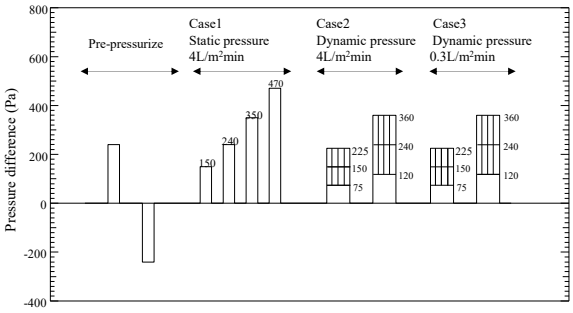

Figure 4. Pressurize process in water spray tests.

2.2 Water Penetration Rate from Siding Joints

The quantity of penetrating water and the water penetration ratio in Case 1 are shown in Figure 5 and Figure 6, respectively. The water penetration ratio means the ratio of the penetrating water and sprayed water. The quantity of the penetrating water in Sp1 and Sp2 exceeded 0.3 L/min m^2 in the range beyond 240 Pa. This value is approximately equivalent to 8% of the water penetration ratio in Figure 6. These values of the other specimens were less than 0.1 L/min m^2 and 3%. Figure 7 shows the water penetration ratio in dynamic presure conditions (Case 2, Case 3). Although the values in Case 2 are less than in Case1, in the event of an equivalent average pressure difference, those in Case 3 are larger than in Case 1. It is speculated that accumulated water in the shiplap joint played a role in stopping the water when the sprayed water was 4 L/min m^2.

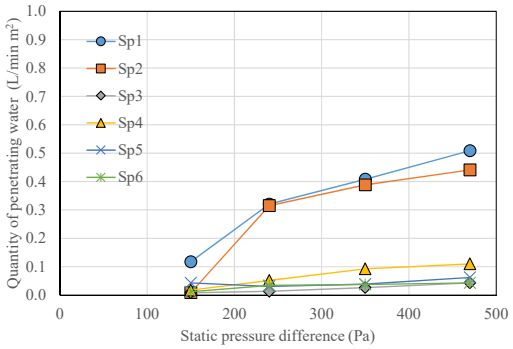

Figure 5. Quantity of penetrating water in Case 1.

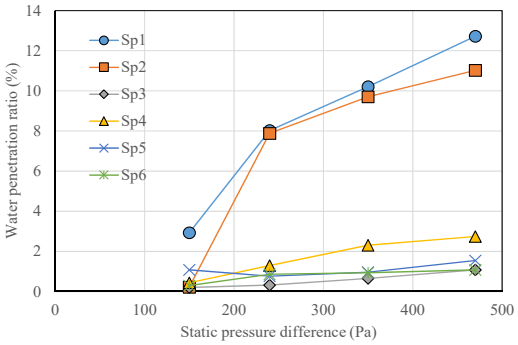

Figure 6. Water penetration ratio in Case 1.

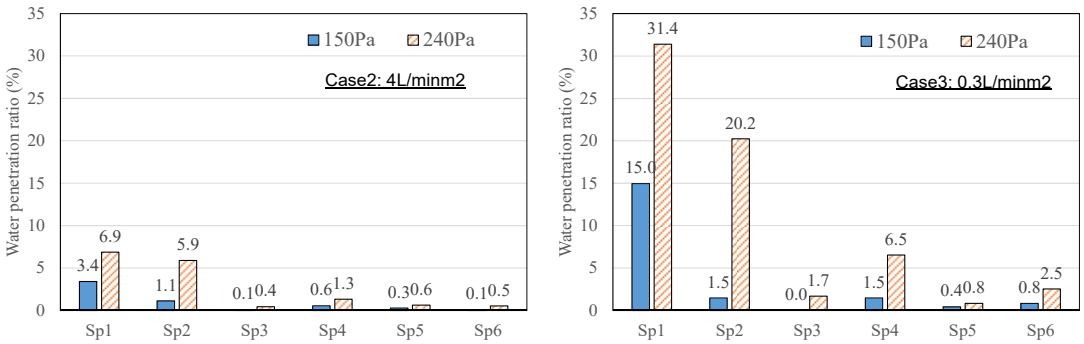

Figure 7. Water penetration ratio in dynamic test (left: Case2, Right: Case3).

According to past research (Sahal and Lacasse, 2005) regarding rainwater penetration through basic components of wall assembly, the quantity of water penetration through electrical outlets and vent ducts was approximately less than 0.25 L/min at 300 Pa of static pressure difference. However, water penetration from these shiplap joints in Sp1 and Sp2 reached 0.4 L/min m^2, meaning that 12 L/min of rainwater enters into the vented cavity when the wall area is 30 m^2. This result indicates that dispersion of the water entry in siding products cannot be neglected in determining the proper configuration of vented cavity in terms of drainage and drying performance.

3 Water Entry at the Top and Bottom of an Exterior with Short Eaves

3.1 Outline of Wind and Rain Blowing Test

In this section, a wind and rain blowing test was implemented to verify the risk of water leakage at the roof-wall interface and the bottom of the vented cavity, as shown in Figure 8. Four types of mock-up specimens incorporating the roof-wall interface were assembled in consideration of actual detail of the insurable contingencies. The width of the specimen was 1820 mm, and the length of the eaves from the center of the beam was 95 mm. A vented cavity connected the attic of the specimen with the top of the wall. Sheathing board such as plywood was not installed in the inner layer of the housewrap, in order to confirm water penetration through an overlap of the housewrap due to water splashing from the bottom of the vented cavity. Airtightness inside the wall was secured by a polyethylene sheet. Type 1, Type 2, and Type 3 shown in Figure 9 differ in details around the eaves. The top edge of the siding in Type 1 butted against the plywood, and additional fascia board or secondary flashing under the roof sheathing was attached in Type 2 or Type 3. The target of the test in Type 4 is the water leakage at the verge, and a bargeboard was attached to the butting of the siding. The specimens were mounted in front of a blowing device, and the roof-wall interface with eaves or verge was directed to the center of the air outlet of the blower. The levels of wind velocity were 5, 10, 15, 20 m/s, which correspond to wind pressure of 15, 60, 135, 240 Pa. The spray rate of water was 32 L/min, and duration time of the test was 15 min.

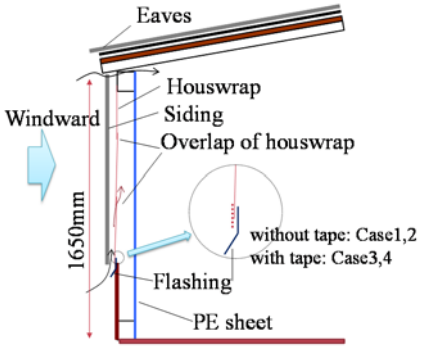

Figure 8. Mock-up specimen for blowing test.

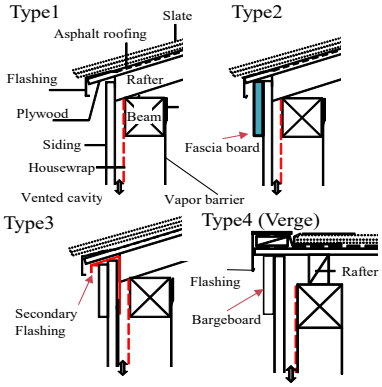

Figure 9. Detail around the eaves and verge.

3.2 Wind Velocity for Onset of Water Leakage and Wetting

Water leakage through the exterior layer in the wind - rain blowing test was confirmed by visual

observation from inside the specimen. Table 1 shows wind velocity for the onset of water leakage. Water splashing into the bottom of the cavity was observed on all specimens with a wind velocity of 5 m/s and above. Continuous splashing through the roof-wall interface was observed in Type 1. Type 1 carries the risk that rainwater penetrates into the thermal insulation layer. Although Type 2 presented better waterproof performance than Type 1 due to the addition of a fascia board at the roof-wall interface, water penetration into the rear face of the housewrap was observed from 15 m/s. Secondary flashing at the top of the siding in Type 3 prevented the water penetration even in 20 m/s. The result on the verge of the roof in Type 4 was approximately equivalent to Type 2.

Table 2 shows the relation between wetting location and wind velocity. Wetting at the ground sill was observed from 5 m/s in Type 1 and Type 2, because of a lack of tape at the bottom of the housewrap. Splashing water reached the overlap of the housewrap at 15 m/s, where the height was 1 m above the bottom of the vented cavity. Although such excess wind pressure at the bottom of the wall generally does not occur in urban areas, a vented cavity above a lean-to roof has the potential to cause pressurization.

These results indicate that imperfect detail for waterproofing at the roof-wall interface causes water penetration not only into the vented cavity but also into the rear of a secondary waterproofing layer, such as the housewrap. In addition, strong winds exceeding 20 m/s increase the water penetration that accelerates water absorption at the surface of sheathing board in wall assemblies. It is necessary for roofs with short eaves to assess safe detail against wind-driven rain.

Table 1. Wind velocity for onset of water leakage.

Observation of water leakage	Eaves			Verge
	Type1	Type2	Type3	Type4
Leakage from top of cavity	5 m/s	5 m/s	none	5 m/s
Splashing from bottom of cavity	5 m/s	5 m/s	5 m/s	5 m/s

4 Water Penetration through Secondary Waterproofing Material

4.1 Water Penetration through a Pinhole in a Water-Resistant Barrier

Nails and staples are generally applied to secure secondary waterproofing material, such as permeable polymer houswrap and asphalt-impregnated felt. However, the fastener interface

carries a risk of water penetration, and past research (Saito, 2015) has tried to quantify water penetration rate through pinholes in roof underlayments after exposure to cyclic temperature variation. To clarify the dispersion of the risk, water penetration tests for representative products were conducted, and reported in this section.

4.2 Outline of Water Penetration Test for Fastener Interface

4.2.1 Case 1 (Without Outdoor Exposure)

The test protocol for the water penetration test was in accordance with Japanese Architectural Standard Specification JASS 12 [Roof construction] (2005, AIJ). Seven products of asphalt-impregnated felt (AF), two products of modified asphalt-impregnated felt (MF), and three products of permeable polymer housewrap (HS) for secondary waterproofing material of wall assembly were selected as the test samples. The AF and MF were immersed in calcium hydroxide for 168 hours before fastening on the substrates, while this alkali treatment was not performed on HS. These test samples were set on substrate and fastened by staples. Two products of staples with 13 mm and 19 mm leg lengths were employed as the fastener for AF and MF, and those with 13 mm leg length were used with HS. Water column containers were placed on the fasteners of the specimen, and colored water was injected into them, as shown in Figure 10. The potential of the hydraulic pressure was set at 30, 50, 100, 150 mm of height, and water penetration was confirmed by visual observation of the colored water leaking after 24 hours. Three spots for test target with the water column container were prepared for each combination of the sample and the staple, and consequently, the number of fasteners was 21 for AF, 6 for MF, and 9 for HS, respectively. Table 3 shows test cases and exposure conditions.

4.2.2 Case 2 (After Outdoor Exposure)

Water penetration tests in Case 2 were performed on three products of HS and one product each of AF and MF. Each sample was fastened to the substrate of plywood using the staple, and the target was nine spots per substrate. Figure 11 shows the configuration of the specimen. To consider the impact of exposure conditions on an actual construction site before installation of the exterior finish, the specimens were exposed to an outdoor environment on a 30-degree angle from the horizontal. The water penetration test was performed after the exposure for 2 weeks in winter. The water level for the water penetration test in Case 2 was only 30 mm.

Table 3. Test cases for water penetration test.

Case	Sample	Leg length of staple (mm)	The number of pinholes [The number of products]	Exposure condition before the test
1	AF	13	21 [7]	Alkalin for 168 hour
		19	21 [7]	
	MF	13	6 [2]	
		19	6 [2]	
	HS	13	9 [3]	-
2	AF	19	9 [1]	Outdoor environment for 7days
	MF	13	9 [1]	
	HS	13	27 [3]	

AF: Asphalt-impregnated felt 430, MF: Modified asphalt-impregnated felt, HS: Permeable polymer housewrap

4.3 Rate of Fastener Interface Securing Watertightness

4.3.1 Case 1 (Without Outdoor Exposure)

Figure 12 shows the relationship between the rate of the fastener interface securing watertightness and the water level. Water leakage was observed at 30 mm of the water level in HS, and all points of HS allowed water penetration through the fastener interface. Contrarily, AF and MF indicated higher performance for watertightness. However, water leakage in AF and MF was detected from 50 mm of water level, and half of the test spots allowed water penetration at 150 mm. Although this experiment in Case 1 showed the vulnerability of HS, it could not indicate a difference between AF and MF in terms of seal performance at fastener interface.

4.3.2 Case 2 (After Outdoor Exposure)

Table 4 shows the rate of watertightness after exposing the specimens in an outdoor environment for two weeks. Dispersion in the difference of the spots was not indicated in each waterproofing material. Although water penetration was detected on AF and HS, MF secured watertightness on all spots of the fastener interface even after outdoor exposure. In general, it takes more than a week for the installation of exterior finishing after fastening the waterproofing material in construction sites. The differing results between Case 1 and Case 2 suggested not only vulnerability in AF but also durability in MF against outdoor exposure, taking into account the construction schedule. Additionally, it can be said that durability against outdoor exposure is important in terms of assessing the performance of the secondary waterproofing layer.

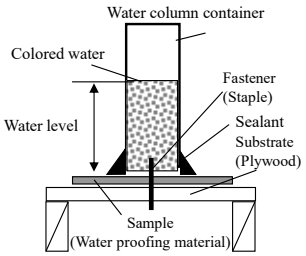

Figure 10. Setup for water penetration test.

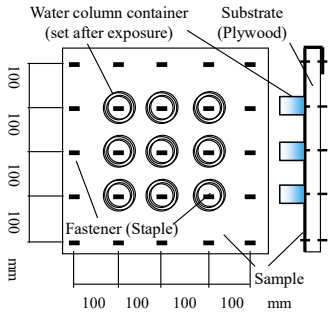

Figure 11. Configuration of specimen (Case 2).

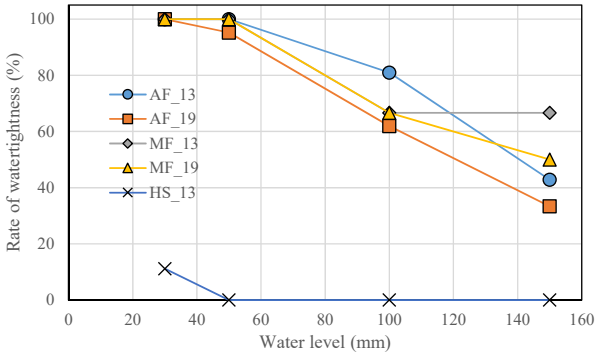

Figure 12. Rate of fastener interface securing watertightness in Case 1.

Table 4. Rate of watertightness in Case 2.

Waterproofing material	Rate of watertightness (%)
AF	0 [0/9]
MF	100 [9/9]
HS	0 (0/9)

5 Conclusions

To confirm the vulnerability of the primary and secondary waterproofing layer to water entry, water penetration tests were implemented on vulnerable parts, such as siding joints, wall-roof interfaces and fastener interfaces. The quantity of penetrated water in the worst specimens exceeded 0.3 L/min m^2 at 240 Pa of pressure difference, and this value is greater than water penetration from electrical outlets and vent ducts in past research (Sahal and Laccase, 2005). The significance in this experiment is that products with vulnerable watertightness occasionally exist, even though there was no remarkable difference in the specification. As for water entry at a wall-roof interface with short eaves, wind and rain blowing tests indicated that conventional details, using fasciaboard and bargeboard, are not useful in preventing water entry into the rear of the siding. Additionally, splashing water reached the pole plate and accumulated on it, when the wind pressure increased. Water penetration through permeable polymer housewrap was confirmed at the fastener interface. The watertightness of AF significantly decreased in outdoor exposure of just 2 weeks.

Although this paper merely addressed a few phenomena relating to water leakage, the results suggest that various factors, such as detail of interface and quality of materials, have significant impact on the extent of water leakage. Lately, consideration of rain penetration in hygrothermal analysis has been recommended in evaluation methods such as the ASHRAE Standard 160 (ASHRAE 2009), and a certain rain penetration ratio is provided. However, results in this paper imply that this value should be modified by the various factors discussed in order to assess the service life of building envelopes in practical use.

A Probabilistic Model for the Evolution of Porous Structure Caused by Solid-Phase Precipitation/Dissolution within Building Materials

Xiong Qing Xiang[1, a] and Meftah Fekri[1, b]

[1]Laboratory of Civil and Mechanical Engineering (LGCGM), National Institute for Applied Sciences, Campus Beaulieu, 35700 Rennes, France

Abstract. *Saline intrusion is a critical issue in building material because of the severe damages caused by the salt precipitation/dissolution process, especially for the porous material, which has good connectivity. When porous material is exposed to aggressive ambient, the pore structure, not only porosity but also pore size distribution, will be altered by salt precipitation/dissolution. As one of the most significant characteristics in the porous material, pore size distribution is always paid much attention in many literatures. However, a quantitative and practical determination method is still absent. This work aims to establish a probabilistic model to investigate the pore size distribution induced by solid-phase precipitation/dissolution. First, a lognormal distribution is proposed for the simulation of initial pore size distribution tested by the MIP method. Then we develop a probabilistic-based porous network to represent the evolution of microstructure due to precipitation/dissolution. To this end, two different transformation models are constructed to interpret the relation between initial pore radius and modified pore radius before and after precipitation/dissolution. With this probabilistic-based porous network, we could illustrate the precipitated profiles that evolve near the capillary interface during the salt precipitation/dissolution process for a given porosity and water saturation degree. Such a method could be used to interpret the mechanism of the local precipitation/dissolution process in pore scales, which cannot be implemented by experimental measurements.*

Keywords: *Pore Size Distribution, Precipitation/dissolution, Capillary Interface, Probabilistic Methods, Transformation Models.*

1 Introduction

The durability of construction material is always prevalently focused research since it is strictly relevant to the long and durable service life of building structures. As is generally accepted, salt precipitation/dissolution is one of the main factors for the deterioration of construction material, especially for the porous construction material, which has highly connected cavity facilitating the transport of moisture, ions, and chemical fluxes (Huang *et al.,* 2015). Salt precipitation/dissolution strongly influences the pore structure, which governs the most important properties of porous material, notably compressive strength for cement-based media (Cristina *et al.,* 2012). For example, salt dissolution induces high porosity, which accelerates the permeability of gases and liquids within the pore structure, thus affects the compatibility and durability of the construction materials. As a result, it brings about high maintenance and repair costs. (Fenaux *et al.,* 2019; Kumar *et al.,* 2003). Therefore, the porous structure directly impacts the durability and resistance of construction material and components. More specifically speaking, research on the processes involved in salt-induced corrosion is of utmost benefit for assessing the durability of construction material.

Apart from the porosity, the pore size distribution (PSD) also plays a vital role in

characterizing pore structure within porous media (Aligizaki *et al.,* 2005). However, the porosity does not give any information about pore size, shape, distribution, and connectivity; thus, the PSD should be employed to give a precise depiction of pore structure. The PSD, which is so complicated that covers several orders of magnitude of pore size, is principally influenced by several aspects, for instance, water, air, chemical reactions, and other fluids. (JR Nimmo, 2013) It is essential to recognize that many efforts of experimental measurements have been devoted to the description of PSD by previous researchers (D.N. Winslow, 1968; S. Roels *et al.,* 2001; E.Gallucci *et al.,* 2007; Yanbin Yao *et al.,* 2012; Gong Fuyuan *et al.,* 2014). However, a quantitative and practical determination method is still absent. Since the pore structure is heterogeneous and anomalous morphology in pore sizes, it is hard to describe it in full detail by experimental measurements. Therefore, the most reasonable method is to assess it by probabilistic models.

In this work, we adopted a lognormal distribution to approach the initial PSD before solid-phase precipitation occurred. Two representative models for pore radius were constructed by employing a monotonic transformation model and a non-monotonic transformation model. After several times of solid-phase precipitation, the new PSD was described by two different probabilistic methods. According to the comparison and parametric investigations, the proposed methods could provide us with an estimated prediction of the modified PSD, filling rate, and water saturation degree.

2 Methodologies

2.1 Transformation Models for Pore Radius

During the process of solid-phase precipitation/dissolution, the initial pore radius goes through a multi-step of transformation with the evolution $r_0 \to r_1 \to \cdots \to r_n \to r_{n+1}$, which is corresponding to the evolution of total porosity $\phi_0 \to \phi_1 \to \cdots \to \phi_n \to \phi_{n+1}$. According to the superposition principle, the new pore radius $r_{n+1}$is the superimposed of the current pore radius r_n and the increment term denoted as $\varepsilon_{n+1}(r_n)$, which is expressed as equation (1). As is mentioned above, precipitation/dissolution occurs near the capillary interface. Thus, the waterfront r_c is introduced into the transformation models of the pore radius. For the sake of simplification, it is assumed that the waterfront keeps constant as the evolution of pore structure. That is to say, the proposed pore system is open to the atmosphere to induce the water to evaporate into the ambient, which makes the waterfront be equilibrium. In this way, the capillary interface keeps constant for each time of transformation.

$$r_{n+1} = f_{n+1}(r_n) = r_n + \varepsilon_{n+1}(r_n) \tag{1}$$

Let us consider two different cases for the increment function $\varepsilon_{n+1}(r_n)$. For the monotonic model (see Figure 1a), water is filled in all the pores with the radius less than r_c. Solid-phase condenses inside the pores with the radius ranging from $r_c - \beta$ to $r_c + \beta$. When pore radius is large enough (*i.e.,* more than $r_c + \beta$), the accumulated solid-phase is assumed to be constant as $\bar{\varepsilon}_{n+1}$. For the non-monotonic model (see Figure 1b), the precipitated solid only occurs near the waterfront with the range from$r_c - \beta$ to $r_c + \beta$; for large pores with radius more than $r_c + \beta$, solid mass is supposed to be small enough to be neglected when compared to the large pore space.

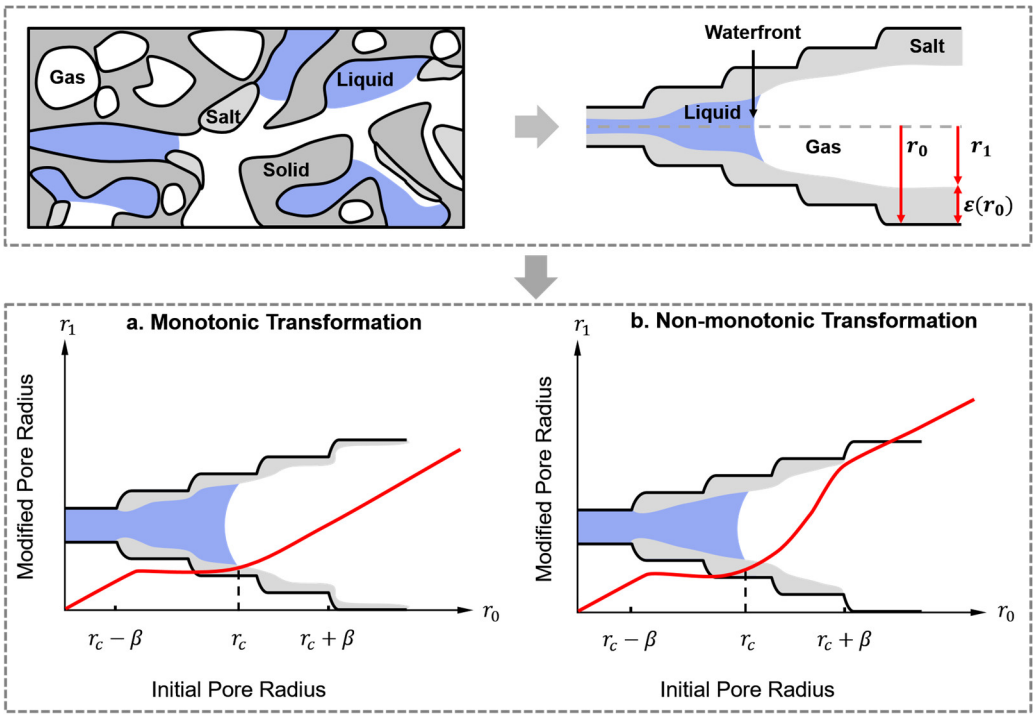

Figure 1. Schematic of the porous model for one single transformation (r_c is the maximum aperture filled with water, the so-called waterfront or capillary interface; β is the opening zone, indicating the range of solid precipitation/dissolution, $\varepsilon(r_0)$ is the increment term for the first time of transformation.).

Table 1. The monotonic transformation model and non-monotonic transformation model for new pore radius.

Function	Monotonic transformation model	Non-monotonic transformation model
$\varepsilon_{n+1}(r_n)$	$\begin{cases} 0 & r_n < r_c-\beta \\ \bar{\varepsilon}_{n+1}H(r_n) & r_c-\beta \le r_n \le r_c+\beta \\ \bar{\varepsilon}_{n+1} & r_n > r_c+\beta \end{cases}$	$\begin{cases} 0 & r_n < r_c-\beta \\ \bar{\varepsilon}_{n+1}H(r_n) & r_c-\beta \le r_n \le r_c \\ \bar{\varepsilon}_{n+1}G(r_n) & r_c \le r_n \le r_c+\beta \\ 0 & r_n > r_c+\beta \end{cases}$
$H(r_n)$	$\frac{3}{4}\left(\frac{r_n-r_c}{\beta}-\frac{(r_n-r_c)^3}{3\beta^3}\right)+\frac{1}{2}$	$\frac{3}{4}\left(\frac{2r_n+\beta-2r_c}{\beta}-\frac{(2r_n+\beta-2r_c)^3}{3\beta^3}\right)+\frac{1}{2}$
$G(r_n)$		$-\frac{3}{4}\left(\frac{2r_n-\beta-2r_c}{\beta}-\frac{(2r_n-\beta-2r_c)^3}{3\beta^3}\right)+\frac{1}{2}$
Remarks	The derived function should satisfy $H'(r_n) > 0$ in the case of salt precipitation, that is, $\bar{\varepsilon}_{n+1}$ is constrained in the range of $[0, -4/3\beta]$	

Table 1 shows the details of two different transformation functions. It should be noted if parameter $\bar{\varepsilon}_{n+1} > 0$, salt dissolution occurs; if $\bar{\varepsilon}_{n+1} < 0$, salt precipitation occurs. For the monotonic transformation model, the derived function $H'(r_n)$ should be positive to make sure the transformation function is one-to-one.

2.2 Probabilistic Methods for Modified Pore Size Distribution

The initial PSD for gel pores and capillary pores is presented in the form of lognormal probability density function that is expressed as:

$$P_0(r_0) = \frac{1}{\sigma_r\sqrt{2\pi}\, r_0} \exp\left(-\frac{(\ln r_0 - \mu_r)^2}{2\sigma_r^2}\right) \tag{2}$$

where μ_r, the location parameter, is the arithmetic mean of the representative pore size and σ_r, the standard deviation, is a measure of the dispersion of these pore size.

The total porosity for n+1th transformation is defined as:

$$\phi_{n+1}(r_{n+1}) = \phi_{n+1} \int_0^{r_{n+1}} P_{n+1}(t)dt \tag{3}$$

As we have the initial PDF $P_0(r_0)$ and two transformation models for pore radius, the new probability density function $P_{n+1}(r_{n+1})$ for n+1th transformation could be determined by the following two methods, which are presented in Table 2.

Table 2. Two probabilistic methods and their properties.

	Method one	Method two
Theoretical foundation	It is based on the assumption that porosity is proportionally distributed to each pore, the ratio of local porosity before and after transformation is equal to that of the ratio of global porosity: $\frac{\phi_{n+1}}{\phi_n} = \frac{d\phi_{n+1}}{d\phi_n}$	Let us consider the cylindrical form of the pores as to the end that the ratio of local porosity before and after transformation is equal to the ratio of pore volume, which could be represented by the following equation: $\frac{d\phi_{n+1}}{d\phi_n} = \frac{r_{n+1}dr_{n+1}}{r_n dr_n}$
P_{n+1}	$\left\lvert\left(\frac{dr_{n+1}(r_n)}{dr_n}\right)^{-1}\right\rvert P_n(r_n)$	$\frac{\phi_n}{\phi_{n+1}}\frac{r_{n+1}(r_n)}{r_n} P_n(r_n)$

According to Figure 1, the capillary condensation occurs in pores with radii smaller than r_c, thus the water saturation degree S_l (SD) can be obtained by the integration of the volume pores with sizes smaller than r_c.

$$S_l = \int_0^{r_c} P_{n+1} dr_n \tag{4}$$

3 Implementation and Parametric Study

The inputs parameters of initial pore size distribution were completed by experimental test mercury intrusion porosimetry (MIP) on masonry cement (see in Table 3 for more properties).

As the limitation of space, only the process of solid precipitation ($\bar{\varepsilon}_{n+1} < 0$) will be discussed in this work. The waterfront could occur in any position of capillary pores, ranging from 0.0025μm to 5μm (Huang et al., 2015), thus, the opening zone β could be any value that

is smaller than r_c.

Table 3. Characteristic parameters of lognormal distribution for the initial pore radius.

Initial porosity ϕ_0	Standard deviation σ_r	Mean Value μ_r	r_{min} (μm)	r_{max} (μm)
0.20	1.2	-1.8788	0.0015	165

3.1 One Transformation for the Monotonic Model

Let us study one monotonic transformation of PSD evolves with four different capillary interfaces both by method one and method two. When solid-phase precipitation occurs, the porosity is assumed to decrease from 0.2 to 0.18, and the opening zone is fixed at 0.05μm. Then we can get the new PSD for the single transformation according to the equations in Table 1 and Table 2.

Figure 2 indicates that significant and sharp salt precipitation occurs near the waterfront for method one (see in Figure 2a). For method two (see in Figure 2b), the variation of pore radius is much smoother than method one. Moreover, the modification was distributed evenly to the whole range of pore size in method two. Thus, it can be concluded that for the porous materials sensitive to the capillary effect, such as the porous material with a large number of fine pores and high permeability, method one is more appropriate to describe the slight salt deposition process than method two. Of course, the extent of salt precipitation also depends on the type of salts, temperature, concentration, and saturation degree of salt solution.

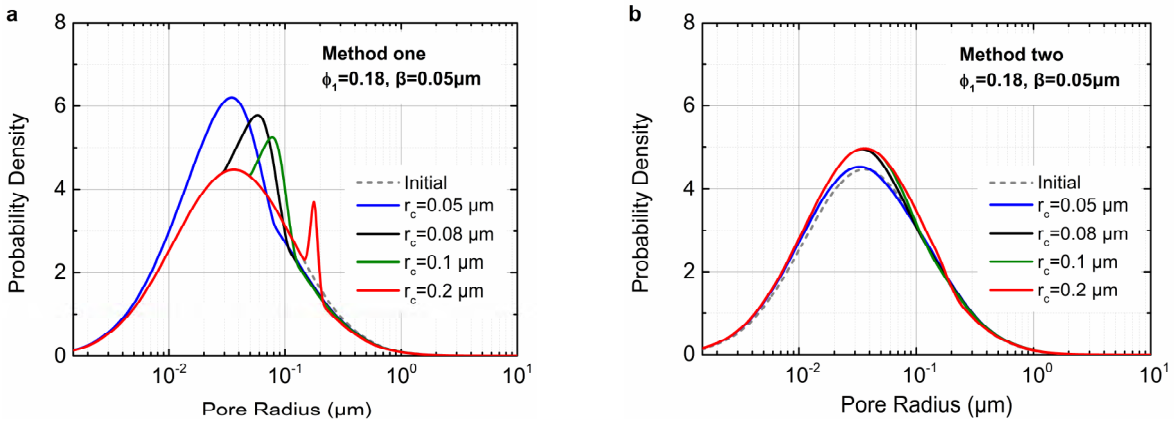

Figure 2. Pore size distribution with different waterfront for single transformation.

3.2 Successive Transformations for the Non-Monotonic Model

For the case of non-monotonic transformation models, we focus on five times of successive transformations with the porosity decreasing from 0.20 to 0.18 in the step of 0.004. The waterfront is fixed at 0.1 μm, and the opening zone is valued at 0.08μm. For non-monotonic transformation, there is no constraint to new porosity, and all we should concern about is that the critical parameter $\bar{\varepsilon}_{n+1}$cannot make the new pore radius negative.

From Figure 3, we can find that both method one and method two generate a bimodal probability density as the porosity decreasing to a specific value. As is similar to the single transformation, the probability density presented by method one shows a noticeable increment

of the peak value. In contrast, the probability density curve implemented by method two shows a slight shift to the left side, indicating produced more fine pores with the effect of precipitation.

As to the filling rate of pore radius due to the solid-phase precipitation presented in Figure 4, by dividing $\varepsilon_{n+1}(r_0)$ with r_0, after one time of transformation, that of the method one is up to 30% while that of the method two accomplishes around 10%. After five times of transformation, when the porosity decreases to 0.18, the porous material described by method one has the filling rate of almost reaching 70%, while method two only achieves over 30%. Thus, at the same porosity, method one presents a more efficient filling rate of pore radius than method two.

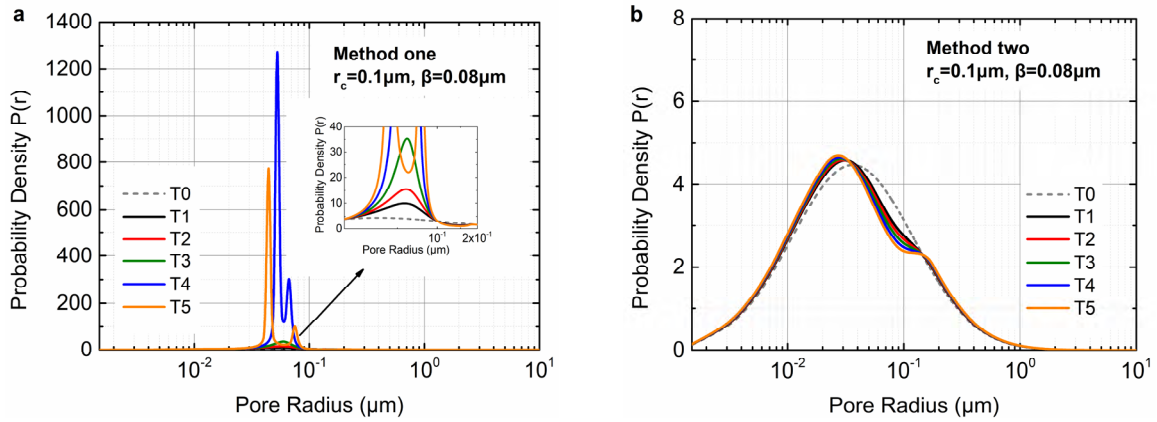

Figure 3. Pore size distribution for successive non-monotonic transformations by two different methods (According to Table 2, method one is related to the reciprocal of the derivative function of the non-monotonic transformation model, which induces the singularity points at the positions where the derivative function is equal to zero. As a result, the PDF tends to infinity at these singularity points. Herein the unbounded PDF is allowed because the integral of the modified PDF from 0 to ∞ is equal to 1.).

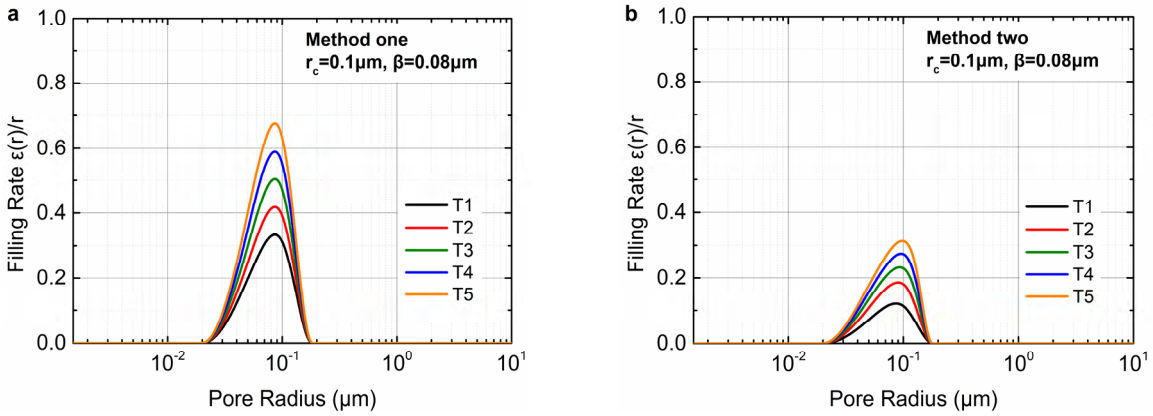

Figure 4. Filling rate of pore radius by two different methods during the process of salt precipitation.

To investigate the evolution of water saturation degree for successive transformations, we consider a case that porosity decreases from 0.2 to 0.185 by 30 steps, as is shown in Table 4.

Table 4. Parameter configurations for the investigation of the water saturation degree in non-monotonic successive transformations.

Initial porosity ϕ_0	Final porosity ϕ_{30}	Transformation Times	Transformation Steps of Porosity	Waterfront r_c (μm)	Opening Zone β (μm)
0.2	0.185	30	0.0005	0.1	0.08

Figure 5 shows the evolution of the water saturation degree with the porosity. It is observed that the water saturation degree calculated by method one shows a slight reduction while that is described by method two increases tremendously with the porosity decreasing. Besides, the incremental trend is more and more evident as the decreased porosity. It may be ascribed to the different filling rates of the two methods. For method two, the reduction rate of the pore volume is lower than that of water volume, leading to the increment of the water saturation degree. However, for method one, the reduction rate of the pore volume is fast enough to catch that of the water volume, and the two rates are almost the same. Consequently, the water saturation degree by method two almost keeps constant.

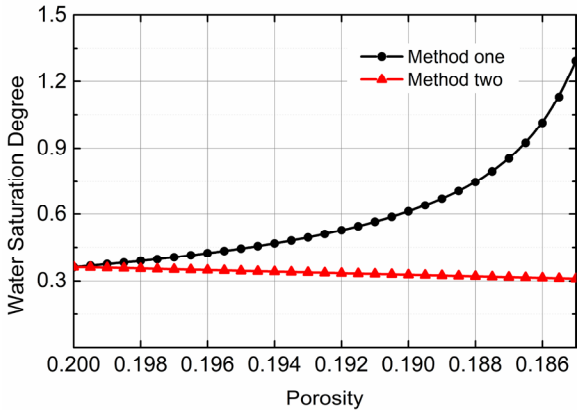

Figure 5. Water saturation degree implemented by two methods in the case of salt precipitation.

4 Conclusions

- When the waterfront moves to large pores, method one shows more evident modification than method two for PSD in the process of salt precipitation. Moreover, method one is more appropriate to the porous material that is sensitive to the capillary effect than method two. Besides, the monotonic model is very limited used, which is only applicable to the slight salt precipitation.
- The existing two probabilistic methods could estimate the filling rate caused by salt precipitation. According to the simulated results of non-monotonic transformation models after five times of transformations, method one has a higher filling rate than method two, which indirectly leads to the stable water saturation degree in method one. Such an approach of method one allows the water condensation in the open system that does not depend on the evolution of the pore structure.
- For further investigation, proper consideration for the mobilization of waterfront in a closed system should be taken into account to fully understand the evolution of

microstructure in the durability research for a porous material.

Assessment of Reasons behind and Level of Destruction of Aquatic Supports in a Hydraulic Ash Removal Bridge

Tomasz Błaszczyński[1] **and Aldona Łowińska-Kluge**[2]

[1] Professor emeritus, Poznan University of Technology, tomasz.blaszczynski@opal.info.pl

[2] Professor emeritus, Poznan University of Technology, lowinska-kluge@wp.pl

Abstract. *The presented article describes a case of damage to concrete in the aquatic supports of a hydraulic ash removal bridge in a power plant. Carrying out an assessment of the causes of concrete damage, as well as determining the possibility of the occurrence of corrosive phenomena within it, and thus, consequently, predicting the durability of the building structure and selecting, on its basis, a proper repair-renovation procedure, required a series of essential studies and analyses to be carried out. Therefore, in the analyzed case, a complex study was carried out on the structure as well as tests on samples of concrete cut out, in the form of core drillings, from the damaged structure (among others: macroscopic, microscopic SEM, XRD, DTA, chemical analyses). Based on these studies, the types of corrosion responsible for the analyzed damage were determined.*

Keywords: *RC Aquatic Supports, Durability, Destruction, SEM, XRD, DTA, Chemical Analyses.*

1 Introduction

For years now, not much attention has been given to industrial reinforced concrete structures. Unfortunately, the consequences of this are progressing phenomena of various types of corrosion, especially when the structures are under conditions posing a risk of corrosion. It is known that the corrosion of materials which buildings are made from is of fundamental importance to their durability (*Błaszczyński et al., 2008*). The reasons behind the corrosion of concrete, and therefore reinforced concrete, can be manifold. Such corrosion usually takes place under the influence of external effects. In the recent years, a frequent phenomenon in building practice is the occurrence of cracking of reinforced concrete structures across their entire width as early as at the stage of their realization. The reason behind such a state of things, as proven in works (*Błaszczyński et al., 2008, Łowińska-Kluge et al., 2012*), is internal corrosion in concrete. Concrete, as a structural material, is subjected to the corrosive effects of the outside environment. One type of corrosion that this material undergoes, frequently neglected by designers, is biological corrosion – a specific case of chemical corrosion. It ought to be pointed out that numerous physical and chemical transformations taking place in concrete are the result of the activity of metabolic organisms, i.e. bacteria, fungi or algae. The destruction of material caused by these living organisms takes place, among others, under the influence of biogeophysical processes, such as the changes in the porosity of material as a result of the development of a biological membrane on the surface of the concrete (*Horbik et al., 2013, Łowińska-Kluge et al., 2016, Mejíaa et al., 2019*).

2 Short Description of Analyzed Structure

Aquatic supports of a hydraulic ash-removal bridge are found in the area of a power plant, or,

doi:10.23967/dbmc.2020.013

more precisely, over the waters of a lake surrounding the actual plant. The lake serves to naturally cool off turbines. The supports are monolithic reinforced concrete structures in the form of reinforced concrete footings, found on a steel grated structure supporting structure, the construction of which is based mainly on channels or I sections.

After many years of service, the supports of the hydraulic ash-removal bridge are in a bad technical condition. Corroded and spalling concrete can be seen, as well as the progressing corrosion of reinforcing steel (Fig. 1, 2).

Figure 1, 2. Damages to pillars in the form of spalling corroded concrete and corroded reinforcing steel.

Centres of biological corrosion are also visible (Fig. 3 and 4).

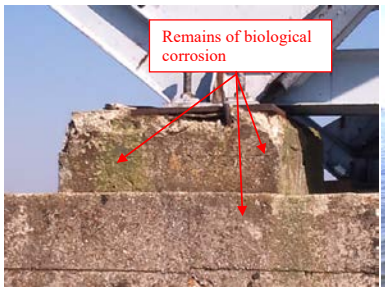

Figure 3. Reinforced concrete support with corrosion Centres.

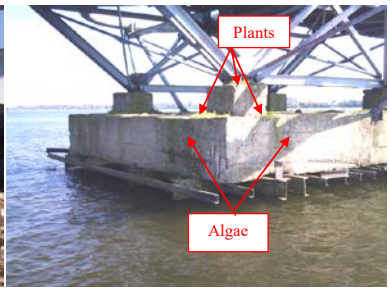

Figure 4. Reinforced concrete support along with the covering vegetation and algae.

3 Performed Laboratory Tests

Laboratory tests were carried out on the collected samples from the objects, which covered: concrete core drillings of ∅ 4.5 mm, defined as Concrete A (Fig. 5) as well as concrete piece samples from areas near reinforcing bars and labelled as Concrete B (Fig. 6).

Figure 5. View of collected samples in the form of core drillings.

Figure 6. View of collected pieces.

3.1 Macroscopic Studies

Based on macroscopic observations, the occurrence of natural aggregate of a similar

granulation as well as certain amounts of carbonate aggregate was determined in the analyzed types of concrete. Concrete samples are characterized by a porous structure and varying dimensions of pores, with the remains of corroded reinforcement bars (Fig. 7a) and carbonate aggregate (Fig. 7b) determined on the majority of the samples.).

The presence of biotic factors in the form of algae and mosses, which can cause biological corrosion, is confirmed on the outer side of samples A and B (Fig. 8).

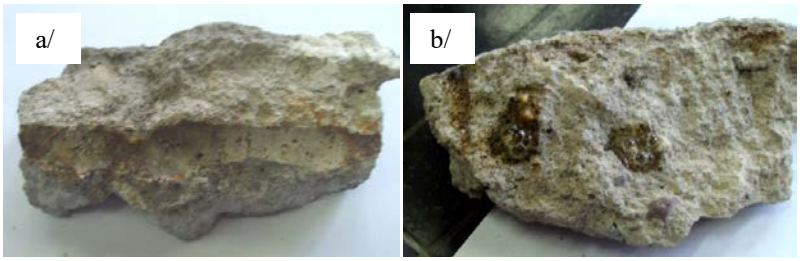

Figure 7. Piece samples of concrete: a/ porous structure and remains of corroded reinforcement bars, b/carbonate aggregate reacting with 10% HCl.

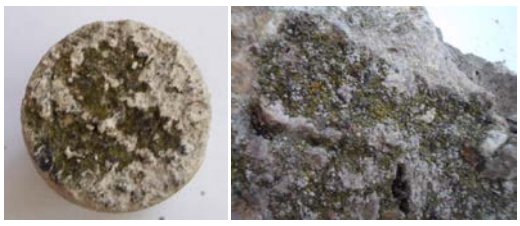

Figure 8. Concrete samples with visible biotic factors.

In order to assess the estimated course of carbonization in the analyzed concretes, the cross sections of concrete samples were sprayed with 1% phenolphthalein solution. Piece samples (Concrete B) are completely carbonized (Fig. 9), whereas in the samples from the core drillings (Concrete A), the carbonized layer is 1-3 cm in thickness (Fig. 10). Carbonization is not noted deeper within.

Figure 9. Pieces of Concrete B; completely carbonized concrete (all the way to the reinforcement bars) with visible remains of corroded reinforcement (pH>9).

Figure 10. Pieces of Concrete A; visible layer into concrete with an alkaline pH, carbonized 1-3 cm in thickness.

3.2 Determining Absorbability

Determining the absorbability of the collected concrete (serving the function of a cement

finish) was carried out using the desiccators - gravimetric method. The moisture content was determined in [%] from Formula (1):

$$n = (m\text{-}m_s)/m_s \cdot 100 \qquad [\%] \tag{1}$$

where:

n – absorbability [%],
m – mass of sample saturated with water to a constant mass [g],
m_s – mass of sample dried to a constant mass [g].

The results obtained for the analyzed concrete are given in Table 1.

Table 1. Absorbability of tested concretes.

Concrete type	Concrete A	Concrete B
absorbability [%]	6.77	7.84

The results presented in the above table are the average from three indications for each type of concrete.

All determined absorbability values exceed 5%. In accordance with p. 5.2 of the PH-88/B-06250 standard: absorbability of concrete should not be higher than 5% in the case of concrete directly exposed to the effects of atmospheric factors, as was the case in the concretes analyzed here.

3.3 Determining the pH Value of Concrete

The pH of aqueous extracts of ground concrete samples taken from different locations was measured. The measurements were carried out using a N5170E Ph-meter. A combined glass electrode was used for the studies. Each of the results is the average from three readings

Table 2. pH value of analyzed concretes.

Concrete type	Concrete A	Concrete B
pH value	10.28	7.29

A typical pH for normal concretes is a pH = 12.3 to 12.7. A pH value = 11.8 is the limiting value at which the C-S-H (tobermorite) and aluminosilicate phases in the cement rock are stable. Concrete at a PH < 11.8 ceases provide protection for steel. All collected samples were characterized by a pH < 11.8, which confirms the corrosion processes of steel taking place within the concretes. The pH of Concrete B points to extensive processes of corrosion.

3.4 Determining Concrete Strength

Studies on the compressive strength were carried out on a universal durometer for static samples. The machine has a electrohydraulic drive with a hydraulic control system. In accordance with the calibration certificate and with p. 4.2.2 of PN-EN 12390-4:2001: *Concrete tests. Part 4: Compressive strength. Requirements for durometers,* the machines ought to be categorized in Class 0.5. The maximum load of the machine was 300 kN.

The tests were carried out in accordance with the PN-EN 12390-3:2002: *Concrete tests. Part 3: Compressive strength of samples for testing.* Compressive strength tests were carried out on samples cut out from the provided drillings. In connection with the small diameters of the boreholes, only samples with a surface of < 225000 mm^2 were obtained, and thus all results should be lowered by a value of 10 to 15%. The carried out tests provided results of compressive strength with values ranging from 11.81 MPa to 27.19 MPa. The obtained average strengths, with a large range of values, allow only for qualifying the analyzed concretes in classes from 10 to 20 MPa, depending on the level of damage.

4 Selected Structural-Chemical Tests

The collected samples were also subjected to necessary structural-chemical tests, such as:

- microscopic examinations,
- necessary chemical analyses.

4.1 Microscopic Tests

In order to determine the structure and type of created compounds, as well as to assess the possibilities as well as directions of further reactions in the analyzed Concretes A and B, microscopic examinations were carried out.

Microscopic examinations were also to serve the purpose of assessing the potential possibilities and directions of further reactions taking place in the analyzed concrete (*Łowińska-Kluge et al., 2006*). The studies were carried out in accordance with the assumed guidelines of microscopic analyses, using a type VEGA TS 5135 MM scanning microscope, at a low vacuum in electrons reflected on non-sputter-coated samples. Over the course of the tests, photographs of characteristic areas of the analyzed samples were taken. Example result has been shown in Fig. 11.

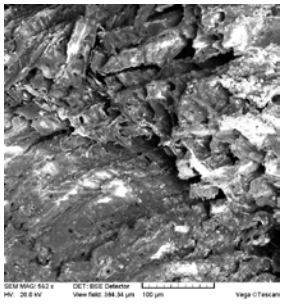

Figure 11. Microscopic SEM image of Concrete B surfaces contaminated with biotical factors (mosses, algae, fungi); very porous structure of cement matrix; visible "fibrous etchings" caused by the activity of biotic factors present in the gel phase.

Non-model microanalyses of EDS using an x-ray microanalysis system of characteristic products of reactions observed in the concrete of the finish and on eave sheet metals were also carried out.

The presence of carbon, calcium, oxygen, silicone, phosphorus, iron, sulphur, small amounts of nitrogen as well as trace amounts of potassium, zinc and aluminium is confirmed on the surface of the carried out non-model EDS x-ray microanalysis of the surface of

Concrete B contaminated with biotic factors (Fig. 11). Calcium silicates and aluminates had probably already undergone decomposition.

4.2 Necessary Chemical Analyses

In an effort to precisely specify the amount of compounds which can influence the properties of the analyzed concretes, chemical analyses of samples of these concretes were carried out.

Chemical analyses were carried out on adequately-sized samples of ground concretes A and B in accordance with the standards (*PN-EN 196-2:1996, PN-EN 196-21:1997, PN-EN 197-1:2002*) as well as the method of classical chemical analysis. The obtained results [%] have been presented in Tables 3 and 4.

Table 3. Determined $SO_{3\ total.}$, MgO, CaO, Na_2O, K_2O and Na_2Oeq contents in the entire concrete.

Concrete	Content of compounds in mean concrete sample [%]*					
	SO_{3total}	CaO	MgO	Na_2O	K_2O	$Na_2Oeq.$
A	2.44	29.53	1.03	0.14	0.387	0.39
B	0.96	32.87	1.53	0.11	0.70	0.57

* The results are the means of three recordings.

In Concrete A, a significantly higher content of SO_3, higher content of Na_2O and lower contents of MgO, K_2O and CaO occur as compared to Concrete B.

Estimated calculations of the amount of indicated compounds for concretes in [kg] and a comparison of the obtained results for the cement only [%] have been presented in Table 4.

An experimentally determined amount of cement was assumed for calculations due to not being familiar with the actual amount of cement used to create the tested concretes. In doing so, 306 kg cement per m^3 were assumed for Concrete A m^3, and 302 kg cement per m^3 for Concrete B. Concrete A has a relative density of 2446 kg/m^3, whereas that of concrete B is 2391 kg/m^3.

Table 4. Estimated amounts of $SO_{3całk.}$, MgO, Na_2Oeq in concrete.

Concrete type	In relation to:	Amount of indicated compounds in concrete		
		SO_{3total}	MgO	Na_2Oeq
Concrete A: - relative density = 2446 kg/m^3, - cement = 306 kg/m^3,	Concrete mass [kg]	(2.44·2446/100) = 59.68 kg/m^3	(1.03·2446/100) = 25.19 kg/m^3	(0.39·2446/100) = 9.53 kg/m^3
	Cement mass [kg]	(59.68·100/306) = 19.50 %	(25.19·100/306) = 8.23 %	(9.53·100/306) = 3.11 %
Concrete B: - relative density = 2391 kg/m^3, - cement = 302 kg/m^3,	Concrete mass [kg]	(0.96·2391/100) = 22,95 kg/m^3	(1.53·2391/100) = 36.58 kg/m^3	(0.57·2391/100) = 13.63 kg/m^3
	Cement mass[kg]	(22.95·100/302) = 7.60 %	(36.58·100/302) = 12.11 %	(13.63·100/302) = 4.51 %

The indicated amounts of SO_{3total} for the analyzed concretes range between 19.50% (A) to 7.60% (B) in relation to the estimated cement mass. The obtained amounts do not fulfil the requirement from Table 3 of the standards (*PN-EN 197-1:2002*) for Portland cement and Portland cements with additives, which, according to the standard, cannot exceed the value of 3.5%.

The indicated amounts of MgO, *i.e.* 8.23% in Concrete A and 12.11% in Concrete B, in reference to cement mass, exceed (according to *Peukert, 2000*), the permissible value of 4%. Over many years, MgO content of 5% in cement was permitted in the standards of most countries. However, cases of the destruction of many structures in the USA and other countries, as well as results of long-term studies, showed that additional safety measures are necessary.

The indicated amounts of alkalis (Na_2Oeq), *i.e.* 3.11% (A) and 4.51% (B) in relation to the cement mass exceed, according to (*Peukert, 2000*), the permissible value of 0.6%.

Sulphur compounds recalculated for total sulphur, MgO and Na_2Oeq in the tested concretes may come from the applied aggregates and their contaminants, as well as from cement.

5 Analysis Along with Assessment

Based on the description of the existing state, carried out tests and earlier analyses, it can be stated that the observed phenomena are mainly caused by leaching, carbon and biotic corrosion. Signs of sulphuric corrosion were not noted, though the use carbon aggregate and small amounts of fly ashes were confirmed in the concrete.

Unfortunately, the contractor refused to provide data on water and air contamination, making it much more difficult to search for reasons behind the occurrence of the present phenomena. The lack of adequate tightness of the surface layer caused constant dampening of the remaining layers of the analyzed concretes. Therefore, the moisture contained and persisting in the concrete led to the slow dissolvent of calcium compounds from the cement stone. This moisture, being the result of precipitation waters, that is soft waters with low carbonate hardness as well as water evaporating from the surrounding lake, leads to the emergence of leaching corrosion. Leaching is a diffusion process, the course of which is significantly influenced by water flow speed and pressure. The aggressiveness of soft water increases in lower temperatures. The leaching of calcium hydroxide begins in the surface layers. Over the course of time, $Ca(OH)_2$ from increasingly deeper layers is leached into the environment. First, $Ca(OH)_2$ (so-called free calcium) is dissolved, and along with the lowering of pH, also the calcium from hydrated silicates and calcium aluminates. These calcium compounds settled on the steel reinforcement bars and, in the presence of moisture, reacted with carbon dioxide (CO_2) that got through from the atmosphere. These gases, along with moisture, also entered the inside of the cement stone with the leaching of Ca compounds. The occurring reactions resulted in the formation of, among others, calcium carbonate and iron carbonate. These products are clearly identified during microscopic studies and over the course of EDS microanalysis. Steel reinforcement bars, in places of contact with concrete, were in a constantly moist environment.

Non-model EDS microanalysis revealed, above all, the presence of products from the cement matrix “interspersed” with products of rebar corrosion, as well as showing the

occurrence of products of the decomposition of the cement matrix and reinforcement bars (in the form of mainly calcium carbonates, iron and zinc). The probable distribution of calcium silicates and aluminates was determined on the basis of the carried out non-model x-ray EDS microanalysis of a zone of Concrete B surface contaminated with biotic factors. The lack of portlandite (significantly lower amount of C-S-H phases), very high amount of calcite (3.5 times higher) and decreased amount of quartz (twice lower), as compared to Concrete A, point to the extensive corrosion of the cement matrix in Concrete B. Sulphur compounds recalculated for total sulphur, MgO and Na_2Oeq content in the assessed concretes may come from the applied aggregates and their contaminants, as well as from cement.

As indicated by the results of the carried out laboratory studies and conducted analyses, the corroded surface layer of the concrete ought to be removed all the way to the reinforcement bars, with the uncovering and cleaning of the rebars. Next, new layers ought to be made in accordance with one of the systemic repair technologies.

Grain Size Analysis of Class C Fly ash Used for Aluminium-Silicate Binders Production

Tomasz Z. Błaszczyński[1] **and Maciej R. Król**[2]

[1] 62-002 Złotniki, Poland, tomasz.blaszczynski@opal.info.pl

[2] Koszalin University of Technology, Śniadeckich 2, 75-453 Koszalin, krol@wilsig.tu.koszalin.pl

Abstract. *Concrete structures are constantly moving in the direction of improving the durability. Durability depends on many factors, which are the composition of concrete mix, the usage of additives and admixtures and also the place, where material will work and carry the load. Taking into account that the consumption of cement on the globe gives way only to the consumption of drinking water, the issue of concrete technology begins to take on an economic and ecological aspect. Mentioned above the aspect of durability is strictly connected to economy. Due to huge amount of greenhouse gasses produced in the process of calcination, the ordinary Portland cements are responsible for even 8% of anthropogenic carbon dioxide production. This paper is focused on properties of materials known as green binders. They can be used to produce aluminium-siliceous binders and green concretes which can also be known as geopolymer concretes. Often used in construction industry, class F fly ashes are also good substratum also for aluminium- siliceous binders. Nevertheless amount of available class F fly ashes do not give the possibility to replace ordinary cements by aluminium-silicate one produced from this type of ash. This raises the need to look for replacement solutions for the substrate of the new green adhesive. As the substrate of new eco-binders there were used fly ash which came from coal and high calcium ash from the burning of lignite, called class C fly ashes. However not processed one, cannot compete with Portland cements due to durability. It surely depends on many aspects of polymerization process, which are for example maturation environment, concentration and type of alkaline activator, but the most important are parameters of fly ash substrate. This is because main attention was paid to granulation of examined class C fly ashes which have been subjected to a grinding process involving milling in a magnetic mill and subjected to ultrasonic waves. The analysis of grain change was presented in the aspect of the possibility of increasing the strength and durability of the cement material.*

Keywords: *Aluminium-Silcate Cements, Green Cements, Type C Fly Ash.*

1 Introduction

In recent years, many different kinds of cementiious materials have been developed. Many of them were alkali-activated cementiious materials. It is mostly because of their high strength and durability. Moreover they have got very low environmental impact due to emissions of greenhouse gasses which was subject in some papers (Błaszczyński *et al.* 2014, 2015; Juenger *et al.* 2011 and Barbosa *et al.* 2000). Most of used in civil-engineering and infrastructural construction fly ashes are type F. The reason of that is because of their excellent properties and wide spectrum of application. Much worse properties, especially in use as additives to cements and mortars gives usage of type C fly ash. According to Yang (Yang *et al.* 2008),

aluminosilicate materials obtained from alkali-activated class F fly ash have main binding phase as the amorphous hydrated alkali-aluminosilicate (Krizana *et al.* 2002; Haha *et al.* 2011 and Guo *et al.* 2010) proved that the major binding phase in alkali-activated ground granulated blast furnace slag similarly like in type C fly ash is calcium silicate hydrate (C-S-H). Because of this fact, main goal of this paper is to present future possibilities of treatment which could increase application range and utilization of C type fly ash.

Alkali-activated slag cements show good mechanical strength. Their strength, compressive and flexural can be even better than in ordinary cements which were shown by Hardjito and others (Hardjito *et al.* 2005; Wallah *et al.* 2006 and Cheng *et al.* 2003). The classical cements set owing to the special phenomenon of solvation, *i.e.* hydration. It is a compound process due to overlapping and a mutual influence of individual clinker phases that react with water. The total hydration process consists of three basic stages. The dissolution of soluble compounds in water, that is the proper hydration, which consists in the creation of the primary phase in a colloidal state (the formation of the plastic mass) and the crystallization of the hydration products (hardening of the plastic mass) what was presented by Błaszczyński and Król (Błaszczyński *et al.* 2015). The initial stage of the proper hydration of cement was presented by Kurdowski (Kurdowski, 2010). It is connected first of all with the C_3A phase. As a result of a fast reaction of this phase, large crystals of hydrated calcium aluminates are produced (Figure 1a). All the stages of hydration, as compared with the setting of the polymeric blend, are presented in Figure. 1.

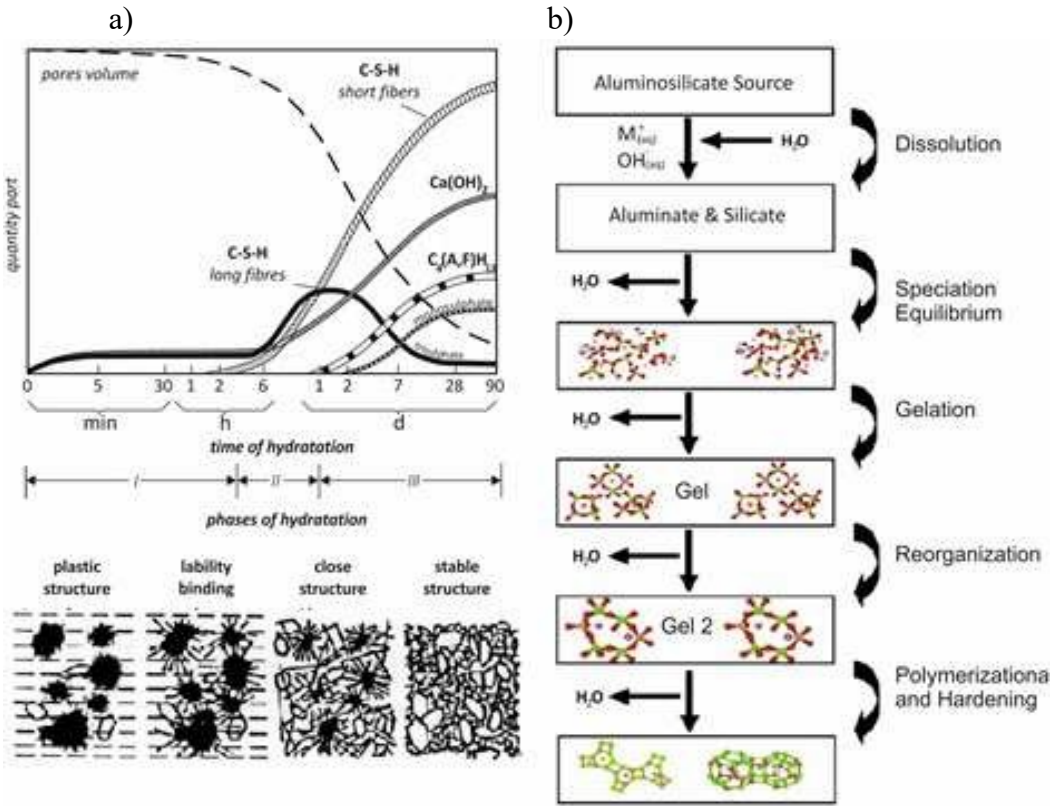

Figure 1. Comparison of phases: a) hydration of the Portland cement, b) polymerization.

The present state of knowledge was collated by Skvara (Skvara, 2007). It gives the possibility to present that a geopolymer based on fly ash is characterized by following properties:

- is built by structure similar to vitreous bodies what was presented by Barbosa and Mackenzie (Barbosa *et al.*, 2000),
- in structure of geopolymers there is presence of sodium and potassium cations (Na^+, K^+), which are not bonded so strong as it is in zeolite, it is a reason of potential efflorescence occurrence,
- structure of material is represented by a porous body,
- porous body of geopolymers contain water,
- the water is used in geopolymerization process as a transport of alkali activator,
- amorphous hydrates and crystalline can be noticed in structure only if material containing calcium are present (*i.e.* blast furnace slag, calcium fly ash).

A number of characteristics and properties of materials that are by-products in various processing processes are strictly conditioned by the technological cycle. Whether in the case of fly ash or blast furnace slag, temperature plays a major role in the quality of the products obtained, in addition to the properties and composition of the substrate. The higher it is, the cleaner the product is, the more finely divided it is, and the more extensive it can be used. What's more, the implication of binders in open atmosphere conditions is also possible, without the need for high-temperature ripening conditions. This situation occurs in the case of both fly ash and blast furnace slag what was topic of Małolepszy and Deja (Małolepszy *et al.,* 1999). The substrate used in the reactions in which the above by-products are formed determines the use of temperatures appropriate for the given reaction and technology. Małolepszy and Deja (Małolepszy *et al.,* 1999) suggest in their work, where the photos taken by scanning microscopes of fly ash samples from power plants and combined heat and power plants, in which various technologies of coal combustion differing among other temperatures of this process were used, that there is possible to systematize the composition of the sample together with the increase of the combustion temperature. Fly ash is artificial pozzolana, which is formed during the combustion of shredded coal in power plants equipped with dust boilers. Pozzolans do not self-harden after mixing with water. However, when they are finely ground after the addition of water, they react with calcium hydroxide, forming a mixture of aluminium silicates and calcium silicates with increasing strength and that has been proven by Barbosa and others (Barbosa *et al*., 2000; Duxson *et al.*, 2007 and Caijum *et al,.* 2011). The pozzolanic activity of ashes is significantly affected by their particle size. As the grain increases, the pozzolanic activity decreases. Fractions smaller than 45 [μm] can characterize pozzolanic activity significant for building materials

2 Experimental Program

2.1 Materials

Fly ash from brown coal combustion with a significant content of calcium compounds was used for the research. In the determined samples, the CaO content ranged from 15 to 24%. The samples were not cleaned of unburned coal, which was present in the composition in the size of approx. 3 to 5%. The chemical composition of tested fly ash is given bellow (Table 1).

As the activator, an aqueous solution of potassium hydroxide with a given molar ratio was used (Table 2). Aggregate was not added to the mix.

Table 1. Summary of the chemical composition used for testing fly ash.

Type of fly ash	SiO_2	Al_2O_3	Fe_2O_3	TiO_2	MgO	CaO	Na_2O	K_20	Ignition losses
TYPE C	44,17	21,79	4,58	1,85	1,49	21,06	0,23	0,19	4,64

Table 2. Properties of used alkaline activator.

Name	Molar mass [g/mol]	Density [g/cm^3]	Viscosity cP
potassium hydroxide	56,11*	2,12	-

2.2 Mixes Design and Specimens Preparation

For the first 12 h, the samples were kept at 80°C, and then were reaching their final proporties in air-dry conditions. After 24 hours of implementation, they were demoulded and successively tested for strength.

The selection of such temperature and treatment time was the result of previous tests. At 80°C, the tested binders obtained relatively the highest compressive strength. Samples made of calcium fly ash had a decrease in strength as the temperature increased to 95°C. Hence, the ideal ripening conditions were a temperature of 80°C and a ripening time of 12 hours in its surroundings. As the alkaline activator, the strongest available bases of potassium hydroxide were used in the concentration of 12M. The influence of activator concentration on the tested samples was not tested.

2.3 Methods

The treatment impact study was carried out on calcium fly ash. They have been checked for grain size. The material was then milled in an electromagnetic mill distinguishing samples in terms of milling time. After milling, the samples were examined for granulation and subjected to ultrasonic waves. After this treatment, the grain size of the material was again tested. This was to break down any agglomerates formed during grinding. Due to the limited amount of substrate that can be tested and the large number of millings, the test was carried out for times of 15, 30, 60, 120, 180 and 240 s, respectively.

Research related to determining the basic mechanical properties of geopolymer binders from treated ash in the form of milling was carried out on 40x40x40 mm cubic samples.

This allowed achieving additional volumes using less ash used. Two series of tests were obtained in this way:

- I - testing the efficiency of grinding substrates in the form of calcareous fly ashes by checking the difference in compressive strength of the ground substrate,
- II - testing the efficiency of grinding substrates in the form of calcareous fly ashes by checking the difference in tensile strength when splitting the ground substrate (Figure 2-3).

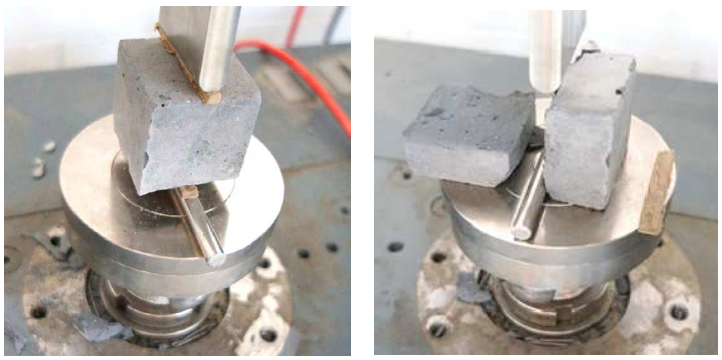

Figure 2-3. View of the sample before and after the splitting test

3 Results and Discussion

First obtained result was the effect of grinding and ultrasound treatment on grain size of tested samples. Grain size after grinding in times of 15, 30, 60, 120, 180 and 240 s, compared to samples additional subjected to ultrasound treatment is shown below (Figure 4-10).

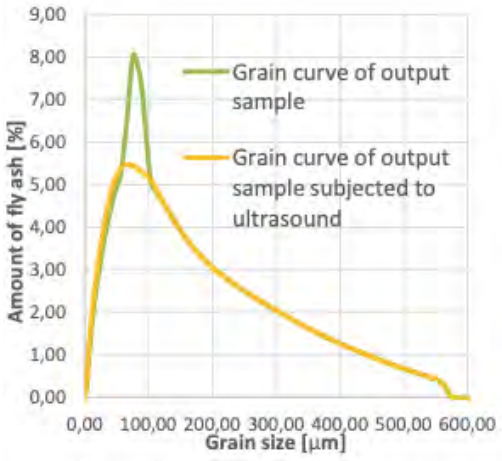

Figure 4. Grain size of output sample.

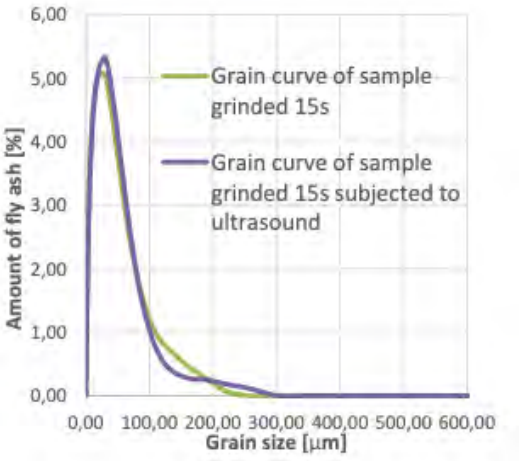

Figure 5. Grain size of sample grinded for 15s.

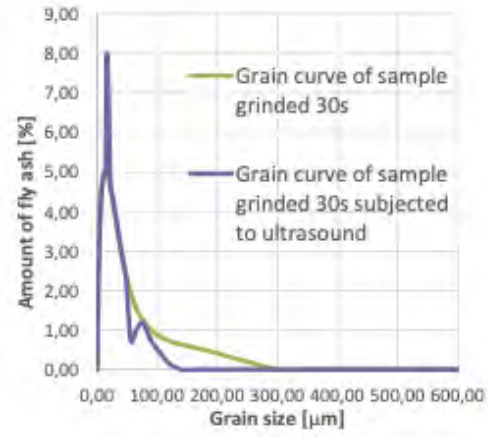

Figure 6. Grain size of sample grinded for 30s.

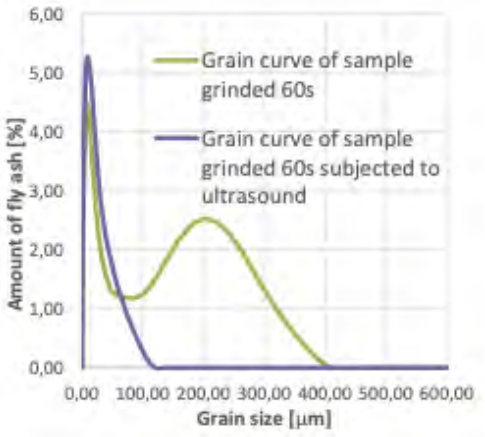

Figure 7. Grain size of sample grinded for 60s.

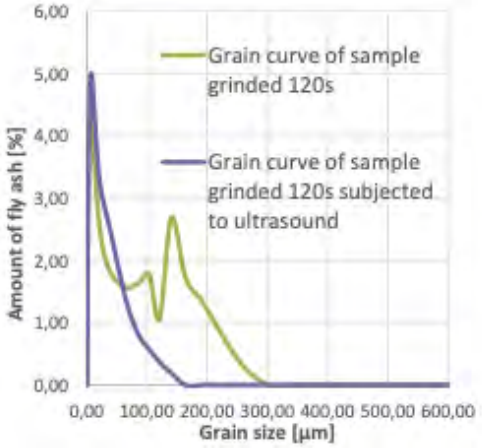

Figure 8. Grain size of sample grinded for 120s.

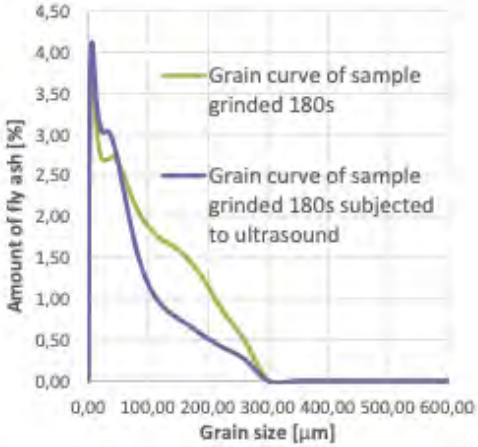

Figure 9. Grain size of sample grinded for 180s.

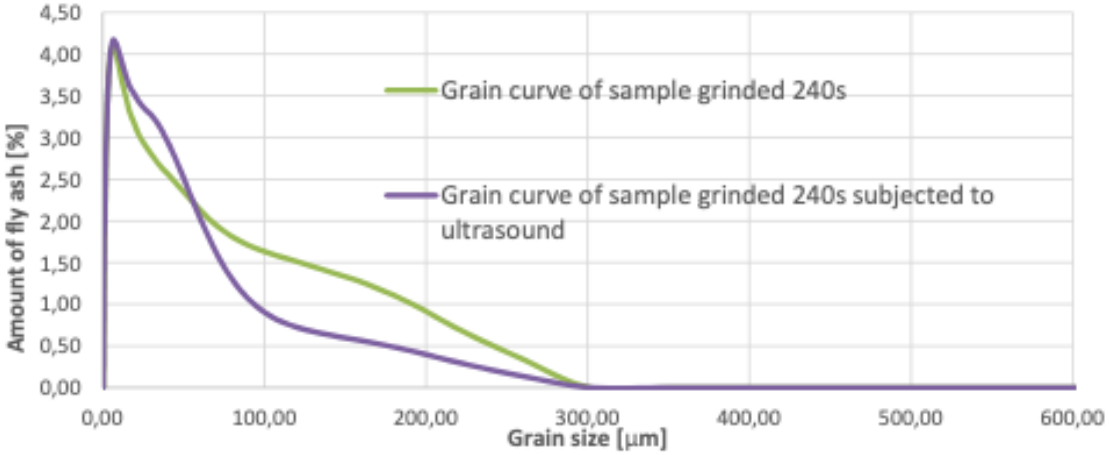

Figure 10. Grain size of sample grinded for 240s.

The most favourable in terms of maximum fragmentation turned out to be grinding time of 60s. During it, the highest ash content below 45 µm was obtained. Further increase in grinding time caused the opposite effect agglomerates began to form in the material. This happened because smaller particles of ash under the influence of fragmentation obtained greater pozzolanic reactivity, due to which under the influence of a small amount of moisture and heat generated during grinding they merged into larger particles. The next stage of treatment was subjecting the material to an ultrasonic wave, which broke the agglomerates formed, making the sample with the largest fragmentation become a milled sample for 120 [s]. The degree of comminution described by the specific surface in this case corresponded to the obtained compressive strength of the tested samples. The increase in tensile strength for the reference sample, which was a mixture constituting 50% of the ground material for 120 s and 25% of the value of the ground material for 30 and 240 [s], respectively, should be considered significant. The material obtained after mixing these components was characterized by the relatively largest amount of the finest material, with a grain size less than 10 [µm] in relation to the amount of material less than 45 [µm], and the most even distribution of grain size in the range of 10-45 [µm] (Figure 11-12).

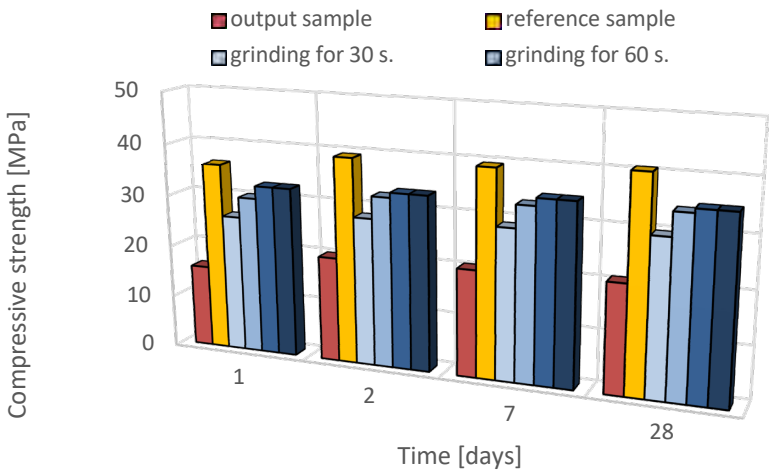

Figure 11. Compressive strength of samples made of treatment fly ash.

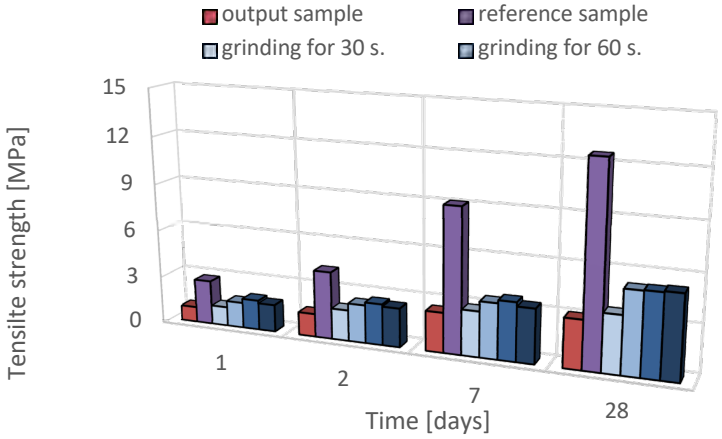

Figure 12. Tensile strength of samples made of treatment fly ash.

4 Conclusions

The strength results of binders made on the basis of calcium fly ash subjected to treatment in the form of ash milling show three basic relationships. First of all, milling of ashes has a significant impact on the achieved compressive and tensile strength of the tested samples. The most effective in terms of strength parameters of samples obtained from the tested ashes is the milling time of 120 s. Its increase did not cause a significant increase in compressive strength and in the case of tensile strength even a decrease in strength. The use of a mix of ashes with different grinding times had a positive effect on the increase of compressive and tensile strength as well as the ratio of these strengths. This was probably caused by a change in the form of granulometric distribution, which has a major impact on the rate and degree of geopolymerization.

Abstract. *Nanjing City Wall, one of the most important cultural heritages in China, has been damaged in a natural environment for centuries. Plants can be a candidate to regulate the micro-environment and mitigate the influence of local climates, which cannot be easily controlled by human efforts. Therefore, we examined the potential of the roadside trees along the City Wall to buffer the hygrothermal cycles that can deteriorate the City Wall. We surveyed the deteriorated state and measured the temperature and moisture content of the City Wall. Measured results showed smaller temperature fluctuation at shaded surface than the unshaded with a maximum temperature difference of 10.9 ℃ in summer. The measured water content decreased with height. A coupled two–dimensional hygrothermal 'City Wall–plant' model was proposed to clarify the influence of the roadside trees on the hygrothermal distribution of the City Wall. The proposed city wall-plant hygrothermal model could predict the surface temperature and water content well.*

Keywords: *Heritage Conservation, City Wall, Plant Regulation, Hygrothermal Distribution, Deterioration.*

1 Introduction

Nanjing City Wall, one of the most important cultural heritages in China, has a long history that can be traced back over 600 years. It is an ancient structure with abundant cultural heritage values, among which are inscriptions (Nanjing City Wall Protection and Management Centre, 2016) (Figure 1) that contain information about responsible organizations and persons on bricks. Nanjing City Wall was deteriorated due to efflorescence, peeling and cracking which damage surface inscriptions.

Related to conservation of cultural heritages, one key consideration is how to mitigate the effects of environmental fluctuations on wall materials. Nanjing City Wall has been exposed to climatic variations such as solar radiation, temperature, relative humidity, and rainfall. The humidity is strongly correlated with formation of the fungal communities that causes biodeterioration (Li*, et al*. 2020). Different ambient relative humidity conditions would result in various degrees of damage by the crystallization pressure of sodium sulphate (Rodriguez-Navarro and Eric, 1999). Moisture significantly reduces the compression strength of the bricks

(Foraboschi and Vanin, 2014) and determines the degree of freeze–thaw damage based on temperature (Feng, *et al*. 2019).

With respect to green urban development, coverage with vegetation offers a potential solution. English ivy has been found to reduce the range and variability of wall-surface microclimates over diurnal, seasonal and annual timescales (Sternberg, *et al*. 2011) and reduce the frequency, duration, and severity of freezing events (Coombes, *et al*. 2018) at historic sites in England. Araoka, *et al*. (2017) investigated the deterioration pattern of the Nanjing City Wall and found that shaded brick walls with trees on their side were relatively well-preserved.

This study aims at evaluating the potential of the roadside trees along the wall to buffer the microclimate of Nanjing City Wall. First, the situation of Nanjing City Wall was investigated and the temperature and moisture content of the wall were measured. Second, a two–dimensional hygrothermal 'City Wall–plant' model was developed to evaluate the influence of trees.

Figure 1. Inscriptions on the City Wall.

Figure 2. Vegetation status at monitoring points.

2 Method

2.1 Measurement

The measurements have been conducted around Jiefang gate(one gate at the northern part of City Wall). Two shaded walls (Sites 1and Site 2) and two unshaded wall (Site 3 and Site 4) were selected and been monitored from April 2019 to December 2019 (Figure 2). Air temperature and relative humidity under the canopy, surface temperature and water content of the City Wall were measured (Figure 3). The meteorological station was 800m apart from the monitored sites. The monitored weather data included the air temperature, relative humidity, rainfall, and horizontal solar radiation.

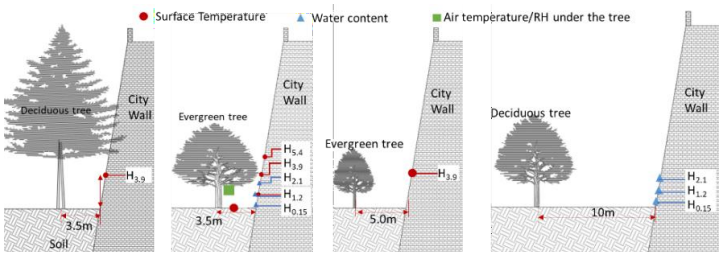

Figure 3. Outline of monitoring at each site. Monitoring period: Jun.- Dec. 2019 (temperature); Apr. - Dec. 2019 (water content). The heights of measured points are denoted as $H_{0.15}$ (0.15m), $H_{1.2}$ (1.2m), etc.

2.2 Simulation Model

2.2.1 City Wall

The simultaneous transfer model of heat and water by Matsumoto. (1978) was adopted in this paper. The water chemical potential μ is used to express moisture state in this paper. The relationship between μ and temperature and relative humidity is as follows:

$$\mu = R_v T In(h) \tag{1}$$

Heat balance equation:

$$c\rho \cdot \frac{\partial T}{\partial t} = \nabla[(\lambda + \lambda'_{Tg})\nabla T + r\lambda'_{Tg}\nabla\mu] \tag{2}$$

Moisture balance equation:

$$\rho_w \left(\frac{\partial \Psi}{\partial \mu}\right)\left(\frac{\partial \mu}{\partial t}\right) = \nabla[\lambda'_\mu(\nabla\mu - g\boldsymbol{n}) + \lambda'_T \nabla T] \tag{3}$$

2.2.2 Plant model

In our model, trees can reduce incident solar radiation to and the nocturnal radiation from the wall, and intercept the rainfall that dropped to vertical projection region (the ground and wall). Furthermore, the rainwater trapped by trees evaporated and removed heat from the plants. The model was based on the plant model by Kondou (1996). Figure 4 shows the thermal and moisture network model of the plant.

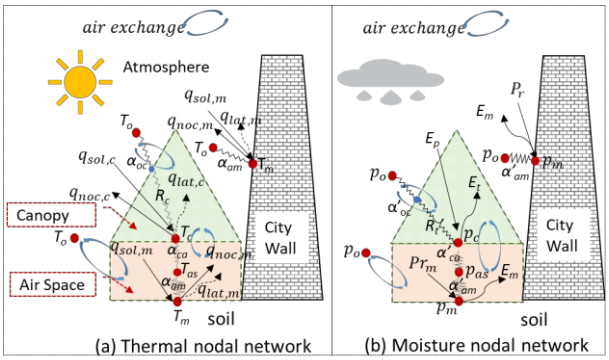

Figure 4. Thermal (a) and moisture (b) nodal networks of the plant-ground model.

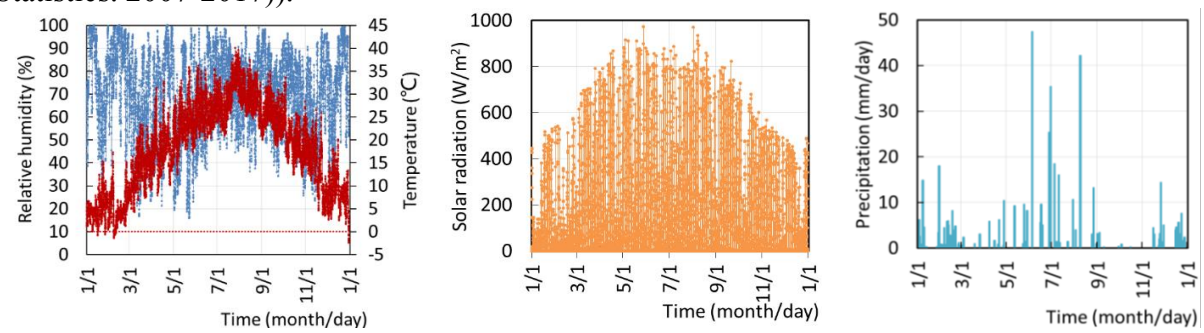
3 Results and Discussion

3.1 Measured Results

3.1.1 Weather data

Figure 5 shows the weather data from Jan. 2019 to Dec. 2019. The temperature fluctuation was 42.6 °C (–2.6 °C~ 40 °C), and the annual average temperature was 18.1 °C. The relative humidity fluctuated between 15.8% and 100%, and exceeded 90% for 1369 hours (Figure 5a). It rained more in the summer, followed by winter (Figure 5c). The annual rainfall was 486.5

mm, much less than the average rainfall of 1206 mm for the last 10 years (Nanjing Bureau of Statistics. 2007-2017)).



(a) Temperature and relative humidity (b) Solar radiation (c) Precipitation

Figure 5. Weather data (Jan. 2019-Dec. 2019).

3.1.2 Air temperature and relative humidity under the canopy

Figure 6 shows the measured air temperature and relative humidity under the canopy at Site 1 along with the meteorological (outdoor) data. During the monitoring period (Jun. 2019 - Dec. 2019), the temperature fluctuation of the air under the canopy and the outdoor air were 35.9 °C (1.8 °C~ 37.7 °C) and 38.4 °C (1.6 °C~ 40 °C), respectively. In summer, the temperature under the canopy was lower than the outdoor temperature for most time, with a 6.1 °C difference of maximum temperature. On the contrary, the relative humidity under the canopy was higher than that of the outdoor values for the most time. The relative humidity difference was usually between -27%~8%.

3.1.3 Surface temperature and water content of City Wall

Figure 7 shows the measured surface temperatures at Site 1 (shaded $H_{3.9}$) and Site 3 (unshaded $H_{3.9}$). Part of the temperature data was missing when the temperature recorder equipment was not powered. The temperature fluctuation at shaded $H_{3.9}$ was 33.2℃ (3.2℃~36.4℃), which was smaller than the temperature fluctuation of 43.7℃ (3.6℃~47.3℃) at shaded $H_{3.9}$. In summer, almost the same daily minimum temperatures and large differences in the maximum values were seen on shaded and unshaded points. In winter, due to the low solar altitude, the unshaded $H_{3.9}$ (Site 3) was partly shaded by trees. Then and the similar temperature fluctuation can be seen at shaded (Site 1) and unshaded $H_{3.9}$ (Site 3).

Figure 8 shows the average water content of 10 bricks at Site 2 and Site 4. Due to lawns on the south side of Site 4 with regular irrigation in summer, this may result in increased water content of the wall. Therefore, this paper compares the water content fluctuation in two cases, separately. The results show the water content decreased with height, while the water content at $H_{2.1}$ was higher than at $H_{1.2}$ in Site 4. It may be due to different water absorption and storage capacity of bricks and reduction of the evaporation rate by herbaceous plant at $H_{2.1}$, and needed to be further studied. During the monitoring period, the water content of each height was obviously affected by rainfall. The water content was higher in rainy season (July and August), while lower in arid season (September and October).

(a) Site 2 (shaded) (b) Site 4 (unshaded)

Figure 8. Average water content of 10 bricks located at Site 2 and Site 4.

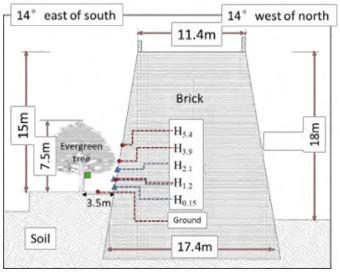

Figure 9. Schematic diagram of calculation model at Site 2.

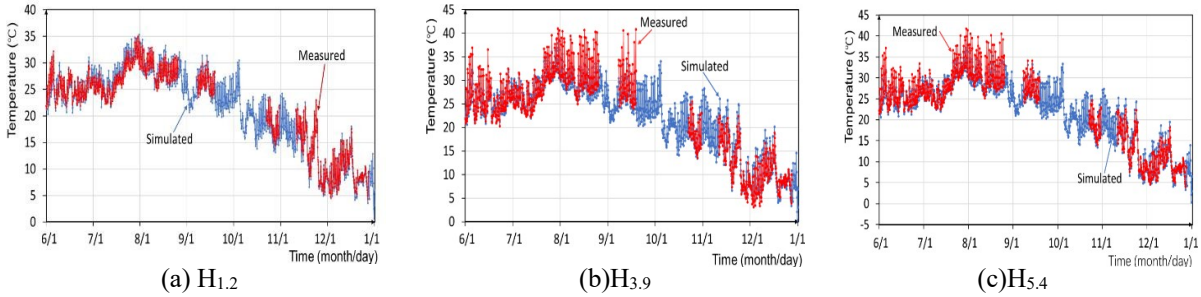
3.2 Validation of Proposed Model (Comparison between measured and calculated results)

Figure 9 shows schematic diagram of a two-dimensional 'City Wall–plant' model. It is set up in FORTRAN language to simulate the Site 2. The tree is evergreen with a height of 7.5m and a distance of 3.5m to the city wall (Figure 9). The weather data (Jan. 2018 to Dec. 2018) was repeatedly used for 10- years calculation as the boundary condition. Then the calculation was conducted with meteorological data in 2019 for one year, and the calculated results were analysed.

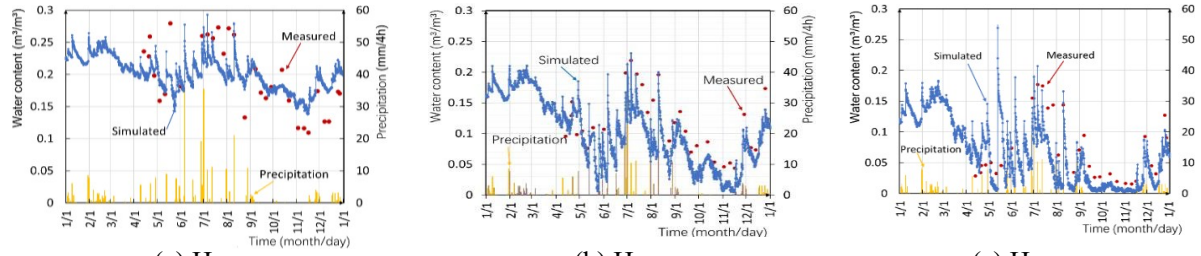
Figure 10 shows the measured and simulated surface temperatures at three points $H_{1.2}$, $H_{3.9}$, and $H_{5.4}$ on the south facade at Site 2. A linear regression analysis was performed with the measured and simulated results, and a good correlation was obtained with slopes 1.00, 0.98, and 0.97 and goodness-of-fit 0.99, 0.98, and 0.96 at $H_{1.2}$, $H_{3.9}$, and $H_{5.4}$, respectively. Figure 11 shows the measured and simulated water content at three heights ($H_{0.15}$, $H_{1.2}$, and $H_{2.1}$). The calculated water content reproduced the time profile of the measured results. The water content assumed a peak value during rainfall, then gradually decreased probably due to evaporation and water movement in the wall. The mean absolute error (MAE) was used to analyse the consistency of measured and simulated values. The MAE at three heights $H_{0.15}$, $H_{1.2}$, and $H_{2.1}$ was 0.029m³/m³, 0.036m³/m³, 0.035m³/m³, respectively.

It can be concluded that the simulated temperatures and water content agreed well with the measured results in unshaded case. Thus, the proposed 'City Wall–plant' model can be used to examine the influence of the surrounding trees on the hygrothermal fluctuations and weathering of City Wall.



(a) $H_{1.2}$ (b)$H_{3.9}$ (c)$H_{5.4}$

Figure 10. Comparison of the measured and simulated surface temperatures at three heights.



(a) $H_{0.15}$ (b) $H_{1.2}$ (c) $H_{2.1}$

Figure 11. Comparison of measured and simulated water content at three heights.

4 Conclusion

This study investigated the influence of trees on hygrothermal performance of Nanjing City Wall. The measured results showed that the air temperature under the canopy was lower than the outdoor air. The temperature fluctuation at shaded surface was smaller than the unshaded one, and the maximum temperature in shaded case was 6.1 ℃ lower than the unshaded in summer. The measured water content decreased with height.

The proposed 'City Wall–plant' model was validated through the comparison between measured and calculated results. Then the model can be used to analyse the trees' impact on the microclimate and surface weathering of Nanjing City Wall.

E_m	evaporation from material (wall or ground) surface [kg/m²s]

Subscripts

a	air
o	outdoor
s	surface
c	canopy
as	air space
m	material (wall or ground)
sol	solar radiation
noc	nocturnal radiation
lat	latent heat
ex	air exchange
oc	the outdoor air -canopy surface
ca	the canopy-air space surface
am	the air space-material (wall or ground) surface

Appendix B. Plant model

The plant model was based on the plant model by Kondou (1996). The equations of heat and moisture balance in plant model are as follows.

1. Heat balance of the canopy cell：

$$(c\rho)_a \cdot V_c \cdot \frac{\partial T}{\partial t} = \{\frac{(T_o - T_c)}{(1/\alpha_{oc} + R_c)} + q_{sol,c} - q_{noc,c} - q_{lat,c} - \alpha_{ca} \cdot (T_c - T_{as})\} \cdot S + q_{ex,c} \quad \text{(B.1)}$$

Where, $q_{sol,c}$ is the solar radiation absorbed by trees($= I_s \cdot (1-\gamma) \cdot A_c$) [W/m²]; $q_{lat,c}$ is latent heat of evapotranspiration ($= r \cdot (E_t + E_p)$) [W/m²] ; $q_{noc,c}$ is the nocturnal radiation of trees ($= \varepsilon_c \cdot I_n$) [W/m²].

2. Heat balance of the air space under the canopy:

$$(c\rho)_a \cdot V_{as} \cdot \frac{\partial T}{\partial t} = \alpha_{ca} \cdot (T_c - T_{as}) \cdot S - \sum_1^{m1} \alpha_{am} \cdot (T_{as} - T_{m,i}) \cdot S_i + q_{ex,as} \quad \text{(B.2)}$$

3. Heat balance of the cell at material surface:

$$\alpha_{am}(T_{as} - T_m) + q_{sol,m} - q_{lat,m} - q_{noc,m} = -\left(\lambda + r\lambda'_{Tg}\right)\frac{\partial T}{\partial x} - r\lambda'_{\mu g}\frac{\partial \mu}{\partial x} \quad \text{(B.3)}$$

Where, $q_{sol,m}$ is the solar radiation absorbed by material (wall or ground) surface ($= I_s \cdot \gamma \cdot A_m$) [W/m²]; $q_{lat,m}$ is latent heat of evaporation from material (wall or ground) surface ($= r \cdot E_m$) [W/m²]; $q_{noc,m}$ is nocturnal radiation of material (wall or ground) surface ($= \varepsilon_m \cdot I_n$) [W/m²].

4. Moisture balance of the canopy cell:

$$C'_a \cdot V_c \frac{\partial p}{\partial t} = \{\frac{(p_o - p_c)}{(1/\alpha'_{oc} + R'_c)} + E_p + E_t - \alpha'_{ca} \cdot (p_c - p_{as})\} \cdot S + j_{ex,c} \quad \text{(B.4)}$$

5. Moisture balance of the air space under the canopy:

$$C'_a \cdot V_{as} \frac{\partial p}{\partial t} = \sum_1^{m2} E_{m,i} \cdot S_i + j_{ex,as} \quad \text{(B.5)}$$

6. Moisture balance of the cell at material surface：

$$\gamma' \cdot P_r - E_m = -\lambda'_\mu \cdot \left(\frac{\partial \mu}{\partial x} - g\right) - \lambda'_T \frac{\partial T}{\partial x} \quad \text{(B.6)}$$

Where,

$$E_t = \rho\beta C_h U \cdot \left(\frac{\partial S_h}{\partial P}\right) \cdot \left(p_{sat}(T_c) - p_o\right) \quad \text{(B.7)}$$

$$E_P = (1-\gamma') \cdot P_r \quad \text{(B.8)}$$

$$E_m = \alpha'_\mu(\mu_m - \mu_{as}) + \alpha'_T(T_m - T_{as}) \quad \text{(B.9)}$$

Abstract. *Numerical results are compared to experimental data on concretes exposed in field conditions for 19 years and subjected to wetting/drying cycles in seawater after a couple of curing days. They were obtained thanks to a hydration model assuming fully hydrated concretes (19 years of curing time) and a reactive transport model in saturated conditions taking into account precipitation/dissolution of minerals and their kinetics and adsorption of ionic species on C-S-H. Numerical results show surprisingly rather good results, especially for concretes with fly ash. For OPC, although model considers average bulk porosity modifications, the experimental apparent diffusion coefficient increases much more. For concretes with silica fume, numerical results also show underestimations of total chloride content also experimental apparent diffusion coefficients are constant. Analysis of hydration calculations show that concretes are not fully hydrated after 19 years. Additional chloride content from reactions between anhydrous phases and chloride ingress may appear.*

Keywords: *Concrete, Chloride Binding, Seawater, Long-Term Exposure, Field Condition.*

1 Introduction

Numerical study of reinforced concrete durability exposed to seawater in field conditions is difficult in several aspects. Environmental conditions can play a significant role in the chloride ingress (temperature, RH, wetting-drying cycles, orientation, wind). Curing time is also important because of possible interactions between concrete and seawater as well as initial presence of chloride in mixing water (Suryavanshi and Swamy, 1996; Caré, 2008 to cite a few).
Previously reactive transport model taking into account precipitation and dissolution of mineral species with their kinetics as well as adsorption of ionic species on C-S-H were successfully used in order to simulate chloride ingress in laboratory concrete specimens (fully hydrated, controlled exposure conditions, saturated conditions) (Tran *et al.*, 2018). However, in field conditions, concrete is not fully hydrated when they are exposed to seawater. Influence of hydration degree on chloride binding capacity of concrete is interesting.

Numerical simulations were done and compared to experimental data on concretes exposed in field conditions for 19 years and subjected to wet- ting/drying cycles in seawater after a couple of curing days. A hydration model following by a reactive transport model taking into account precipita- tion/dissolution of mineral species with their kinetics as well as adsorption of ionic species on C-S-H were used. Regarding all the phenomena to take into account, severe hypotheses were done such as saturated materials and 19 curing years. The aim of this study is

doi:10.23967/dbmc.2020.196

to identify if such a severe hypothesis is sufficient in order to give a good approximation of chloride ingress.

2 Experimental Study and Numerical Approach

2.1 Experimental Study

Several concretes from the French project BHP2000 are exposed to sea- water and wetting-drying cycles in La Rochelle harbor (western French coast) since 19 years after 1 curing day (Baroghel-Bouny *et al.,* 2013). 4 HPCs with or without silica fume (SF) and 3 normal-strength FA concretes which can appear as interesting mixtures with respect to current sustainable-de- velopment considerations were studied. All concretes described in this article were casted with the same cement (CEM I 52.5 PM ES CP2, see Table 1). Concrete mix-design are described in Table 2.

Table 1. Chemical and mineralogical composition of the binder (%).

	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	K_2O	Na_2O
CEMI	21.39	3.49	4.16	65.12	0.82	2.86	0.30	0.12
Fly Ash	55.86	25.40	6.05	1.83	0.63	0.11	4.77	0.24
Silica Fume	94.75	0.07	0.08	0.34	0.28	0.05	0.28	0.18

Table 2. Mix-design, along with average 28 days cylinder compressive strength and 90 days porosity accessible to water (measured after water curing).

Concrete	Gravel/sand	Cement	FA	SF	Water	W/binder	σ_c	Porosity
M25FA	992/905	195	48	-	187	0.77	23.5	0.157
M30FA	986/879	223	95	-	166	0.52	48.5	0.141

M100SF	1049/871	377	-	38	124	0.30	109.0	0.084

3.2 Numerical Approach

A physically and chemically based model was developed to simulate ionic ingress in the materials. Calculations are managed with TOUGHREACT software (Xu *et al.*, 2012). The chemical part uses the thermodynamical database Cemdata18 (Lothenbach *et al.*, 2019). Hydration and interstitial solution calculations precede this reactive transport simulation (see Figure 1 for the description of the simulation steps). Input data are limited to chemical and mineralogical composition of the binder, concrete mix-design, average bulk porosity and effective diffusion coefficient of concrete.

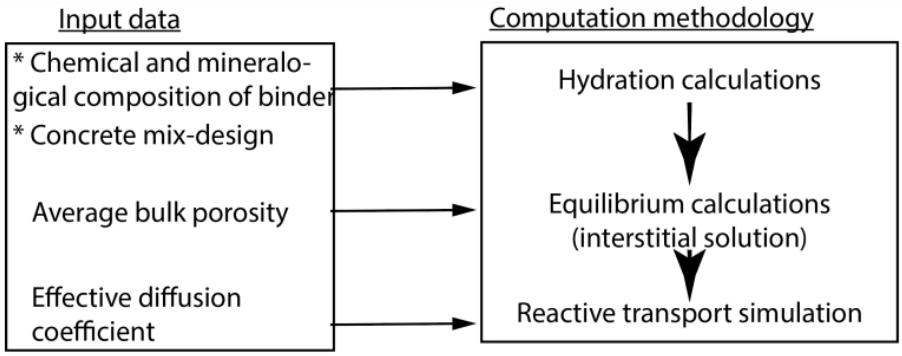

Figure 1. Flow chart of the reactive transport model.

The reactive transport model considers precipitation and dissolution of mineral species and their kinetics and adsorption of several ionic species on C-S-H (Cl^-, Na^+, K^+, Ca^{2+}, SO_4^{2-}). It has been validated on different experimental data such as laboratory concretes exposed to different solutions containing chloride (Tran *et al.*, 2018). Nevertheless, ingress of seawater in concrete exposed to field conditions after only few curing days is a difficult subject. In the case studied here, hydration was not complete when concretes were exposed to seawater leading to interactions between ionic species contained in seawater and anhydrous phases.

Although concretes are exposed to wetting-drying cycles, the present numerical model assumes that concrete is saturated by adopting a pure fickian approach (see Equation below). In fact, the wetting-drying cycle period is short (12 hours) and the mean value of the relative humidity in La Rochelle harbor is high (close to 67% (Baroghel-Bouny *et al.*, 2013)). Except for the first millimeters where carbonation can occur, this hypothesis seems to be reasonable (Soive *et al.*, 2018).

$$\frac{\partial \phi c_j}{\partial t} = div\left(D_e \vec{\nabla} c_j\right) + q_j \quad (1)$$

where φ is the average bulk porosity, c_j the concentration of species j [mol.m^{-3} of solution], D_e the effective diffusion coefficient [m^2.s^{-1}] (supposed to be equal for all species) and q_j source or sink term [mol.m^{-3}.s^{-1}]. Ions can chemically react with the matrix to precipitate minerals (*e.g.* ettringite, brucite, Kuzel and Friedel's salts) or to dissolve others (portlandite, monosulfate). They also can be bound (adsorbed or absorbed) to the surface of the matrix. As described in previous studies (Baroghel-Bouny *et al.*, 2013; Soive *et al.*, 2018), all mineral precipitation/dissolution kinetics also need to be taken into account. In addition, the effective diffusion coefficient D_e can evolve with average bulk porosity value change as follows:

$$D_e = \phi \tau D_W \quad (2)$$

where τ and D_w are the tortuosity and the diffusion coefficient of ionic species in water.

A 1D diffusion model is adopted. 250 elements are used to simulate ionic species ingress in 10cm structural depth. By sake of simplicity and to avoid complex calculations of ionic species ingress during hydration, hydration duration is supposed to be equal to the greater exposition duration (19 years). Of course, this is a very first approximation owing to the competition between hydration and seawater ingress at first time exposure. Chemical reactions between seawater and anhydrous species are not considered.

4 Results and Discussion

Total chloride content profiles were measured after 2, 4, 10, 16 and 19 years of exposure. Comparison between experimental data and numerical results with 19 curing years is exposed in Figure 2. Knowing the limited number of input data and the difficulty to catch all the phenomena, the numerical simulations show hopeful results.

Three aspects can be underlined: the "convection zone", the evolution of apparent diffusion coefficient as a function of time and possible chemical reactions between chloride and anhydrous phases.

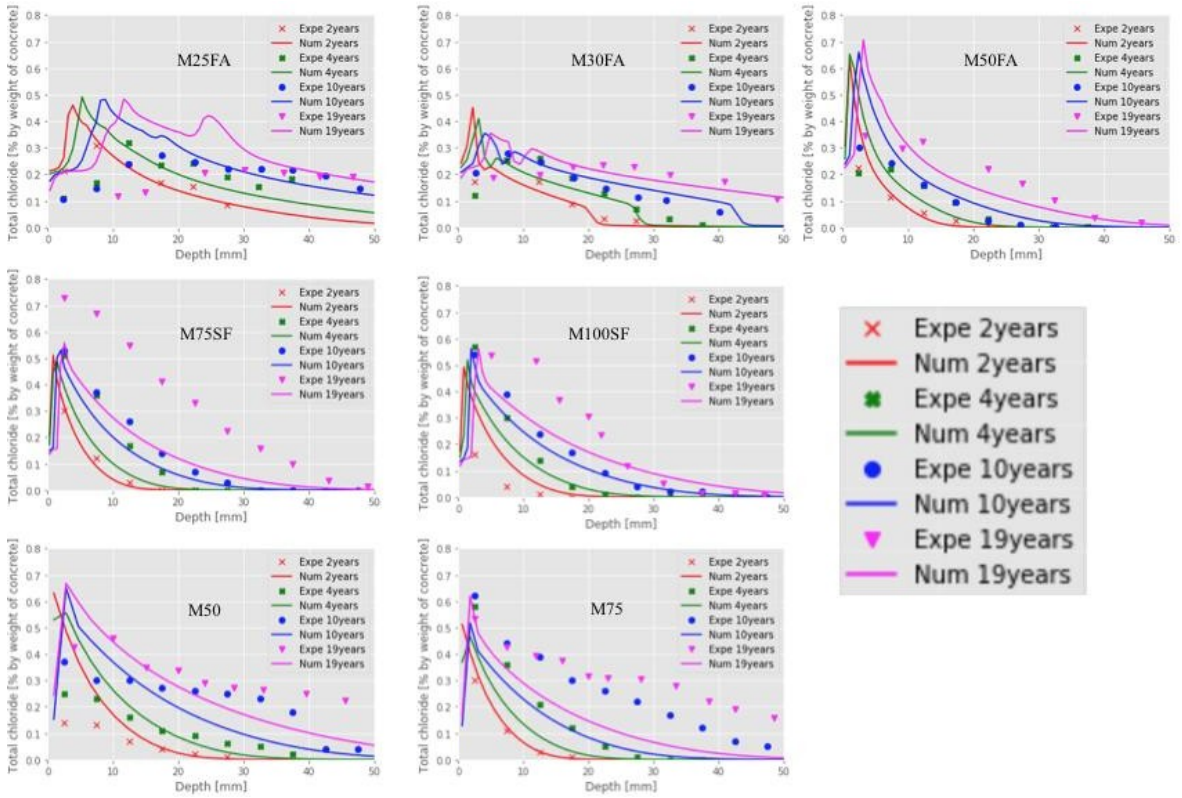

Figure 2. Comparison between experimental data and numerical results for total chloride profiles for 2, 4, 10, 16 and 20 years of exposure (19 curing years).

4.1 The « Convection Zone »

For concretes with fly ash (M25FA, M30FA, M50FA), results are rather good except in the first millimeters and although numerical model does not consider wetting/drying cycles. The depth at which total chloride content is maximum is to underline. This zone is often associated with the "convection zone". Nevertheless, even with a model that simulate the ingress of ionic species in saturated concrete such as the present one, this phenomenon is observed. As reported by Jakobsen *et al.* (2016), chemical and mineral zonation appear. Three zones (magnesium, sulfur and chloride-rich zones) are found irrespective of the age, location or binder composition. Figure 3 show that the model can qualitatively simulate these zones. However, in this "convection zone", results are very different from experimental data. The use of a model considering wetting-drying cycles is necessary in order to catch phenomena in this zone (convection, local chloride concentration increase).

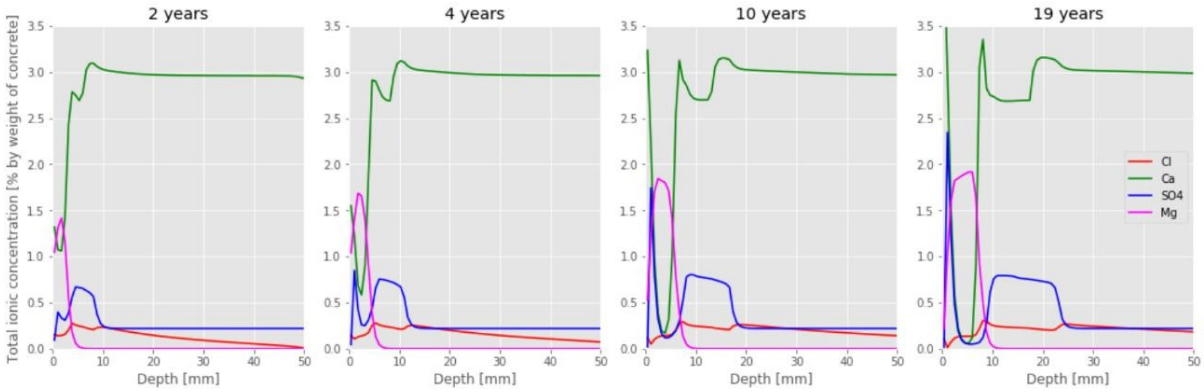

Figure 3. Ionic species ingress after 2, 4, 10, 16 and 20 years of exposure for M25FA (19 curing years)

4.2 The Evolution of Apparent Diffusion Coefficient with Time

For OPC (M50, M75), whereas profiles are close to experimental data after 2-year exposure, total chloride contents are underestimated for greater exposure durations. These differences can be partly explained by the fact that apparent diffusion coefficient (which includes both effective diffusion and binding) for M50 and M75 increases with time (by inverse analysis calculations on experimental data) from 1.6 10^{-13} to 2 10^{-13} $m^2.s^{-1}$ and 3.6 10^{-13} to 1.6 10^{-12} $m^2.s^{-1}$, respectively (see Figure 4). The present model considers microstructure evolution (average bulk porosity) due to mineral dissolution or precipitation (see Equation 2). It is also able to compute the evolution of chloride binding. However, the apparent coefficient increase is much greater than the one computed. Deeper experimental data investigations must be done in order to determine if other phenomena that are not modeled can appear, such as cracks, properties differences between concrete first millimeters and deeper.

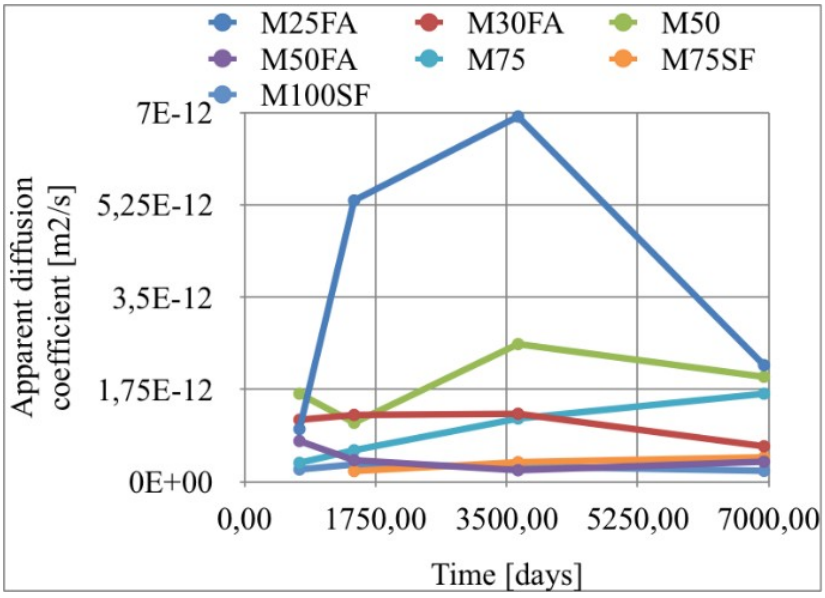

Figure 4. Apparent diffusion coefficient calculations by inverse analysis.

4.3 Possible Chemical Reactions between Chloride and Anhydrous Phases

For concretes with silica fume (M75SF, M100SF), underestimations ap- pear after 2-year exposure. Nevertheless, as can be seen in Figure 4 and contrary to M50 and M75, the apparent diffusion coefficients are constant. By analyzing hydration results of M75SF thanks to a hydration model developed at Cerema (Lavergne *et al.*, 2018) (see Figure 5), results show that anhydrous phases are still present after 19 curing years (6500 days) as well as a lack of monosulfate. These results confirm that hydration is slower for these concretes. However, presence of seawater can affect the hydration process by accelerating hydration or precipitating minerals containing chloride (Friedel's salt) (Li *et al.*, 2018). Unfortunately, the present model is not able to calculate chloride ingress in concretes that continue to hydrate.

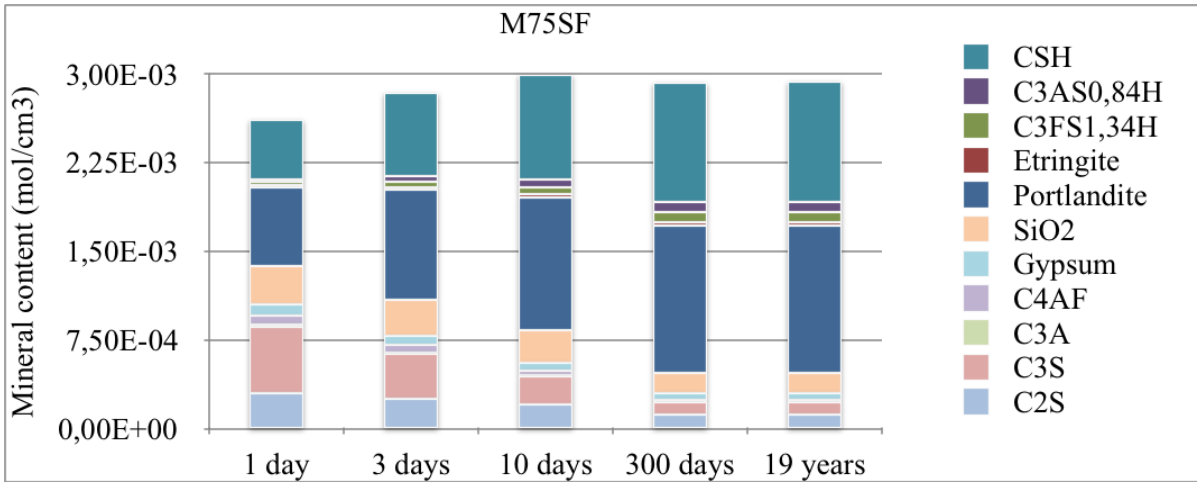

Figure 5. Hydration results after 1, 3, 10, 300 and 6500 curing days.

5 Conclusion

Experimental data on concretes exposed to tidal zone in field conditions for 19 years and subjected to wetting-drying cycles in seawater after a couple of curing days were compared to numerical results. Two OPCs, three concretes with fly ash and two concretes with silica fume with the same cement were studied. The numerical results were obtained thanks to a hydration model and a reactive transport model considering precipitation/dissolution of minerals and their kinetics and adsorption of ionic species on C-S-H.

A pure fickian approach in saturated materials is assumed. In addition, due to difficulties to model interactions between ingress of ionic species and hydration, numerical model assumes that hydration lasts for 19 years (last measurement value).

Knowing the limited number of input data and the difficulty to catch all the phenomena, the numerical simulations show hopeful results, especially for concrete with fly ash. In addition, the model can qualitatively simulate chemical and mineral zonation (magnesium, sulfur and chloride-rich zones) as reported in the literature. For OPC and concretes with silica fume, numerical results underestimate chloride content. For OPC, although numerical model considers porosity change due to mineral precipitation/dissolution, it is not able to simulate increase of apparent diffusion coefficient as observed on experimental data. Further investigations must be done in order to observe if cracks are visible. For concretes with silica fume, underestimation cannot be fully explained yet. One explanation can be the lack of additional chloride content coming from reactions between chloride and remaining anhydrous phases. Indeed, by analyzing results of hydration calculations, results show that anhydrous phases are still present even after 19 years and that additional chloride content can exist.

Abstract.*In the article, a comparative analysis of the effects of selected substances applied to create secondary horizontal damp proof courses of masonry walls by means of the chemical injection method on the properties of masonry mortar was carried out. Particular attention was given to the influence of impregnation on the hygric properties of mortar. The resistance to destructive factors accompanying the dampening of masonry wall structures was also subjected to observation.*

Keywords: *Injection, Damp Proof Course, Renovation, Dampening.*

1 Introduction

The problem of the excessive moisture content of brick walls in historical objects is present in many European countries because of their rich cultural heritage and dense accumulation of historical buildings (Hoła, 2017).The masonry walls of historical buildings - made of ceramic brick or stone - are often characterized by a high thickness and a lack of damp insulations. It refers primarily to horizontal insulations, which began to be executed in a modern way at the beginning of the twentieth century. The lack of damp insulations causes direct and prolonged contact of a wall with the ground (Adamowski, in., 2005; Franzoni 2014). As a result, water molecules that are contained in the substrate along with salts dissolved in them penetrate elements of the masonry wall making it damp. These elements are both ceramic brick and mortar from joints, and in walls made of stone these joints are usually of a large width. Capillarity, the process of which was described inter alia in (Camino *et al.* 2014; Raimondo *et al*. 2009, Hoła *et al.* 2017), causes water molecules to be transported into the wall and into its higher parts. In the case of a masonry wall with a large thickness, from which evaporation of moisture is naturally difficult, the degree of moisture content gradually increases with time (Goetzke-Pala *et al.* 2016; Gutarowska *et al.* 2007).

Groundwater together with the salts contained in it rises due to capillary action to ever higher parts of the walls made of capillary-porous materials, such as burnt clay brick, brickwork joint mortar and plaster. Also the concentration of salts in the brickwork and plaster components increases by the year (Rirsch *et al.* 2010; Torres *et al.* 2010; Espinosa;i in.,2008). The negative effects of the excessive build-up of moisture in the wall include: a decrease in brickwork strength, susceptibility to frost damage, falling off plaster, spalling mortar in the joints between bricks, an increase in the heat transfer coefficient of the building envelope and susceptibility to fungal decay and mouldiness(Franzoni *et al.* 2011; Gentillini *et al.* 2012 Solymez,1999; Blaszczynski, 2007).

The dampening of walls as a result of the capillary transport of water is one of the main

reasons behind damage in buildings, whereas the drying out of a wall by carrying out a secondary horizontal damp proof course in the wall is the most important element of renovation (Venzmer, 2008). One of the means of recreating horizontal insulation in a wall are injection (chemical) methods. Although the injection membrane, by assumption, is formed in the entire cross-section of the wall, in practice, the injection agent migrates mainly in the masonry mortar (Hölzen, 2006), especially in cases when injection openings are created (when using pressure injection as well as when applying injection creams) horizontally, in the supporting joint of the masonry wall.

2 Capillary Transport of Moisture in Mineral Construction Materials

The vast majority of materials applied in the inside walls of buildings are those described as capillary-porous, and thus characterized by a porous structure, with the pores connected with each other by a system of capillaries or partially separated by walls. The properties of capillary-porous bodies depend largely on the total volume of pores, the volume distribution of pores depending on their diameter (porosity structure), as well as the specific surface area of the pores. Although various criteria can be found in literature as far as the division of pores occurring in a material is concerned, the division given by the International Union of Pure and Applied Chemistry (UPEC) has been generally accepted, which, depending on the so-called effective pore radius (assuming for the sake of simplification their spherical shape) ref, distinguishes three groups:

- micropores: $r_{ef} \leq 2$ nm,
- mezopores: 2 nm $< r_{ef} \leq 50$ nm,
- macropores: $r_{ef} > 50$ nm.

It ought to be noticed, however, that capillary absorption and the transport of water is possible only in pores with a radius from 10-7 to 10-4 m (from 100 nm to 0.1 mm), also referred to as capillary pores. Pores with a diameter of less than 10-7 m, (gel pores), can fill up with water only as a result of capillary condensation, whereas pores greater than 10-4 m (air pores) can fill up with water only under pressure.

In addition to the structure and distribution of pores in a material, capillary transport of moisture is determined by the wetting properties of a liquid in relation to the material, or in other words – by the properties of the material in relation to water penetrating into the capillaries (Bonk, 2006; Balak, 2007). As a result of the surface tension forces of water, the surface of a liquid, upon contact with a solid body, creates the so-called contact angle, or the angle between the surface of the solid body and that contacting the surface of the liquid drawn at the point of contact (on the border of three phases). The value of angle θ is a measure of wettability:

- $0 < \theta < \pi/2$ – liquid wets, hydrophilic material
- $\pi/2 < \theta < \pi$ – liquid does not wet, hydrophobic material.

In the capillaries of a body characterized by good wettability, the surface of the liquid forms a concave meniscus (slightly rises when making contact with a solid body), whereas in the case of bodies with inadequate wettability – the meniscus is convex (falls).

It is very difficult to construct a model describing the capillary transport of moisture in porous materials, mainly due to the complex geometry of pores – seeing as how the network is formed from pores of various shapes (cylindrical, wedge-shaped, crevicular, spherical) as well as a diverse system of connections (open pores, pocket pores, closed pores). Capillaries also

create discontinuous systems, as well as systems of complex shapes.

Attempts at investigating the mechanism of the capillary movement of moisture are described by Pogorzelski (Pogorzelski, 2004), using a simplified model of a capillary body in the form of a bundle of parallel capillaries of an identical radius for this purpose. In accordance with the Young-Laplace equation, a difference in the pressures Δp will occur on both sides of the meniscus causing a rise of liquid in the capillary, up to the differences in the pressure evening out by the forces of inertia, friction (resulting from the Hagen-Poiseuille Law) as well as gravitational force. Basing on these assumptions, formulas for the rate of capillary movement (at vertical movement) were indicated:

$$\upsilon = \frac{dl}{d\tau} = \frac{r^2}{8\eta l}\left(\frac{2\sigma\cos\Theta}{r} - g\rho l\right) \tag{1}$$

As well as maximum capillary rise (determined by Washburn's equation):

$$H = l_{\max} = \frac{2\sigma\cos\Theta}{r\rho g} \tag{2}$$

where:l – length of capillary, τ – time of rise, r – capillary radius, η – dynamic density of liquid, σ – surface tension, Θ – contact angle, g – Earth's pressure, ρ – liquid viscosity.

Formulas (1) and (2) express two basic laws describing the capillary absorption of water. The first states that the rate of the capillary rise is higher in materials with "thick" capillaries than those with thin capillaries. In materials with thin capillaries, the level of rise is significantly higher. At a very small or very large radius of a capillary, the rates as well as the maximum level of rise are reduced to zero (in other words, capillary transport does not take place). In reality, although capillary-porous materials have a significantly more complex structure than that described by the model of a bundle of identical parallel capillaries (Pogorzelski,2004), in the case of capillaries with a radius of less than 0.1 μm, the rate of absorption vanishes, whereas in the case of capillaries with a radius exceeding 100 μm, the maximum possible rise falls to zero.

3 Materials and Methods

A cement-lime mortar with a volumetric composition of 2:0, 5:8 (hydrated lime: CEM I 32.5 Portland cement: sand with a granulation of 0-2 mm). The fresh mortar was placed in a mould made from PVC pipes 200 mm in diameter, cut in 300 mm sections. After the initial hardening of the mortar, that is two days after preparing the moulds, the samples were placed in polyethylene bags for another five days. After a period necessary for the mortar to reach full strength, it was subjected to dampening, placing the moulds in a tray with water (on a grate) so that the samples were constantly submerged in approximately 10 mm. After two days, the moulds were taken out of the water, wrapped in foil and left for two weeks in order to ensure even distribution of moisture in the mortar (Monczynski, 2019) (Figure 1).

Holes were made in the samples and gravitational injection, using an injection cream, and pressure injection (under a pressure of 0.2 MPa increased after 30 s to 0.5 MPa) using methyl silicates as well as silicone microemulsion (SMK), carried out. After a further four weeks, the mortar was taken out of its moulds and cut using a circular saw into cubic samples with sides

measuring approx. 45 mm.

Figure 1. Mortar samples during moulding, dampening and carrying out injections.

4 Results

Studies on absorbability were carried out on twenty-four cubic samples which, after drying at a temperature of 105±5°C and weighing, were placed in a tub, on a grate, and then submerged in water to approximately a quarter of their height (Wójcik, 2008). After 24 hours, that is after the completion of sample dampening as a result of capillary rise the samples were submerged to half their height and, following another 3 hours, to three-quarters of their height. The complete submersion of samples (minimum of 20 mm above the upper edge of the samples) took place 30 h after the commencement of the experiment. After complete impregnation, the samples were removed from water, dried with a rag and weighed (WTA, 2015). Absorbability in relation to the dry mass of the mortar was described according to the formula:

$$n_m = \frac{m_m - m_s}{m_s} \cdot 100\% \tag{3}$$

where: n_m – absorbability in relation to mortar mass [%], m_m – mass of sample saturated with water [g], m_s – mass of sample dried to a constant mass [g].

Studies on the phenomenon of capillary rise carried out on twenty-four cubic samples of a mortar dried to a constant mass, which, upon weighing, were placed on a grate in a flat tray which was then filled with water so that they would be submerged in water at a depth of approx. 10 mm. The measurement of capillary rise was carried out 1, 3, 6 and 24 h after submersion, weighing the samples (after first drying them with a rag). The increase in the mass of samples during individual measurements was calculated according to the formula:

$$m_i = \frac{m_c - m_s}{m_s} \cdot 100\% \tag{4}$$

where: m_i – increase in sample mass [%], m_c – mass of sample dampened by capillary rise of water, after 1, 3, 6 and 24 h respectively [g], m_s – mass of dried sample [g].

The water absorption coefficient was indicated according to the expression:

$$w_{24} = \frac{m}{A \cdot \sqrt{t}} \tag{5}$$

where: w_{24} – water absorption coefficient after 24 hours following submersion [kg/m^2·h^{0,5}], m – mass of absorbed water [kg], A- absorption surface [m^2],t – absorption time [h].

The results of studies on absorbability and capillary rise have been presented in Table 1.The compression test was carried out in an Instron 8500 Plus testing machine. Forty cubic samples

were used for the tests. The applied load was controlled by a force of 50 N/s – this value was selected so that the compression test of an individual sample would fell in the range of 30 to 90s. Due to the irregular shape of the samples, they underwent evening/smoothing with 220 grit sanding mesh (Gutarowska *et al.* 2004). Determining the resistance to frost is carried out by determining the mass loss caused by periodic freezing and thawing. Twenty-four samples were prepared for the test.

The samples were marked as follows:

- MKA – mortar impregnated with alkaline methyl silicate, ,
- SMK – mortar impregnated with silicone microemulsion,
- KI – mortar impregnated with injection cream,
- 0 – mortar lacking impregnation (controls).

Table 1. Results of studies on capillary rise and absorbability.

	m_1	m_3	m_6	m_{24}	w_{24}	n_m
0	11.7%	11.8%	11.8%	11.9%	1.89	11.8%
MKA	12.0%	12.1%	12.2%	12.3%	1.93	12.0%
SMK	11.5%	11.7%	11.7%	11.9%	1.87	12.0%
KI	7.8%	8.0%	8.1%	8.4%	1.35	10.2%

The compressive load (including breaking load), as well as movement under compression, were measured. The average compressive strength is presented in Figure 2.

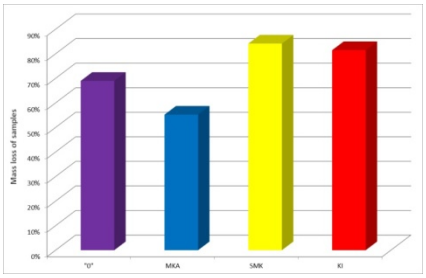

Figure 2. Average loss (percent) in mortar mass after freeze/thaw cycles.

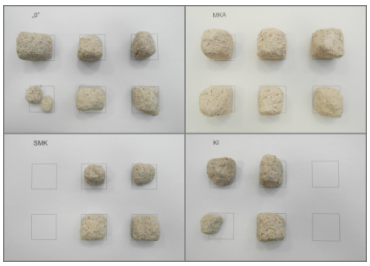

Figure 3. Mortar samples after 25 freeze/thaw cycles.

All were dried to a constant mass and next weighed. Next, the samples were submerged in water in order to completely dampen them. The saturated samples were removed from the water and placed for 4 h in a freezer, at a temperature of −20±2°C.Upon freezing, they were transferred to a tub with water at a temperature of 20±2°C for at least 4 h. Twenty-five freeze–thaw cycles were carried out, and next the sample was dried to a constant mass and weighed once again. The freeze-thaw resistance was indicated based on the formula:

$$\Delta m = \frac{m_d - m_f}{m_d} \cdot 100\% \tag{5}$$

where:Δm – the difference in the mass of the sample prior to testing and after testing [%], m_d– the mass of the sample dried to a constant mass prior to the first cycle [g], m_f – mass of sample dried to a constant mass following the last cycle [g].

Average losses in mass expressed as percentages are presented in Figure 2. Figure 3 shows the appearance of the samples upon the completion of the test. Testing the resistance to the crystallization of salts was carried out on twenty-four cubic samples which, after drying and weighing, were placed for 2 h in 14% solution of sodium sulphatedecahydrate (Na2SO4·10 H2O). Next, the samples were dried at a temperature of 105 ±5°C for a minimum of 16 h. In order to ensure high air humidity at the first stage of drying, a tray containing water was placed in the dryer prior to its initiation. After completion of the drying process, the samples were cooled for approx. 2 h to room temperature and once again submerged in a saline solution.

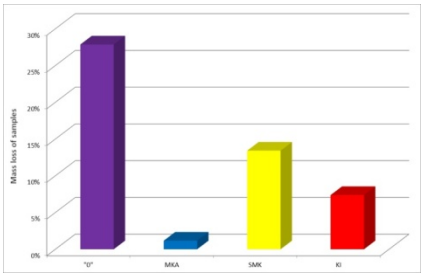

Figure 4. Average percentage loss of mass after testing the resistance to the crystallization of salts.

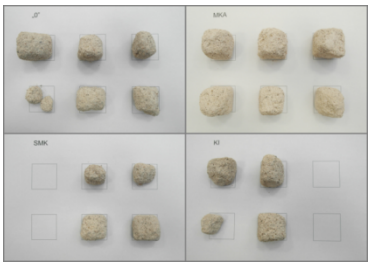

Figure 5. Mortar samples after 15 cycles of testing resistance to salinification.

Upon carrying out 15 such cycles, the samples were stored in water at room temperature for 24 h and next dried to a constant mass and weighed. The resistance to the crystallization of salts was indicated analogously to freeze-thaw resistance. Figure 4 shows the average percentage loss in mass, whereas Figure 5 presents the appearance of the samples after testing.

5 Conclusions

Impregnation of mortar was carried out with dampness resulting from close to maximal capillary rise of water. The results of studies on the capillary rise of water and total absorbability confirm that a high level of dampness makes it difficult or even impossible to apply agents based on alkaline methyl silicates and silicone micro emulsion. Injection creams, on the other hand, work very well in such cases (an over 13% reduction in total absorbability and nearly 29% decrease the capillary absorption coefficient were observed). All analyzed injection agents had a beneficial effect on the compressive strength as well as resistance to the harmful effects of construction salts. Alkaline Methyl silicates caused an increase in freeze-thaw resistance of the mortar. Due to the fact that the mortar subjected to the effects of agents based solely on hydrophobisation (silicone microemulsion and injection creams) caused a decrease in resistance to freezing and thawing, these substances should not be applied if there is no possibility to dry the wall before winter and it is not protected against freezing.

The results of the carried out studies also confirm that chemical injection treatment of the wall should not be carried out without accounting for specific conditions, such as the level of dampness, the location of the wall, conditions of the surroundings, etc. It should also be kept in mind that walls are conglomerates comprising materials characterized by various technical parameters.

Client's Expectations vs Contractor's Pricing. Fair Prices or Bid Rigging

Hubert Anysz and Andrzej Foremny

Warsaw University of Technology (WUT), Civil Engineering Department, Al. Armii Ludowej 16, 00-637 Warsaw, Poland, h.anysz@il.pw.edu.pl, a.foremny@il.pw.edu.pl

Abstract. *The road construction sector is a specific part of the construction industry. It happens very rarely that a section of a road is financed also by a private entity. The other factor distinguishing it – is a significant value of road construction contracts. The Client's estimates of the value of the prospective contracts have to be based on the market prices in case of public procurement. However, this market is dominated by public orders. There is no comparison to the value of works ordered on the private part of the construction market, which is found more efficient by economists. Widely applied the "design and build" type of orders make the comparisons of the unit prices more difficult. The huge differences between the Client's estimates and the winning prices in the road construction public tender procedures are the bases of speculations about the fairness of the procedures. These differences can have a varied origin. There are several reasons for them e.g. varied contractor's risk, the size of the structure, type of order, the dynamics of the road construction market. Nevertheless, fraudulent practices can make the winning price much higher than the Client's estimate. The article is an attempt to finding the limit i.e. what part of these differences can be explained by fair, market reasons. If the found limit is exceeded, it should make the Client carefully consider the offers placed. The analysis is based on collected data concerning almost 400 tender procedures for the sections of roads in Poland in 2014-2017.*

Keywords: *Bid Rigging, Collusion, Road Construction Market, Bid Price, Client's Estimation.*

1 Introduction

Exceptionally high values of the construction contracts are observed in the road construction branch in Poland, Rynekinfrastruktury.pl (2019). Public procurements in the construction industry are specific. The Code (2004) enforced preparing a client's estimation of the contract value, before the announcement of a tender to enable a client to decide which type of tender procedure should be applied (as it is price dependent). Based on the ordinance (2004), that estimation should be based on market prices of construction works. The same base should be used for the "design and build" type of orders. The amount estimated by a client is announced together with disclosing the contractors' offers – not before. The extreme relation of the winner's price to the client's estimation (exceptionally low or high) usually becomes a base for suspicions and gossips about forbidden practices of offerors (dumping prices or collusion, bid rigging). The process of choosing the most attractive offer may lead to refusing the offer with exceptionally low price, not allowing – in the client's opinion – for executing all works on the subject, in the planned period. There is no such strong client's right for the case of exceptionally high prices given by all offerors. When the client's budget is short, insufficient to finance an unexpectedly expensive project, the tender procedure can be cancelled. This postpones the execution of the planned project for many months. If the prosecutor's office is informed, they can investigate if any illegal practice has accompanied certain tender procedure, OECD (2012). The choice of the most attractive offer (*i.e.* signing the contract with a contractor) with a very high price means indirectly acceptance of the offered price level. The paper concentrates on the

doi:10.23967/dbmc.2020.020

problem: how to distinguish high market offer prices in the tender for road construction works, from unrealistic high offer prices – pointing the illegal, collusive practices among offerors.

There are two opposite trends observed on contractors' offer prices. During economic growth, when the demand is increasing *(i.e.* the number of tenders being announced by clients increases), the contractors' means of production are fully utilized. Any new contract requires engaging the external forces on a much higher level. The new suppliers should be agreed to match this increasing demand. That makes offer prices higher. Oppositely, after the period of economic prosperity, the number of the tender procedures announced decreases. Partly, the contractors' means of production – after completing a contract – have no place of engagement. To manage them efficiently, contractors search for some new contracts by lowering the offer prices to make the chance of the win higher. The average number of contractors placing their offers in certain procedure increases then.

As every project is unique, to compare the price level between tender procedures the following – winner price to client's estimation (PtE) – ratio is defined (Anysz, 2019):

$$PtE = \frac{bid\ price\ chosen\ by\ a\ client\ as\ the\ best\ one}{client's\ estimation * 1{,}23} \quad (1)$$

It is required by Polish law to give the bid price including VAT but it is required to prepare a client's estimation in net values (excluding value-added tax) (code, 2004; ordinance, 2004). So, the denominator is corrected by the present Polish VAT rate for this type of construction works.

2 Price Level in Polish Road Construction Sector (2014-2017)

2.1 Database

Tender procedures completed by the choice of contractor for building or modernizing sections of roads are analysed. There were 388 tender procedures ended between Jun 2014 and Jul 2017 found, with winning bid price exceeding 10 million PLN. The following set of information about them is collected:

- bid prices of all (valid) tenders,
- names of clients and offerors,
- bid prices chosen by clients as the winning ones,
- the clients' estimated values of prospective contracts
- the dates of clients' decisions about choosing the contractors.

It was possible to collect the complete database concerning 382 tender procedures.

2.2 Price Level – PtE Distribution

The values of PtE ratio are calculated. Its basic statistics are presented in Table 1.

Table 1. Basic statistics of PtE.

Number of procedures	Mean average	Median value	Min	Max	St. dev.
382	0,607	0,578	0,195	1,793	0,216

It has occurred that in more than 82 % of tender procedures PtE value is over 0,4 and below 1,0. In approximately 14 % tender procedures winning bid price was very low ($PtE \leq 0{,}4$) and the chosen tender had the price over clients' estimates ($PtE \geq 1$) in 4 % of analysed procedures. The histogram of PtE values is presented in Figure 1.

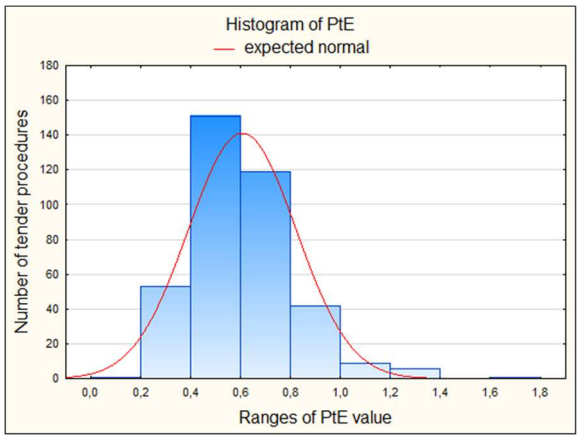

Figure 1. Histogram of PtE values in 382 tender procedures (Anysz, 2019).

2.3 Reasons for PtE Variations

The main reason for such significant variations of PtE value is the different aim of evaluations done by a client and a contractor. A client is obliged to apply market prices of different kinds of construction works i.e. average prices observed on the market. It is aimed to assess, which procedure of public procurement should be applied. Secondly, a client based on that can prepare a budget for the planned construction. A contractor calculates their bid price based on their costs, efficiencies of their brigades, etc. It is aimed at finding the price allowing for winning the contract, and for achieving the profit, which is necessary for a company to survive and business development. Taking into consideration the aims of evaluation, the contractor's bid price is unique, precisely adjusted to the company and market conditions. A client's evaluation is adjusted to the market conditions and based on average prices. Another reason also making PtE spectrum so wide is the fact that a client's estimation is prepared before the announcement of the tender procedure. The law limits the validity of such evaluation to six months. During this period, in a dynamically changing market, even average prices can change much. The next reason is an error of estimation. Finally – the standing of a national economy, and dynamics of the construction market influences the bid prices. Another group of reasons for PtE variations are illegal, collusive practices which makes bid prices vary from not abused market trends.

3 Market Phenomena Influencing the Bid Prices

Polish National Statistical Office (GUS) publishes on a monthly, quarterly or yearly basis much information collected on the market. One of the groups of published indicators is tendencies. The group of tendencies searched for this paper is "Business tendency survey in construction - current database - monthly data" (GUS, 2019). For 36 months analysed, the mean average of PtE in each month was calculated. Then, Pearson's correlations (Aczel, 1992) were checked

with different indicators of business tendencies (month to month; without any time shift). It has occurred that it is a quite high correlation coefficient – equals to 0,659 – between average PtE and the indicator "expected prices" assessed based on opinions of companies employing over 250 employees. It is the highest correlation among indicators published by GUS concerning the construction industry . Shifting the time of expectations one or two months haven't produced a higher correlation coefficient (see Figure 2).

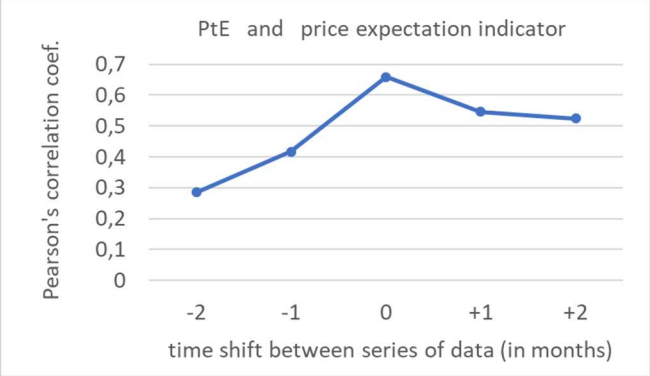

Figure 2. Pearson's correlation between PtE and price expectation indicator with time shifts.

As prices rise during the market growth, it can be said that PtE partly, positively reflects the trends on the market. Analysis of data collected does confirm findings of the number of tenders and their dependence on market prosperity proves that there are more tender procedures with the higher number of offerors when the market does not develop ($PtE \leq 0{,}4$). Procedures with more than 8 tenders almost don't appear (except 1 case) during the market growth – high bid prices dominate ($PtE \geq 1{,}0$). It can be observed in Figure 3.

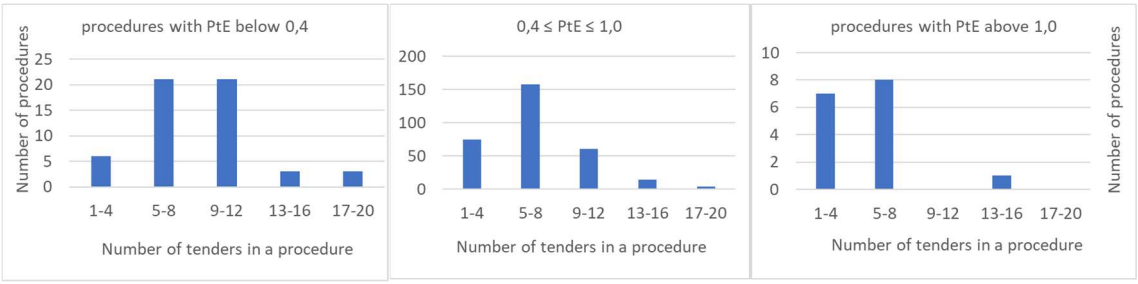

Figure 3. Histograms of the number of tenders for the procedures with different ranges of PtE (Anysz, 2019).

Moreover, the average PtE calculated monthly has the strong negative Pearson's correlation (-0,691) with an average number of tenders in a procedure. Described above dependencies are based on officially published (GUS, 2019) "expected prices" in the construction industry indicator (collected opinions of companies employing 250 and more persons) and collected real data concerning the tender procedures in the road construction sector. This is proof, that contractors observe the market tendencies and they adjust the bid price level to the market situation.

4 Fair Price or Bid Rigging

4.1 Fair Prices

As described above, differences between clients' estimation and the bid prices of the winners are natural. Clients are obliged to use market prices which are created in the cycle presented below – in Figure 4.

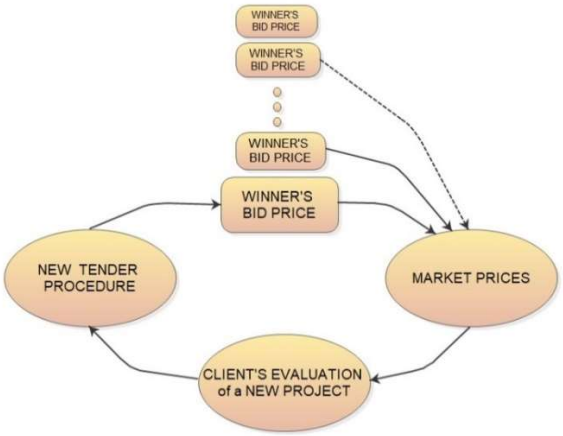

Figure 4. The mechanism of creating market prices.

As the winner of the tender procedure is chosen by a client, it can be understood, that the chosen contractor has fulfilled all formal criteria and their offer is the best (according to the criteria set by a client). The same refers to the price given by a winner – it creates one of the market prices. A certain client's estimation of a new project is based on unit market prices e.g. of 1 m3 of an embankment, 1 m3 of a concrete structure, etc.

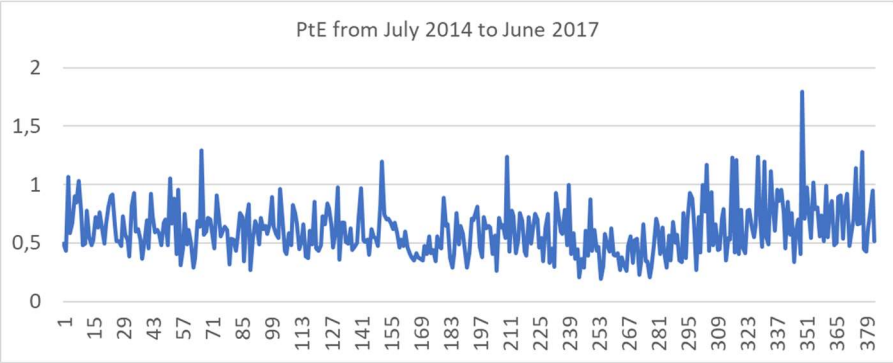

Figure 5. PtE values. Procedures from the year 2015 start from procedure No 71, 2016 from procedure No 163. 2017 from procedure No 311 (Anysz, 2019).

However, the market unit prices are created by previous orders. So, if any tendency could be observed on the market, the bid prices have to differ from the client's evaluations. Collected data allows presenting PtE for all examined 382 tender procedures. They are sorted by date

starting from July 2014 (see Figure 5).

4.2 Indicators of Collusive Practices

4.2.1 Low number of the tenders

Many sources are pointing the low number of tenders as an indicator of possible collusion (OECD, 2012; UOKiK, 2017; Huber and Imhof, 2018). It is also consistent with common sense, as it is much easier to keep the secret – illegal collusive agreement – among a few its participants that among several of them.

4.2.2 Narrow range of the bid prices

Another important factor that can pay a client's attention to the possibility of bid rigging is the range of the prices offered. The range R was defined (Foremny and Anysz, 2018) as:

$$R_{\mathrm{i}} = \frac{(V_{\mathrm{av\,i}} - V_{\mathrm{min\,i}})}{V_{\mathrm{av\,i}}} * 100\ \% \tag{2}$$

where:

R_i – the range for procedure i

$V_{min\,i}$ – the lowest value of an offer in procedure i

$V_{av\,i}$ – the mean average value of offers in procedure i

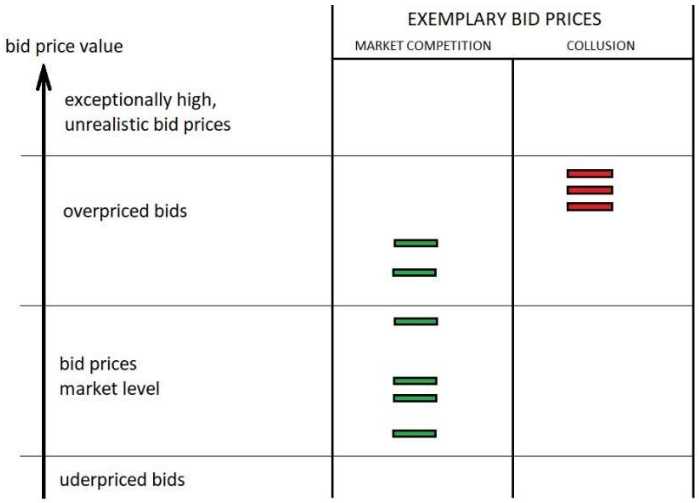

Figure 6. Exemplary bid price levels in case of market competition and collusion

The average R for examined 382 procedures is 13,5 %. In the case of collusion, where every bid price is over the market level, involved offerors increase their bid prices over the market level. However, their prices can't be recognized irrationally high. That makes the space for their bid prices much more narrow than in the case of market competition (see Figure 6). The range R is low then.

4.2.3 Other indicators

There are many more indicators (Ferwerda *et al.*, 2017; OECD, 2013; International Competition Network, 2010) of possible collusion, bid rigging (*e.g.* location distance of an offeror's enterprise vs location of offered services, simultaneous attendance in procedures of the same set of offerors, frequency of interaction through trade associations, staff moving between companies, market transparency, e.g. in bid rigging where openness makes it easier to monitor for cheating, excess capacity and inventories, ending of a price war and/or concerted moves to "discipline the market", existence of joint ventures etc.). Nevertheless, they are not so obvious, intuitive as indicators presented in the two previous sub-chapters. Moreover, they are more dependent on the specifics of a certain branch or market sector. Then the result of a tender in the road construction industry are announced, and the winner's price is high, it becomes the subject of many newspaper articles, controversies and speculations if the price is fair. These were an inspiration to verify what level of extremely high prices (chosen by clients as the best ones) can indicate the possibility of collusion or bid rigging.

5 Extremely High PtE as Collusion Indicator

5.1 Proposed model

It is, hereby, proposed to observe extreme deviation of PtE from its average value – especially in a case where – in a certain procedure – PtE is extremally high. As it was described above (*i.e.* in chapter 3), the state of the market influences the bid prices level. Thus, referring PtE to its average based on a long time is irrelevant. The simple moving average (SMA) (Gençay and Stengos, 1998; Elder, 1992) is presented in Figure 7 (yellow line) based on the following formula:

$$SMA(PtE) = \frac{\sum_{i=1}^{n} PtE_i}{n} \tag{3}$$

where:

PtE_i - the value of PtE in i tender procedure (one of the procedures completed in 30 predeceasing days),

n - the number of procedures completed in 30 predeceasing days.

Within random 30 days periods (chosen from July 2014 – June 2017) the number of completed procedures varies, so n varies for SMA calculated for different days. The 30 days period is chosen to calculate SMA according to the fact – described above, in chapter 3 – that the highest Pearson's correlation (PtE and "expected prices") was achieved for 30 days period (from 30, 60 and 90 days periods). Similarly to analysis of stock exchange prices with Bollinger bands (Baiynd, 2011; Lento *et al.*, 2007), the band around SMA is created by upper (L_U) and lower limit (L_L) defined as:

$$L_U = SMA + k \tag{4}$$

$$L_L = SMA - k \tag{5}$$

where: k - constant, greater than 0

When it is assumed that if for the chosen (by a client) bid price

$$PtE > L_U \tag{6}$$

in a given tender procedure, that may imply collusion existence, then there is a problem of choosing the value of the constant k. When it is set too small (close to 0), collusion can be expected in almost every tender procedure where

$$PtE > SMA \tag{7}$$

When k is too high, in none of bidding procedures PtE exceeds the upper limit – it means that the market is perfectly competitive.

Let's analyze one of the reasons, why bid prices differ from a clients' estimations – mistakes in contractors calculations of their bid prices. If the lowest bid price (mistakenly calculated so low) is chosen by a client as the best one and it is below SMA, the mistake can be done in only one offer. When a client chooses the bid price for which PtE is high above SMA, and it is the lowest bid price in a certain procedure, it means that all offerors made mistakes in their bid price calculation (if a mistake caused exceptionally high bid price). Moreover, the reasonable assumption can be made that the size of underpricing and overpricing made by mistakes in the bid prices calculations are statistically the same.

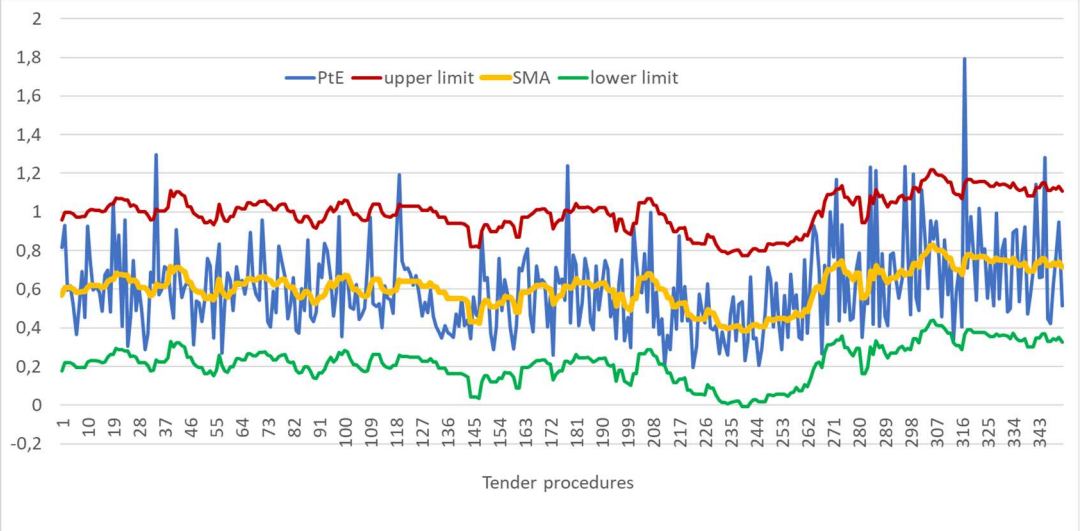

Figure 7. SMA, symmetric SMA band for $k = 0{,}39$ with PtE on the band

Making a mistake by one offeror is much more probable than by all offerors. As the mistake of only one offeror can push the bid price to the very low level, the following value of k can be set:

$$k\colon\ \forall SMA(PtE)\ \ L_L < PtE \tag{8}$$

For the data collected $k = 0{,}39$ made inequation (8) satisfied. Four lines are simultaneously presented in Figure 7, PtE, SMA and its band limits for $k = 0{,}39$.

It can be expected that the peaks of PtE exceeding the upper limit haven't been caused by mistakes in offerors' price calculations. The band is symmetric around SMA. The cases where

all bids are mistakenly highly overpriced (the lowest bid price, chosen by a client creates PtE) are very rare or even don't exist. Therefore, the collusion can be expected in all these PtE peaking tender procedures.

5.2 Verification of the Model

The best possible verification – the sentence of a court punishing collusive behaviors – is unavailable. There are 4 tender procedures found (among the analyzed set) which were a subject of such court procedure but all investigations dropped due to lack of collusion evidence. There are 11 tender procedures peaking above the upper limit – constructed from SMA increased by 0,39 (see Figure 7). It is possible to check, if other indicators of possible collusion i.e. low range of bid prices (calculated according to (2)) and the low number of offerors, confirm the possible non-concurrent character of offerors' behaviors in these procedures.

Table 2. Tender procedures with PtE exceeding the upper limit.

PtE peaking procedures	PtE	Number of offerors	Range R [%]	Possibility of collusion
1	1,295	8	13,4	low
2	1,195	1	0,0	high
3	1,239	15	20,9	low
4	1,168	5	4,5	high
5	1,233	6	16,8	low
6	1,213	6	25,0	low
7	1,236	1	0,0	high
8	1,196	4	6,7	high
9	1,793	5	3,8	high
10	1,143	1	0,0	high
11	1,281	5	15,5	moderate

Taking into consideration the average range R for all analyzed tender procedures (equal to 13,5 %) and the average number of participants in a tender procedure (6,9), the level of possibility of a collusion is assigned. The assessment is "high" for less than six offerors and the range R lower than 7 %. If there is only one offeror, there is no range of bid price values but the range equal to 0,0 is presented in Table 2. There are 6 tender procedures where collusion possibility is high, out of 11 tender procedures pointed by the model. There is no such an upper limit other than $1{,}295 < L_U < 1{,}793$ above which, all tender procedures would have a high level of possibility of collusion. Even for so high upper limit, there is only one tender procedure and its level of possibility of collusion is high – procedure labeled as 9 in Table 2. Nevertheless, as it is the only case, it can't be named the rule.

6 Conclusions

The model built for the real database of Polish tender procedures in the road construction industry, aimed at collusion finding, couldn't be verified directly. The indirect verification – through other indicators that usually accompany bid rigging, shows that comparison of PtE ratio with upper limit L_U (based on SMA) can't be the single collusion indicator. None of the

described bid rigging cases in the literature support the statement that in case of collusion all indicators have to point the collusion existence. The very high bid price level, defined here as PtE exceeding a single moving average of PtE increased by 0,39, is a separate indicator of unusually bid prices. One of the possible reasons can be collusion or bid rigging. It is proposed to observe it along with other factors i.e. the number of offerors and bid price range in each tender procedure. These three indicators are easily obtainable i.e. they don't require any advanced analytics (as other indicators). So, they can be applied easily by clients, who make decisions about spending public financial resources. The road construction contract values are one of the biggest and the type of construction works comprised by them is homogenous. The proposed model can be applied in other branches. However, it is to remember, that the data – the base for SMA calculation - should be collected within one branch to provide relevant information. A client's analysis done before the choice of a contractor may lead to successful price negotiations and finally to lowering the price. This means higher efficiency of spending public financial resources.

Abstract. *The article deals with the analysis of background resources for the evaluation of socio-economic impact methodology elaboration of the territory development in the field of commercial, service and residential properties, mixed constructions and multifunctional buildings in the first phase of their life cycle. The research team investigated the possibilities of using the information and procedures for the evaluation of socio-economic impacts of the territory development. Relevant data for the evaluation was identified and analysed on the research sample of 12 major urban districts of the city of Brno. Technical and social parameters that appeared relevant for the economic evaluation of the surveyed location development were identified based on the available data on individual territories. The first identification step was their description. Subsequently, suitable metrics for their evaluation were examined. Findings about what socio-economic impacts these locations create in the field of interest and whether these impacts are efficient in terms of their functioning represent the output of the paper. This includes determining the overall economic efficiency of the implementation phase of their life cycle. This output then forms base for the future research focusing on the possibility of including other variables that shall focus on the operational phase of the life cycle and extend the assessment to a wider timeframe.*

Keywords: *Territory Development, Socio-Economic Evaluation, Multicriteria Analysis.*

1 Introduction

The method of assessing the economic efficiency of the territory development depends on the extent and specifications of the technical determination of the change in the current situation. From the development point of view, it can be a specific large-scale development project, for which the basic project documentation has already been elaborated at the architectural study level; furthermore, one of the stages of the project documentation can be processed for a particular sub-project. At the level of information provided by the specific technical documentation, it is possible to evaluate their economic efficiency with a certain amount of experience and knowledge, e.g. using the CBA method (projects of road and highway sections, railway corridors, waterways, specific buildings for civil or commercial purposes (Guide, 2014)). The authors of this article focus on a more general view of the territory development and its future potential use, already at the land use plan level. At this level, no specific

development projects are defined, however the territory is being prepared for a specific use or combination of uses. The land use plan sets out the urban concept, the concept of landscape arrangement and the concept of public infrastructure, it defines the built-up area, areas and corridors and sets the conditions for the use of these areas.

The research is aimed at finding suitable criteria that can be used to assess the socio-economic efficiency of the territories that are defined as areas or sets of areas, or parts of areas, defined on the basis of the prevailing character. The individual areas constituting the territory may be areas for housing, recreation, civic amenities, mixed residential, transport infrastructure, technical infrastructure, production and storage, mixed production, public areas, green areas, water and water management, agricultural, forest, natural, mixed undeveloped areas, mineral extraction and specific. The research question is whether the territories formed by the combination of the above-mentioned areas can be expressed by economic quantity that would prove their efficiency level. The municipality, in which cadastral the territory is located has to incur certain expenditures on preparation for its intended use. The question is whether there may be any revenues and/or socio-economic benefits that the new territory can bring to the municipality/society.

2 Analysis of the Current Situation

Urban sustainability is a multi-dimensional concept that includes environmental, economic, social and political dimensions (Huang *et al.*, 2009; Olewiler, 2006). The strategic plan towards sustainable development is fundamentally based on knowledge of the local economic opportunities, the local environmental conditions, and cultural and social characteristics (Scipioni *et al.*, 2009). Many authors describe the territory in various detail views. Moussiopoulos (2010*)* develops this concept in a framework of 13 discrete thematic areas, namely: (I) Economy–Population, (II) Land and Urban Planning, (III) Energy, (IV) Transportation, (V) Agriculture–Livestock–Fishery, (VI) Industry, (VII) Tourism, (VIII) Air Pollution–Climate Change, (IX) Water Resources and Sea Environment, (X) Solid Waste, (XI) Biodiversity, (XII) Health, (XIII) Education–Research and Technology.

(Nijkamp, 1995*)* sets main criteria and sub-criteria following A. Functional restructuring of the area (residential, tertiary and cultural function), B. Economic valorisation of the area (property value of real estate, commercial value, socio-economic value), C. Common utility (public recreational and supporting services) and D. Historic – environmental value (conservation and restoration value, aesthetic aspect of urban assets, integration with the historical city center).

For deciding on effective activities in the area it is sometimes necessary to quantify these variables. Research of the authors in the first phase focused only on a part of economic and socio-economic aspects, where it was able to define technical and socio-economic input variables, create their aggregation and produce relevant outputs.

3 Methodology

Changing the location purpose from the current prevailing use to another entails certain costs that the municipality has to incur in order to implement the new use of the location. These are mainly requirements for the construction of roads and backbone networks. At the same time, changes in the use of locations, depending on their character of the usable areas, can bring a

certain capacity of new residents and new jobs.

In order to work effectively with the technical-economic data, the characteristics of the locations were primarily defined. The basic attribute for their determination was the structure of the layout of the individual areas of the location, which may be residential (r), compact (c), empty (e), construction limited (l) or zoned (z). Average lengths of roads and backbone networks in m/ha were determined for each structure. Furthermore, possible incremental capacities of permanent residents and incremental capacities of new jobs were determined for each location. These data, which create important inputs into analysis presented in this paper, were taken from the results of the relevant scientific research oriented on evaluation of development opportunities prepared and proposed for the land use plan.

Based on the average length of roads and backbone networks in m/ha (water, sewerage, gas, electricity, central heating), including their average technical parameters together and their average unit prices according to national price databases, the cost in €/ha was determined for each location and the cost in €/m2 was derived from them. The total cost of the change in the use of the location (Criterion K1) is the sum of the costs of the areas that the location contains.

$$K1 = \sum_{i=1}^{n} CA_i \tag{1}$$

Where

K1… Total costs of the location in €

CA… Cost of i-th area in €

n… Number of areas in the location

Based on the incremental capacity of residents and the tax revenues of the municipality per capita, the potential revenue of the municipality (Criterion K2) can be determined according to the following relation:

$$K2 = I \times R_T \tag{2}$$

Where

K2… Total revenue of the location in €

I… Incremental capacity of residents

R_T… Tax revenue of the municipality per capita in €/cap.

The potential social benefit (Criterion K3) was determined on the basis of the incremental capacity of the new jobs in the location, where the unit of benefit is the socio-economic benefit arising for the company in creating one new job.

$$K3 = L \times B_J \tag{3}$$

Where

K3… Total socio-economic benefits of the site in €
L… Incremental capacity of jobs
B_J… Benefit of the society from one created job in €/job

The output of the economic model is the determination of the overall location efficiency (E), which is defined as the sum of the product of the location classification values in a given criterion (K) and its weight (w).

$$E = \sum_{i=1}^{n} K_i \times w_i \tag{4}$$

The rating scale for each criterion values are listed below. The criteria weights were expertly chosen as follows:
Criterion K1 weight $w_1 = 0.60$,
Criterion K2 weight $w_2 = 0.20$,
Criterion K3 weight $w_3 = 0.20$.

According to the fact that this is a "yield" criterion, higher value of overall efficiency E represents higher efficiency of the territory.

4 Results

Interim research results are presented on a case study. The case study includes the evaluation of 12 locations boroughs of the Statutory City of Brno.

4.1 Values of Input Variables

Based on the above-mentioned procedure, the costs for backbone networks were determined for individual representatives of the location structures. The values are given in Table 1.

Table 1. Model costs of the backbone network in €/ha.

Type of structure	Cost of Water [€/ha]	Cost of-Sewerage [€/ha]	Cost of Gas [€/ha]	Cost of Electricity [€/ha]	Cost of Central Heating [€/ha]
r	141,438	100,836	67,140	36,633	391,744
c	118,206	84,273	56,112	30,616	327,397
e	157,267	112,120	74,653	40,733	435,583
l	61,882	44,118	29,375	16,028	171,396
z	120,436	85,863	57,170	31,194	333,575

The costs of roads by length per hectare were further divided into groups according to the

assumed width of the road, considering the widths of 8, 12 and 24 m. The values obtained are shown in Table 2.

Table 2. Model costs of roads in the territory according to their widths in €/ha.

Type of structure	Width 8 m [€/ha]	Width 12 m [€/ha]	Width 24 m [€/ha]
r	228,275	342,413	684,826
c	190,779	286,169	572,338
e	253,821	380,732	761,464
l	99,875	149,813	299,625
z	194,379	291,569	583,137

The value of revenue per capita used is based on the statistical data of the set municipality, in the case of the mentioned case study - the final account of the Statutory City of Brno (SCB, 2018) in the current value of € 1,020/resident.

The average value of a socio-economic benefit arising for a society in creating one job without considering specific job positions is assumed for the Czech Republic at the current value of € 12,401/job (SEI, 2019).

4.2 Values of the Individual Criteria

The case study deals with 12 considered locations located in the cadastral territories of the individual city districts of the Statutory City of Brno. The location is described in the Table 3 below.

Table 3. Values of criteria K1, K2, K3 v €/m2.

Location in the cadastral area	Area ha	Incremental capacity of residents	Incremental capacity of jobs	K1 - costs €/m²	K2 - revenues €/ m²	K3 – benefits €/ m²
Prizrenice 1	62.52207	2,736	3,871	55.47	106.88	76.80
Prizrenice 2	58.32664	3,215	4,272	57.70	125.59	90.82
Cernovice 1	39.97897	458	4,668	65.20	1.17	144.80
Bosonohy 1	39.72692	1,407	874	45.00	3.63	27.27
Reckovice	38.96985	4,033	1,959	55.63	10.55	62.34
Styrice	38.76289	883	674	87.77	10.86	261.56
Bosonohy 2	34.87699	28	2,030	53.32	5.43	187.89
Komin	32.67942	982	573	47.34	3.09	21.76
Bohunice	31.46935	3,031	1,966	59.61	9.84	77.46
Dolni Herspice	30.93395	90	1,807	55.31	0.31	72.46
Prizrenice 3	30.68411	3,612	944	61.33	12.03	38.16
Cernovice 2	28.72383	380	3,191	62.42	1.37	137.77

4.3 Description of Classification Grades to Calculate the Overall Location Efficiency

For all the above-mentioned evaluation criteria, the following tables show the methods of their evaluation based on the classification according to the selected categorisation.

Criterion K1 – classification scale for cost value intervals per m^2

In terms of their cost per m^2, the assessed locations were divided into 5 classification grades (1 - least expensive, 5 - most expensive) according to the cost intervals given in the following Table 4.

Table 4. Classification grades for the cost interval per m2 of the designed location area.

Cost interval per m^2 [€/m^2]	Descriptor	Classification grade
< 39.06	Low cost	1
39.06 – 58.58	Lower cost	2
58.59 – 78.13	Average cost	3
78.14 – 97.66	Highest cost	4
> 97.66	High cost	5

Criterion K2 – classification scale for revenue value intervals per m^2

In terms of their revenue per m^2, the assessed locations were divided into 5 classification grades (I - highest revenue, V - lowest revenue) according to the revenue intervals given in the Table 5.

Table 5. Classification grades for the revenue interval per m2 of the designed location area.

Revenue interval per m^2 [€/m^2]	Descriptor	Classification grade
> 23.44	High revenue	I
20.35 – 23.44	Higher revenue	II
9.78 – 20.34	Average revenue	III
3.91 – 9.77	Lower revenue	IV
< 3.91	Low revenue	V

Note: For the calculation of the overall efficiency for this yield criterion, the classification grade "I" = 5 points, the classification grade "V" = 1 point (higher revenue is preferred).

Classification scale for the social benefits value interval

The assessed locations were divided into 5 classification grades (A to E, A - highest social benefit, E - lowest social benefit) according to their societal benefit intervals given in Table 6.

Table 6. Classification scale for social benefits interval per m2 of the designed location area.

Social benefit interval per m² €/m²	Descriptor	Classification grade
> 97.66	High benefit	A
58.65 – 97.66	Higher benefit	B
19.54 – 58.64	Average benefit	C
3.90 – 19.53	Lower benefit	D
< 3.90	Low benefit	E

Note: For the calculation of the overall efficiency for this yield criterion, the classification grade "A" = 5 points, the classification grade "E" = 1 point (higher benefit is preferred).

4.4 Resulting Ranking of the Locations According to Overall Efficiency

Table 7 shows the evaluation of locations according to individual classification grades and the overall efficiency of the location E according to the above-listed relation is determined as the sum of the products of the classification grade values in the relevant criterion and its weight.

Table 7. Overall efficiency of the locations, sorted by the value of the overall efficiency E descending.

Location in the cadastral area	K1 (cost per m2)	K2 (revenue per m2)	K3 (benefit per m2)	E (overall efficiency)
Prizrenice 1	4	V	A	4.20
Prizrenice 2	4	III	C	4.20
Cernovice 1	4	III	A	3.60
Bosonohy 1	3	V	A	3.40
Reckovice	3	V	A	3.20
Styrice	3	V	B	2,60
Bosonohy 2	2	I	B	2.40
Komin	2	V	C	2.40
Bohunice	2	III	B	2.40
Dolni Herspice	2	V	C	2.20
Prizrenice 3	2	I	B	2.20
Cernovice 2	2	V	B	2.00

Locations are sorted according to values of efficiency, according to the values of individual criteria is also clear how the individual criteria for overall efficiency involved. The overall efficiency ranges from 2 to 4.2 points of the 5-point scale.

5 Conclusion

The article deals with determination of the procedure for the evaluation of the economic efficiency of designed locations. The economic evaluation is made to compare the extent of economic intensity, potential revenue and socio-economic benefit of individual development

locations among themselves and to determine the possible succession for their implementation - a change in their use. For this reason, an economic model of costs, revenues and benefits related to the transformation of the current location into its proposed use was developed. The economic model is designed for the basic economic awareness of the costs, revenues and benefits of the areas under consideration at the level of detailed technical data that are part of the land use plan. For this reason, it works with the average values of the territory representatives. Value analysis procedures were chosen for comparison of designed locations. Future research will focus on another part of the life cycle of the municipal property thus created, namely the cost of repairing and maintaining in the operational phase, where it will be necessary, among others, to examine its average lifetime.

Abstract. *Evaluation of the economic efficiency of investment projects in transport infrastructure in the Czech Republic is methodically based on the Departmental Methodology of the Ministry of Transport. Economic cash flows, generated in accordance with the CBA principles, are modelled within this methodology on the basis of the evaluation of socio-economic impact of individual projects. In the case of the railway infrastructure constructions, the socio-economic impacts used by the methodology do not include benefits associated with increasing safety and reliability of the railway infrastructure network due to new security systems implementation. Determination of socio-economic impacts associated with specific types of incidents on the railway which are caused by insufficient railway infrastructure security and which could be eliminated by the implementation of the higher-level signaling equipment forms the subject of the research. The research is based on the analysis of a database of incidents occurring on the railway in the Czech Republic in the 2009 – 2018 period, which describes the basic impacts associated with a particular incident. Statistical data on the railway infrastructure is also used to determine the impact of incidents in addition to the database. The key outcomes of the research are the determination of methodological steps for the evaluation of the impacts of incidents on the railway and a case study for their verification. Future research will focus on making evaluation of the above-mentioned benefits more detailed. Research outcomes will improve decision-making process on selection and financing of the projects related to railway infrastructure safety for their future implementation.*

Keywords: *Socio-Economic Impacts, Investment Project, Railways, Incidents, Evaluation.*

1 Introduction

The paper focuses on presentation of partial results of the research concentrating on the evaluation of benefits associated with increasing safety and reliability of the railway infrastructure. Improvement of safety and reliability is anticipated in particular by the implementation of suitable safety systems into the railway infrastructure to prevent the occurrence of incidents. The research outputs presented in this paper are mainly focused on the evaluation of economic impacts of the incidents. The research is based on the analysis of the database of incidents (RIA, 2018) provided for the purpose of the research by the Railway

Infrastructure Administration (SŽDC), within which the incidents registered for the period 2011–2018 are divided into various sub-categories. Within the framework of the paper, the number of relevant categories is reduced solely to those categories of incidents which occur on the railway infrastructure and for which it can be assumed that they can possibly be prevented by previous implementation of suitable track or station signalling systems. The research does not take into the account the accidents at the level crossings.

2 Present State References

The research can be based on the conclusions of a number of scientific and scholarly texts. A key basis for assessing the economic efficiency of investment projects in the public sector is the Guide to Cost-Benefit Analysis of Investment Projects (Sartori, 2014), published by the European Commission in 2014, which includes general rules for economic evaluation of public investment projects as well as framework methodologies for economic evaluation of public investment projects in particular areas of public investment; for these areas are also presented illustrative case studies. National methodology for evaluating the efficiency of investment projects in the area of transport infrastructure, called the Departmental Methodology (MoT CZ, 2017) is based on this methodology. The Departmental Methodology is focused primarily on assessing the financial and economic efficiency as well as risks of investment projects in transport infrastructure in the specific conditions of the Czech Republic. The issue of evaluation of impacts of incidents has not been dealt with in more detail in scientific literature, however, topics related to it definitely form the subject of the research. The issue of the relationship of incidents and human factor is dealt with in the research of (Baysari, McIntosh, Wilson, 2008), (Madigan, Golightly, Madders, 2016), the view of engine drivers has been more closely addressed in the Swedish study (Forsberg, 2016). The socio-economic aspects of incidents on the railway infrastructure are the subject of the following research articles (Klockner, Toft, 2018) and (Read, Lenné, Moss, 2012). Latent and active errors leading to railway incidents are dealt with in the paper by (Zhou, Lei, 2018).

3 Methodology

The subject of the research presented in this paper is to define methodological steps for evaluating the impacts of incidents on the railway infrastructure.

In particular, the following data from the information provided by the “Incident Statistics” (RIA, 2018) is considered within the research project:

- Impact on health
  - Death,
  - Serious injury,
  - Minor injury,
- Material damage,
- Costs,
- Number of delayed passenger trains,
- Total delay of passenger trains,
- Number of delayed freight trains,
- Total delay of freight trains,
- Cause of incident emergence

- Technical,
- Human factor,
- Others.

This paper evaluates especially the following characteristics of incidents:

- Impacts on health,
- Delay of passenger trains; and
- Delay of freight trains.

3.1 Impacts on Health

Incident impacts on health are based on the average number of casualties (dead, injured) and the unit cost associated with death, serious or minor injuries. Unit costs associated with traffic accidents are taken from the Departmental methodology of the Ministry of Transport and are described in more detail in Table 1.

Table 1. Cost associated with traffic accidents.

Traffic accident	Unit cost €/person
With death	839,306
With serious injury	202,968
With minor injury	26,202

Source: Departmental Methodology of the Ministry of Transport (MoT CZ, 2018)

3.2 Delay of Passenger Trains

Determination of the impacts associated with the delay of passenger trains is based on the average overall delay of passenger trains due to incident occurrence. The total delay of passengers travelling on delayed trains is then determined using the average train delay taking in account the average train occupancy. The total cost associated with the train delay resulting from the incident is then derived using the data from the Departmental Methodology which shows the passenger time values.

The average train occupancy for the whole railway network was determined using the data from the Czech Railways Statistical Yearbook of 2018 (CRG, 2018). In particular, information on the total transport performance of 2018 (assumed at 8,224.9 passenger-kilometres) and on the running of passenger trains for 2018 (123,596 train-kilometres in total) were used. The resulting average train occupancy for the entire railway network was set at 66.55 persons per train based on the above-mentioned data.

For the subsequent research, planned refinement of the average train occupancy calculation in terms of the division of the railway network into national and regional lines has been planned; where the national train lines are expected to have a higher average train occupancy than the regional train lines.

Passenger time values are taken from the Departmental Methodology and are shown in Table 2.

Table 2. Time values of passengers on the railway infrastructure.

Passenger transport		**€/person-hour**
Working time		24.21
Non-working time	Short transport	9.43
	Long transport	12.11
	Other – short distance	7.91
	Other – long distance	10.14

Source: Departmental Methodology of the Ministry of Transport (MoT CZ, 2018)

In accordance with the Departmental Methodology, it is generally assumed that in the case of non-working time, the ratio between commuting and other transport is balanced. Likewise, it is assumed that the ratio between long and short transport is also balanced. The ratio between business travel and non-business travel is considered to be 10/90. Based on the information provided, the average value of the passengers' time can be estimated at € 11.33 /person-hours. This value was taken in the account in the case study. In the follow-up research, it is possible to focus on a more precise ratio between the individual reasons for transport (commuting, other), depending on whether the transport is situated on the regional or national line.

3.3 Delay of Freight Trains

The determination of the impacts associated with the delay of freight trains is based on the average overall delay of freight trains due to the incident occurrence. From the total average delay of a freight train, the total delay of freight transported on delayed trains together with considering the average weight of the freight is subsequently determined. Using the data from the Departmental Methodology on the values of freight transport time, the total costs associated with the train delay due to incidents, has been subsequently derived.

The average weight of freight carried by train was determined for the entire railway network using data from the Statistical Yearbook of the Czech Railways Group in 2018 (CRG, 2018). Specifically, information on the total transport performance of 2018 (assumed at 11,085.9 million tkm (tariff tonne-kilometres) and on the running of freight trains also for 2018 (a total of 24,348 million train-kilometres) was used. The resulting average train freight weight for the whole rail network in relation to this data was set at 455 tonnes/train.

The values of freight transport time have been taken from the Departmental Methodology and are given in Table 3.

Table 3. Time values of freight traffic on the railway route.

Commodity	**€/tonne-hour**
Commodities with low added value	0.013
Normal cargo	0.248
Commodities with high added value	0.742

Source: Departmental Methodology of the Ministry of Transport (MoT CZ, 2018)

The percentage representation of the above-mentioned commodities can be derived from information on freight transport by commodity groups of goods from the Statistical Yearbook of the Czech Railways Group from 2018 (CRG, 2018, p. 8). Total weights of goods transported by individual commodity in 2018 are shown in Table 4.

Table 4. Freight transport by commodities in 2018.

Commodity	ths. tonnes
Iron and engineering products	7,979.7
Construction material	7,569.2
Lignite	6,637.1
Black coal and coke	7,352.9
Other building materials and ceramics	2,470.9
Chemical products and liquid fuels	4,764.6
Wood and paper products	4,733.2
Food and agricultural products	1,454.6
Combined transport	571.8
Automotive	1,589.6

Source: (CRG, 2018)

By assigning the commodities listed in Table 4 to one of the following groups:

- Commodities with low added value (e.g. bulk substrates),
- Normal cargo,
- Commodities with high added value (perishable goods by means of transport),

it is possible to determine the average share of the listed categories of commodities on the transport performance and thus the average value of the freight time in case of a freight train delay. The average value of freight transport time value was set at € 0.246/tonne-hour.

The quantities stated in the methodology are then used to determine the average economic impact of an incident of a given type. Within the research, only those incidents that may arise in connection with the insufficient security of the railway infrastructure in the area of the railway station or the railway line between the stations are considered. At the same time, only those incidents resulting from a human factor error are considered for the calculation of the average impacts of incidents. The following categories of incidents are therefore taken into account for this research:

A1 Collision of railway vehicles resulting in death or injury to at least 5 persons or large-scale damage,
A2 Derailment of a rail vehicle resulting in death or injury to at least 5 persons or large-scale damage,
A3 Collision of a rail vehicle with an obstacle in the passage resulting in death or injury to at least 5 persons or large-scale damage,
B1 Collision of railway vehicles resulting in consequences minor than in a serious accident,
B2 Derailment of a rail vehicle resulting in consequences minor than in a serious accident,
B3 Collision of a rail vehicle with an obstacle in the passage resulting in consequences minor than in a serious accident,
C1 Collision of railway vehicles resulting in consequences minor than in a serious accident or accident
C2 Derailment of a rail vehicle resulting in consequences minor than in a serious accident or accident,
C3 Collision of a rail vehicle with an obstacle in the passage resulting in consequences minor than in a serious accident or accident,
C6 Unauthorized movement of the rail vehicle behind a signalling device prohibiting

driving resulting in consequences minor than in an accident,
C12 Unsecured movement of a rail vehicle resulting in consequences minor than in an accident,
C16 Failure of signalling systems resulting in consequences minor than in an accident,
C19 Unspecified incident, arising in connection with the movement of the rail vehicle resulting in consequences minor than in an accident.

4 Results

Interim research results can be presented on a case study. The case study includes the determination of the average impact of an incident of a defined category on the railway infrastructure. The basic characteristics of the assessed incident are as follows:

Category:	A1 Collision of railway vehicles resulting in death or injury to at least 5 persons or large-scale damage
Number of incidents included in the analysis:	15
Nature of the cause:	human factor
Average number of deaths:	0.2
Average number of seriously injured:	0.33
Average number of minor injured:	3.8
Average delay of passenger trains:	941.82 min. (15.70 hours)
Average delay of freight trains:	83 min. (1.38 hours)
Average financial impact at 2018 prices:	436,162 €
Average occupancy of passenger trains:	66.55 person/train
Average freight weight of freight trains:	455 t/train

Table 5 contains the calculation of the total average impact of category A1 incident. Data for the calculation are taken from the methodology chapter.

Table 5. Average impact of category A1 emergency.

The nature of the incident impact	Unit impact	Number of units	Impact per item (€)
Killed persons	839,306 €/pers.	0.20 pers.	167,661.29
Seriously injured persons	202,968 €/pers.	0.33 pers.	66,979.35
Minor injured persons	26,202 €/pers.	3.80 pers.	99,566.13
Delay of passenger trains	11.33 €/pershr.	1,044.84 pershr.	11,834.50
Delay of freight trains	0.246 €/tonnehr.	627.90 tonnehr.	155.20
Financial impact at 2018 prices	436,162 €/inc.	1 inc.	436,162
Total economic impact			**782,358.93**

Source: own elaboration

The case study shows the procedure for determining the average economic impact of an incident occurring on the railway infrastructure. It is evident from the results that the average economic impact of one A1 incident is € 782,358.93. This procedure can be applied at other cases of incidents listed in the Methodology chapter. The subject of further research is supposed to be the calculation of the average economic impacts of other categories of incidents, this

calculation will be further refined by dividing the railway infrastructure into regional or national lines, where the average economic impacts of incidents on a regional line may be different from those on the national lines especially with regard to train occupancy or the level of security on the railway line.

4 Conclusions

The paper has been elaborated within the research project focused on taking into account the benefits resulting from increasing safety and reliability of the railway infrastructure in the economic evaluation of railway infrastructure projects. Specifically, the paper deals with identification of methodology for the evaluation of impacts caused by the occurrence of incidents on the railway infrastructure. The evaluation methodology is based on common principles of economic analysis of public investment projects and is based on data provided by the Departmental Methodology and data from the database of incidents. The proposed methodology includes, in particular, impacts on the health or lives of casualties involved in an incident, impacts in the form of delays of passenger and freight trains and impacts in the form of material damage and costs. The proposed methodology has subsequently been verified on a case study of the category A1 emergency. Follow-up research is supposed to include also an evaluation of other incidents that may potentially arise in the context of a lack of security and which could be prevented by the possible prior implementation of the new security systems.

Abstract. *Nowadays, dynamic progress in the field of modern technologies influences the development of unmanned aerial vehicles. The potential application area of this type of technology is constantly growing. The equipment is available to almost everyone and its use is becoming ever easier. The aim of the article is to present the possibility of using unmanned aerial vehicles in construction projects, for economic and time reasons, as well as to perform work in places that are inaccessible or too dangerous for humans. The article is the result of literature research, expert opinions and author's own analyses. The article draws attention to the fact that unmanned aerial vehicles may have a number of applications and unlimited possibilities. The use of modern technologies enables the flight at different heights and within a radius of many kilometers. Due to the fact that they are equipped with various types of cameras, they constitute a useful observation tool in various projects. The article presents thermal imaging tests in the area of construction and indicates that the value of energy consumption depends mainly on the effectiveness of insulation - increase in thermal insulation, while the effective way of their diagnosis is the use of thermal imaging camera. The authors of the article conduct research on a wide range of applications of unmanned aerial vehicles in construction projects.*

Keywords: *Unmanned Aerial Vehicles, Thermal Imaging, Modern Technology, Construction.*

1 Introduction

Unmanned aerial vehicles have been used in recent years in the civil market in a variety of economic sectors. They usually support aerial photography or filming. The equipment is available for almost everyone. In most cases, it is necessary to have ground-based staff to install or operate the platform itself and its systems. It should be noted that unmanned aerial vehicles combined with appropriate detectors and sensors are an excellent method of diagnosing and controlling the technical condition of objects. The combination of a thermal imaging camera and an unmanned aerial vehicle provides a useful tool for thermal imaging tests that can detect areas such as heat escapes from a building, thus preventing heat loss and significantly reducing building operating costs.

2 Unmanned Aerial Vehicles

Unmanned Aerial Vehicles (UAVs) is a generally accepted and used in engineering and science term. This term is also used by EUROCONTROL, the European Organisation for the Safety of Air Navigation, of which Poland has been a member since 2004 (Maj-Marjanska and Pietrzak, 2011). Unmanned aerial vehicles are defined by the U.S. Department of Defense as "powered, aerial vehicles that do not carry a human operator, use aerodynamic forces to provide vehicle lift, can fly autonomously or be piloted remotely, can be expendable or recoverable. It can carry a lethal or nonlethal payload" (Maj-Marjanska and Pietrzak, 2011). Unmanned aerial vehicles fly thanks to the use of two basic principles: lifting force and reactive torque. In this type of devices, counter-rotating propellers are used, which stabilise the fuselage during spinning. An unmanned aerial vehicle may be remotely piloted beyond visual line of sight (by an operator), or fly autonomously (by itself using an autopilot or another on-board system). However, most of them are piloted within their operators' line of sight. In both cases, ground-based staff are needed to install and operate the systems and the platform. The most important interface between the machine and the user is the radio system, the range of which is measured in kilometres. Many types of materials are used to construct modern unmanned aerial vehicles. The most popular include glass fibre, carbon fibre, as well as various types of plastics or metals. The materials listed above are characterised by a very good weight to strength ratio, but they are also very expensive. Modern aerial vehicles (military, civil ones) are the objects (systems) of very complex technical construction. They are usually built of many on board devices and subsystems, some of which make flying possible, while others provide the performance of specific functions within the combat mission. Their multifunctionality makes it possible, among other things, to perform aerial reconnaissance (Becmer and Romanek, 2011). The UAVs adopt different configurations and sizes - usually quadrocopters and octocopters, which are equipped with four or eight propellers respectively. The main propulsion systems include propellers and engines, which play a significant role here. The size of the propellers (blades) determines the lifting force, as well as the flight stability. The UAVs fuselage is stabilised by the counter- rotating propeller movement (Audronis, 2015). The selection of the right engines, which have to cope with the aerodynamic resistance, is an extremely important task. Thanks to them, UAVs can hover in the air for up to several dozen hours, uninterrupted.

UAVs can be equipped with various types of detectors, e.g. hazardous substances, automatic data analysis and transmission devices, as well as thermal imaging cameras. These devices are mostly used for filming and photographing. Real-time video playback makes unmanned aerial vehicles an ideal tool for, among other things, monitoring of dangerous goods transport routes or supervision of mass events (Audronis, 2015). The combination of UAV with such devices as digital cameras, directional microphones, thermal imaging sensors and network transmitters creates a number of new possibilities. They can be used both in site protection and in investment

control or logistics. They may be considered a tool that extends the range of offered services, but also significantly reduces operating costs. The potential for the use of aerial vehicles is being increased by the constantly developing structures of unmanned aerial vehicles and their resistance to atmospheric phenomena, greater range, as well as easier and more precise control. The dynamically developing market of telemetry and CCTV surveillance systems, with which unmanned aerial vehicles can be equipped, also contributes to the extended possibilities of using such devices (Bartkowiak, 2017).

3 Concept and Application of Thermal Imaging Testing

Thermal imaging, also called thermography, is a process of registering thermal radiation, emitted by physical bodies. The aim of the thermal imaging testing is, first of all, to present the image of heat emitted by physical objects in the Medium Wavelength Infrared (wavelength from about 900 to 1400 nm). This process makes it possible to record the thermal radiation emitted by all physical bodies in the temperature range typical of everyday conditions. It should be emphasised that objects do not need to be illuminated by an external light source. Such operation allows for a very accurate temperature measurement of objects in the places that interest us. Generally, thermal imaging testing is carried out in order to determine the level of emission and loss of thermal energy in, among others, industrial or residential buildings. This type of testing contributes to the determination of the object's thermal state. In addition, this method makes it possible to search for various inconsistencies and irregularities. Observation of heat emitted by objects in the field of vision is possible thanks to the use of a thermal imaging camera. It should be noted that all bodies whose temperature is higher than absolute zero are sources of radiation in the Medium Wavelength Infrared, i.e. infrared radiation with a wavelength of about 0.9 to 14 μm. Therefore, the functioning of a thermal imaging camera is based on a physical phenomenon concerning electromagnetic waves emitted by every body whose temperature is higher than absolute zero. Moreover, the intensity of infrared radiation is proportional to the body temperature.

The use of infrared has many advantages, especially when it is difficult to predict the temperature field distribution. Infrared has the advantage of producing accurate images of a thermal field in a non-contact manner. Even if it is difficult to determine where the problem is, it will appear in an easy to interpret thermal image.

4 Author's Own Research

Thermal imaging is more and more often used in various areas of life, including heat engineering, construction, power industry and medicine. A professional high-resolution thermal imaging camera should be used in order to obtain reliable results. Thermal imaging testing is common in the construction sector. The most frequently performed thermal imaging services during the year are, for example, detection of water leaks from the central heating system, leak detection and assessment of walls and ceilings dampness degree. Thermal imaging also makes it possible to search for leaks in underground pipe heating systems or to conduct testing. However, such projects require appropriate conditions and experience of the camera operator. Companies and individuals who own buildings control the water-tightness of facades and roofs to minimise heat loss. Improper construction may lead to significant financial losses over time, especially in winter. A tool that enables easy measurement in individual places is a thermal imaging camera. Using this type of camera, it is possible to determine the temperature in a place that may be leaky, *e.g.* between a window and a frame.

Thermal imaging may be considered one of the best ways to evaluate the quality of renovation work, such as thermal efficiency improvement of a building. Thanks to the combination of UAV and thermal imaging camera, this type of measurement can be performed even at considerable heights and in places not easily accessible to people. The advantage of this method is, first of all, accuracy, economy and a fast performance of measurements, thanks to which it is possible to rectify defects quickly (Kowalski and Bielecki, 2014). For this type of measurements it is also recommended to use radiometric cameras, thanks to which one may read the temperature in the given point of the registered infrared image.

The essential element during thermal imaging testing is the thermal transmittance, so the rate of transfer of heat through a structure, also known as U-value, calculated on the basis of thermographic measurements. Using the formula below we can calculate the heat transfer coefficient:

$$U_i = \frac{h_{si}(T_i - T_{si})}{T_i - T_e} \tag{1}$$

$$U_e = \frac{h_{se}(T_{se} - T_e)}{T_i - T_e} \tag{2}$$

$$U_{ie} = \frac{h_{si}\, h_{se}(T_i - T_{si})}{h_{se}(T_i - T_e) + h_{si}(T_i - T_{si})} \tag{3}$$

U- heat transfer coefficient
h_{si} - internal surface heat transfer coefficient
h_{se} - external surface heat transfer coefficient
T_i - temperature inside the building
T_e - temperature outside the building
T_{si} - internal surface temperature for partitions
T_{se} - external surface temperature for partitions (Kisilewicz and Wróbel, 2008).

Testing with the use of thermal imaging in open field may be subject to errors resulting from the so-called environmental factors. Direct sunlight strongly affects the readouts from the thermal imaging camera. Both sunlight and shade can affect the distribution of surface temperatures of the building for hours after the sun has stopped shining. Therefore, differences in thermal conductivity can lead to major temperature differences. Rain, which lowers the surface temperature of the material, is an equally dangerous factor. The evaporation of rainwater cools the material, which leads to a disturbed temperature distribution (Cwojdzinski, 2014)

When using a thermal imaging camera to detect insulation gaps or energy losses, it is best if the temperature difference between the inside of the building and the outside is at least +10 °C. With a high-resolution camera of high temperature sensitivity, the temperature difference can be smaller. Therefore, building inspections are often carried out in winter.

Currently, the authors are also conducting research on the application of UAV in the following areas:
- drawing up three-dimensional, detailed maps of the buildable lands, containing relevant data and information that may be of particular importance for the study phase and during conceptual preparation;

Testing with the use of thermal imaging in open field may be subject to errors resulting from the so-called environmental factors. Direct sunlight strongly affects the readouts from the thermal imaging camera. Both sunlight and shade can affect the distribution of surface temperatures of the building for hours after the sun has stopped shining. Currently, the authors are also conducting research on the application of UAV in the following areas:
- drawing up three-dimensional, detailed maps of the buildable lands, containing relevant data and information that may be of particular importance for the study phase and during conceptual preparation;
- ongoing monitoring of the construction site and work in progress;
- controlling and supervising the works performed by the contractor, as well as supporting persons responsible for supervision;
- control over the supply of building materials and specialist equipment to the construction site;
- simulations that will provide the client with information on the topography and suggest what the best place for foundations excavation would be;
- monitoring the location of construction equipment that changes its position on the site, as well as supervising employees, properly performing their assigned duties and complying with occupational health and safety rules.

The authors' preliminary research shows that the application of UAV in the above mentioned projects will improve the effectiveness of their implementation.

5 Conclusions

Decreasing prices and increasing availability result in growing popularity of UAV. Thanks to the autopilot function, the device is easy to operate for almost every user. Determining parameters such as flight speed and altitude, flight course, monitoring of objects or phenomena in hard to reach locations is not a major problem. The possibility of using UAV with thermal imaging or HD cameras makes unmanned aerial vehicles a useful tool for conducting various types of tests. The conducted tests indicate that it is possible to identify areas of heat loss in the building and assess the temperature distribution. Moreover, the result is fast, accurate and non-invasive thanks to the use of an unmanned aerial vehicle combined with a thermal imaging camera. It allows, among other things, to identify defects in buildings, such as missing insulation, mortar flaking, dampness problems, and to assess the condition of heating, ventilation and air-conditioning systems. Such measurements are not only accurate, but also very cost-effective. Regular autonomous UAV flights may provide in a short period of time current and detailed data concerning the implemented construction projects.

Multiple-Criteria Cost Analysis for Simulated Life Cycle of Office Building

Michał Krzemiński

Department of Production Engineering and Construction Management, Institute of Building Engineering, Faculty of Civil Engineering, Warsaw University of Technology,
Al. Armii Ludowej 16, 00-637 Warsaw, Poland, m.krzeminski@il.pw.edu.pl

Abstract. *The article presents an office building life-cycle estimating possibility with the use of multiple-criteria evaluation and simulations modeling techniques. The first part describes the life cycle of an office building with a focus on the places where it is necessary to make strategic decisions. These decisions are most often associated with (the incurring of) high financial costs. It is, therefore, necessary to choose a tool supporting the decision-making process. Presents for evaluation several criteria were developed, a number of which concern office buildings. It should be remembered that the multiple-criteria assessment means not only the criteria but also weights which are assigned to them. The article discusses different ways of assigning weights to criteria, e.g. the Simos method. The use of several different methods of multiple-criteria evaluation was suggested, for example the method of weighted sum, the ideal point method and the entropy method. The analysis was based on simulation models. The full cost model was built in MS Excel. For modeling the Crystal Ball software was used. The software applied allowed not only to determine confidence in the selected scenarios, but also to point to the criterion or factor which has the greatest impact on the final result. Such information can be obtained through the use of sensitivity analysis.*

Keywords: *Office Building, Life-Cycle, Multiple-Criteria Analysis, Crystal Ball.*

1 Introduction

The definition of the life cycle of an office building can be fully based on the definition of the life cycle of a building as such. According to the definitions in ISO 15686-5: 2008, the life cycle of a building can be described as successive, interrelated periods of time between the selected time and the time of withdrawal or disposal of the building, in which certain criteria are assessed (*e.g.* costs, energy consumption, etc.).This period can be specified in the analysis, *e.g.* as a period equal to the time of renting or owning, or may cover the entire life cycle of a building, while the life cycle period is subject to the definition of the scope and specificity of operational requirements for a given building component. The definition includes a reference to the criteria of assessing the life cycle of an existing building. In the article, the author approaches the topic through the prism of strategic decisions accompanying the entire period in which an office building project is considered. These decisions are made throughout the entire life cycle of the project, at the initial, design, implementation and operational stages.

2 Strategic Decision Points

The most important points of strategic decisions, according to the author, are listed below. They have also been briefly characterized.

- Location Selection - different types of places: best, good, average, cheap, dedicated office buildings (*e.g.* near/in logistics centers ...).

doi:10.23967/dbmc.2020.202

- Widely understood construction technology that often affects the initial cost of the object. The cost is associated with the standard, which in many cases is the result of the location in which the object is designed.
- Permanent/Short-term tenants. There are various office buildings. In many cases, the assumption is that they are built for long-term tenants who are also strategic tenants and who often attract smaller ones. However, there are more and more advertisements of objects in which space is sublet for short periods of time, sometimes even for days.
- Renovations/Modernizations. The aims of renovation / modernization are an important issue. The existence of an office object is only justifiable when it brings profit. It is known that in time a building ceases to be as attractive as it was at the beginning. The aim of renovation, as it is understood by the author, is mainly to maintain the standard and output functionality. The aim of modernization, however, is to change the object in a way which makes it possible to place it at the top of the list of attractive objects in a given environment, which is its reference environment.

3 Renovations/Modernizations

According to the author, the scope of renovation and modernization works can be divided into four basic types, which are listed below. A set of criteria was also developed to evaluate these variants.

- basic renovation - aimed only at maintaining the object in working condition,
- full renovation - aimed at restoring the building to its original condition,
- inexpensive modernization - aimed at making the facility slightly more attractive,
- expensive modernization - aimed at restoring the facility's full attractiveness.

4 Criteria for Variants Assessement

The set of criteria includes four elements. The first three measurable criteria, which do not require any special ranking scale, are: cost, given in relation to a square meter of rentable space, time - given in days, and forecasted rental income, also given in relation to a square meter of rentable space. For the last criterion, which is the scope of works, a four-point scale was adopted. A description of the scale is presented below. It should be noted here that the increasement of scope may result in entering more and more serious construction works. With proper planning, the permit obtaining process and the design process should not pose a problem, but the construction process itself may already be problematic as unplanned delays, like on any construction site, may occur.

- 1 - the smallest scope of renovation and modernization works understood as the exchange of those elements only which are necessary to be replaced in order to meet the requirements, more technical than aesthetic. In this case, there is rather no risk of delays.
- 2 - is the scope of renovation which is characterized by incurring the expenditure necessary to restore the object to the condition of commissioning. It assumes greater work effort than in the first case as well as the probability of greater costs generated by the need to replace elements that admittedly meet the technical requirements but no longer meet the aesthetic requirements. Sometimes in the case of, *e.g.* facades, this can already be a high cost within the meaning of a significant range. Slight delays are

possible here.

- 3 - this note corresponds to renovation / modernization in which, apart from bringing the object to its full technical and aesthetic usability, minor changes are also made to the object. Such changes are, for example, a slight reconstruction of the facade including the modernization of the entrance portal. Changes can also be carried out inside the building and may involve, for example, the rearrangement of partition walls. In this case there is a risk of delay, which in extreme situations may become perceptible.
- 4 - such a note should be attributed to the renovation / modernization, which in principle will carry a significant scope of construction works. It may include works related to the complete reconstruction of the façade or to the modernization of communication routes, *e.g.* the addition of subsequent elevators. Such renovation/modernization can be considered as a reconstruction of the facility which carries a significant risk of delays.

5 Weight Scenarios, Assigning Weights Using the Simos Method

The original Simos method is based on the following three steps. First step is when the Decision Maker (DM) gives a set of cards with the name of one criterion the names of various criateria and a set of white cards. The number of white cards depends on the DM. In the next step the DM is asked to rank the cards from the most to the least important. If two cards are of the same importance they should be placed in the same line. In the last step the white cards are placed between the cards with the names of criteria. The assumption is that if two white cards are placed between criteria A and B, it means that A is three times more important than B. Basing on this we can describe Siomos algorithm in four steps. The first is the creation of the rank. Next, the distance between criteria is established by using the white cards. Step three is the calculation of non-normalized weights. In the last step normalized weights are calculated. The most important card should be placed at the bottom and the least important on the top of the table. In figure 1 below we can see the example of the usage of this method based on previously described criteria.

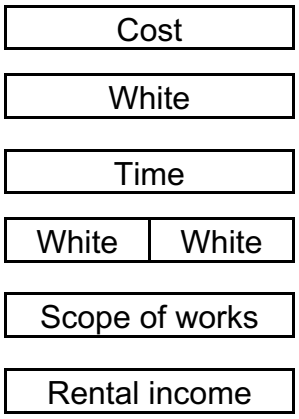

Figure 1. Cards order according to Simos method.

Table 1 below shows the results of calculations done with the use of Simos method.

Table 1. Criteria weight calculations with the use of Simos method.

	Cards number	Position	Non-normalized Weights	Normalized weights
Cost	1	1	1	0,06
White card	1	2	...	...
Time	1	3	3	0,18
White card	2	4;5	...	...
Scope of works	1	6	6	0,35
Rental income	1	7	7	0,41

In the fourth line of the table we can find two white cards. The author's assumption was that these two cards make bigger span between the criteria.

6 Multi-Criteria Assessment Methods

Weighted sum and ideal point methods are among the most basic methods of multi-criteria assessment. They are widely known and, according to the author, there is no need to quote their definitions and descriptions. The entropy method described below is more interesting.

The entropy is a thermodynamic parameter of the state of a system. However, in the statistical interpretation, it determines the degree of not ordering the harvest (or the degree of uniqueness). According to the Polish language dictionary, entropy in thermodynamics means the amount equal to the sum of the quotients of the heat portion taken by the system in a reversible process. In information theory it is the measure of indefiniteness, chaos, a degree of disorderness. The Entropy method allows us to estimate the validity of the analysed criteria describing the options in question based on the discrepancies in each. In theory, the information was first applied by Claude Shann and later refined by B. McMillana and L. Breiman. Based formula in entropy method is:

$$E_j = -\frac{1}{\ln n}\sum_{i=1}^{n} p_{ij} * \ln p_{ij} \tag{1}$$

where:
j - number of criterion,
i - number of assessed variant (from 1 to n),
p - assessment value.

It is easy to notice that if all the criteria have the same value of assessment, the entropy equals 1. For weights vector modification we use volatility level z based on following formula:

$$z_j = 1 - E_j \tag{2}$$

Criteria weights vector is modified by using:

$$w_j^0 = \frac{\frac{z_j}{\sum_{j=1}^{m} z_j} * \bar{w}_j}{\sum_{j=1}^{m}\left(\frac{z_j}{\sum_{j=1}^{m} z_j} * \bar{w}_j\right)} \tag{3}$$

where: $\bar{w}_j$ – weights established by DM, w_j^0 – new weights.

7 Example

Analyzed example concerns medium class office building located in Warsaw in range of 5 km from Palace of Culture and Science. Unnecessary data was collected in table below.

Table 2. Assessed investment options matrix.

	Variant 1	Variant 2	Variant 3
Cost	180	210	270
Time	15	40	60
Scope of works	1	2	3
Rental income [monthly]	50	55	75

Standarized grades used for assessment are in below table number 3.

Table 3. Standardized grades matrix.

	Variant 1	Variant 2	Variant 3
Cost	0,47	0,54	0,70
Time	0,20	0,54	0,81
Scope of works	0,27	0,53	0,80
Rental income [monthly]	0,66	0,60	0,44

The rental income were variated with Crystal Ball software use. On below figure there is example for rental income in third variant. Author made assumption that the best will be triangular distribution I range -10% to +5%.

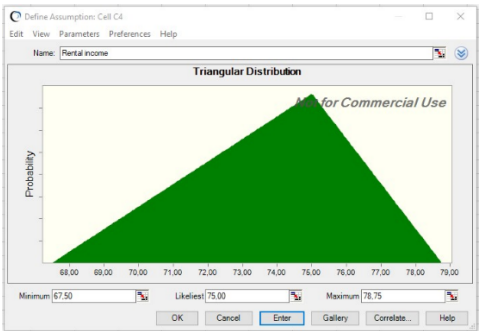

Figure 1. Triangular distribution for rental income variant 3

Calculation results were collect in below table 4. As it was previously mentioned calculation were made with three method use. Weighed sum, ideal point and entropy method. With accordance to all of this three method order was the same. The best was investment variant number one(minimum was looking for). Probably because cost of renovation and rental cost were going together proportionally, but the risk of delay grow quickly in meaning scope of works criterion. The result also shows how important this criterion actually is.

Table 3. Standardized grades matrix.

	Variant 1	Variant 2	Variant 3
Wighted sum	0,43	0,56	0,65
Ideal point	0,29	0,54	0,71
Entropy method	0,17	0,34	0,48

8 Conclusions

The article defines the life cycle of a building object together with the definition of strategic decision points. The assessment of the points regarding the decision on renovation or modernization was mainly considered.

A set of criteria have been developed to make the choice of the right option easier. In addition to the criteria, a weighting scenario was created with the use of Simos method. The entropy method used in the assessment was also described. During calculation, the expected rental income was established with the use of CrystalBall software.

The calculations made for the presented example show that this approach to the subject, in which various advanced methods are combined in multi-criteria assessment, gives good results and can be used assessing renovation and modernization options for office buildings.

Possibilities of Reducing Energy Costs in the Life Cycle of Office Buildings

Edyta Plebankiewicz, Krzysztof Zima and Damian Wieczorek

Department of Construction Management, Faculty of Civil Engineering, Cracow University of Technology, Warszawska 24 St., 31-155 Kraków, Poland, eplebank@L3.pk.edu.pl

Abstract. *Buildings absorb energy at every stage of the life cycle. The paper analyses the phases of the life cycle of an office building indicating the possibilities of reducing energy consumption. In particular, attention was paid to the most energy-intensive phase, that is the use phase. Both simple actions and more advanced solutions allowing to reduce the energy demand of a building during the use phase are characterized. For an exemplary office building, life cycle costs were calculated taking into account selected solutions improving energy efficiency.*

Keywords: *Life Cycle Cost, Office Buildings, Energy.*

1 Introduction

Buildings are the largest energy consumer in Europe, utilizing about 40% of final energy, of which more than 55% is used for room heating and cooling. At the same time, it is estimated that about one third of the world's energy consumption is related to the use of office and residential buildings. An additional problem is that most of this energy is supplied from non-renewable sources, which contributes to environmental degradation and significant heating/cooling costs (Arendt *et al.*, 2015). It should also be remembered that oil and gas resources are limited and no longer so readily available (Firląg, 2018).

The aim of the paper is to analyse the possibility of reducing energy consumption in office buildings in all phases of their life cycle.

2 Energy Consumption of Buildings in the Various Life Cycle Phases

From the point of view of energy consumption and environmental impact, the life cycle of a building involves the following phases:

- the manufacturing the products necessary for the construction of the building,
- the construction of the building,
- the use of the building,
- the end of the life cycle.

Each of these phases entails energy demand. Detailed modules related to energy demand, being part of particular phases of the building life cycle are depicted in Table 1.

The energy consumption in the different phases of a building's life cycle depends on many factors. However, in general, when analysing the energy consumption of buildings in Poland, it is estimated that at the stage of construction of a building the energy consumption amounts to about 10%, at the stage of use (with implementation performed according to the current standards) – to about 72%, for the needs of renovation – to about 15% and for the demolition of the building – from 1 to 3% of the total accumulated energy demand in relation to the life cycle of the building, as illustrated in Figure 1.

doi:10.23967/dbmc.2020.111

Table 1. Phases of the building life cycle.

Life cycle phase	Life cycle modules
A – Product phase	A1 – Extraction and manufacture of raw materials
	A2 – Transport
	A3 – Manufacturing the product
B – Construction phase	B1 – Transport
	B2 – Construction
C – Operation phase	C1 – Usage
	C2 – Maintenance
	C3 – Repair
	C4 – Replacement
	C5 – Renovation
D – End of life cycle phase	D1 – Demolition
	D2 - Transport
	D3 – Recycling/reuse
	D4 – Stockpiling

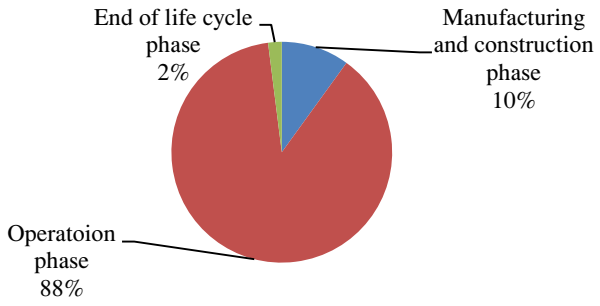

Figure 1. The energy consumption of buildings.

Since the greatest amount of energy is consumed in the operation phase of the building, therefore this issue is addressed mainly in the present paper.

However, the other phases cannot be ignored. In general, the energy consumed by the building include the following:

- embedded energy, that is energy accumulated in the building during its construction in the form of energy used for the production of materials, transport (A – product phase), building-in processes (B – construction phase) and energy necessary to perform repairs and maintenance (C – operation phase);
- operational energy, namely energy used for heating, ventilation, air conditioning, lighting and energy (C – operation phase);
- processing energy, meaning energy necessary for the demolition of the facility and waste management (D – end of life cycle phase).

The first phase of the building life cycle is related to the manufacturing building materials and products necessary for the construction of the building. According to the Guide of the Building Research Institute (Adamus, 2014), approximately three billion tonnes of raw

materials are used each year for the production of building materials, which accounts for 40-50% of global production. Characteristically of the construction industry, it is estimated that it uses more than 10 000 different types of materials, many of which are obtained through the exploitation of non-renewable resources. Table 2 shows the amount of embedded energy for common building materials, as revealed by European and US sources.

Table 2. The amount of embedded energy for common building materials.

Material	Embedded energy in MJ/kg, according to:	
	European sources	US sources
naturally dried wood	0.5	0.3 ÷ 1.1
processed wood	8 ÷ 24	8 ÷ 24
plastic materials	80 ÷ 110	55 ÷ 120
local stone	5 ÷ 6	0.8
prefabricated concrete	2	2
ceramics	2.5 ÷ 8	2.5 ÷ 7
glass	12 ÷ 26	14 ÷ 30

Table 3 depicts the amount of energy associated with the transport of building materials. As can be seen from this summary, the largest energy consumption is in road transport.

Table 3. The amount of energy associated with the transport of building materials.

Type of transport	Energy consumption in MJ/t:	
	Canada	Great Britain
road transport	1.18	4.50
rail transport	0.49	0.60
water transport	0.12	0.25

It should be emphasized that the proper selection of construction materials and products has an impact not only on the energy consumption during their manufacture and transport, but also on the energy demand in the operation phase, related to the need for repairs and renovations which are largely dependent on the characteristics of the material itself.

In general, the amount of the embedded energy of a building can be minimised by applying the following principles:

- design of objects with a long service life, made of durable materials and not requiring repair or overhaul;
- ensuring that the different materials can be easily separated from each other for repair and demolition;
- the use of locally available materials;
- the use of materials with a high recycling rate;
- avoidance of materials generating troublesome waste;
- minimising the use of highly energy-intensive materials;
- preference for renewable energy materials,
- the use of materials that reduce energy consumption during the operation of the building, which indicates the choice of sustainable materials.

3 Energy Consumption in Office Buildings at the Operation Stage

In every building, by far the highest energy consumption occurs during the operation phase. A specific feature of such buildings as commercial facilities is that their energy consumption per square metre is on average 40 % higher than that of residential buildings. Their electricity consumption is particularly high, due to complex lighting, air conditioning or ventilation systems. Also, the climate in countries such as Poland, for example, means that in standard buildings the heating season lasts 220-240 days a year, hence 70% of energy in buildings is used for heating and cooling.

Moreover, in comparison to other buildings, modern office facilities have a specific consumption of electricity associated with their high demand for energy needed to power computer and other office equipment. Figure 2. illustrates the energy consumption of an average office building in 2012. The data comes from the research conducted by an institution established in the USA, dealing with the collection and analysis of data on energy issues: the U.S. Energy Information Administration.

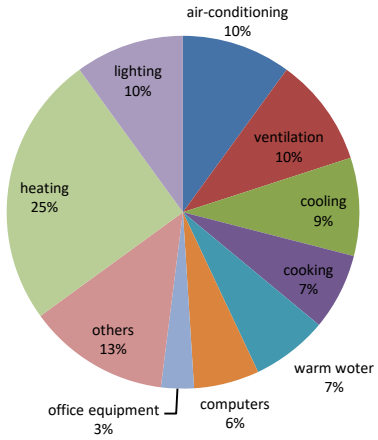

Figure 2. Energy consumption of a commercial building in 2012.

As Figure 2. reveals, the highest energy consumption in 2012 was due to the demand for heating of the building, while the power supply of office equipment and computers accounted for less than 9% of its total consumption. Moreover, forecasts for 2050 show that although demand for energy for heating and lighting in office buildings, for example, will decrease significantly, energy demand for computer hardware and other office equipment will increase by more than 20% (Figure 3).

Such specificity of office buildings should probably be one of the important factors when considering the possibility of reducing energy consumption. This does not mean, however, that no action should be taken to reduce the energy required for heating, cooling or ventilation.

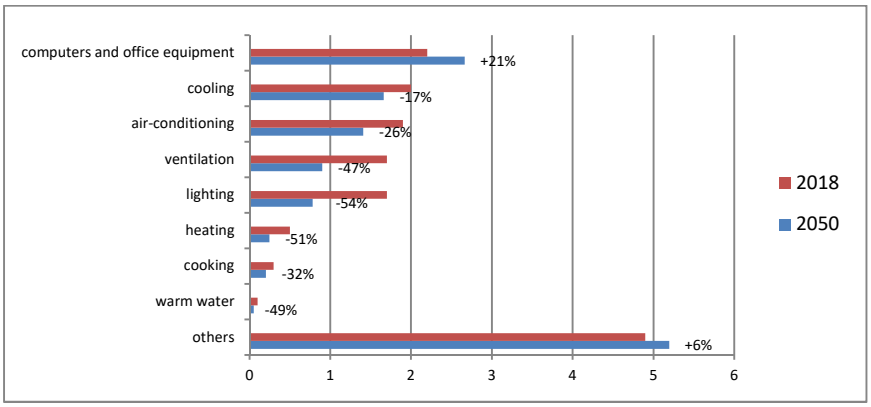

Figure 3. Current and planned energy consumption in office buildings (kilowatt hours per 1square foot).

4 Opportunities for the Reduction of Energy Consumption

Research results indicate that almost 75% of buildings are low energy efficient, which means that there is still significant potential for rational energy savings in buildings. According to the European Commission, a statistical building in the European Union countries consumes 15-25% more energy than it needs. In Poland, on the other hand, energy consumption in buildings is more than twice as high as in other EU countries. The Polish economy is also about 2.7 times more energy-intensive than in the European Union and 5 times more so than in Japan. Improvement of energy performance of buildings is therefore the biggest challenge for the coming decades (Skanska Property Poland, 2016).

Actions reducing energy consumption in buildings can be linked both to relatively simple as well as more advanced solutions aiming at decreasing heat loss in a building.

It can be observed that the largest heat losses in a building are related to the heat transfer through the building envelope, where the largest losses are those through glass envelope, such as windows and doors, amounting to about 60-70% of the total energy balance. Ventilation, on the other hand, causes losses of 30-40%. Therefore, it is necessary to minimize heat losses, while maximizing the use of energy gains.

Heat losses can be reduced by the following improvements in (Ministry of Investment and Economic Development in Poland, 2018):

- ventilation - application of mechanical ventilation with heat recovery (recuperation) and high tightness of the building,
- windows and doors - use of energy-saving woodwork,
- external walls - appropriate wall insulation,
- roof - appropriate roof insulation,
- floors on the ground - adequate insulation of the floor on the ground,
- thermal bridges - use of solutions minimizing the occurrence of thermal bridges.

In the case of existing buildings, this will involve thermal upgrading, such as replacing window frames, replacing central heating systems, or optimising heating by insulating hot water pipes, heat and small heat pump systems in the radiator. A simple change in habits can also lead to a reduction in energy consumption, such as (Kopietz-Unger, 2012):

- appropriate setting of air temperature in rooms, up to approx. 10%,

- exposing the radiators, about 10%,
- lowering the temperature of domestic hot water to approx. 6.6%,
- use of aerators, approx. 8%,
- the change from rib radiators to convection heaters, about 14%.

More complex solutions include the use of alternative solutions for heating water or building interiors. The increased use of alternative energy sources contributes to the development of low-carbon energy sources. Such solutions include the efficient use of solar collectors to heat water. Studies on the benefits of using natural energy sources, in particular solar panels, are presented in (Kale *et al*., 2018). The following conclusions can be drawn from the project:

- energy-saving approach to the solar collector system requires an initial investment of 1.3-16%,
- with minimal initial investment in solar panels, one can save 4.3% of the total cost within 30 years,
- with the proposed solar panel, 54 - 64% of the total cost can be saved within 25 years.

The use of solar systems can be effectively used to cool rooms. The solar system absorbs solar radiation and converts it into heat energy, which is subsequently transferred to a cooling exchanger and then to a central heating system for cooling.

An interesting solution is the use of photovoltaic cells to produce electricity. In Poland, from 1 m2 of solar cells it is possible to obtain up to 100 kWh of electricity. The condition is that the generated energy will not be used for water heating and heating purposes.

The solution used increasingly more often is the use of cooling and heating ceilings. Such ceilings use the thermal mass of the building to act. Pipes are placed in the concrete ceiling to transport cold and hot water. At night, the system brings coolness to the ceilings, and during the day, the cooled surfaces take heat from the building and thus lower the room temperature. This solution not only ensures comfort and healthy microclimate in rooms, but it also allows to reduce energy consumption. Unlike traditional air-conditioning systems, they operate in temperatures close to the environment, which contributes to increasing the efficiency of the source of heat and cold. An analysis performed on the example of a London office building with a total area of 1000 m2 showed that this type of ceiling provides annual savings of between 12 and 31% compared to conventional installations in the form of fan coil units, displacement ventilation or chilled beams of similar capacity. Manufacturers assure that the investment costs are low, with savings of 10-30% compared to conventional air conditioning systems and low maintenance and service costs up to 30%, compared to conventional air conditioning systems.

Modern office buildings contain rooms of a different character, such as: halls and reception areas, atria, server rooms, engine rooms, garages, offices, conference rooms, restaurants, retail and service premises. Each of them requires a separate system to guarantee different levels of comfort and safety. In order for all these elements to constitute a coherent and well-functioning whole, advanced automatic control and regulation systems, BMS (Building Management System), should be applied in office buildings, which in some cases are supplemented with functionalities allowing for energy consumption management, that is BEMS (Building Energy Management Systems). Their basic function is to ensure proper indoor environment parameters (user comfort) with rational energy consumption. According to the data from Distech Controls Inc., the manufacturer of building automation systems,

Building management systems never cost more than 1% of their value. However, on average 45% of energy consumption depends on their quality, that is 25% of the value of the investment over the 30 years of the life cycle of the building. Depending on the type of the building, lighting consumes 30-40% of the electricity, of which 10-58% can be saved. Over 65% of energy costs is absorbed by heating and air conditioning, and potential savings amount to 8-45%.

5 Cost-Benefit Analysis of Solutions that Improve the Energy Efficiency Standard of an Office Building

Simulations concerning analyses and benefits resulting from energy-saving construction were performed by the Polish National Energy Conservation Agency on the example of buildings of different purpose (Węglarz, 2017). One of the buildings under analysis was an office building. The model office facility selected for the analysis was a 6-storey building with a usable area of 2 124 m^2. On the basis of simulations and additional own analyses, the authors performed calculations which enabled the assessment of costs and benefits resulting from the application of solutions that increase the energy efficiency of the office building.

For standard buildings, the classic and most frequently used installation solutions were adopted, that is water heating systems with convector heaters and boilers for coal, natural gas, fuel oil, LPG or the application of a heat substation with a connection to a district heating network. In a high standard building, it was assumed that, in comparison to a standard building, the insulation thickness of the envelope was increased by 20 cm and that windows with a penetration coefficient of 0.5 W/(m^2·K) were used.

In addition, for the model building with energy-saving standards, the following were applied: higher thickness of pipeline thermal insulation, better quality control valves and thermo-valves, water-saving fittings in the hot water installation and mechanical ventilation with heat recovery of 85%. For the building with collectors, the use of flat solar collectors with an area of 32 m^2 was predicted.

Table 4. presents the costs of energy depending on its source, accepted for analysis.

Table 4. Energy costs depending on the source of energy (Węglarz, 2017).

Source of energy	External costs	
	EUR/MWH	EUR/GJ
Coal	11.00	3.06
GZ50	0.42	0.12
Electricity	57.00	15.83
Fuel oil	1.54	0.43
LPG	1.54	0.43
Network heat	10.40	2.89

The results of simulation analyses for an office building and coal heating are presented in Table 5.

Table 5. Results of simulation analyses for an office building for coal heating

	construction cost [EUR]	Annual energy cost [EUR/year]	LCC [EUR] (30 year; r=5%)
Standard building	1 373 692	8 428	1 915 361
High-standard building with cooling and heating ceilings	1 432 377	6 730	1 900 120
High standard building with collectors	1 506 222	1 966	1 868 795
High standard building with heat pump	1 536 054	2 096	1 731 453

6 Conclusions

Buildings absorb energy to varying degrees at every stage of their life cycle. By far the greatest demand for energy occurs during the operation phase of a building. Reducing energy consumption during this phase is necessary for both economic and environmental reasons.

The life cycle cost analysis of an office building conducted in the present paper showed the effectiveness of the use of cooling and heating ceilings, solar collectors and heat pumps.

1 Introduction

In modern pro-ecological architecture, many trends can be identified, which lead to the design of architecture in accordance with the idea of sustainable development. One of them is circular design. The main assumption in this design approach is to use materials that can be obtained in close proximity to the design area, with the possibility of their reuse, or using bio-materials. According to this, structural and material solutions of modern buildings are an important element of considerations in accordance with the idea of sustainable design, in which the aim is to minimize their negative impact on the environment. These searches turn towards low-tech technology, which uses natural and low-processed materials, which are possible to obtain in selected locations. Construction in the raw earth technology is a modernization of the traditional technology, in which it is possible to apply pro-ecological values associated with the used material. The use of earth as "waste" from the excavated material after excavation of the foundations of the building, for the construction of external and internal walls of the designed object is an important element inscribing the project in the idea of circular design. The paper presents research on insulation properties of walls in an experimental earth building located in

Pasłęk in Poland. The aim of the research was to determine the potential of the applied raw earth technology in a local climate. The accepted design assumptions for the veranda design were verified due to the effects achieved in the empirical research on the thermo-humidity conditions in an experimental building. On the basis of the conducted research with the use of specialized tools, the positive and negative sides of the selected technology and building material were determined within the scope of a veranda designed as a heat accumulating element.

One of the trends of contemporary architecture is the use of traditional technologies and among them diverse raw earth solutions, wooden structures supplemented with straw bale walls, and use of various recycled materials.

In an experimental building described below located in the Ecological Park in Paslek in Poland the following types of raw earth technologies were used: rammed earth in formwork, earth pressed blocks, strew clay blocks and clay render. The project was carried out at the Faculty of Architecture of the Warsaw University of Technology by the team: prof. Teresa Kelm, arch. Jerzy Górski PhD, arch. Marek Kołłątaj, Dorota Długosz-Nowicka PhD, who cooperated on technological issues and carried out laboratory tests. Structures and installations designers participated in the preparation of the Construction Design.

Preparation of the project and construction of the building became possible thanks to the grant from the Ministry of Science and Higher Education in the years 2005 – 2008, involvement of the city authorities of Pasłęk and with the help of sponsors. The municipality of Pasłęk, had been interested in ecology for many years, made the plot available for construction to promote the idea of ecological construction in its area. The building was commissioned in 2012. and handed to the city. The building is administered by the management of the Ecological Park and used as an information, educational and exhibition centre.

The construction of the building was used for didactic programme on ecological construction with the use of raw earth technology, carried out in the form of seminars, practical classes, workshops and local inspections on the construction site. Also finished building is an object of further research and observation on the behavior of the structure during its exploitation. The results of such examinations will be shown in this paper.

2 Design Assumptions and Implementation Details

2.1 Spatial and Functional Characteristics of the Building

The building is detached, one-storey, without basement and is roofed by a single pitched, north-facing roof covered with extensive greenery. It is located in the south-eastern corner of a plot of land with an area of about 1 ha. It is flat meadow at a side of local lake, used by the Ecological Park to organize in summer outdoor events. In order to achieve the energy-optimal surface area of the facades, the longer axis of the building is located in the east-west direction. The facade with the largest surface area and the largest number of glazing is on the southern side, the facade on the northern side is smaller and has no openings. The main entrance to the building is located on the western side. It leads through the vestibule to the one-spatial didactic and exhibition hall located in the eastern part of the building and connected through two glass doors with a large fully glazed veranda located within the southern facade. The main room is connected with the external terrace located along the eastern elevation of the building and with the utility part

(kitchenette, toilet) located in the western part. The development area of the whole building is 105 m^2, usable area 75.5 m^2 and cubic capacity 250 m^3.

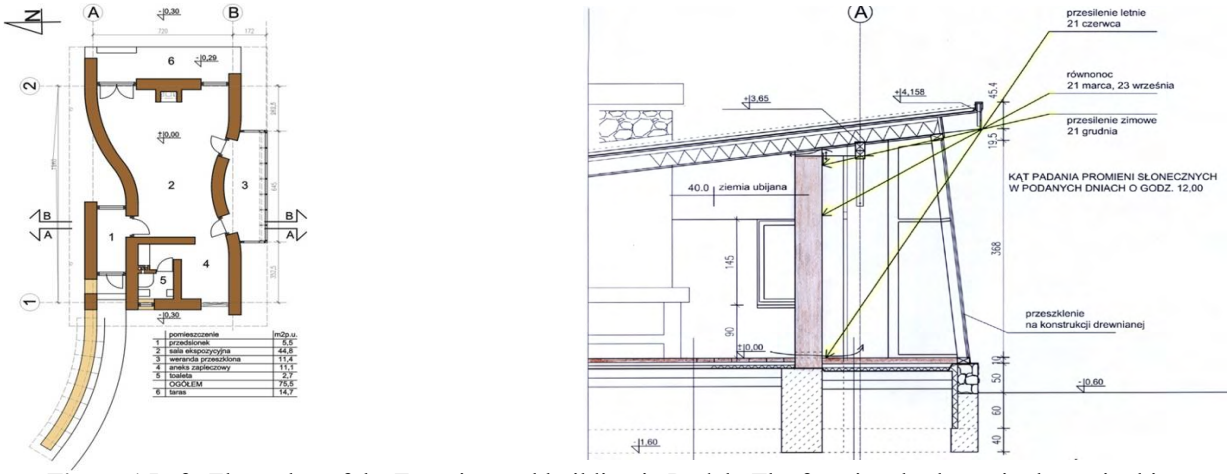

Figure 1. Left: Floor plan of the Experimental building in Pasłęk. The functional scheme is shown in this drawing 1. Vestibule, 2. Exhibition hall, 3. Veranda, 4. Back room annex, 5. Toilet, 6. Terrace; Right: Section through the veranda and the accumulation wall. The eaves is designed to shade the accumulation wall in summer. (accumulation wall not thermally insulated).

2.2 Construction Solutions

In the project, energy-efficient solutions were applied during both the implementation and the operational phases. The technology of rammed earth in the formwork was applied to the structural and external walls using the soil from the excavations on the plot (reduction of the costs of transport of construction materials). They are supplemented with an internal layer built of straw-clay blocks and thermal insulation. The partition walls are made of pressed earth blocks.

The foundations of the building are benches and foundation walls made of reinforced concrete and thermally insulated with foamed polystyrene inserts, and damp-proof with bitumen membrane. Taking into account the necessity of protecting the earth mass of the walls against water and ground dampness, the aboveground wall is elevated about 50 cm above the ground level and supported by a concrete foundation finished with natural stone.

The external walls are designed and constructed as three-layer partitions. The load-bearing layer is situated outside in form of rammed earth monolithic walls compacted in formwork using a pneumatic compactor. The raw material (soil from site) was supplemented - in order to obtain a mixture meeting the technical requirements for this type of elements - with modification additives like sand or gravel. Moreover, due to the contact of the walls with the air moisture, a stabiliser - 6 to 8 % by weight of cement - was added to the earth's mass. The load-bearing layer is topped off with a reinforced concrete ring beam with anchors for fixing the wall plates (roof structure). The internal layer of the partition was made of blocks made of clay and straw compacted mass, and the gap between the layers was to be filled with cellulose backfill (Ecofiber) replaced by mineral wool due to the price. Mineral wool is also used to insulate the roof. The inner blocks are finished with earth plaster to regulate the humidity of the interior or have a natural surface impregnated with varnish in order to stop the material from

chipping. Partition walls are made of blocks made of pressed earth without any additional finishing. The floors on the ground were damp insulated with bitumen membrane laid on the underlay concrete and thermally with polystyrene. A broken stone slab floor with concrete subfloor is a thermal accumulation mass.

The unconventional order of external wall layers (rammed earth load-bearing layer as external one) was dictated by research considerations - verification of the influence of climatic factors (humidity from the air) on the earth mass and of water vapour permeation through the partition layers, determination of the dew-point, etc. It was assumed that the external surface of the compacted earth wall would be left without any finishing, as a natural illustration of an unusual technology. External walls above the window openings are made as wooden frame walls, insulated with mineral wool with internal vapour-barrier insulation, external wind-barrier insulation and wooden boarding on both sides. The roof is a single pitched, with wooden wall plates, purlins and rafters. A layer of weather-resistant tundra greenery was laid on the roof. In order to protect the rammed earth walls from direct rainwater, the roof eaves were extended from the wall line at a distance of not less than 80 cm.

The fully glazed veranda with wooden construction has a southern sloping wall. It is separated from the main room by a thick, non-thermally insulated accumulation wall made of rammed earth and room is connected with veranda by two glass doors. The windows and exterior doors are made of wood. The building has a sewerage system, cold and hot water, and electricity. The main source of heating is a freestanding wood-burning cast iron fireplace.

Figure 2. Left and in middle: View of the experimental earth building located in the Ecological Park in Pasłęk. Right: The inside of the veranda. Wooden structure glazed with low-emission composite panes. On the right there is an accumulation wall made of compacted raw earth and a door connecting with the main hall.

2.3 Energy Performance of Building Components Using Raw Earth Technologies

The experimental building in Pasłęk was designed in terms of space and materials so that the assumed construction solutions could be used for later analysis and research. At the design stage, theoretical calculations were carried out, which can later be compared with the achieved effects .

The characteristics of the basic earth and insulating materials of external walls are presented below.

The thermal conductivity coefficients of λ [W/mK] of the materials used in the walls were as follows:

- Heavy earth (for rammed earth in formwork) – 0,870
- Light weight (straw and clay blocks) – 0,350

- Cellulose insulation (Eco-fibre)/(Mineral wool) -0,040

Building material solutions of the other elements (ceilings, floor, glazing) complement the design's assumptions concerning energy efficiency. The coefficient of heat transfer through the partition for the external wall - U0 (1/Rt) - was 0.34 W/m^{2}K. The designed building was classified as a public utility building, so the expected heat transfer coefficient through the partition complied with the regulations of that time. A significant role in the energy management of the object is the passive use of solar energy. This is achieved by using a glass veranda on the south side, glazed terrace doors and windows. The amount of solar energy penetrating into the room in the form of short wave radiation depends on the size of the glazing and the type of glass in the set, especially the type of external glass. Solar energy is stored in the compacted earth wall (without thermal insulation) between the veranda and the main room and in floors made of materials that well store heat - stone and in partition walls made of pressed blocks. The stored heat is retained in the interior by the use of double glazing with low-emission internal glazing and insulating properties of the external partitions.

2.4 Inspections and Technical Examinations

The building was subject to local inspections during its execution and operation by the design team and other persons from the Faculty of Architecture of the Warsaw University of Technology.

The building has been used in various ways for over 7 years and direct feedback from users was important and it shows that the internal climate is very comfortable. During the heating period, a wood-burning stove was sufficient as a source of heat. Solid walls and flooring were a good heat accumulator and the heat buffer in the glass veranda accumulated heat on sunny days in cold period and supplemented the overall heat balance. Multi-layered external walls and roof containing thermal insulation assured even internal temperature both in hot and cold periods.

During inspections also the structural and construction problems were observed. There are no signs of uneven settling, i.e. the dimensions and structure of the foundations are correct. The visible, stone-covered plinth is in a very good condition. Above the plinth a wall made of compacted earth does not show any negative effects of climatic factors. The principle of protecting the rammed earth from moisture by raising the walls above the stone plinth and protecting them from direct rainfall by roof eaves has proved its worth.

Site inspections in 2018 apart from construction problems, also took into account the issues of internal microclimate, insulating quality of partitions and energy management. In 2019 we repeat measurements incorporating some modifications as the result of previous experiences.

The measurements were carried out at different times of the year (spring, summer, late autumn). Field tests were carried out in the following methods:

- examination of heat transfer through external partitions with thermal imagine camera for identification of possible thermal bridges,
- outside the building, measuring air temperature, wall surface temperature, humidity, insolation, wind speed,
- inside - measuring air temperature and humidity, wall surface temperature and humidity.

The building has been used in various ways for over 7 years. Direct feedback from users is important, as it shows that the internal climate is very comfortable. During the heating period,

a wood-burning stove was sufficient as a source of heat. Solid walls and flooring were a good heat accumulator and the heat buffer in the glass veranda accumulated heat on sunny days and supplemented the overall heat balance.

Researches were divided into three parts: measurement of wall moisture (using TROTEC BM 22) in summer and in autumn, measurements of room temperature and humidity (using Testo 410-2) in summer and in autumn, and research with thermal camera (using SeeK Thermal) in autumn.

2.4.1 Measurements of Wall Moisture Using TROTEC BM 22

The first research of moisture took place on 1st August 2018. The temperature outside was 30°C and humidity outside the building was 45%. In the case of a veranda, the humidity of the partition wall from the outside decreased for 0,1%, which is caused by the relation between the southern exhibition and the positions of the points inside the veranda, which is heated by the sun during the summer period. Since the differences between the individual measurement points outside and inside the building are of the order of several decimals, it can be concluded that the walls will retain their stability.

The second research of moisture took place on 29 October 2018. The temperature outside was 5,46°C and humidity outside the building was 75%. In the case of a veranda, the humidity of partition wall from outside decreased for 0,2-0,3%. The wall moisture was higher in summer than in autumn. The amplitude of the moisture behind the accumulating wall inside the building about 0,1% and in veranda 0,2-0,3%. The difference probably depends on heating system in autumn.

2.4.2 Measurements of Room Temperature and Humidity Using Testo 410-2

The first research of temperature and humidity took place on 1st August 2018. The temperature outside was 30°C and humidity outside was 45%. The collected measurement results show higher humidity values inside than outside the building. Using this device, the humidity on the veranda was analysed, where the lowest percentage values of humidity were noted. The humidity in point 7 on the veranda was even up to 19.8% lower than in other points inside the building. It follows that a veranda with a glass wall reduces the humidity inside the building. The veranda also recorded the highest temperatures of 39°C and 40.5°C, while in other rooms the temperature ranged from 28.5°C to 29.8°C.

The second research of temperature and humidity took place on 29 October 2019. The temperature outside was 5,46°C and humidity outside the building was 75%. The humidity in veranda was the same or lower (about 1,3%) than in inside the building behind the partition wall. The temperature in veranda was lower than in inside of the building about 0,4-0,6°C.

The amplitude of temperature in summer and in autumn in veranda was 23,6°C, but delta of humidity was 5,5%. The amplitude of temperature behind the partition wall (accumulating wall) was 12,3°C and delta of humidity was 11,4%.

2.4.3 Research with Using Thermal Camera SeeK Thermal

During the visit on 29 November 2018 the SeeK Thermal thermal camera was used. Temperature measurements with the thermographic camera were taken between 14:00-15:00. During the analysis, the object was heated by a fireplace for about 2 hours.

Figure 3. Measurements with a thermal camera in the interior near the accumulation wall and the glass part of the southern wall.

The wall accumulation analysis from the inside showed the temperature difference depending on the finishing materials used. On the veranda side, in three measurement points of the wall, the same result of 17°C was obtained. From the main room side the temperature varies from 23°C towards the eastern elevation, through 22°C to 20°C from the western elevation side. In case of covering the wall with wooden cladding, the temperature was higher and constant, regardless of the measurement point, and it was 25°C.

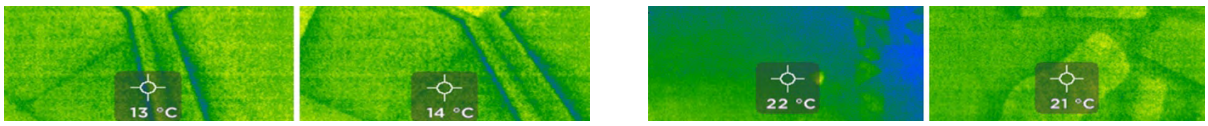

Figure 4. Measurements with a thermal camera of a glazed curtain wall on a veranda and a floor in the interior of the main utility part and veranda.

The difference in temperature in the veranda room and the main utility room is noticeable, which is caused by the adopted technical and material solutions of the external partitions. Measurements with a thermal camera show lower thermal insulation of the veranda external partitions made as a glazed curtain wall. The glazing temperature was 14°C, and the structural elements were 13°C. The temperature of the floor, finished with stone, in the part of the veranda and the main utility room was comparable. The temperature of the floor on the veranda was 21°C. The purpose of this floor is to accumulate heat generated by solar radiation penetrating through the glass wall of the veranda. The temperature of the floor in the main heated usable part was higher and amounted to 22°C. Despite the temperature difference in the rooms and external partitions, the floor temperature is similar in both rooms. It can be assumed that the stone flooring accumulates the heat generated by solar radiation, as assumed at the design concept stage.

3 Conclusions

Research has shown that there is no significant heat transfer from the veranda space, because no openings were introduced to allow ventilation and the doors, which were proposed in the design to perform this function, were closed during the use by users. Due to financial reasons external shading roller shutters, which were proposed in design, were abandoned. The research has shown that despite the fact that the object is located at the border of the forest at the southern orientation, the height of the trees crowns does not provide adequate shade. As a result, the veranda is overheated. The introduction of external roller shutters would improve the quality of the microclimate inside. At the same time, it should be emphasized that the designed accumulation wall fulfils its function and constitutes a barrier that stores heat and constitutes a thermal barrier between the veranda and other rooms. Openings in the accumulation wall should be added to allow for a correct flow of heated air from the veranda to the inside of the building. The wall made with the use of rammed earth technology meets the conditions of thermal insulation, maintaining proper temperature both in winter and in summer. The material is characterized by appropriate thermal capacity, ensuring thermal and humidity stability of the building. The rammed earth technology can be implemented in Poland in the temperate climate zone. The construction of the experimental building in Pasłęk met with interest in the scientific and architectural environment related to ecological construction. The building was awarded by an international jury of the European Union's Terra (In)cognita programme for design and innovative implementation and received the Outstanding Earthen Architecture in Europe Award in the year 2011.

Fire Properties of Novel Cellulosic Material Modified with Expandable Graphite

Anielkis S.R. Batista, Wojciech Ł. Grześkowiak and Bartłomiej Mazela

Faculty of Wood Technology, Poznan University of Life Sciences, Wojska Polskiego 38/42, 60637 Poznan, Poland, e-mail: anielkis.batista@up.poznan.pl, wojciech.grzeskowiak@up.poznan.pl, bartlomiej.mazela@up.poznan.pl

Abstract. *Expandable graphite (EG) is an intumescent additive known to improve fire properties of various materials. Intumescent fire retardant (IFR) based on EG is a protection method for flammable materials taking the attention of researchers in the past few years (Xie et al., 2000). New studies indicate that EG is a good source of carbonization agent for effective and environmentally friendly intumescent systems (Feng et al. 2013). Although EG is used in a growing number of IFR systems as a blowing agent that will suppress flammable gases up to 75%, while reducing the flame spread index, its application to cellulosic material is not so popular in the cellulose industry today (Krassowski et al., 2012). The current study focuses on flammability, concerning cellulose modified material (CMM). The objective of this work was CMM encrusted with EG. The general aim of the research was to determine its basic fire resistance properties. The scope of the research included measurement of the following parameters: time to ignition (T_i), time to flame out (T_f), total heat peak (THR) and mass loss (ML). Samples of CMM sheets were manufactured with the use of hydropulper and rapid-koethen devices. Two types of EG (i.e. ES20 C200 and ES100 C10) were used. Sodra Black Cellulose fibres (700 kg/N^3) was used in this experiment. Cellulose milling time was 30 min. and drying time of 40 min. The drying temperature of the final sheets was controlled and kept at 93^0C to avoid graphite activation. Final sheets were conditioned at room temperature at 20^0C and relative humidity 60%. With heat flux of 35 kW/m², all samples were tested on MLC apparatus. The addition of EG was found to increase the flame retardant effectiveness of cellulosic material. Although T_i for all CMM species were lower than that of control samples, this fact actually favored the promotion of char forming, which led to a longer combustion process for all CMM.*

Keywords: *Mass Loss Calorimeter, Char, Expandable Graphite Cellulose, Flammability.*

1 Introduction

Fire retardant formulation (FRF) based on expandable graphite (EG) is a fire reinforcement method for flammable materials taking the attention of researchers in the past few years (Xie and Qu, 2000). As a carbon-layered crystal, EG consists of sheets of carbon atoms strongly bound to each other (Kruger, 2017). The literature indicates that EG is a good source of carbonization agent for effective design of environmentally friendly intumescent systems (Feng *et al.,* 2013). There are insufficient detailed reports in literature on the behaviour of EG-intumescent fire retardants (IFR) systems concerning cellulosic materials. Although EG is used in a growing number of IFR systems as a blowing agent that will suppress flammable gases up to 75%, while reducing the flame spread index, its application to cellulosic material is not so popular in the cellulose industry today. Depending on the processing methods, fire retardants (FR) are often categorized as: Additive or non-inert compounds. Additive FRs are often mixed inside the matrix of the polymer during its processing. These FR are usually inert

to de polymer. Reactive FRs are dose polymerized with a resin during processing of cellulosic material to become integrated into its molecular network structure. These FRs are also known as chemically modified FRs (Jesbains *et al.,* 2011). The footprints of fire retardants points to an effective ideal fire retardant that should be thermo-stable, compact with the protected polymer, should not change the physical-chemical properties of the protected polymer, and have low toxicity under heat exposure or during burning (Camino and Costa, 1987). In order to understand the dynamics of fire retardants it is required to have detailed knowledge of the mechanism of the thermal-degradation progress related to the polymer.

Inventions related to EG are usually linked to its thermal properties, therefore related to reducing the flammability and/or combustibility. In fact, the use of expandable graphite as part of flame retardant agents and fire protection is being promoted by laws and regulations that push the prohibitions of halogenated based fire retardants due to environmental concerns related to the emission of toxic gases from the thermal degradation of halogenated base flame retardants. The European Union is one of the organizations promoting the development of new halogen-free flame retardants (Acuna *et al.,* 2019). EG is a novel product in use in various inventions. Many patents claim that EG properties can be used for diverse of applications. Not only in the field of fire retardants where EG is used to protect fibrous materials, but also in electrical applications. As solid composite, EG was used in lithium/Sulphur batteries as cathode; the solid composite comprised of up to 75wt-% of expanded graphite (Schmidt *et al.,* 2017). Rubber melded body material with enhanced fire resistance. In this rubber composition, one of the main components was EG (Sakai and Nakano, 2019). EG is also used in devices of heat recovery unit, on this invention due to its heat resistance, EG was installed as a retention membrane (Murata and Koga 2019). EG is a multi-porous material with an average pore size distribution of about ~2 nm, this structure allows EG to accommodate other chemical espies in between is sheets to form other composites, it has been found to improve the conductivity properties of the polymer structure. From the exfoliation process of expandable graphite, we can obtain a good electrically conductive material, this is leading to several study of the electrical conductivity of some EG composites (Celzard, *et al.,* 2000). In solar energy storage researches, EG is one of the materials that can enhance the thermal conductivity of solar cell. In the works of Xiao *et al.,* (2013), sodium nitrate, potassium nitrate and their solution were used as the base material. The conductivity of the based material was of about 10 wt.%. With the addition of expanded graphite that has high thermal conductivity, the conductivity of the final material increased at about 40%. In his work, Xiao *et al.,* (2013) agreed that the theoretical results and the experimental results are in agreement. It is clear that the novel product has a diversity of fields/research areas to contribute with its property in this literature review we consider that the thermal conductivity properties and the potentially electrical conductivity properties are at the top potential characteristics that researchers at observing. Most articles do not address the aesthetic aspect of their final product. When combining EG with other additives the appearance of the final product is not so attractive the final application, especially when it is related to coatings fire retardants formulations. Other concern is related to cost of EG. The market to this product is growing at a fast speed. According to the Markets and Markets (2019), the global graphite market is projected to reach 29.05 billion dollars by 2022. This is a considerable amount that indicates that the global market is interested on these eco-friendly products. In the academy it is conclusive that the use of EG will increase as novel products

are developed.

To achieve this goal, the present preliminary experiment will use Mass Loss Calorimeter (MLC) infer the thermal stability of the CMM. MLC is frequently used to explore flammability properties of different type of materials, delivering a suitable sort of technical data (Krassowski *et al.,* 2012). Recent analysis of thermal stability of lingo-cellulosic materials under controlled conditions showed the decomposition temperatures (T_d) for lignin, hemicelluloses and cellulose. This last component, with $T_d = 320^0$C, char 6% by mass (Mazela *et al.,* 2018; Fox *et al.,* 2012). The current study focuses on flammability concerning cellulose component only.

The objective of this work was cellulose-based model material (CMM) encrusted with expandable graphite (EG). The general aim of the research was to determine its basic fire resistance properties. The scope of the research involved measurement of the following parameters: time to ignition (Ti), time to flame out (Tf), total heat release peak (THR) and mass loss (ML).

2 Methods

Samples of cellulose sheets were manufactured with the use of hydropulper and Rapid-Koethen devices. Cellulose sheets were encrusted with two types of EG (ES100 C10 and ES20 C200). EG was dispersed in a cellulose pulp at the preparation stage. ES20 C200 had higher amount of fine-grained fraction (90% <75µm) and thus was characterized by lower expansion volume (20 ml/g) in comparison to ES100 C10 type. Three variants of cellulose sheets were prepared: control sheets (pure cellulose) and sheets encrusted with graphite ES200 C20 or ES100 C10. Sodra Black Cellulose fibres (700 kg/m^3), with the following dimensions of fibers: 2.05 mm length, 30.0 µm width, were used for the process of cellulose sheets manufacture. The cellulose milling time was 30 minutes and the drying time 40 minutes. The drying temperature of the final sheets was maintained at 93^{0}C to avoid graphite activation notwithstanding the manufacture of EG advises that activation temperature is at about 320^{0}C. The final sheets were conditioned at room temperature at 200^{0}C and relative humidity 60%. All the samples were subjected to MLC measurements (Fig. 1). Heat flux at 35 kW/m^2 was estimated as suitable level for all tested samples. This work inferred conclusions on flammability properties of CMM by measuring time to ignition (Ti), time to flame out (Tf), total heat release peak (THR) and mass loss (ML). It was possible to account for all important aspect mentioned above however it was not possible to account for repeatability the samples. This led to some discrepancy in some sample properties (i.e. thickness) as shown on table 1. bellow.

Table 1. Characterization of samples.

Samples	Thickness	THR (MJ/m^2)	T_i (s)	T_f (s)	THR peak (MJ/m)
Cellulose 01	0.89	9	25	94	230.72
Cellulose 02	0.88	7.2	21	79	222.41
Cellulose 03	0.89	8.3	24	89	236.05
EG200-01	1.45	6.7	22	100	98.03
EG200-02	1.4	6	21	102	89.55
EG200-03	1.4	6	20	99	97.61
EG100-01	1.4	4.4	19	108	73.32
EG100-02	1.5	4.4	19	107	75.42
EG100-03	1.4	4.8	19	123	74.96

It is clear that the mass (g) of each sample are not the same. With the standard deviation calculated to be 0.1 for cellulose samples, 0.5 for EG200 and 0.3 for EG100.

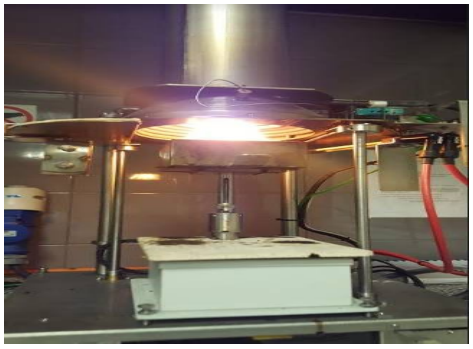

Figure 1. MLC apparatus set at 35kW/m^2.

3 Results

T_i for CMM encrusted with ES100 C10 and ES20 C200 was estimated at the average on 19.0 and 21.0s respectively. This corresponds to T_i of ES100 C10 2s faster than that of ES20 C200, while for control samples it was estimated on 23.3 s, control samples resisted 22% more time than the more "fragile" sample (ES100 C10). As we can confirm in the figure 2. In average, T_i for CMM encrusted with ES100 C10 and ES20 C200 were observed to ignite 4.3 s and 2.3 s, respectively faster than control samples.

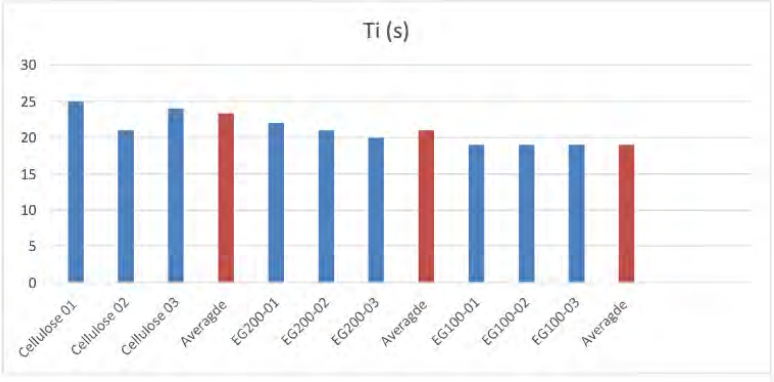

Figure 2. Time to ignition of all samples.

Figure 3. shows among others, the average T_f value for CMM encrusted with ES100 C10 was112.7 s, while pure cellulose and CMM with ES20 C200 did register an average of 87.7 and 108.0 s, respectively. In this case however, ES100 C10 showed a resilient behaviour, taking 28% more time to terminate its combustion process. ES100 C10 showed earlier char formation, this fact can help on fire protection properties.

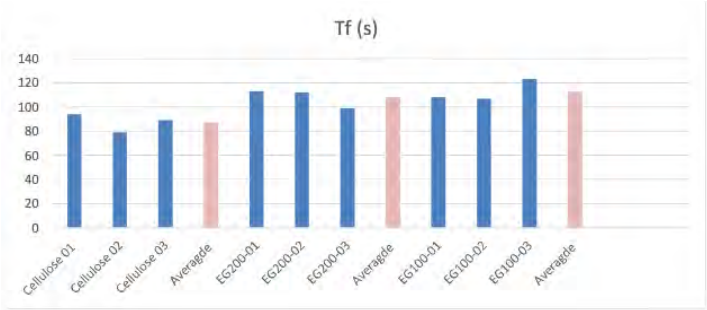

Figure 3. Time to flame out of all samples.

Maximum THR was observe to be 229.72 kW/m^2 for pure cellulose, 91.87 kW/m^2 for CMM with ES20 C200 and 71.51 kW/m^2 for CMM with ES100 C10, as presented in the in figure 4. ES100 C10 is a material that burns with a resilient behaviour. That is, this material suppresses better the refuel of the combustion process. Less heat released from the combustion process is redirect to the fire feed. One can observe that ES100 C10 have a more attractive fire property.

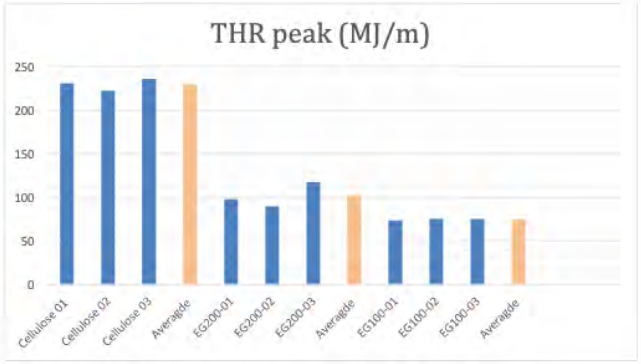

Figure 4. Time to flame out of all samples.

4 Conclusions

- The addition of EG was found to increase the flame-retardant effectiveness of cellulosic material.
- Although T_i for all CMM species were lower than for control samples, this fact actually favored the promotion of char forming. The improved physical characteristics of char is achieved by increasing the amount of the insulated layer and reducing crack formation. This aspect allowed the combustion process of CMM with ES100C10, to be 25s longer than combustion process of pure cellulose and almost 5 s longer than that of CMM with ES20 C200. In addition, the maximum HRR for CMM with ES100C10 was 69% smaller than its compared value for pure cellulose and 22% smaller than its compared value for CMM with ES20 C200.
- CMM with ES100 C10 is consequently the best performing system in terms of the observed parameters.

Abstract. *The proportion of electricity generated by coal-fired thermal power plants has been rising in Japan as a result of the nuclear plant accident caused by the Great East Japan Earthquake of 2011. Coal-fired electricity generation has a large environment impact, so the commercial application of integrated coal gasification combined cycle (IGCC) has been promoted. IGCC is an efficient generating method combining a steam turbine and a gas turbine. However, IGCC plants generate coal gasification molten slag (CGMS) and it is necessary to establish effective utilization methods for this slag for further promotion of IGCC technology. In this paper, the fresh properties, hardened properties and durability of concrete containing CGMS as fine aggregate are investigated. The results show that, in comparison with concrete using conventional fine aggregate, the air content introduced by an air-entraining agent is lower and bleeding is increased when CGMS is used as a fine aggregate. As for the hardened properties, compressive strength is slightly lower, while freeze-thaw resistance is significantly reduced. In additional tests, it is found possible to improve freeze-thaw resistance by increasing the air content.*

Keywords: *Coal Gasification Molten Slag, Fine Aggregate, Freeze-Thaw Resistance, Integrated Coal Gasification Combined Cycle (IGCC).*

1 Introduction

With environmental concerns restricting the extraction of natural aggregate, Japan's concrete industry is finding it difficult to secure supplies and is pursuing research to develop substitute aggregates. On the other hand, following the Great East Japan Earthquake and tsunami of 2011, the composition of Japan's electricity supply has tilted toward thermal power generation in place of the nuclear power that was predominant. Currently coal-fired power generation accounts for approximately 32.3% of all electricity generated in Japan. Conventional coal-fired power stations emit tremendous quantities of CO_2, so technology to reduce CO_2 emissions is needed. For this reason, the use of the highly efficient Integrated Gasification Combined Cycle (IGCC) has been promoted. With IGCC technology, impurities from coal that has been heated in a gasification furnace are melted and discharged as coal gasification molten slag (CGMS). CGMS is an amorphous material formed by rapid granulation in water. Establishing a method for effective use of this CGMS is essential to expansion of IGCC utilization. It is thought that using CGMS as concrete aggregate could make a major contribution to society. However, no standards have yet been established for such use of CGMS. This study investigates the potential for use of CGMS as a concrete aggregate. The fundamental properties of concrete incorporating CGMS are estimated and problems that must be resolved are isolated in order to provide data for the establishment of standards for the use of CGMS aggregate.

2 Characteristics of CGMS Fine Aggregate

The characteristics of the CGMS and crushed sand used as fine aggregates in this study were measured and compared. Figure 1 shows electron microscope pictures of the CGMS fine aggregate (symbol: Sg) and crushed sand (symbol: Sc) used in this study.

Table 1 gives the chemical composition of CGMS. The main components are silicon dioxide, aluminum oxide, calcium oxide and iron trioxide, which account for more than 90% by weight, with trace amounts of other minerals. These are all oxides of naturally existing elements.

Figure 1. (a) Coal gasification molten slag and (b) Crushed sand.

Table 1. Chemical composition of CGMS.

Detection component	Quantitative value (%)	Detection component	Quantitative value (%)
SiO_2 (Silicon dioxide)	30.4	K_2O (Potassium oxide)	1.2
Al_2O_3 (Aluminum oxide)	11.1	TiO_2 (titanium dioxide)	0.8
CaO (Calcium oxide)	23.1	MgO (Magnesium oxide)	11.5
Fe_2O_3 (Iron trioxide)	21.5	SO_3 (Sulfur trioxide)	0.0

2.1 Test Items

Density, water absorption, particle size distribution, bulk density and solid content, content under 75μm sieve, and solid volume percentage for shape determination were measured according to ISO, ASTM and EN.

In order to estimate strength and elastic deformation for use as aggregate, an aggregate strength indicator test was developed and used to characterize the CGMS and crushed sand aggregates. A steel container with an inner diameter of 33 mm and a height of 88 mm was used for this test. Figure 2 outlines this aggregate strength indicator test. The test is carried out as follows.

Under fully dried condition, aggregate with particles in the range 1.2–2.5 mm is separated by screening. Then 60 g of the separated particles are placed in the steel container and the upper surface is smoothed using the finger. A round steel loading bar is then inserted and a precision universal testing machine used to apply a compressive load P (kN) while at the same time measuring the displacement d (mm) using a laser displacement gauge. Loading continues up to a maximum of 90kN. A load-displacement curve is drawn from the measurements and the gradient of the proportional section of the curve is calculated as the aggregate strength index using Equation (1) below.

$$I(kN / mm) = P(kN) / d(mm) \quad (1)$$

where: I is the aggregate strength index value;
P is the compressive load; and
d is the displacement.

After the test, the particles are screened through a 0.30 mm sieve and then a 0.15 mm sieve, and the 0.30 crushing value (%) and 0.15 crushing value (%) are calculated from the quantity passing each sieve. These crushing values are calculated using the following equations (2) and (3).

$$0.30 \text{ crushing value} = B(g) / A(g) \times 100 \ (\%) \quad (2)$$

$$0.30 \text{ crushing value} = C(g) / A(g) \times 100 \ (\%) \quad (3)$$

Where: A is the weight of crushed aggregate;
B is the weight of aggregate passing the 0.30mm sieve; and
C is the weight of aggregate passing the 0.15mm sieve.

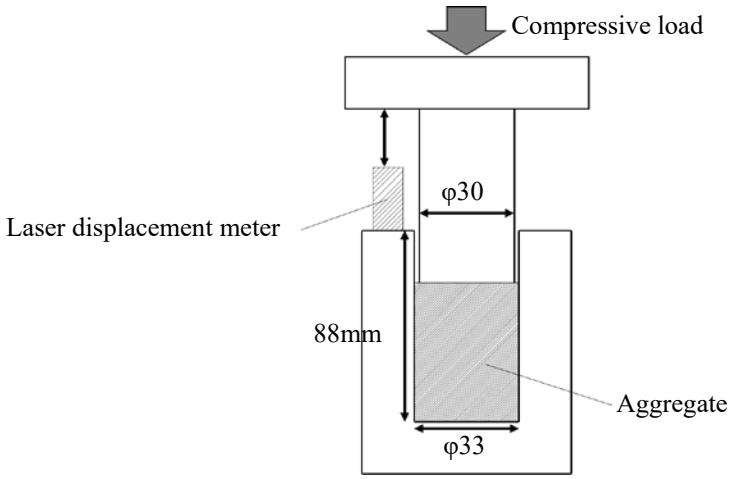

Figure 2. Outline of aggregate crushing test for strength index value.

2.2 Test Results

Table 2 shows the standard test results for the CGMS fine aggregate and crushed sand. Figure 3 shows the particle size distributions of the two fine aggregates as determined by sifting. The CGMS fine aggregate used in this study had a larger density of 3.08g/cm^3 in saturated surface-dry condition compared with crushed sand. Its water absorption rate is 0.70%, which is lower than that of crushed sand.

From these results, it is inferred that CGMS fine aggregate has a smooth surface and it is possible to reduce the restrained water volume on the surface of the aggregate. This leads to the expectation that the unit volume of water needed for a given slump can be reduced as compared to crushed sand. As the solid content and the solid volume percentage for shape determination are almost the same as the crushed sand values, it is thought that CGMS fine aggregate has appropriate particle shapes and sizes. From these data, improved fluidity can be expected for fresh concrete made with CGMS fine aggregate.

Figure 4 shows the relationships between compressive load and displacement in the aggregate strength indicator test. The resulting strength index values are shown in Table 3. These results show that CGMS fine aggregate has a higher strength index value than crushed

sand, resulting in greater resistance to deformation under external force. Moreover, the crushing values indicate that CGMS fine aggregate is more brittle than crushed sand.

Table 2. Characteristics of CGMS fine aggregate and crushed sand.

		Test method	Test value	
			Sg	Sc
Density in saturated surface-dry condition	g/cm^3	ISO 7033:1987	3.08	2.64

3 Fundamental Properties of Concrete Using CGMS as Fine Aggregate

3.1 Materials

Ordinary portland cement (symbol: C, density: 3.16 g/cm^3) was used as binder. Crushed sand (Sc) and CGMS fine aggregate (Sg) were used as fine aggregates. Crushed stone (symbol: G; density in saturated surface-dry condition: 2.61 g/cm^3) was used as the coarse aggregate.

Additionally, a high-performance water reducing admixture (symbol: SP), an air-entraining admixture (symbol: AE) and a deformer (symbol: DF) were included as admixtures.

3.2 Mixture Proportions

Table 4 shows the mixture proportions of the concrete used to cast specimens. The water-cement ratio was fixed at 50%. Sand fine aggregate was replaced by CGMS at volume ratios of 0%, 50% and 100%; the replacement ratio is expressed as Sg/S. The target values of fresh properties were 12.0±1.5 (cm) for slump and 4.5% ± 1.5% for air content. The rate of high-performance water reducing admixture addition was also fixed to 0.75% by mass, after an initial study in which the target values of fresh properties were obtained at this addition rate with Sg/S=100%. In order to obtain the target values at Sg/S=0% and Sg/S=50%, the unit volume of water was adjusted so as to carry out evaluations based on the unit volume of water that satisfied the target values, while keeping the SP addition rate constant.

Table 4. Mixture proportioning of concrete for fresh property testing.

W/C (%)	s/a (%)	Sg/S (%)	Unit content (kg/m^3)					Admixture addition rate (C×%)		
			W	C	Sc	Sg	G	SP	AE	DF
50	47	0	178	356	824	0	926	0.75	0.05	0.05
		50	180	360	410	478	921		1.40	0.05
		100	174	348	0	971	935		2.40	0.05

Table 5. Results of fresh properties tests.

W/C (%)	Sg/S (%)	Unit water (kg/m^3)	Slump (cm)	Air content (%)	Temperature (°C)	Bleeding rate (%)
50	0	178	12.0	4.0	20	7.00
	50	180	12.0	4.7	27	6.97
	100	174	11.5	3.9	27	9.24

3.3 Test Methods

The fresh properties measured were concrete slump, air content, concrete temperature, and bleeding ratio. The hardened concrete was tested for compressive strength. Durability was investigated by carrying out freeze-thaw tests, drying shrinkage tests and accelerated carbonation tests. These were all in accordance with ISO and ASTM.

3.4 Test Results

Table 5 shows the results of the fresh properties tests. The bleeding rate was found to increase at higher Sg/S ratios. With Sg/S = 100%, the unit water volume was lower but the bleeding rate increased. This is thought to be because the CGMS fine aggregate has a smooth surface and low water absorption rate, so there is a greater surplus of water when the mix includes more CGMS. And also, it is considered that water content increased. Then the same slump value could be obtained at lower unit water amount.

Figure 5 shows the results of the compressive strength tests. Concrete with CGMS fine aggregate has a slightly lower strength compared with concrete without it. This is considered to be because CGMS itself is not as strong as crushed sand, noting that the crushing values of CGMS fine aggregate are larger. Further, with the increased bleeding, it is also considered that voids in the interfaces with coarse aggregate particles increased, resulting in weaker interface bonding between coarse aggregate and cement paste.

Figure 6 shows the results of the freeze-thaw tests. Concrete including CGMS fine aggregate

showed very poor frost resistance. It is thought that this is because of the weaker interface bonding between paste and coarse aggregate particles, resulting from the high bleed rate. The expansion pressure of freezing water in the voids causes this reduced resistance. There is a need for studies aimed at improving the freeze-thaw resistance of concretes containing CGMS fine aggregate.

Figure 7 shows the results of the drying shrinkage tests. With higher Sg/S, drying shrinkage strain decreased. The reason for this is considered to be that, since the aggregate strength index of CGMS fine aggregate is larger, its deformation resistance is larger. With a higher Sg/S ratio, the unit water content decreased. As a result, drying shrinkage was reduced.

Figure 8 shows the results of the accelerated carbonation test. With a higher Sg/S ratio, the carbonation rate increased. More bleeding occurred at higher Sg/S, so a coarser microstructure formed in the concrete, allowing CO2 to enter the concrete more easily.

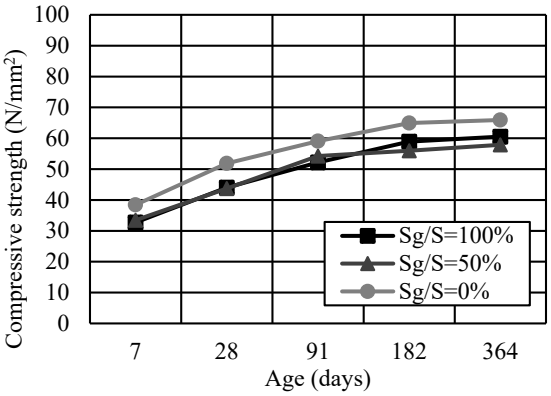

Figure 5. Results of compressive strength test.

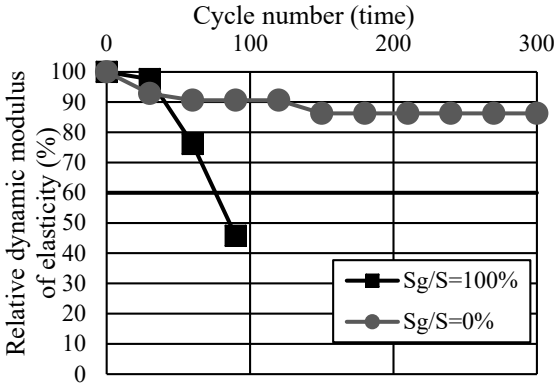

Figure 6. Results of freeze-thaw test.

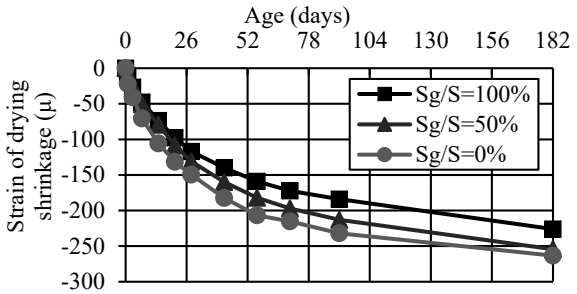

Figure 7. Results of drying shrinkage test.

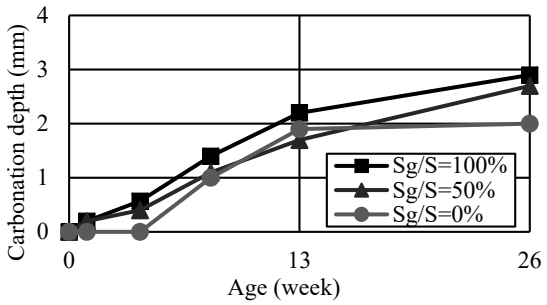

Figure 8. Results of accelerated carbonation test.

4 Experiment to Improve the Frost Resistance of Concrete Including CGMS Fine Aggregate

The results of the freeze-thaw test show that the resistance of concrete made with CGMS fine aggregate is significantly reduced. A possible method of improving freeze-thaw resistance by increasing the air content was examined.

Table 6 shows the mix proportions of the concrete used in this experiment and the results of the fresh properties tests.

The water-cement ratio was fixed at 50%. Sand fine aggregate was replaced by CGMS at a volume ratio (Sg/S) of 100%. The target values of fresh properties were 12.0 ± 1.5 (cm) for slump and the three values of air content: 4.5 ± 1.5%, 6.0 ± 0.5% and 7.5 ± 0.5%. As an additional test, the air-void spacing factor was measured by the linear-traverse method. This test was implemented in accordance with ASTM C 457-98.

Table 6. Mixture proportioning of concrete for freeze-thaw testing and results of fresh property tests.

Symbol	W/C (%)	Unit content (kg/m^3)				Admixture addition rate (C×%)			Air content (%)	Slump (cm)	Temperature (°C)
		W	C	Sg	G	SP	AE	DF			
Sg-4.5	50	174	348	971	935	0.75	2.40	0.05	3.9	11.5	27
Sg-6.0		171	342	978	942		1.40	0.05	5.5	10.5	27
Sg-7.5		169	338	983	947		2.20	0.05	7.7	13.0	28

4.1 Test Results

Figure 9 shows the results of the freeze-thaw test and Figure 10 shows the relationship between air-void spacing factor and durability factor. As can be seen in these results, freeze-thaw resistance was greatly improved by increasing the air content.

The experiment demonstrated that the entrainment of air in concrete containing CGMS fine aggregate is low during mixing. In order to obtain the target air content, it was necessary to add a large amount of AE admixture. These results indicate that CGMS contains a large amount of non-combustion carbon and this will require further study.

The air-void spacing factor was lower when the target air content was adjusted to 6.0% and 7.5% than when it was adjusted to 4.5%. This is because the number of air voids increased as the amount of air increased. And it is thought that bleeding rate was suppressed by increasing air content.

These results demonstrate that the freeze-thaw resistance of concrete containing CGMS fine aggregate can be improved, but further study is needed.

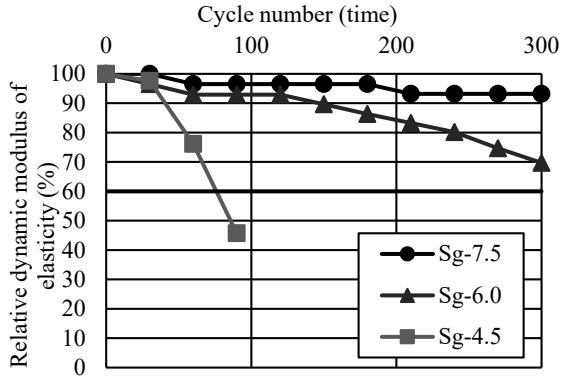

Figure 9. Results of freeze-thaw test.

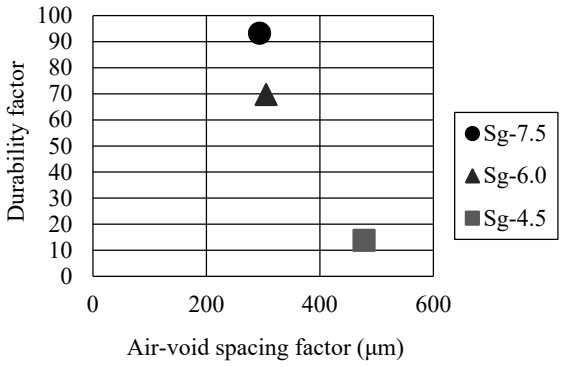

Figure 10. Relationship between air-void spacing factor and durability factor.

5 Conclusions

Experiments to determine the basic properties of concrete containing CGMS as fine aggregate showed that fluidity improved while compressive strength decreased slightly. In other results, drying shrinkage strain was reduced while carbonation resistance decreased.
In terms of durability, tests of freeze-thaw resistance were not very good. However, freeze-thaw resistance was shown to be improved by increasing the air content of the fresh concrete.

Abstract. *This paper introduces the ForestValue research project CLICKdesign – delivering fingertip knowledge to enable service life performance specification of wood. The consortium is working on a primary innovation to move from the complex, fragmented and general to the easy-to-use, consolidated and specific by provision of a digital tool for specifiers. Other materials tackle this and provide designers and architects with software. The specification of performance of wood products is complex and fraught with inconsistency and requires use of multiple platforms for data, experience, standards and national recommendations. CLICKdesign will provide a tool that has within it the decades of research, the complexity of the standards specification systems and the variation of approach due to tradition, materials and culture across Europe and beyond. A simple tool for nonexpert public users will be available as well as a tool accessible to professional users that will be refined with industry to ensure relevancy and accelerate uptake and use.*

Keywords: *Durability-Based Design, Knowledge Transfer, Modelling, Performance, Service Life Planning.*

1 Introduction

Concrete, steel and polymeric sectors deliver software to architects and students enabling easy performance-based specification and design. It also enables easy teaching of design best practice and informs learning gathered by product manufacturers. This does not happen for wood comprehensively in Europe, though specific initiatives e.g. UK Structural Timber

Association guidance (www.structuraltimber.co.uk) and the German Carpenter Association's Guideline on Building Facades, Terrace decking, and Balconies (BDZ 2011, 2016) do exist. In addition, technical specifications are integrated into increasingly used Building Information Modelling (BIM) and life cycle analysis (LCA) which includes service life data. Service life planning and performance classification are thus core issues in the building sector underpinning material/product specification and use. The absence of durability performance-based specification for wood is currently a limit of opportunity. Well-functioning 'performance models' are essential to predict the service life and functionality of buildings.

2 Project CLICKdesign Context

2.1 Analysis of the Problem

The established specification of wood is not performance based, historically standards refer to ineffectual terms to bridge the performance gap such as "a reasonable working life". Wood engineers utilising Eurocode 5 find the ineffectual language doesn't stand scrutiny and is of little value. Awareness of the cultural legacy of wood in construction around us, traditional uses and skills are constant reminders of the enduring possibility of wood if knowledge is applied, including knowledge of species and material qualities, knowledge of design details and construction skills, knowledge of local conditions, climatic or other challenges. This knowledge is fragmented, localised and in some cases difficult to analyse and use especially by non-wood experts. This is the problem. The solution is to put this knowledge at the fingertips of the specifier, in their language so more can meet their ambitions to deliver low carbon construction, through performance based design with wood.

The existing decision logic of specification of durability, and implied performance, considers first the suitability of a timber species for use in construction. This first considers the natural durability of the chosen timber species (EN 350: 2016) and notes the intended end use (EN 335: 2013), *e.g.* Use Class 4 for a fence post. EN 460: 1994 compares the requirements of Use Class with the natural durability and indicates whether natural durability is sufficient for the end use or whether preservative treatment is required. The European Standards related to specifying preservative treated timber, EN 351-1: 2007 and EN 351-2: 2007 require the specification to be written in terms of the end results of the treatment process i.e. penetration and retention in the wood of a preservative formulation found to be effective in a series of standard biological test methods laid down in EN 599-1: 2013. The specification of service life has evolved around the end results achieved following preservative treatment with service life referred to in an unquantified and ambiguous way using terms such as "reasonable working life" or "satisfactory performance". Standards that started to define desired service lives were a step in the right direction as the desire for information on performance of wood products grew in part buoyed by the application of LCA for construction products that pivots on their service life requirements. In Germany, France and UK there are national documents that set out frameworks for performance. In the UK the British Standard BS 8417: 2011 sets out a framework for specifiers to interpret the European standards and to base specifications on penetration and retention requirements linked to treated products and 'desired service life'.

The established wood species and treatment combination for a specific use class works well but has gaps that miss many additional opportunities for timber in construction through good

design detailing, the aesthetic performance, other tools to enhance natural properties, the impact of surface cracks on performance, surface roughness and the more subtle moisture dynamic of the wood material.

Different types of performance models have been established for various building materials but cannot be transferred to wood-based materials. For performance modelling of wood products biological agents need to be considered with particular attention for mould, decay fungi, termites and other insects as well as the strong societal values of regional vernacular, skills and traditions that only wood as a material brings. Different approaches to adequately reflect the influence of biotic and abiotic factors on the performance of wood have been reviewed and evaluated (Brischke and Thelandersson 2014) with respect to their usability in the building trade. They found that efforts in developing performance models for both fungal decay and mould growth have been intensified in recent years (*e.g.* MacKenzie *et al.*, 2007, de Freitas et al. 2010, Viitanen *et al.*, 2010, Isaksson *et al.*, 2013, Niklewski *et al.*, 2016). A high heterogeneity among the numerous attempts became visible, different strategies have been followed, and were roughly distinguished according to the respective objectives, governing variables (*e.g.* mass loss, strength loss, remaining strength, decay ratings, service life, aesthetic appearance), data sources and the resulting level of accuracy.

A framework of how exposure, dimension, design details, and the material-intrinsic ability to take up and release water can be linked to model the moisture risk in wood products and thus performance is the central need. First attempts prepared using various dosimeter models were made in previous European research projects, namely the WoodWisdom-Net projects WoodExter and DuraTB, the Swedish WoodBuild program, and the FP7 project PerformWOOD. Good progress has been made during recent years in service life planning and performance prediction of wood-based components and structures, but as repeatedly became evident, the complexity of performance is still not captured in these processes.

The cross-links and interactions between exposure models, different decay and degradation models, and material resistance models need to be deeply elaborated to allow their utilization for comprehensive performance prediction. Furthermore, the degradation processes described and forecasted with the help of models need to be assessed for the respective purpose. Hence, one needs to distinguish between aesthetic performance, functional performance, mechanical performance and other aspects of performance (Jones and Brischke 2017). In particular, the effect of fungal, bacterial or insect damage on the overall mechanical stability of wooden structures is still neither fully understood nor adequately modelled for engineering purposes.

2.2 Beyond the State-of-the-Art

Project CLICKdesign is shown schematically in Figure 1 and includes:

- Forecasting surface aesthetic changes developing the kinetic and/or intensity of such changes due to location, microclimate, architectural design and materials used.
- Development of damage spatial distribution significance on mechanical performance. Studying spatial distribution of fungal decay and its interaction with moisture transport and resulting gradients in buildings.
- Development of a termite/insect performance measure for the first time in Europe.

- Robust integrated performance classification based on the whole set of external parameters for the first time the foundation established for decay, material and integrity aspects, aesthetic limits and performance and termite/insect performance aspects.
- Providing a CLICKdesign tool that utilises European standards, the latest research findings and wood databases such as the IRG Durability Database (http://www.irg-wp.com/durability) and puts it at the fingertips of specifiers and users. This will increase market confidence with users for selecting wood as a reliable product and enhance an optimised performance of timber in the built environment.
- Features wholly not integrated into specification now. The significant variations due to climate change present changes to exposure dose for wood products and the distribution and locations of wood destroying organisms e.g. termite risk zones in Europe.
- Inspiring new wood and wood-based products using the tool, supported by training outreach, and creating business opportunities for industries to innovate.

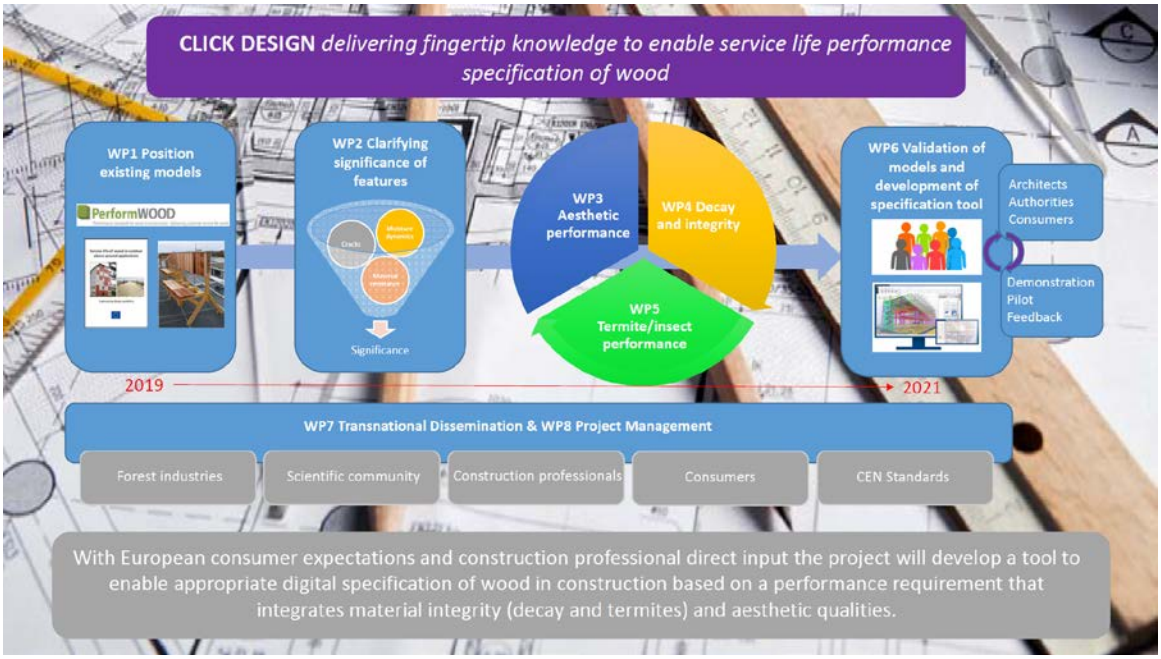

Figure 1. CLICKdesign project schematic showing proposed work packages.

The project builds on the foundations of the basic models and previous research work that comprise the existing knowledge landscape (Figure 2). Existing performance classification research has drawn together aspects of design detailing, climate and material and looked at forecasting performance compared to performance observed for construction products in buildings across Europe (PerformWOOD, WoodExter). Whilst this worked well as a rule of thumb it was missing two key features: aesthetics and insects.

In addition, modelling the effect of fungal decay on mechanical properties of wooden structures is being made, going beyond the simple limit states of previous work e.g. ‘onset of decay’ or ‘failure’. Including these features has never been done before alongside the relatively mature model position that we have established in Europe for materials, strength, decay, design and performance.

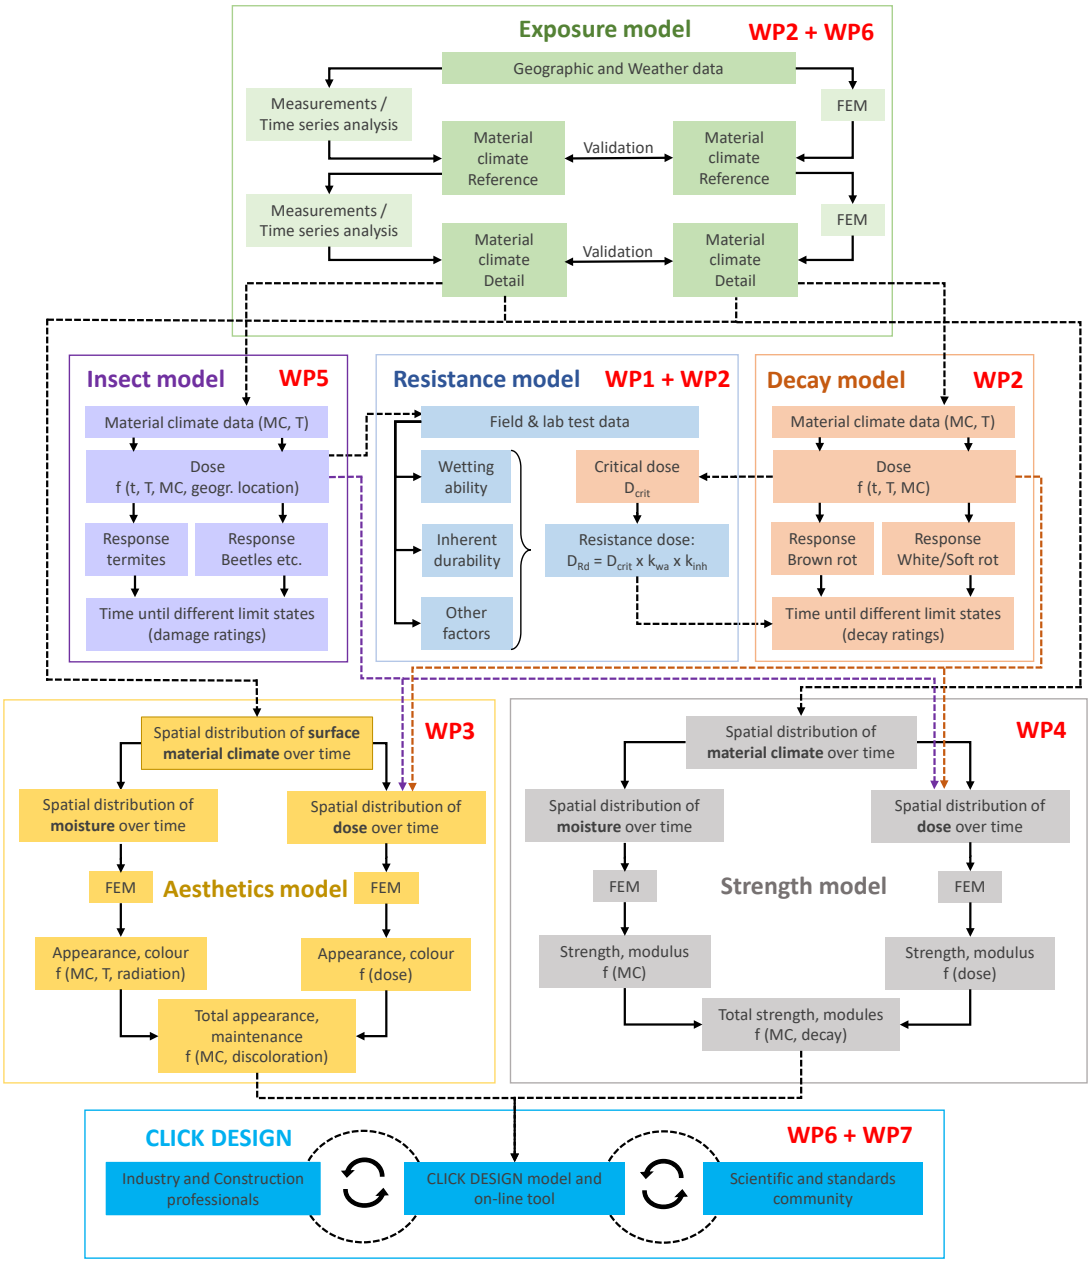

Figure 2. Different elements of performance modelling addressed in CLICKdesign.

For exterior cladding and other applications of wood and wood-based products the acceptance of changes in aesthetics (weathering, colour change, mould) is the key customer parameter (Gobakken 2009, Gellerich *et al.*, 2017). Forecasting of surface changes in terms of discoloration, roughness, overall appearance is therefore indispensable and needs to be linked with other performance models. This is especially critical for Use Class 3 (outdoor above-ground) wood performance classification and for pan-European uptake.

Different parameters need to be taken into account in order to define the risk for a wooden element of being degraded by biological agents, including termites and other insects. Subterranean termites are widely distributed in warm climates across the countries of southern Europe, both in rural and in urban areas. The most serious harm caused by subterranean termites to buildings is the degradation of the wooden elements, in particular those ensuring the integrity of the building such as the timber frame, load-bearing elements and structural panels.

Key to the success for CLICKdesign is that the tool finds application across Europe's rich diversity of geographic, climatic and cultural regions. The integration of climatic conditions (meso, macro and micro) into the models is fundamental and one approach where this is being tackled. The weather through experiences in projects such as DuraTB and Woodlife are translatable into microclimate in the wood and its response. A relationship connecting climate parameters to the material climate makes it possible to analyse a wide range of regional climates through use of open meteorological databases such as ECMWF www.ecmwf.int. Dosimeter approaches developed to describe the interrelationship between material-climatic parameters (exposure dose), material-specific resistance (resistance dose) and wood degradation (response) can then be used to study the regional-specific performance. The same methodology is also be employed for predicting degradation by termites and other insects. For that purpose, input variables need to be different and will be sought from existing field test data and short-term resistance tests performed within CLICKdesign. Success will be possible using a structured approach that couples models and enables direct localisation for the user. In addition, factors that differ between countries and regions of Europe we are cognisant of fostering the different traditions of use of wood, differences in expectations on service life and warranties, differences in cultural aspects towards product maintenance and language accessibility.

2.3 Project Facts

Project CLICKdesign started 1 March 2019 and runs for 3 years. A consortium of 8 European organisations is delivering the core research components of the project comprising building physics, wood science, BIM, service life modelling and entomology. It also has a direct link to the expert research team in FPI Innovations, Canada to look at global application and a diverse pan-European industry group of 18 members who will help pilot and bring together the modelled components of performance of wood in use to develop an open source tool.

2.4 Project Highlights to Date

Whilst additional DBMC papers (*e.g.* Digital transformation of biological processes and building design theory) are reporting on some of the detail a summary of highlights against work package (WP) are shown in Table 1.

3 Conclusions

The specification of performance of wood products is complex and fraught with inconsistency and requires use of multiple platforms for data, experience, standards and national recommendations. CLICKdesign will provide a tool that has within it the decades of excellent research, the complexity of the standards specification systems and the variation of approach due to tradition, materials and culture across Europe. The tool will be accessible to professional

users and will be refined with industry to ensure relevancy and accelerate its uptake and use. The project supports “fit for purpose” product specification and enables specifiers and users to understand the impact of their choices on performance.

Table 1. Summary of project CLICKdesign highlights up to November 2019.

Work Package	Achievements
1 Position existing models	A full review of existing models has been completed and an analysis extracting useful features completed.
2 Clarifying missing features	Research on missing features from existing models and testing of these features that impact on performance is underway including splash water effects, cracking, microclimate, vegetation and driving rain.
3 Aesthetic performance	Definition of a numerical parameter for aesthetic quality is underway alongside limit state definitions. A tool is ready that can be used to simulate changes in visual appearance due to weathering for facades.
4 Decay and Integrity	Hygrothermal models are being refined to include aspects of the spatial distribution of decay in wood to understand impact on structural integrity and enable deeper finite element analysis.
5 Termite/insect performance	A measure of the performance of relevant construction materials with regards to insect degradation is being laboratory tested to help define the performance measure.
6 Validation of models and specification tool	A specification tool has been developed to enable focus on its adaption and the inclusion of aesthetic and insect models.
7 Dissemination	Through conferences and articles over 15,000 construction professionals, regulators and product manufacturers have been reached.
8 Project management	A new self-funding partner the University of Vigo has joined the project which brings new expertise and includes Spain into our European reach.

Abstract. *This study explores the permeability of the partial replacement of cement using ultra-fine reactive fly ash (URFA) and silica fume. URFA is an industrial by-product from thermal power plants and it has a smaller spherical particle size (0.1 μm to 10 μm) than the general fly ash. The fixed water-to-binder ratio was 0.45 and the replacement of cement was used as 5% and 10%. The combinations of URFA and silica fume in composites were used as 5% URFA plus 5% silica fume and 8% URFA plus 2% silica fume. The results show that the inclusion of URFA was enhanced to increase the workability, and help to produce pozzolanic reaction and C-S-H colloids. The colloids were filling the pore structures to increase the compactness of specimen, which is consistency with the increased the compressive strength and reduction of the dry shrinkage. It also was reduced the chloride ion penetration and non-steady state migration coefficient, which is helpful for improving the mechanical properties and permeability. The composites with 10% URFA had a better performance. For blending specimen, it was also a tendency to improve mechanical properties and permeability; and the combination of 5% URFA and 5% silica fume in composites enhanced better performances.*

Keywords: *Ultra-Fine Reactive Fly Ash, Chloride Diffusion, Durability, Pore Structures.*

1 Introduction

Fly ash is a popular pozzolanic material with high SiO_2 and Al_2O_3 content. When cemented with water, the cementing performance is relatively low (Yang et al., 2018), but it will be activated by hydroxide ions (OH^-). Fly ash is usually added to cement as a pozzolana because it can be cured in wet conditions or underwater and further protect hardened materials from chemical attack. In most cases, fly ash is obtained from thermal power stations and is recycled as a pollution control measure, usually blended with ordinary cement to improve cement performance (Li *et al.*, 2014).

Fly ash is sufficiently reactive when it reacts with water and CaO in the cement (Telesca *et al.*, 2017). At room temperature, C–S–H gels are formed in the internal structure of the mixture, thereby forming hydraulic cementitious materials (Temuujin *et al.*, 2009; Duan *et al.*, 2017). Fly ash is also used to improve the performance of concrete in the fresh and hardened state, for improving workability, attaining high compressive strength at the early age, achieving long-term compressive strength, low drying-shrinkage and creep coupled with

excellent durability properties (Zuquan *et al.*, 2007; Xu *et al.*, 2017; Ahmad *et al.*, 2019; Tan *et al.*, 2019).

Several prominent researchers have devoted time to exploring the characteristics and application of fly ash in cementitious materials over the years and the general categories in which fly ash can be grouped regarding its effect on concrete includes morphological, active and micro-aggregate effects (Aiqin *et al.*, 2003; Aiqin *et al.*, 2004; Li *et al.*, 2013; Gardner *et al.*, 2015; Xu *et al.*, 2017). In concrete, fly ash has several functions as the concrete ages. In the early age stage, fly ash can act have a physical effect in that it fills up spaces in the microstructure of the concrete and it is also involved in the formation of ettringite. In the long term, they mainly participate in the hydration reaction in the form of silicon-aluminum binders (Shi *et al.*, 2006). At a later age, fly ash has two effects: it enhances the cohesion between molecules within the particle structure, and also absorbs the $Ca(OH)_2$, reducing its effect (Kolias *et al.*, 2005; Brostow *et al.*, 2016). However, Most of the molecules of the fly ash remain un-reacted even after a long period of curing, so fly ash may also be considered as a composite material with the ash particles serving as reactive micro-aggregates (Nadesan *et al.*, 2018). Structurally, fly ash is composed of lots of fine spherical micro-spheres, which are large glassy particles existing in a crystalline internal structure of fly ash. Due to density difference, the internal molecules of fly ash which are also called micro-beads or micro-spheres, are classified as sinking beads and floating beads (Li *et al.*, 2014). These micro-spheres are obtained from pulverized fuel ash (also called pulverized fly ash in some countries).

In the past decade, ultra-fine reactive fly ash (URFA) having very fine particles have been extracted by processing conventional fly ash, and it is becoming increasingly popular in the construction industry (Bagheri *et al.*, 2013). These fine particles often have a similar chemical composition with the conventional fly ash, but it has reduced surface area per particle. Recent research has shown that URFA exhibited better pozzolanic activity and more desirable performance in concrete than normal fly ash (Elsayed *et al.*, 2011; Duan *et al.*, 2018; Han *et al.*, 2019). When heated, micro-spheres heat up and crackle until they burst at about 260°C; their shells start to splinter at about 1100°C and finally collapse at about 1300°C. The superfine particles obtained can then be used to partially replace Portland cement in cementing material systems and their particulate structures. This study aims to determine its suitability as a pozzolanic additive to improve the performance of cement-based materials.

2 Experiments

2.1 Materials

Type I Portland cement was used in this study and it had a specific gravity of 3.15 and fineness of 3310 cm^2/g. The fine aggregates are natural river sand, it has an SSD specific gravity of 2.69, an absorption of 1.45% and a fineness modulus of 2.73. The specific gravity and specific surface area of silica fume is 2.20 and 22500 m^2/kg, respectively. Silica fume having an average content of 94.1% silicon dioxide was used in powder form. URFA was provided by TRIAXIS Corporation from a power plant in Inner Mongolia. The specific gravity and specific surface area of URFA is 2.20 and 3380 m^2/kg, respectively. URFA has an average content of 49.11% silicon dioxide, 28.07% aluminum oxide and 8.84% calcium oxide.

The SEM photo of URFA particles is shown in Fig. 1 and the average particle size was between 0.1 μm to 10 μm.

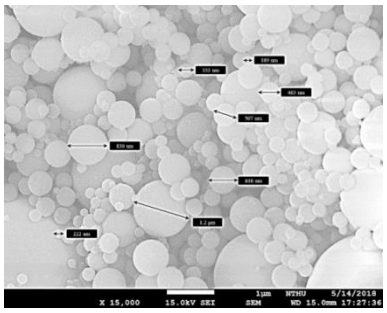

Figure 1. SEM photo of URFA.

2.2 Mix Design and Test Methods

According to the ASTM C109 specification, the water/cementitious ratio (w/c) of the mortar specimens was kept constant at 0.45, while the mass ratio of the cementitious /fine aggregates was 1: 2.75. Table 1 lists the mix designs for all mixes. The specimens were numbered using the letters and numbers to indicate the kind of replaced materials and dosage of the replaced materials. OPC, F, S denotes ordinary Portland mortar, URFA and silica fume; 5 and 10 refers to specimens containing 5% and 10% replaced materials. Table 2 presents the tests performed, the dimensions of the specimens and the standards.

Table 1. Mix design (kg/m^3).

Mix no.	Water	Cement	URFA	Silica fume	Fine aggregates	SP
OPC	242.6	547.9	0	0	1506.7	4.0
F5	243.0	520.5	27.4	0	1496.6	3.6
F10	244.0	493.1	54.8	0	1486.5	2.5
S5	241.9	520.5	0	27.4	1496.6	4.7
S10	240.9	493.1	0	54.8	1486.5	5.7
F5S5	242.1	493.1	27.4	27.4	1486.5	4.5
F8S2	243.4	493.1	43.8	11.0	1486.5	3.2

Table 2. Test methods.

Test Target		Specimen Dimensions (mm)	Referenced Standard
Fresh properties	Flow test	-	ASTM C230
Mechanical properties	Compressive strength test	50 × 50 × 50	ASTM C109
Durability	Drying shrinkage test	285 × 25 × 25	ASTM C596
	Rapid chloride penetration test	ϕ100 × 50	ASTM C1202

Micro-structure observations	Mercury intrusion porosimetry test	10 × 10 × 1	ASTM D4404
	SEM observation	10 × 10 × 1	ASTM C1723

3 Results and Discussion

3.1 Flowability

The results of flow test for all mixes are summarized in Table 3. The fluidity of the mortar specimens was controlled at 110±3% using appropriate amount of superplasticizer. The results indicated that the dosages of superplasticizer had a decrease trend with the increase in the replacement of URFA due to the due to its perfect spherical shape and micro-sized particles. However, the flowability had a decrease trend with the increase in the inclusion of silica fume due to its larger surface area. The desired flow and rheological properties will determine the optimal design mix that 10% URFA in mortar specimens should be used. The combination of silica fume and URFA in mortar specimens still had great flowability and F8S2 specimens had lowest dosages of superplasticizer at the desired flow.

Table 3. Example of the construction of a table.

Mix no.	Flowability (%)	Superplasticizer dosages (wt.% of cement)
OPC	112.3	0.73
F5	111.8	0.65
F10	110.0	0.46
S5	109.8	0.85
S10	108.3	1.04
F5S5	110.8	0.82
F8S2	109.8	0.58

3.2 Compressive Strength

The results of compressive strength test for all mixes are illustrated in Figure 2. As expected, the specimens containing 10% silica fume had highest compressive strength for all ages. The strength development trend of F10 specimens was closed to that of the S5 specimens. Compared with silica fume, URFA has a much smaller specific surface area, so it can increase bulk density without excessively increasing the total solid surface area. It is able to fill the voids in cement to increase the packing density of the cementitious materials. The compressive strengths of the F5S5 specimens were higher than that of the S5 specimens and F8S2 specimens; and the compressive strengths were lower that of the S10 specimens. URFA is considered to be a good filler for increasing parking density without excessively increasing surface area. It has a particle size of micrometer-scale and is spherical in shape. It is finer than cement and ordinary fly ash. Inclusion of URFA showed improved properties in compressive strength due to the active pozzolan reaction and filling effect.

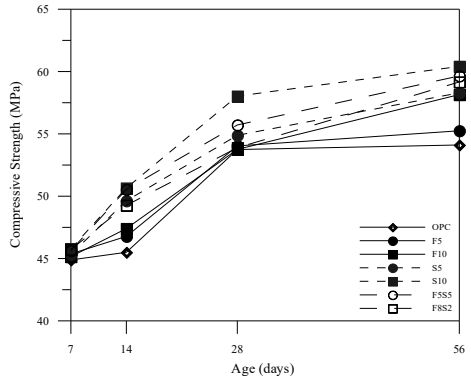

Figure 2. Compressive strength development curves.

3.3 Drying Shrinkage

The results of drying shrinkage test for all mixes are summarized in Figure 3. It indicated that drying shrinkage of the specimens containing URFA was lower than that of the specimens containing silica fume and control specimens. URFA can efficiently inhibit the dry shrinkage of mortar specimens due to the smaller specific surface area. URFA has a late hydration reaction and the dispersion effect on the cement particles can reduce the total hydration heat of the paste, and improve the drying shrinking performance.

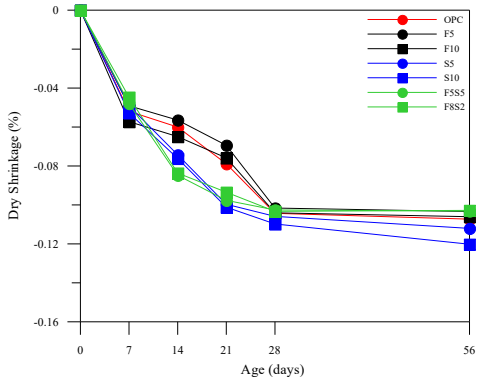

Figure 3. Dry shrinkage curves.

3.4 Chloride Penetration

The results of rapid chloride penetration test for all mixes are illustrated in Figure 4. The results indicated that the total charge passed of control specimens was higher than 10000 coulombs and the operated temperature of control specimens was higher than 90 ˚C. The test of control specimens has been stop because the temperature of the solutions should not be allowed to exceed 90 ˚C in order to avoid damage to the cell and to avoid boiling off the solutions. As expected, the specimens containing 10% silica fume had lowest total charge passed due to the finer particles. The trend of F5S5 specimens is closed to that of S5 specimens, which is due to the pore structure modification. Finer silica fume and URFA particles mixed into the mortar specimens improved the compactness through pozzolanic reactivity and pore filling effect. It may be as mainly hydrated reaction that $Ca(OH)_2$ reacted

with SiO_2 or Al_2O_3 to form C-S-H or C-A-S-H colloids.

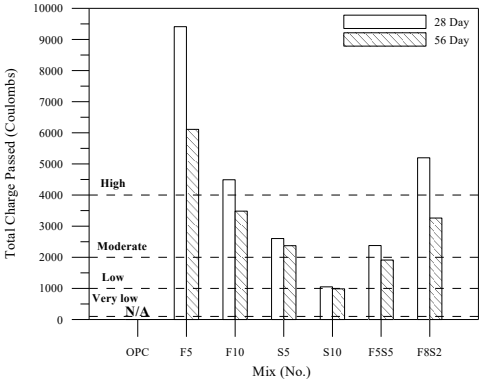

Figure 4. Total charge passed histograms.

3.5 Pore Structures

The MIP test results of the specimens containing URFA and control specimens are shown in Fig. 5. It indicated that the cumulative intrusion of specimens containing URFA significantly decreased that the control specimens. It was confirmed that the finer particles of URFA was useful to the pore structure modification, which is in agreement with the results of chloride penetration tests and compressive strength tests.

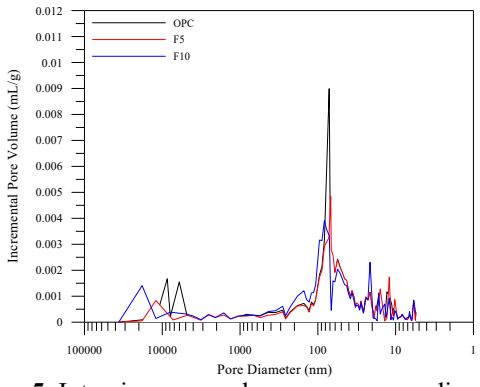

Figure 5. Intrusion pore volume versus pore diameter.

3.6 SEM Observations

It took SEM images of the various specimens at 28 days at 5000x magnification as illustrated in Figure 6. The results showed small porosity and smooth surface in the URFA or silica fume specimens than in the control specimens. Many pores in the URFA or silica fume specimens were filled with ettringite and C-S-H gel. C-S-H gel is the product of the hydrated reaction between water and tricalcium silicate or dicalcium silicate. Finer particles are needed to fill these pores. As shown, most of the pores have been filled with ettringite and C-S-H gel, which presents a dense appearance and reduces the chance of penetration of harmful substances. However, an increased amount of URFA may cause a partial reaction in the hydration process. Non-react particles of URFA can be seeing in the surface of the micro-structures. URFA is excellent cementitious filler for improving the flowability and strength of

cement pastes as shown in SEM photos and it needs more curing age to keep a continued hydration reaction.

(e) F8S2 specimens

Figure 6. SEM photos for each mixtures (x5000).

4 Conclusions

- In order to produce a balance with a desired increase in packing density and suppression of an increase in undesired surface area, URFA microspheres thinner than cement but thicker than silica fume would be a better choice.
- URFA has a particle size of micrometer scale and is spherical in shape. It is finer than cement and ordinary fly ash. The specimens containing URFA can increase the packing density so as to enhance the performance of mortar specimens. It also can significantly decrease the dry shrinkage.
- SEM observations and MIP analysis confirmed that the finer particles of URFA were useful to the pore structure modification, which is in agreement with the results of chloride penetration tests and compressive strength tests.
- Environmental friendly and helps to reduce the carbon footprint produced in cement production, since it can be used to replace cement in cement mixtures, and from a life cycle assessment perspective. It is feasible to consider URFA as a relatively CO_2 free resource.

Abstract. *One of the design team's tasks is assuring that their project has a low negative impact on the environment. This comes from regulations as well as expectations of direct benefits (reduction of operating cost, the project's improved image in the eyes of the public, etc.). To fulfill this task, one needs to define criteria for assessing the design options. These are to correspond to the individual qualities of the project, and they should be significant and possible to assess. The paper, divided into two parts, presents a review of the literature concerning the criteria for the assessment of design solutions defined as "green" or "environmentally friendly". Part I presents the method of the analysis and investigates into the number and type of criteria adopted in the sample of papers being the object of analysis. Part II focuses on the ways of defining criteria values, weights, and methods of multicriteria assessment.*

Keywords: *Sustainable Construction, Component Selection, LCA, Literature Review.*

1 Introduction

It becomes apparent that humanity's appetite for resources became too much for the planet Earth to bear (Meadows *et al.*, 1972; Turner, 2008). Exponential population build-up combined with the global pursuit of economic growth results in the exponential growth of the demand for housing and infrastructure as well as production facilities. Construction means consuming a lot of energy, water, land, and minerals for creating millions of tons of materials, moving them to the destination and installing, followed by dismantling and relocating with the amount of effort comparable with that during erection. Technological progress makes construction components increasingly complex and sophisticated, which adds to the problem: highly processed products consume even more resources and are difficult to recycle. In the face of resource depletion and the likely suffocation with its own refuse within decades, humanity is dragged (Komatsu *et al*., 2019) towards the sustainable economy (D'Amato *et al*., 2019) and, in particular, sustainable construction (Goh *et al.*, 2020).

One of the aspects of construction sustainability is reducing the project's and the resulting built facility's negative impact on the environment. This impact is typically assessed in the course of some form of Life Cycle Analysis (LCA) (Ortiz *et al.*, 2009). The LCA has become an established practice in optimizing designs and assessing the quality of the built environment. The idea, described among others by ISO 14040 standard, evolved into a plethora of methodologies, tools and individual reports on analyses for estimating the impact of built assets on the environment from the perspective of:

- particular construction materials/products (*e.g.* Häfliger et al., 2017),
- functional components of particular buildings (*e.g*. Kellenberger and Althaus, 2009),

doi:10.23967/dbmc.2020.177

- whole buildings in the context of the way of use and building maintenance scenarios (Bucoń, 2019; Häfliger *et al*., 2017; Hasik *et al*., 2019),
- neighborhoods/cities (Bak *et al.*, 2019; Goldstein et al., 2013; Jeong and Ramirez-Gomez, 2018; Nematchoua *et al.*, 2020).

They typically share the element of assessing the environmental consequences of using particular construction materials in the building's fabric, so the materials' contribution to the overall environmental impact. However, even in this narrow aspect, the scope, criteria, and measures used in the analyses are not identical (Doan *et al.*, 2017; Park *et al.*, 2017).

On the one hand, there exist standards on reporting the environmental impact of products, (ecolabelling). As for the construction products, the European EN 15804 standard that sets requirements for voluntary Environmental Product Declarations (EPDs) (Kuittinen and Linkosalmi, 2015; Piasecki, 2014). On the other hand, the standards and methodologies evolve (Allacker *et al.*, 2017). Due to the proliferation of LCA methodologies, the comparability of information on a product's environmental qualities becomes an issue (European Commission, 2013; Galatola and Pant, 2014; Passer *et al.*, 2015). Many researchers and practitioners compare the environmental qualities of construction products using their own criteria and measures.

The paper is the first part of a review of the most recent literature on the comparison or assessment of construction products and components to select the "environmentally friendly" ones. The authors provide a classification of research problems covered by the sample, discuss papers devoted to designing "green" materials and selecting sustainability criteria for construction materials, products, or components. Finally, they investigate into the number and type of criteria in use, thus into how the authors understand the environmental impact of construction products or built facilities.

2 Materials and Methods

2.1 Benchmark Set of Criteria and the Scope of Analysis

The standards on EPDs are in use for some time, and the number of declarations in the databases is growing: this idea of standardized communication of environmental product properties seems to establish itself in practice. For this reason, the authors expect that the presentation of solutions to problems directly or indirectly related to construction material, component, or construction method selection in the field of architecture, building, and civil engineering are likely to draw from the methods elaborated by the environmental scientists.

Table 1. Classification of life cycle stages for assessing environmental impact of construction products, based on EPD (ITB, 2013).

Product stage	Construction process	Use stage	End of life	Benefits and loads beyond the system boundary
A1. Raw material supply A2. Transport A3. Manufacturing	A4. Transport to site A5. Installation	B1. Use B2. Maintenance B3. Repair B4. Replacement B5. Refurbishment B6. Operational energy use B7. Operational water use	C1. Deconstruction C2. Transport C3. Waste processing C4. Disposal	D. Reuse-recovery-recycling potential

Table 2. Indicators of environmental impacts, aspects of resource use and waste, based on EPD (ITB, 2013).

Environmental impacts	Environmental aspects of resource use (modified)	Environmental information of waste categories
Global warming potential	Total use of renewable primary energy (as raw mat. or energy)	Hazardous waste disposed
Depletion potential of the stratospheric ozone layer	Total use of non-renewable primary energy (as raw mat. or energy)	Non-hazardous waste disposed
Acidification potential of soil and water)	Use of secondary material	Radioactive waste disposed
Eutrophication potential	Use of renewable second. fuels	Components for re-use
Formation potential of tropospheric ozone	Use of non-renewable second. fuels	Materials for recycling
Abiotic depletion potential (ADP-elements) for non-fossil resources	Net use of fresh water	Materials for energy recovery
Abiotic depletion potential (ADP-fossil fuels) for fossil resources	-	Exported energy

Therefore, in the literature review process, the sources' approach to the life cycle phases was juxtaposed to life cycle phases used in LCA and adopted for EPDs (Table 1). In this paper, the "environmentally friendly" aspects were considered only those covered by the scope of the environmental impacts, aspects of resource use, and generation of waste as defined in EPDs (Table 2) prepared according to EN 15804:2012 before its amendment in 2019 (ITB, 2013).

2.2 The Sample

The query was arbitrarily limited to one database (Web of Science), publications from the years 2016-2020, and the following structure of search terms to identify within the title, abstract and author-specified keywords:

criteria AND construction AND (material OR product) AND (select* OR choice OR choose) AND ("environmentally friendly" OR green OR sustainable) (1)

The query produced a reasonable number of 110 publications. The selection was manually refined, on the basis of content analysis, to find papers that focused explicitly on:

- analyzing criteria for selecting materials or component options or options of construction methods based on their environmental impact,
- presenting methods or tools for assessing the environmental impact of materials or components or construction methods to justify their selection or ranking,
- individual presentations of selection/ranking problems as above (case studies),
- arguments for "green" properties" of new materials if juxtaposed with "traditional" materials.

For this reason, a considerable number of papers were excluded as proposals of new certification systems for whole buildings, general-purpose multicriteria methods where "green" features served only as examples of possible criteria, and papers focused on ecology (impact of built structures on particular species). One paper was excluded for not being available in English, and four proved unreachable (no access to full text). Therefore, the final sample comprised only 43 publications.

2.3 The Method

The sample of papers was analyzed in terms of aspects of sustainability covered by the analysis, scope of life cycle stages, sources of input, and mathematical methods used for selecting the best option (if applicable).

3 Results and Discussion

3.1 Topics of the Sample

The papers of the sample were classified into four groups according to their research problem (some paper dealt with more than one):

- designing environmentally-friendly materials (9 papers),
- selecting a set of sustainability criteria for comparing construction products or components of built structures (7 papers),
- assessing the sustainability of alternative solutions (materials, material supply chains, component design) (33 papers),
- optimizing construction components (2 papers).

3.2 Type and Number of Environmental Criteria

Nine papers from the sample focused on introducing environmental criteria into the design of materials themselves (Table 3). One of them (Imron *et al.*, 2017a) argued for eco-friendly properties of a new drywall material containing waste from food production, though, at the early stage of research, the argument was based only on intuitive SWOT analysis with two arbitrarily selected environmental criteria. Nevertheless, the advantages were utilizing waste and thus reducing the consumption of non-renewable resources.

Table 3. Papers devoted to material design (selecting components for a mix).

Paper	Aspects	Life cycle	Criteria list	Weights, method of calculation	Env. criteria	Criteria values:	Method
(Imron *et al.*, 2017b)	En	A	Arbitrary	-	2	-	SWOT
(Ahmed *et al.*, 2019)	T,Ec, En, S	not explicit	Team of experts	Team of experts, AHP; sensitivity analysis	6	T. of experts (pairwise comp.)	AHP, TOPSIS
(Falqi *et al.*, 2019)	T,Ec, En, S	not explicit	Arbitrary	M. experts, arithmetic mean of fuzzy ratings	5	M. experts, arithmetic mean of fuzzy ratings	fuzzy TOPSIS
(Kurda *et al.*, 2019)	T, Ec, En	A1-A3	Arbitrary (LCA)	Arbitrary (no. of scenarios)	2	Databases & calculations	SAW
(Rashid *et al.*, 2018)	T, En	A1-A3	Arbitrary	Arbitrary	2	Databases & calculations	AHP, TOPSIS
(Reddy *et al.*, 2020)	T, Ec, En, S	not explicit	Arbitrary	Not applicable	1	Databases & calculations	PSI
(Reddy *et al.*, 2019b)	Ec, En, S	A-D	Arbitrary	M. experts, relative importance index	5	M. experts	AHP
(Reddy *et al.*, 2019a)	Ec, En, S	A-D	Arbitrary	M. experts, AHP	5	M. experts	AHP
(Suarez Silgado *et al.*, 2018)	Ec, En	A1-A3	LCA	Arbitrary; sensitivity analysis	11	Databases & calculations	VIKOR

The remaining papers from this group presented a multicriteria selection of components (such as recycled aggregates or supplementary cementing materials made of waste) for concrete or asphalt mixes. All authors proposed a combined index to select the best mix out of the set of samples. However, the types of criteria incorporated in the indices were an individual selection of environmental (En), economic (Ec), social (S), and, in some cases, technological (T) properties of the mix and the hardened material. The number of environmental sub-criteria varied from one to eleven; the most common among them were: energy use and global warming potential. The authors did not agree on the life cycle stages included in the assessment.

In four papers out of seven, the authors decided to use criteria originating from some established LCA methodologies and calculate their values according to relevant life cycle inventory databases. Two papers (Kurda *et al.*, 2019; Suarez Silgado *et al.*, 2018) came from Europe, where such databases are available. One paper originated from Pakistan (Rashid *et al.*, 2018) and based on data found in the literature. The last one was from India (Reddy *et al.*, 2020); its only environmental criterion was service life estimate. Other authors resorted to expert ratings of criteria values expressed in some form of Likert scales or as pairwise comparisons.

Seven papers from the sample focused primarily on selecting sustainability criteria for comparing construction products or components of built structures. Khoshnava *et al.* (2018) observed that, in practice, the choice of ”green” criteria was done arbitrarily by the decision-makers. Therefore, the authors undertook a literature review and a broad survey among construction professionals to decide on a general-purpose set of criteria and their relative importance, as perceived by the experts from Malaysia. The product of their research was a list of 23 criteria (out of them, 14 related with environmental impact) and their ranking. Amer and Attia (2019) conducted a broad survey among European architects to define the set of criteria and their relative importance specifically for the sustainable design of vertical extensions of buildings. (Herda *et al.*, 2017), considering the problem of comparing construction products and switching to sustainable construction in Kenya, pointed to the lack of reliable databases of product properties that correspond to local conditions. Hoxha, Haugen and Bjorberg (2017), to propose a list of “green” criteria of material selection to appeal to the wider public, decided to investigate into the understanding of sustainability in Kosovo by means of a survey among non-professionals. Rashdan and Ashour (2018) reviewed the literature to define a list of aspects worth consideration in sustainability assessment of interior design products. Li *et al.* (2019) reviewed literature on factors incorporated into LCA and life cycle costing (LCC) related with assessing benefits of using solid waste for road pavement, finding that there is still no agreement on what properties and impacts should be included in such analyses. (Ishak *et al.*, 2017), to measure the self-assessed level of compliance of Malaysian construction products manufacturers with the rules of “green” production, compiled a list of as many as 33 environmental criteria based on the literature.

4 Summary and Conclusions

Judging by the analyzed sample of papers, there exists no agreed set of environmental criteria for comparing sustainability of alternative construction products, components and construction methods (Figure 1).

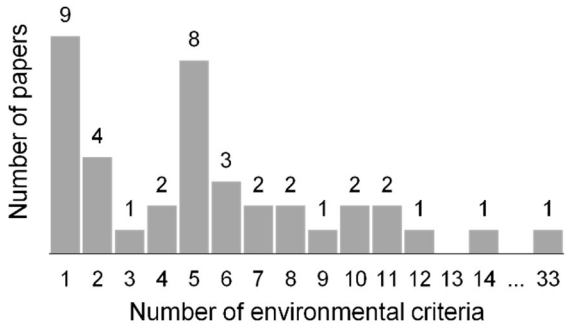

Figure 1. Frequency of selecting a particular number of criteria in the sample of papers.

Interestingly, even in the case of similar problems, the numbers and the type of criteria differed significantly. For instance, Potkany, Gejdos and Debnar (2018), Svajlenka and Kozlovska (2018), and Hassan and Johansson (2018) compared options of building frames basing on a set of sustainability measures without combining them into one index. They all did it within "cradle to gate" boundaries. Respectively, they used: six criteria known from EPD's (Table 1): primary energy input for production (PEI), global warming potential (GWP), acidification potential (AP), eutrophication potential (EP), ozone depletion potential (ODP), and photochemical ozone creation potential (POCP), three criteria (PEI, GWP, AP), and a single criterion (GWP).

Even the authors who decided on a single factor related to the environmental impact chose different criteria: energy embodied in the material used for a component, energy embodied up to the construction phase, potential for recycling, quantity of waste, GWP, or other. Moreover, most authors identified the criteria in the course of a literature review and interviews with experts to refine the list to suit a particular decision problem. Only 14 admitted drawing directly from particular LCA methodologies.

It is likely that the sample of papers analyzed above is not representative of the state-of-the-art in research on sustainability in construction. However, it indicates that this field is still in the stage of development.

Abstract. *One of the design team's tasks is assuring that their project has a low negative impact on the environment. This comes from regulations as well as expectations of direct benefits (reduction of operating cost, the project's improved image in the eyes of the public, etc.). To fulfill this task, one needs to define criteria for assessing the design options. These are to correspond to the individual qualities of the project, and they should be significant and possible to assess. The paper, divided into two parts, presents a review of the literature concerning the criteria for the assessment of design solutions defined as "green" or "environmentally friendly". Part I presented the method of the analysis and investigates into the number and type of criteria adopted in the sample of papers being the object of analysis. This part focuses on the ways of defining criteria values, weights, and methods of multicriteria assessment.*

Keywords: *Sustainable Construction, Component Selection, LCA, Literature Review.*

1 Introduction

In the face of resource depletion and the likely suffocation with its own refuse within decades, humanity is dragged towards a sustainable economy and, in particular, sustainable construction (Goh, Chong, Jack and Mohd Faris, 2020). One of the aspects of construction sustainability is reducing the project's and the resulting built facility's impact on the environment. This impact is typically assessed in the course of a Life Cycle Analysis (LCA) (Ortiz, Castells and Sonnemann, 2009). The idea of LCA evolved into many methodologies that share the element of assessing the consequences of using particular construction materials in the building's fabric. However, even in this narrow aspect, the analyses' scope, criteria, and measures are not identical (Park, Yoon and Kim, 2017). The standards and methodologies evolve (Allacker, Mathieux, Pennington and Pant, 2017). Due to the proliferation of LCA methodologies, the comparability of information on products' environmental qualities becomes an issue (European Union, 2013).

This paper is a second part of the review of the most recent literature on selecting the "environmentally friendly" material and component options in construction. The authors discuss a sample of papers devoted to assessing the sustainability of alternative solutions (materials, material supply chains, component design) and optimizing construction components, focusing on the ways of defining criteria values, the criteria's relative importance, and selecting the methods of multicriteria assessment.

2 Materials and Methods

The sources' approach to the life cycle phases was juxtaposed to the life cycle phases used in LCA and adopted for Environmental Product Declarations (EPDs). The "environmentally friendly" aspects were considered only those covered by the scope of environmental impacts, aspects of resource use, and generation of waste as defined in EPDs prepared according to EN 15804:2012. The query was limited to one database (Web of Science), publications from the years 2016-2020, and a particular structure of search terms, as presented in Part I. The selection was manually refined. The final sample comprised 43 publications. The sample was analyzed in terms of aspects of sustainability covered by the analysis, life cycle stages considered, sources of input, and mathematical methods used for selecting the best option (if applicable).

3 Results and Discussion

77% of papers of the sample focused on assessing the sustainability of alternative solutions. The problems differed much in terms of the object of the analysis: from comparing particular types of materials in the context of a local market, through types of complex components of buildings or civil engineering structures, to alternative ways of conducting whole projects or selecting supply chains to serve certain projects or regions.

Table 1 list the papers whose authors proposed some form of an integrated measure of sustainability with reference to alternative construction products (like bricks, windows, water pipes, paints) offered in a particular market.

Table 1. Works on ranking or selecting most sustainable construction products in a certain market/region (not adopting a project perspective).

Paper	Aspects	Life cycle	Criteria list	Weights, method of calculation	Env. criteria	Criteria values:	Method, output
(Govindan *et al.*, 2016)	Ec, En, S	not explicit	Arbitrary	M. experts, DEMATEL +ANP	10	Expert ratings: 1-5 scores used in example	TOPSIS,combined index
(Bissoli-Dalvi *et al.*, 2016)	En	A-D	Arbitrary	1 expert, ISMAS	7	Expert: ratings in 3-level scale	ISMAS, combined index
(Roy *et al.*, 2019)	Ec, En,S	not explicit	Arbitrary	M. experts, fuzzy pairwise comparisons, linear programming; sensitivity analysis	4	M. experts,, Fuzzy ratings	IVIF-CODAS. combined index
(Zhang *et al.*, 2017)	T, Ec, En	A1-A3+ disposal	Arbitrary	M. experts, DEMATEL +ANP; sensitivity analysis	5	Expert ratings in scale 1-5 in example	G-TOPSIS, combined index
(Mathiyazhagan *et al.*, 2019)	Ec, En,S	not explicit	team of experts /literature	M. experts, integrated by averaging; BWM	9	Expert ratings	fuzzy TOPSIS, combined index

(Maiolo *et al.*, 2018)	T, Ec, En	A1-A3	LCA (Impact 2002+)	Acc. to Impact 2002+	n/a	databases & calculations	multiplying two indices, combined index

A common feature of these papers is analyzing the options in abstraction from projects they might be used for. In this group, all papers but two presented analyses from the perspective of developing countries and based on criteria values rated by experts (though some methods were applicable also for measurable criteria).

For instance, Govindan, Madan Shankar, & Kannan (2016) used DEMATEL combined with ANP to establish the set of criteria and their relationships on the basis of opinions of multiple experts, and then TOPSIS for the assessment of options. They illustrated their approach on the example of selecting the "most sustainable" type of brick as perceived by the construction professionals (clients, architects, contractors) in UAE market. In this case, all 10 criteria related to the environmental impact would be possible to express as quantitative measures established in the course of LCA, but the authors were vague about the way of the source of their values; judging by the presentation of illustrative example, the values were expresses as arbitrary scores in a 1-5 scale. Bissoli-Dalvi *et al.* (2016) compared the sustainability of different types of windows used in Brazilian housing using an original ISMAS method. Due to the lack of databases of environmental product properties, they resorted to an individual set of "green" criteria and expressed their values by ratings in a unified 3-point scale (-1 for "worse than average requirements", 0 for "standard practice", 1 for qualities considered "better than acceptable"). The ratings were then treated as additive scores that, after being weighted, were combined into a quantitative index for direct comparison of options.

Rochikashvili and Bongaerts (2016) aimed at conducting the comparison of products to appeal to non-experts. For this reason, the authors did not use precise measures of environmental impact. Their criteria were selected arbitrarily and grouped into 4 categories: benefits, costs, opportunities, and risks. The sub-criteria related to the environmental impact belonged to the latter. Maiolo et al. (2018), to select the best type of water pipes applicable in particular soil conditions, conducted a thorough LCA (cradle to gate) of 10 products offered in the market using Impact 2002+ methodology, assuming Western European conditions. Then they combined its overall measure of environmental profile with the coefficient capturing mechanical properties. This was the only paper from this group resting upon precise measures of environmental impact.

Shipping large quantities of materials, as required in the case of construction projects, generates high cost, consumes fossil fuels and pollutes the natural environment. Therefore, the A2 and A4 phases of the lifecycle are a natural focus of construction sustainability researchers. In the sample, two papers were devoted to analyzing supply chains. Ahmadian *et al.* (2017) considered different sources, levels of prefabrication, modes and distances of transport. Designing their BIM-based supply chain management system, they argued that the environmental criteria should be project-specific and might be defined by experts, though they should refer at least to the material production, transport to the site and installation phase, as well as they should consider the potential of re-use and recycling. Basti (2018) analyzed the problem managing large quantities of earthquake debris, a current problem of Italian regions struck by natural disasters. He focused on environmental issues of deconstruction, transport, depositing, and reusing this material, as well as on constraints resulting from regulations. This was done not in a "per project" approach, but from the point of municipal strategies that consider the network of local enterprises to be engaged in the process, restrictions on road use for heavy transport, selection of means of transport with regard to location of debris processing, landfilling and reuse areas.

The biggest part of the sample of papers dealt with the problem of comparing alternative products of complex components from the perspective of a project (particular location, particular quantities, individual constraints due to the design of the building/civil engineering structure – Table 2).

Table 2. Works on comparing options of building components assuming perspective of a particular project.

Five works produced sustainability measures without combining them into overall scores

(less convenient for comparison, but not affected by subjectivity in normalizing criteria values and setting weights). Among them, two papers considered a sole measure of the environmental impact. Among them, two papers considered sole measures of environmental impact: Ananin *et al.* (2018) looked for the best type for walls of a residential building in Russia with the lowest energy embodied in wall materials, while Gomez-Soberon *et al.* (2016) compared 3 options of floors according to the type and quantity of waste generated by replacement.

As the number of factors worth considering in the assessment may be large, some generalized measures to facilitate a clear distinction between options may be useful. 11 papers presented such measures. Among them, Chen *et al.* (2019) presented an interesting problem of designing components to the liking of various stakeholders by using Quality Function Deployment and ELECTRE III. They proposed a new group decision making method and illustrated its use on the example of selecting flooring for office space. With this approach, the set of criteria was individually defined for each case, expressing the stakeholders' point of view.

Casanovas-Rubio *et al.* (2019) assessed sustainability of trenching methods. Their method, MIVES, normalizes criteria scores by utility functions based on relative preferences expressed by experts. The values of criteria were expressed as precise numbers (e.g. water consumption in dm^3 per 1m of trench) or as scores (if the effort to estimate the precise measure was considered too great; however, justification for calculating the scores was provided). The analysis produced a single measure, Sustainability Index for Trenches, to compare the options. Alberti *et al.* (2018) used the same method to assess sustainability of two options of a structural component, namely a tunnel slab of reinforced concrete, that differed in the type of reinforcement. Interestingly, they based on the evidence on the components' performance over 3 years of use in the same conditions. This was a unique feature of this research.

Santos *et al.* (2019) presented a decision-support tool for ranking alternative pavement designs. The tool allows the user to define their own weights of criteria or to select the weights as found by the authors in a survey. All 10 sustainability indicators related with environmental impact were measurable, clearly defined in the literature, with the methods of calculation or sources of values of confirmed reliability. To exclude selection of options that compensate poor performance in some aspect by good performance in others, an outranking method with threshold values was selected as the core of the decision support tool. Out of the sample of papers, this one was considered to present the most convincing line of reasoning for selection of criteria (though the authors direct the reader to their subsequent publications for details) and methods for the ranking of options.

The remaining papers (not listed in Table 2) were not devoted to assessing predefined component options, but to solving multicriteria design problems. BuHamdan *et al.* (2019) presented a simulation model built to assess effects of combined design changes in a number of components (the size of glazed area, type of windows and thermal resistance of envelope) on the building's cost, measures of environmental impact in the construction, operation and demolition phase. Marti, Garcia-Segura and Yepes (2016) constructed an automated design optimization tool that prompts the best beam profile, concrete class and contents of prestressing and reinforcing steel of a prefabricated U-beam used in bridge construction. The model produces solutions that satisfy structural requirements at minimum cost and embodied energy in phase A of the lifecycle.

4 Summary and Conclusions

Values of the criteria related to the environmental impact were either calculated or rated arbitrarily by experts, in the latter case using a variety of rating scales or in the course pairwise comparisons. Among 35 papers that compared/ranked options or aimed at finding an optimal solution, a dependence was observed (p-value in χ^2 test of 0,00124) between the location of the object of analysis and the authors' method to define the criteria values (Figure 1). This observation is rather obvious: the geographical coverage of construction products' life cycle inventory databases is only slowly expanded on South America, Africa, and Asia.

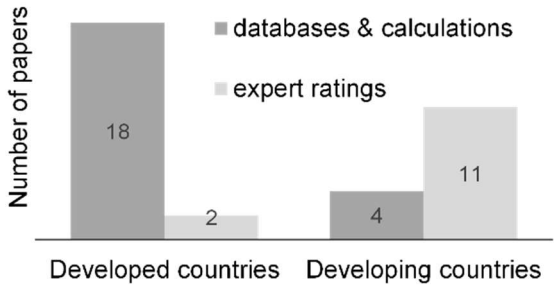

Figure 1. Methods of defining criteria values vs origin of the paper.

Nevertheless, a detailed and laborious calculation of criteria values in interval or ratio scales was not automatically an asset. As most of the authors who calculated criteria values this way (14 out of 22) aimed at providing an integrated index of sustainability to make the comparisons easier, they normalized the values in a way specific to the method of multicriteria analysis. Frequently, the precision of criteria measures was lost in this process, especially if measures were subject to pairwise comparisons. Four authors decided to directly account for the uncertainty of criteria ratings by expressing them by fuzzy or grey numbers.

Defining criteria weights, a key aspect of most multicriteria assessment methods, was most frequently done by collecting expert opinions. They were collected during panel meetings for direct consensus (10%) or independently, in interviews or questionnaire surveys (40%). Thus, 50% of authors based on weights prompted by the literature or decided to use arbitrary values, then check the sensitivity of their results to changes in criteria weights. Multiple opinions were aggregated in a number of ways: from mean scores to elaborate analysis in stakeholder groups.

As for the multicriteria assessment methods in use, the most popular of the established ones were TOPSIS (6 papers), AHP (5 papers), and VIKOR (3 papers). Some authors used a combination of methods or proposed their own to precisely account for the character of the problem. Nevertheless, out of 27 works that provided one combined measure for ranking options, 9 did not explicitly refer to any form of checking the sensitivity of the results to weights nor juxtaposed their ranking with rankings obtained by means of other methods.

The sample of papers analyzed above is certainly not representative of the state-of-the-art research on the environmental impact of construction. However, it indicates that this field is still in the stage of development. There is no agreement on the type of criteria, on their importance, nor the methods of assessment in analyzing the sustainability of construction products and components.

Abstract. *The exterior finish layer in building facades is exposed to considerable environmental loads, which can reduce the service life of the materials, increasing the need for replacement. New climate challenges impose to look more carefully at the long-term performance and durability of building components and materials. Thermal stresses due to daily temperature fluctuations and UV exposure can significantly damage facades and degrade their performance. This research measures the long-term performance of a responsive cementitious finish plaster. The developed cement plaster is combined with phase change materials (PCMs), and thermochromic (TC) pigments to control solar radiation and surface temperatures dynamically on the exterior façade year around. The main objective of the study is to quantify the effect of long-term UV exposure on the optical performance of the cement plasters. PCMs with three different melting temperatures of 18°C, 24°C, and 28°C were combined with two different colors of blue and red TC paint with a transition temperature of 31°C. Accelerated UV aging of the samples was performed using lab tests to simulate exposure to UV radiation for two years. The solar reflectance of the samples was characterized before and after the accelerated UV aging tests. The results of the aging tests revealed that UV exposure impacts the solar reflectance of the finish material based on the method of integrating the TC paint to the cement plaster. In the case of TC paint applied to the surface, the solar reflectance of the plasters with only the TC is reduced by 15% after aging, while the ones combined with PCMs have a similar solar reflectance value after aging.*

Keywords: *Durability, Building Façade, Thermal Energy Storage, Thermal Stress, Accelerated Aging, Urban Heat Island.*

1 Introduction

One of the main climate challenges in urban areas is the shifting weather patterns with increasing trends of temperature fluctuations in dense cities that can impact urban thermal comfort. The urban heat island (UHI) effect particularly is a known phenomenon that refers to the occurrence of higher ambient temperatures in cities compared to suburban areas (Santamouris *et al.*, 2016). This event is specifically due to higher solar absorption in urban surfaces such as building facades. In addition, the high surface temperatures of facades can lead to higher heat transfer through the building envelope leading to thermal comfort problems and higher energy demands. However, thermal stresses exposed to exterior building façade surfaces can critically impact the durability of the finish materials. The exterior finish layer in buildings is exposed to considerable environmental loads, namely thermal stresses and UV radiation, that over long-term exposure leads to degradation (Pisello, 2017). The temperature fluctuations experienced on the exterior surface of finish materials decrease the durability of the material (Hernandez-Perez *et al.*, 2014; Pisello, 2017).

doi:10.23967/dbmc.2020.163

Increasing the lifetime of the building façade by reducing exterior thermal stresses, therefore, becomes critical. By reviewing the literature, several strategies can be found that have been proposed for regulating external solar and thermal loads. The most prominent strategy is the application of cool/white or reflective coatings on exterior roof and façade surfaces. Such coatings have high solar reflectance and emittance, thus leading to lower surface temperature and better performance under UV exposure (Ascione *et al.*, 2018). With the growing application of cool coatings globally, the literature has mainly focused on their benefits in the cooling season. However, the heating penalty associated with lower solar gains on the surfaces with cool coatings could be comparable to their advantages in the cooling season (Ascione *et al.*, 2018; Garshasbi and Santamouris, 2019).

Several strategies to optimize the performance of reflective coatings have been evaluated, such as combining reflective coatings with phase change materials (PCMs) (Pisello *et al.*, 2017). This combination has been proposed to benefit from the large heat storage capacity of PCMs to buffer the peak temperatures and decrease the thermal fluctuations, which directly affect the durability of the finish materials (Pisello *et al.*, 2017). Another approach that is gaining attention is the use of dynamic coatings with variable optical properties using thermochromic (TC) coatings or paints (Karlessi *et al.*, 2011; Perez *et al.*, 2018). TC paint changes its colors in response to temperature, allowing a change in its optical properties at a specific transition temperature. The solar reflectance and emittance of the TC paint are increased with higher temperatures as it turns to whiter shades, and as the temperatures go down, the solar absorptivity of the paint is increased. Evaluating the key material properties of these smart materials is a crucial step to identify their potential in regulating solar and temperature loads in exterior finish applications. Several studies have focused primarily on this topic to identify the experimental methods to measure the characteristics of these materials (Zinzi, 2016). Additionally, to assess the impacts of environmental loads on the durability and performance of such smart materials, accelerated aging tests using lab equipment have been used extensively (Jelle, 2011; Karlessi *et al.*, 2015).

In this study, the application of TC paint and PCMs integrated into cement plasters is investigated in the climate context of Toronto, Canada. Cement plasters are a typical façade finish material used in different types of buildings in Toronto. The combination of the TC paint and PCMs in this study is used to address both thermal and solar exposure using different mechanisms of dynamic solar control and thermal energy storage. Different configurations of cement plasters with TC paint and PCMs have been developed and characterized for their optical and thermal properties. The aim of this paper is to evaluate how long-term exposure to solar radiation, particularly the negative impact of UV degradation impacts the optical performance of the samples. The objective is to compare the main optical property of the samples, namely solar reflectance in the primary stage to the post-aged stage using lab tests.

2 Methodology

2.1 Development of Cement Plaster Samples

The cement plaster was made based on the ASTM C926-18b standard for exterior plaster applications and mixed with microencapsulated PCMs and TC pigments. Three PCMs with different melting temperatures (T_{mp}) of 18ºC, 24ºC, and 28ºC were used. Blue and red Leuco

dye TC pigments with a transition temperature of 31°C were used in this study. Based on the dynamic properties of the TC paints selected, the color transition to white occurs above 31°C, and below 31°C, the paint turns back to its original color. The cement plaster samples were made into 10 cm x 10 cm tiles with a thickness of 1.2 cm. The PCMs and the TC paints were each added to the tiles based on a mass fraction of 2.5% of the base cement plaster tiles. Therefore, samples with both PCMs and the TC paint included a total of 5% of the materials and a 95% ratio of the cement plaster mixture. More detailed information on the sample production process can be found in Soudian and Berardi (2019).

One of the main variables in this study is two different types of cement plasters considering the integration of the TC paint in the plaster. Type 1 samples include the mixing of both the PCMs and the TC pigments inside the cement plaster mixture, as shown in Figure 1a. Type 2 samples include the mixing of PCMs inside the cement plaster mixture, while the TC paint is painted on the surface of the plaster tiles (Figure 1b). A total of twelve Type 1 samples and eight Type 2 samples were created.

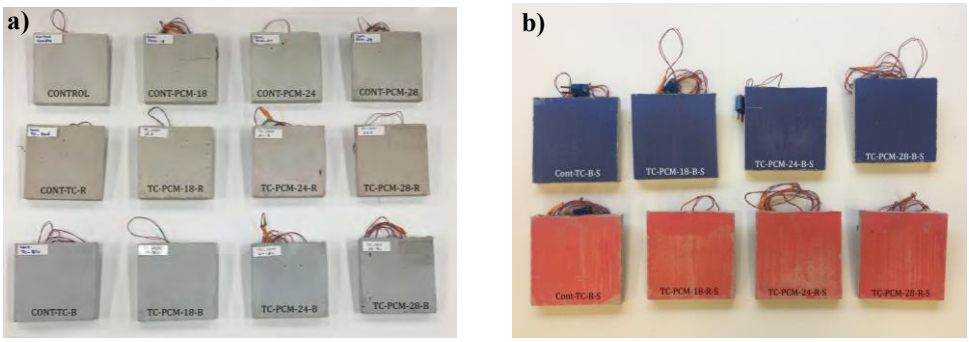

Figure 1. a) Type 1 samples; b) Type 2 samples.

2.2 Optical Characterization Tests

To measure the optical properties of the samples -considering their dynamic color change- the samples were subjected to one heating cycle and one cooling cycle prior to the measurements. The heating cycle was performed in an oven set to 45°C, which is above the transition temperature of the PCMs and the TC paints. In the cooling cycle, the samples were cooled to 8°C in a fridge. Figure 2 shows the color change of the Type 2 samples in both cycles. The spectral reflectance of the samples was measured according to the ASTM E903-12. The measurements were made using a Perkin Elmer's Lambda 750S UV-Vis/NIR spectrophotometer with 60 mm integrating spheres. The reflectance measurements were conducted in the range of 300-2500 nm with 10 nm steps (Soudian *et al.,* 2020).

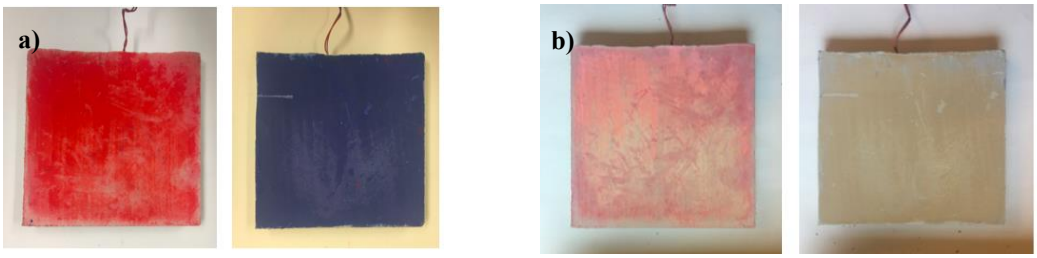

Figure 2. a) Type 2 samples at 8°C; b) Type 2 samples at 45°C.

2.3 Accelerated UV Aging

A QUV accelerated weather testing machine was used for the accelerated UV aging tests. The tests were performed according to ASTM G154-16. The UV acceleration factor (AF_{UV}) was calculated from Equation (1), where ϕ_{lab} indicates the total UV energy in the aging machine, and the ϕ_{nat} is the average natural outdoor energy for a given period.

$$AF_{UV} = \phi_{lab} / \phi_{nat} \quad (1)$$

The total UV intensity considered for the 340 nm UV lamps in the apparatus was set to 1.55 W/m^2, and the total energy calculated for one day of operation of the machine is 12.5 kWh/m^2. This setting represents the Cycle 6 configurations of the ASTM G154-16 standard. The average daily solar irradiance value for the city of Toronto is 126 Wh/m^2 obtained from Natural Resources Canada (2016). Therefore, the AF_{UV} calculated is 57. Based on the AF_{UV} and the exposure conditions determined by the standard, the samples were aged for seven days representing a two-year exposure to UV radiation. Figure 3 shows the testing apparatus and the cement plaster samples mounted on the QUV machine. The samples were subjected to an 8-hour cycle of UV exposure at 60ºC, followed by a 4-hour cycle of condensation at 50ºC.

Figure 3. Cement plaster samples in the QUV aging apparatus.

3 Results

3.1 Initial Characterization: Pre-Aging

All the samples showed a greater change in solar reflectance/absorptance in the near-infrared range (NIR) compared to the UV and the visible light (VIS) range, as shown in Figures 4 and 5. A distinct difference between the solar reflectance of Type 1 and Type 2 samples was observed in the heating and cooling cycles. At 45ºC, Type 2 samples with the TC paint on their surface showed an average of 13% higher range of solar reflectance in the NIR compared to Type 1 samples. The solar reflectance of all the eight Type 2 samples is higher than the control cement plaster sample, having a range of reflectance between 60%-80%, while the control sample has an average of 49.5% solar reflectance. In contrast, considering the importance of solar gain in colder temperatures, at 8ºC, Type 1 samples showed 12% higher solar absorptance in the NIR compared to the Type 2 samples. A much lower solar absorptance performance was observed in the case of Type 2 samples, as shown in Figure 8b, and all the samples have a lower percentage of solar absorptance in the NIR compared to the control sample.

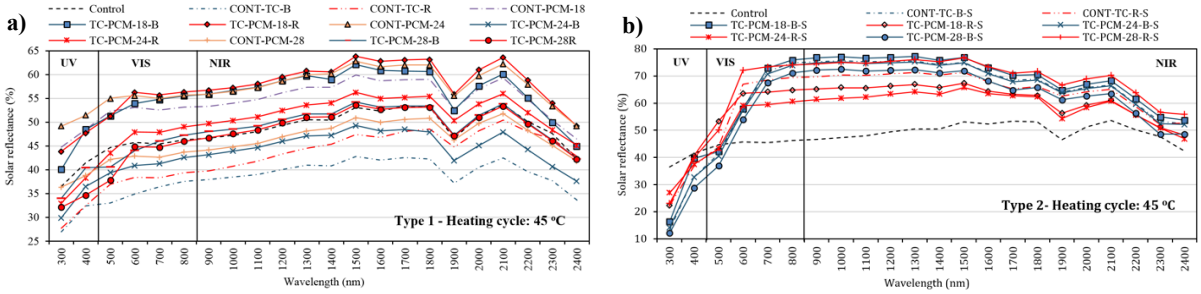

Figure 4. Solar reflectance at 45 °C: a) Type 1 samples; b) Type 2 samples.

The solar reflectance results of the samples with the blue and the red paint shows a higher solar reflectance recorded for the blue colored Type 2 samples. However, in Type 1 samples, all the mixed and control samples with the red TC paint showed a higher range of solar reflectance in the heating cycle. In Type 1 samples, the average solar reflectance of the control sample is higher than the control samples with only the TC paint. Considering the combination of the PCMs with TC paint, the best results are obtained by using the PCM- 18, as the combined samples show a 22% better performance than the CONT-PCM-18 sample, and 28% higher solar reflectance than the control samples with only the TC paint. In the cooling cycle, the overall solar absorption of Type 2 samples is considerably less than the control PCM samples, as well as the combined Type 1. This observation shows that applying the paint on the surface affects the potential to retain solar gains. It is observed that the total solar absorption range of the TC paints on the surface is much lower between 32% to 36%, which could pose challenges in the heating season for material durability and overall heat transfer through the envelope.

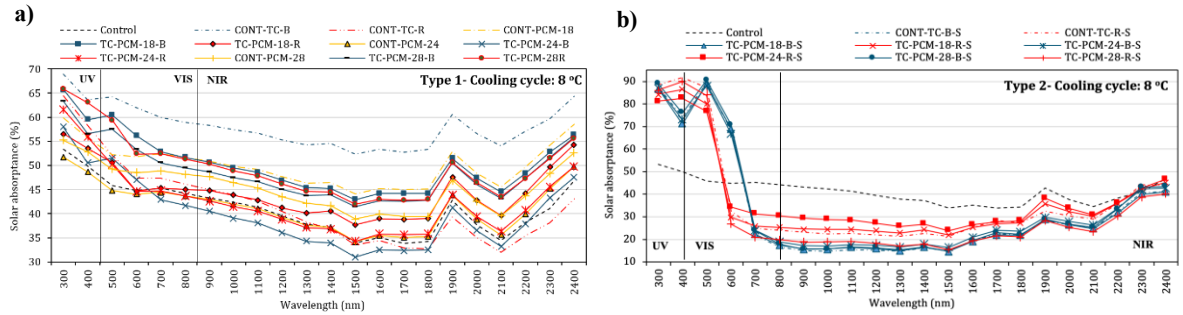

Figure 5. Solar absorptance at 8 °C: a) Type 1 samples; b) Type 2 samples.

3.2 Characterization- Post-Aging

The effect of the two-year accelerated UV aging on the visual appearance of the samples is shown in Figure 6. Compared to the initial images taken prior to the aging (Figure 1), the Type 2 samples have lost their colors, and in Type 1 samples, the slight color differences due to the TC paint is no longer visible. The performance of the samples is expected to be affected due to such considerable color variations.

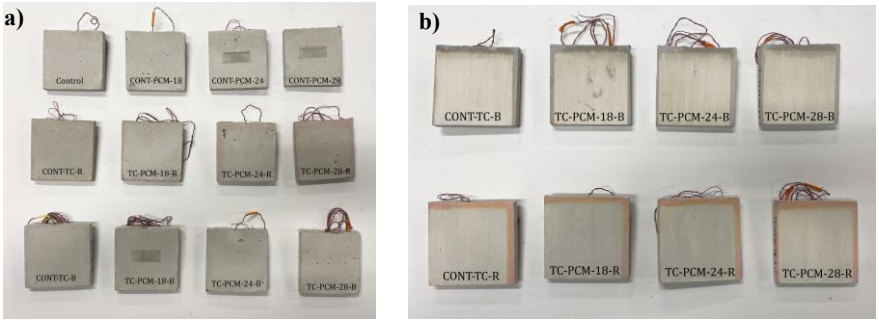

Figure 6. Visual changes to the samples a) Type 1 samples; b) Type 2 samples.

3.2.1 Solar reflectance measurements: Post-Aging

The same procedure to measure the solar reflectance of the samples was performed after the two-year aging tests. The results are shown in Figures 7 and 8 for the heating and the cooling cycles. Similar to the pre-aging results, the overall solar reflectance of the samples at 45ºC is higher in the Type 2 samples compared to Type 1 samples. However, the overall performance of the Type 1 samples in reflecting solar radiation is reduced considerably compared to the control sample. As shown in Figure 7a, the solar reflectance of the control sample in the NIR is higher than all the samples within the 1600-2500 nm wavelength. A general trend could be observed in both types of samples as the post-aging results show an increase in solar reflectance values in the UV and VIS range while the total reflectance in the NIR is reduced.

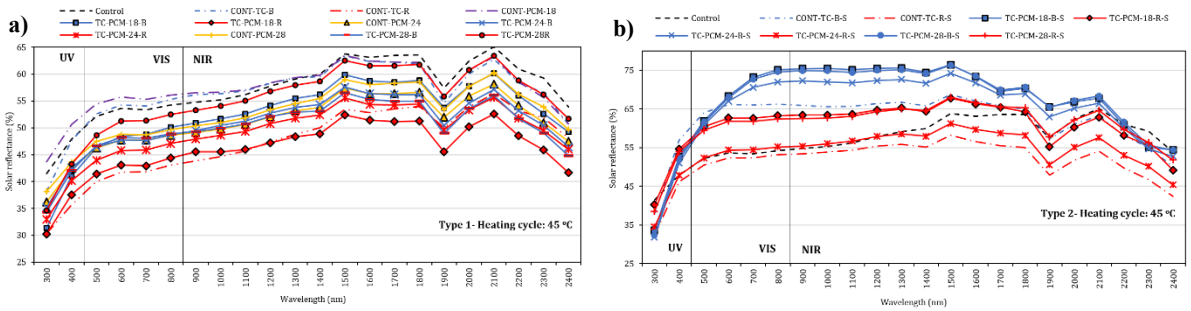

Figure 7. Solar reflectance at 45 ºC- Post-Aging: a) Type 1 samples; b) Type 2 samples.

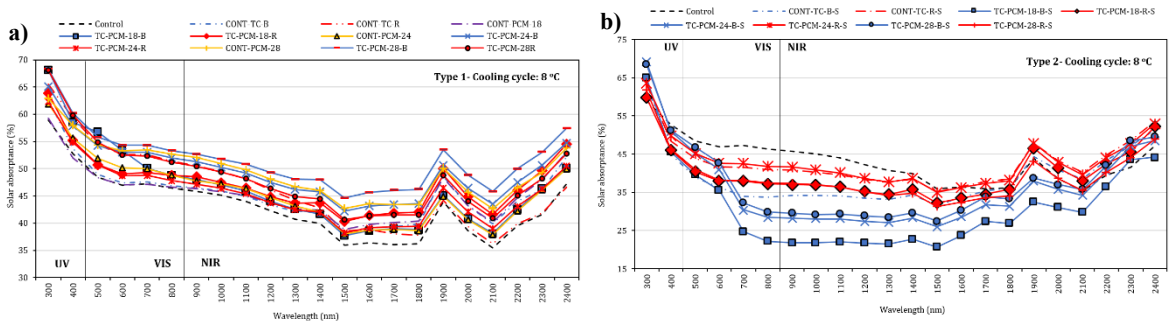

Figure 8. Solar absorptance at 8 ºC- Post-Aging: a) Type 1 samples; b) Type 2 samples.

In the cooling cycle, the aging did not significantly change the solar absorptance characteristic of the Type 1 samples, as shown in Figure 8a, and similar to Figure 5a, the control

sample holds the lowest rate of solar absorption at 8°C in the NIR. The total solar absorptance of the samples with the red paint in Type 2 samples is higher than the blue colored ones. The post-aging results show that the total solar absorptance of Type 2 samples have increased by 10% in the NIR.

3.3 Performance Change Comparison

By reviewing the pre and post aging results of solar reflectance values for all the samples, no specific trend could be established between the color of the TC paint and the T_{mp} of the PCMs. To better illustrate the effect of the two-year UV aging on the samples, Figure 9 shows the change in solar reflection characteristic of each sample in the heating cycle. As the figure shows, the impact of aging on the control samples with only the TC paint varies considerably between Type 1 and Type 2 samples. In Type 1 samples, the solar reflectance was increased after aging, in the Type 2 samples, solar reflectance decreased after the surface color faded.

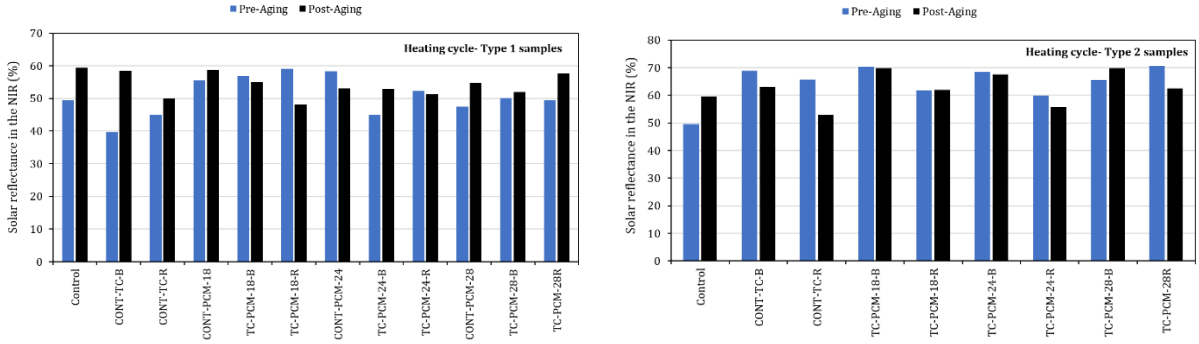

Figure 9. Rate of change in solar reflectance after the aging.

The impact of the PCMs in preserving the solar reflectance of the samples is more evident in the Type 2 samples, as the samples with both the TC and the PCM show the smallest percentage of change in solar reflectance in the NIR compared to the ones with only the TC paint. The results of the solar absorptance in the cooling cycle shows that in all Type 2 samples, the total solar absorptance is increased after the UV aging by an average of 30%.

4 Conclusions

This study evaluated the effect of accelerated UV aging on the optical performance of cementitious plasters integrated with TC paint and PCMs. This façade finish material intends to regulate thermal stresses exposed to exterior surfaces of building facades due to UV rays and temperature fluctuations. The dynamic properties of the TC paint to control solar radiation and the heat storage capacity of PCMs to control temperature on the surface could help increase the durability of the exterior façade finishing against thermal stresses. The results of the UV aging tests revealed that the impact of aging on the solar reflectance properties of the samples depends primarily on the method of TC paint integration in the cement plaster. Overall, at 45°C which is above the transition temperature of the selected TC and the PCMs, the solar reflectance of Type 1 samples with only the TC paint was increased, while the opposite occurs in the Type 2 samples. As the TC color fades on the surface of Type 2 samples, the total range of solar reflectance decreased in samples with only the TC paint. The solar reflectance properties of the

samples are primarily related to the TC paint. However, a lower rate of change in solar reflectance was observed in the combined PCM and TC scenarios, indicating the benefit of PCMs. A detailed analysis of the performance of the prototypes to regulate thermal stress is underway using temperature cycling tests to observe how the PCMs interact with the TC paints.

Experiences from Interior Super Insulation of a Brick Wall from the 1800s

Pär Johansson and Paula Wahlgren

Department of Architecture and Civil Engineering, Chalmers University of Technology, SE-412 96 Gothenburg, Sweden, par.johansson@chalmers.se

Abstract. *Many brick buildings in Sweden today face a large need for renovation measures to prolong their service life and make other uses possible. Conventional thermal insulation materials, such as fibre glass and EPS, demand a thick layer of insulation to reach the energy targets. Super insulation materials, such as vacuum insulation panels (VIP) and aerogel blankets (AB), are thermal insulation components with a 3-10 times higher thermal resistance than conventional insulation materials. In this study, the effect of interior insulation using super insulation materials is investigated, using experiences from a case study in a brick wall from the 1800s. Earlier research has shown that interior insulation decreases the drying-out capacity of an exterior wall and increases the risk for freeze-thaw damages in brick walls. The case study building is an industrial building from 1896 with 470 mm homogeneous brick masonry walls insulated with both aerogel insulation and with vacuum insulation panels. Six heat flux sensors were installed in the wall and used to evaluate the thermal resistance of the wall with and without insulation. The initial measurements showed that the rate of water flow in the bricks is approximately three times higher than that in modern bricks. The average calculated U-value was reduced by 70% for the AB and 81% for the VIP layers, while measurements at the three occasions gave a reduction of 72-83% for the AB and 72-84% for the VIP layers, i.e. in the same order of magnitude.*

1 Introduction

The construction sector is responsible for approximately 37% of the energy use in Sweden (Boverket, 2019). Around 78% of this energy is accounted to heating and cooling of buildings and the rest to construction, renovation and demolition activities. The amount of energy for heating has increased the last years and was 7% higher in 2016 than the average energy use in the preceding 10-year period and 8% higher than the previous year (Boverket, 2019). Around 25% of the energy for heating is used in the part of the building stock built before 1941 (Swedish Energy Agency, 2014). The focus on energy savings in society to mitigate carbon emissions, has led to implementations of several European directives on energy performance in buildings. The current intention is to enforce national renovation strategies of buildings to reach low or zero carbon dioxide emissions from the building industry by 2050. There is also an increased focus on embodied energy and life cycle assessment of materials that are used in the construction sector (Boverket, 2018).

There are several challenges associated with decreasing the energy use in existing buildings, especially in buildings located in areas of national interest for cultural heritage or listed buildings. The conflict between energy efficiency and heritage values in buildings have been touched upon on in several research projects and are common in everyday practice when renovating buildings for improved energy performance. Here, one of the challenges is to reduce the energy use while not tampering with the character defining elements of a building, such as the expression of the façade, the foundation, the volume of the building, the decoration of the

façade, the windows and the window frames. Generally, walls can be insulated either on the interior or exterior side. Concerning moisture performance, external insulation is beneficial as this increases the temperature of the original construction. Unfortunately, this is not allowed in many listed buildings. Therefore, interior insulation may be the only solution. Earlier research has shown that interior insulation decreases the drying-out capacity in the outer wall and increases the risk for freeze-thaw damages in brick walls (Johansson *et al.*, 2014). Interior insulation will also negatively affect the thermal storage capacity of the building and change the interior appearance of the walls, which is particularly important to consider for historical and/or listed buildings (Johansson *et al.*, 2019).

In this paper, a study based on a case study building of using super insulation materials in retrofitting of exterior walls is presented. The case study building, the background and planning of the study was presented in Johansson and Wahlgren (2018). In Johansson *et al.* (2019), the focus of the study was on the cultural heritage aspects and the conflict between energy efficiency and heritage values in buildings. Here, various parameters influencing the heat flux through the wall is discussed based on calculations and measurements from three separate occasions during the year. Two of these occasions were presented in Johansson *et al.* (2019) and in this paper measurements from the autumn season is added. These measurements add new information since the wall now has been heated for a longer time period while the average temperature is the same as in the spring season. The aim of the project is to propose practical guidelines and recommendations for using super insulation materials in listed buildings. This research is based on evaluation of vacuum insulation panels (VIP) and aerogel blankets (AB) in a case study building in Gothenburg, Sweden, where the thermal and moisture performance is monitored.

2 Super Insulation Materials

New materials and solutions are being developed that can contribute to improving the energy performance of historic buildings, without altering their character defining elements. Super insulation materials (SIM), such as VIP and AB, are thermal insulation components with a 3-10 times higher thermal resistance than conventional insulation materials, and thus thinner layers can be used. In the IEA Annex 65 'Long-Term Performance of Super-Insulating Materials in Building Components & Systems' several SIMs were investigated, and case studies were collected from all over the world. More information and conclusions are given by Adl-Zarrabi *et al.* (2020). In that project, SIMs were defined by having a thermal conductivity;

- below 25 mW/(m·K) if air filled such as aerogel,
- below 20 mW/(m·K) if gas filled such as gas filled panel (GFP), and
- below 15 mW/(m·K) if evacuated such as VIP.

As mentioned above, two examples of SIM are VIP and AB, see Figure 1. VIP are rigid panels which cannot be cut on site and are sensitive to puncturing. Therefore, attention must be paid in the design of details and envelope components. AB are more like conventional fibre-based insulation materials. They can be cut at the construction site and adapted to the specific measurements. VIP were first tested in buildings in the early 1990s which was later followed by several case studies both in laboratory and in the field while AB have been installed in various building assemblies since the early 2000s (Adl-Zarrabi *et al.*, 2020).

The long-term performance of SIMs must be determined based on case studies in field and laboratory. Full scale experiments provide knowledge of practical and technical difficulties as well as data for service life estimation. For certain conclusions to be drawn from the case studies, monitoring is essential. Unfortunately, monitoring is only performed in few case studies. These experiences are gathered and evaluated from a long-term performance perspective by Adl-Zarrabi *et al.* (2020).

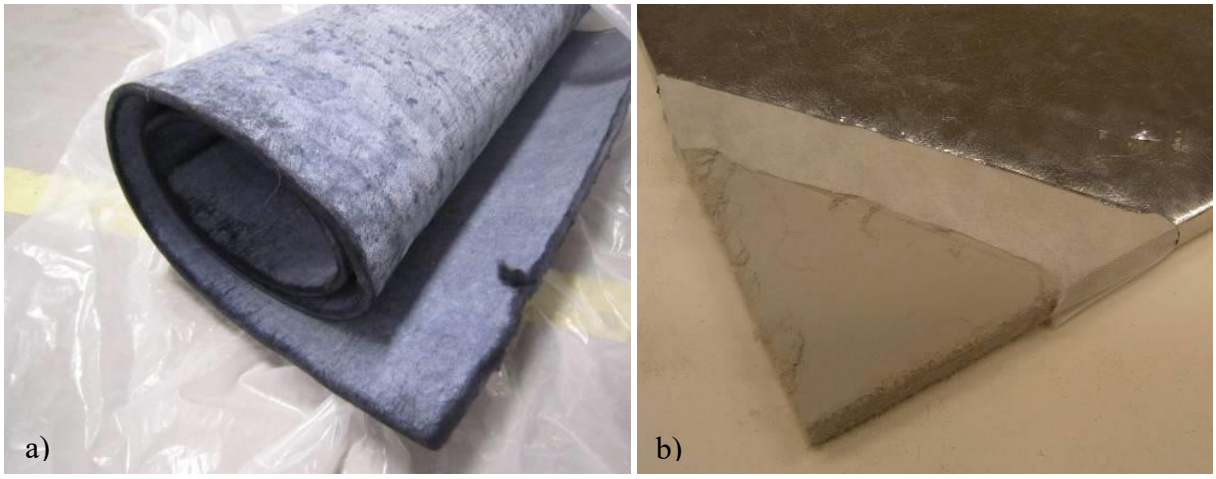

Figure 1. Super insulation materials; (a) aerogel blanket (AB), (b) vacuum insulation panel (VIP).

VIPs have different core materials (fumed silica, glass fibre, polyurethane, expanded polystyrene and others) and different envelopes (metalized film, aluminium laminate, stainless steel, woven glass fibre, or combinations). The thermal conductivity is 0.014-0.020 W/(m·K) for AB and 0.002-0.008 W/(m·K) for VIP (Heinemann *et al.*, 2020). The hygrothermal properties for ABs and VIPs differ substantially. The VIP envelope only allows a minimal amount of vapour and liquid water transfer at the edges between the VIPs (Johansson *et al.*, 2014), while the vapor diffusion resistance of AB is around μ=5 (-) which is a factor five higher than mineral wool. The blankets are coated with a water-repellent substance which reduce the liquid water transfer through the material.

3 Case Study Building

The case study building, the background and planning of the study is presented together with results from hygrothermal numerical simulations and a laboratory study of interior insulation of a brick wall in Johansson and Wahlgren (2018). The building where the tests are carried out is a long narrow brick and concrete building, once used as a paper machine hall, originally erected in 1896, see Figure 2. The building is one of the oldest in the area. For this case study the conservation officer at the city museum followed up on development of built heritage and monitor that appointed heritage values are being respected in transformation situations.

In the end it was difficult to predict all the uncertainties in the laboratory measurements using the hygrothermal numerical simulations (Johansson and Wahlgren, 2018). The first results from the case study building showed that there was a moisture excess of 0.8 g/m^3 in the building compared to outdoors. Inside a part of the building, a small room (2.1 x 2.6 x 4.0 m)

was constructed, consisting of floor, walls and roof insulated with 170 mm mineral wool, and the exposed brick wall with an interior mortar layer. Prior to the installation of the sensors, the existing plaster was removed from the interior brick surface. There was substantial capillary suction from the ground and from the exposure to driving rain from south-west, which is the dominant wind direction. The old plaster was loose up to approximately 1 meter above the concrete slab and came down easily, without applying force, while the upper part of the wall required demolition hammer to remove the plaster. The initial estimations showed that the rate of water flow in the bricks was approximately three times higher than that in modern bricks.

Figure 2. (a) The industrial building from 1896, photo from 1918, (b) the exterior of the tested external wall, (c) interior of the building when it was in operation as a paper mill.

The exterior wall is divided in three parts where AB and VIP are installed in 500 x 1,200 mm^2 panels, see Figure 3, and compared to a non-insulated reference. The air in the room is circulated by a fan to create homogenous temperature and moisture conditions in the entire room. It is heated to around 23°C and ventilated by natural ventilation with approximately 0.5 h^{-1} air exchange rate. The installation of the AB and the VIP was done in mid-June, 2018. The temperature and relative humidity of the air is measured by three sensors. The measurement accuracy is ± 2.5% for relative humidity in the range of 10 to 90% and ±0.5°C for temperature at 25°C. The temperature can be measured between -40 to 85°C. There were some initial problems with the equipment and electric power supply which made the indoor temperature vary more than planned.

The heat flux sensor Hukseflux HFP01 (thickness 5.4 mm, diameter 80 mm) was used to evaluate the thermal resistance of the wall with and without insulation. The heat flux in W/m^2 is calculated by dividing the voltage output by the sensor's sensitivity. The sensors were calibrated by the producer and delivered with a calibrated sensitivity and calibration uncertainty of 3% for each sensor.

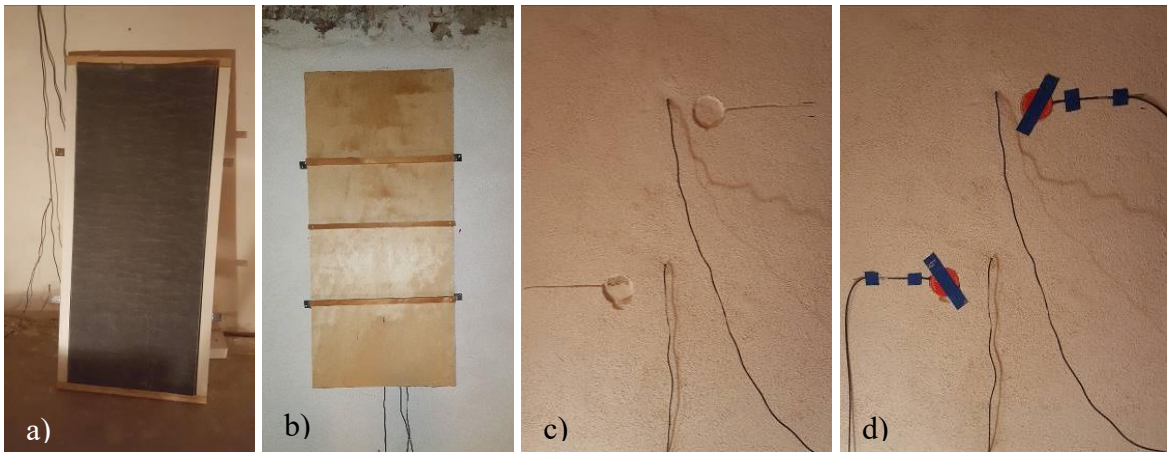

Figure 3. (a) AB insulated panel (removable for inspection), (b) installed AB and VIP panel, (c) before installation of two heat flux sensors inside the mortar layer, and (d) after installation of two heat flux sensors.

The sensor is a thermopile sensor which measures the temperature difference across the ceramic plastic composite body. Air gaps between the sensor and surface of the wall, and between the sensor and the surrounding environment could add additional resistances to the sensor thermal resistance. The sensor was placed in the mortar between the insulation and brick masonry in the wall panels with insulation, while the sensor was facing the indoor environment for the wall without insulation.

Each wall set-up (reference, AB, VIP) has two sensors, bottom and top and the heat flux was measured at three occasions (March, April and November) at all six locations. The first results from the heat flux measurements showed that the heat flux is substantially reduced in the wall with interior insulation (Johansson *et al.*, 2019). A difference between the top and bottom measurement locations was found, where the top location had a higher heat flux for the reference wall and the wall panel with VIP, while the wall panel with aerogel had a lower heat flux at the top location, compared to the bottom location. The higher heat flux closer to the bottom of the wall could be caused by the higher moisture content in the wall closer to the foundation and ground water. The deviation between the different parts of the wall could be explained by the difference in solar radiation between them, where the reference wall is less exposed to solar radiation than the parts with interior insulation. This part of the wall therefore has a higher temperature difference between the interior and exterior surfaces, and consequently a higher measured heat flux which results in a lower U-value (Johansson *et al.*, 2019).

4 Results from Heat Flux Measurements

The measured temperature difference between the indoor and outdoor air was averaged over the 3 preceding days due to the high thermal inertia of the brick wall. The thermal inertia was studied numerically by Johansson *et al.* (2019), where it was concluded that an outdoor air temperature measured for 3 days is enough for the estimation of the U-value from the heat flux measurements. The measurements were performed early in the morning before sunrise, after a cloudy night with stable outdoor temperature. The momentary U-value and percentage difference compared to the reference wall based on the measurements and calculations (following SS-EN ISO 6946:2017) are presented in Table 1.

Table 1. U-value and percentage difference compared to the reference wall based on heat flux measurements in the brick wall in the bottom and top of the wall. The average outdoor temperature was 5.1°C, 9,7°C and 4.5°C.

Location	March		April		November	
Aerogel bottom	0.310	77-84%	0.296	81-84%	0.357	70-72%
Aerogel top	0.292	78-85%	0.264	83-85%	0.339	71-73%
VIP bottom	0.308	77-84%	0.254	84-86%	0.341	71-73%
VIP top	0.323	74-84%	0.277	82-85%	0.358	70-72%
Reference bottom	1.331	-	1.549	-	1.188	-
Reference top	1.957	-	1.817	-	1.269	-

When calculating the U-value of the non-insulated wall based on the thermal conductivity of dry brick (λ=0.61 W/(m·K)) and wet brick (λ=1.0 W/(m·K)), this results in U-values ranging from 0.997 to 1.476 W/m^{2}K. Corresponding U-values for the part with 20 mm VIP are 0.264-0.286 W/m^{2}K and for the wall with 20 mm AB the range is 0.394-0.452 W/m^{2}K. The thermal conductivity is also influenced by the temperature. For this case, the influence is negligible as the dependency is typically around 0.0002 W/(m·K)/K for bricks.

The fact that the measured U-value of the non-insulated wall is lower in November than in March and April can be a result of the wall having dried out during spring and summertime. Since the interior insulation decreases the drying towards the interior side, drying is expected to be significantly slower for these cases, resulting in more moisture, which could explain the smaller variations in U-value for the insulated walls.

For the wall with VIP, the U-value based on heat flux measurements were more in line with the calculated U-value than for the non-insulated wall. The measured U-value for the wall with VIP was up to 35% higher than what was expected from the calculations. On the other hand, the measured U-value for the wall with AB was lower than what was expected from the calculations during all three measurement periods, for both the case with dry and wet brick. Cuce and Cuce (2016) experienced similar deviations in their study of interior insulation with AB. They developed a numerical statistical method to account for all effects by other factors.

In this case study, the different wall panels may be subjected to different amounts of solar radiation. The wall panel with AB is most exposed to solar radiation which may have influenced the measurements more here than for the other parts of the wall, resulting in a lower heat flux than expected due to the lower temperature difference (higher outdoor temperature). The other factors that could influence the measurements is the evaporation of water from the wall. This could increase the heat flux by around 5% which decreases the measured U-value for the reference wall but does not influence the parts of the wall with interior insulation.

One of the studied periods was unusually dry (summer 2018). For this case, the temperature difference between cooler lower parts and slightly warmer upper parts was smaller than other studied periods. This means that there might still be evaporation but that the source might not be rain but possibly evaporation of moisture from the ground. That moisture was rising from the ground was evident from the condition of the wall.

5 Conclusions

Many brick buildings in Sweden today face a large need for renovation measures to prolong their service life and make alternative uses possible. In a case study building, interior insulation

was proposed as a measure for combining energy efficiency and heritage preservation. The 470 mm homogenous brick masonry wall was investigated regarding the thermal performance of the wall with interior insulation. Earlier research has shown that interior insulation decreases the drying-out capacity of the exterior wall and increases the risk for freeze-thaw damages in brick walls. In this study the building was exposed to both heavy rain and rising ground water. No significant drying took place from the parts with interior insulation and water was added to the wall from the rain outside and through the foundation. Therefore, the owner has now planned to cover the building with an external rain protective envelope Measurements of the heat flux show that additional superinsulation substantially decreases the U-value of the wall. Assuming wet bricks, the average calculated U-value was reduced by 70% for the AB and 81% for the VIP layers, while the measurements gave a reduction of 72-83% for the AB and 72-84% for the VIP layers, i.e. the same order of magnitude. With planned measures to make the wall dryer, the interior insulation will be monitored continuously with the aim of contributing to the development of recommendations on how SIMs can be used in historic buildings

Abstract. *Vacuum Insulation Panels (VIPs) encompass a higher thermal resistance per unit of thickness compared to any other kind of insulation. However, their aging has often shown some critical concerns among stakeholders. To support the broader use of VIPs in the building sector, a comprehensive analysis of the physical properties of VIPs and in particular of their thermal conductivity over long-periods is required. This research investigates the effect of the temperature and relative humidity on the service life and thermal conductivity of VIPs. The scope of this study is to validate existing aging models for VIPs. First, the experimental results of the thermal conductivity for five VIPs both in pristine and in laboratory-accelerated conditions are described. Then, an analytical aging method is employed to validate the collected data. Results show that the aging has a more significant impact on the performance of VIPs with a core of fiberglass-core than with VIPs with a core of fumed silica.*

1 Introduction

It is widely acknowledged that buildings account for more than 32% of total global energy consumption and contribute to 19% of the GHG emissions. The global energy-related CO_2 emissions from the building sector more than doubled between 1970 and 2010, and are projected to increase by another twofold by 2050 (Berardi, 2017). Several researches confirmed that the heat transfer (*i.e.* losses) through the building envelope is the most significant energy factor for building efficiency as such, significant attention exists for super-insulating materials. High-performance materials such as Vacuum Insulation Panels (VIPs) offer a high thermal resistance value with minimized thickness, thanks to their low thermal conductivity (0.003-0.005 W/mK) which is about five times lower than that of traditional insulation materials (Johansson *et al*., 2014; Karami *et al*., 2015). VIPs are non-homogeneous insulation materials consisting of a porous core which is evacuated from air and vapor, tightened, and then heat-sealed. VIPs materials are in the early market stages in the building sector and data about their thermal performance over the building lifetime is missing (Baetens *et al*., 2010; Kalnæs and Jelle, 2014).

Consequently, many international research efforts have focused on the thermal properties of VIPs over time (Wegger *et al*., 2011; Isaia *et al*., 2017; Mac Lean *et al*., 2017). Several works have proposed methods to predict the service life of VIPs with Fumed Silica (FS) core and on the development of models to determine their moisture content. Theoretical approaches to predict their long-term performances by means of interpreting accelerated aging tests done in laboratories have also been proposed (Table 1). The increase in pressure and humidity inside a VIP panel over time is often pointed as the main aging mechanism for VIPs (Schwab *et al*., 2005).

The objective of this paper is to evaluate experimentally the thermal conductivity of some VIP after several aging exposures and to assess the accuracy of existing thermal conductivity aging models through verification of collected results for different core materials of VIPs.

Table 1. Literature review summary of previous studies related to the topic of the present paper.

Study	Core type	Test type	Equivalent test period	Parameters of study results	Results
Simmler *et al*., 2005	-	laboratory work	5.5d at 23°C/80% RH, 9h at 30°C/90% RH, 65h at 65°C/75% RH, 152h at 80°C/80% RH	Ageing mechanism with results for different temperature and humidity	Pressure increase rate is about 2.1 mbar per year, while moisture accumulation rate is 0.18 mass% per year
Wegger *et al*., 2011	Va-q-VIPB 2009	laboratory work	25 years	Evaluating the accelerated ageing of VIPs for various procedures	Acceptable agreement with that of the accompanying theoretical analysis
Saber *et al*., 2015	fumed silica	in-situ test	a year	Effects of thickness and thermal conductivity on effective thermal resistance	The thermal resistance of the wall with VIP is higher than the wall with failed VIP or XPS
Kucukpinar *et al*., 2015	organic nano-foam	mock-up test	More than a year	Monitoring heat flow through the panels over months	Nanoporous foam VIPs are still effective
MacLean *et al*., 2017	VIP	pilot wall	-	long-term thermal performance of VIPs	Confirming the good performance of the VIPs compared to XPS
Batard *et al*., 2018	fumed silica	laboratory work	25 years at 23 °C for 80% RH	Comparison data of linear and dynamic model	Similar results for linear and dynamic models with a comparable increase of conductivity over time
Pons *et al*., 2018	fumed silica	laboratory work	10 years at 23 °C and 80% RH	Mild artificial aging of six VIPs samples	- The surface hydrophilicity of core aged VIPs is twice higher than the new one

2 Theoretical Background and Research Methodology

The thermal conductivity of VIPs is a critical characteristic to study. Solid conduction, air convection, and radiations determine the primary heat transfer mechanisms that control the insulation capacity of the panel. The thermal conductivity of VIPs has been proposed as a summation of different effects as reported in Eq. (1) (Wegger *et al*., 2010; Alotaibi *et al*., 2014):

$$\lambda_{tot} = \lambda_s + \lambda_g + \lambda_r + \lambda_{wv} + \lambda_w + \lambda_{cop} \quad (1)$$

where λ_s represents solid conduction through the material, λ_g shows gas conduction through the porous of material, λ_r presents radiation heat transfer between inner pore, λ_{wv} is the permeation of air and moisture through pores, λ_w is the thermal conduction over time based on adsorbed water within the core material, and λ_{cop} is the thermal conductivity accounting for second-order effects between the mentioned thermal conductivities. In Eq. (1), the λ_{wv} and λ_{cop} components have a lower value compared to other terms, and can often be neglected. The gas thermal conductivity is independent of the density, and its reduction provides a significant opportunity to improve the performance of the VIPs (Kwon *et al*., 2009).

A different way to express the thermal conductivity of VIP is by taking into account their aging, as described by Eq. 2 (Caps *et al*., 2008):

$$\lambda_{tot} = \lambda_{init} + \frac{\lambda_0}{1 + \frac{0.032}{p\Phi}} + bX_w(t) = \lambda_{init} + \frac{\lambda_0}{1 + \frac{0.032}{p\Phi}} + c\left(1 - exp\left(-\frac{t}{\tau_w}\right)\right) \quad (2)$$

where λ_{int} is a summation of solid and radiation thermal conductivities, λ_0 is the conductivity of air for atmospheric pressure, p is gas pressure, and Φ is the pore size of the pores.

As evident, to fully study the behaviour of Eg (2), long periods would be needed. Consequently, accelerated aging methods are often used to find failure modes in a shorter time, which is resulted after many years at a normal temperature. In this study, exposure of VIP to elevated temperature was used to age several VIP samples. The increase of temperature could grow the kinetic reaction rate within the molecules of materials which causes chemical deprivation. For this purpose, accelerated aging temperatures of building materials are often select around 70 ˚C (Jelle, 2012; Kunic, 2012). Arrhenius law was used to calculate the time equivalent to 25 years of aging. To determine the relationship between the aging test condition and the real condition, accelerated factor (AF_{temp}) was presented:

$$AF_{temp} = e^{-\frac{E_a}{K}\left(\frac{1}{T_A} - \frac{1}{T_U}\right)} \quad (3)$$

where AF_{temp} is the acceleration factor under stressed temperature, E_a is the activation energy of failure mechanism, K is the Boltzmann constant which equals 8.617×10^{-5} eV/K, T_A is the accelerated temperature, and T_U is the use condition temperature. The accelerated temperature of VIPs samples was 70˚C, and the constant use condition temperature was assumed at 15 ˚C. The thermal conductivity was measured, before and after the aging of each sample, in order to assess VIP thermal performance according to the ASTM C518 using heat flowmeter equipment HFM 436. The measurements were carried out in a temperature range of -10 ˚C to 30 ˚C with 5 ˚C temperature step. The temperature difference between the plates was kept at 10 ˚C.

3 Results

3.1 Pristine and Aged Thermal Conductivity

The thermal conductivity of various VIPs with different core panels including fiberglass, fumed silica, compressed microporous silica, and compressed microporous silica with celluloses fiber, were tested in this study. Different types of multilayer films which are common in the market were selected. The employed films include metal foils (AF), metalized films (MF) and polymer films (PF). The most common types can be described as follows:

- AF: In these ones, the thickness of the aluminum in the center is up to 5-10 μm and this layer is laminated by a polyethylene terephthalate (PET) as a protective layer in outer and polyethylene in the inner side of the layer (Wegger *et al*., 2011; Kalnæs *et al*., 2014).
- MFs: In these ones, there are three barrier layers of aluminum metalized PET and polyethylene (PE) sheets on the inner side with an aluminum coat of 20-100 nm thickness (Simmler *et al*., 2005; Ghazi Wakili *et al*., 2011; Alotaibi, 2014). This is a standard solution to make VIPs applicable in buildings because multiple aluminum layers provide a better impermeable layer in comparison to one-layer aluminum. However, MF type has a low thickness which is an issue as a low thickness results in higher gas and moisture permeance compared to the AF laminates. Table 2 reports the main characteristics of the selected VIPs.

Table 2. Experimentally characteristics of VIPs provided by manufacturers.

Sample type	Envelope type	Thermal conductivity (W/mK)	Company density (kg/m^3)	Core material	Pressure (mbar)	Size (cm x cm)
1	*NA*	0.0028	250	Fibreglass	≤ 5	30 x 30
2	MF3	0.0048	190	Fumed Silica	≤ 5	24 x 13.7
3	MF2	0.0037	208	Compressed microporous silica	≤ 5	30 x 30
4	MF2	0.0070	200	Compressed microporous silica + celluloses fibre	≤ 2	30 x 30
5	MF2	0.0070	250	Compressed microporous silica	≤ 5	30 x 30

The initial thermal conductivity of all samples is shown in Fig. 1. The experimental results validate that fiberglass provides the lowest thermal conductivity; in fact, the core of fiberglass, an open porous composite, allows easier air evacuation (Quenard and Salle, 2005; Kwon *et al.*, 2009). Pressed powder microporous silica would be the second option for high performing VIPs. The results in Fig. 1 shows a generally consistent behaviour of the VIPs and their lower thermal conductivity at lower temperatures (Berardi, 2019).

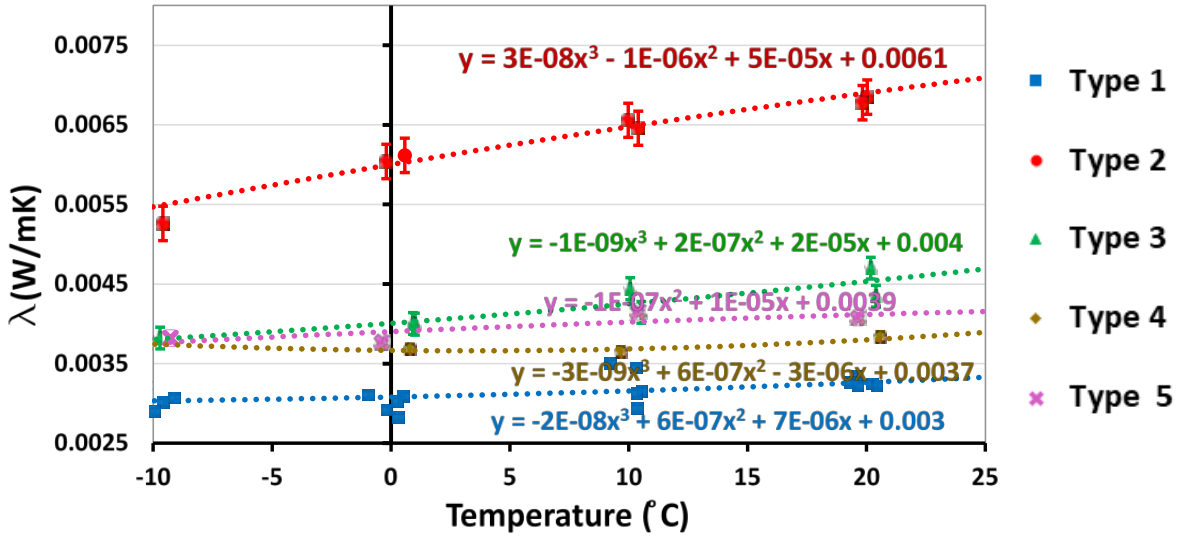

Figure 1. Value of pristine thermal conductivity for five types of VIP samples.

The induced changes in thermal conductivity of VIP samples with the exposure at high temperature, simulating their accelerated aging, are presented in Fig. 2. The results are shown for the average temperature between the two plates of the HFM of 18 ◦C. The thermal conductivity results were collected every five years of aging for each type of sample.

As can be seen in Fig. 2, Types 1 to 5 have a close initial thermal conductivity in the range from 0.003 W/mK to 0.0045 W/mK. While Type 1 with fiberglass core has the lowest initial thermal conductivity in comparison to the other samples, an increasing trend of thermal conductivity occurred compared to the other types in the same size. Types 3, 4 and 5 have an approximately constant thermal conductivity over 25 years. The type of the envelope and the thickness of the foil through the laminate affected the thermal conductivity. In fact, Type 5 which had an MF3 envelope showed minimal aging effects.

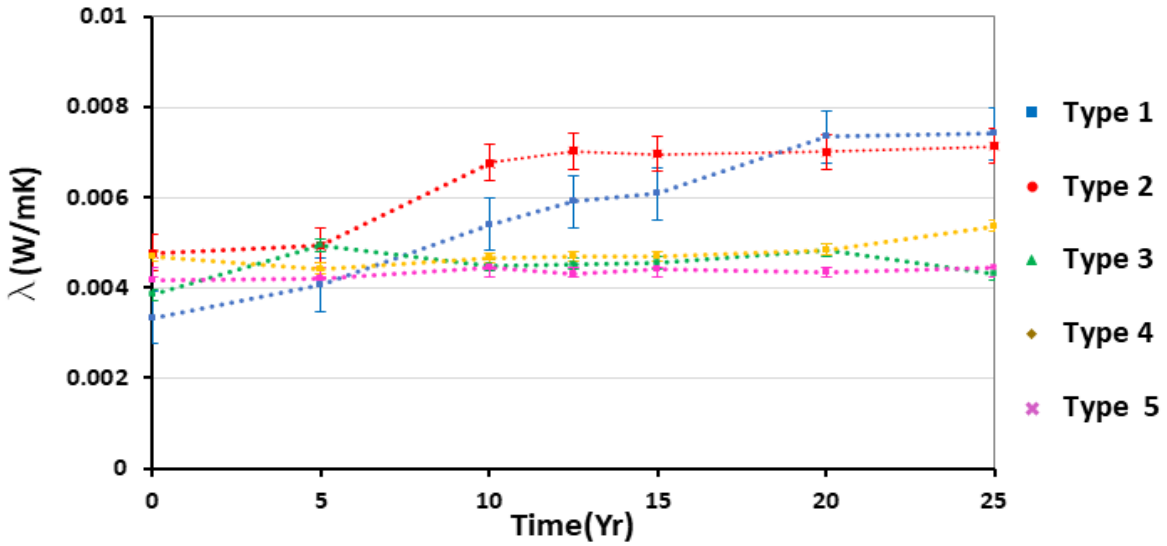

Figure 2. Dynamic variation with the accelerated aging of the thermal conductivity of the VIPs at 18 ºC.

3.2 Ageing Model Verification

Here, the studies in (Simmler *et al*. 2005b; Kim 2017, Mukhopadhyaya *et al*., 2011) are used as a reference model for evaluating the thermal conductivity trend. According to these papers, a simple version of the ageing thermal conductivity is:

$$\lambda_{tot} = \lambda_{init} + \lambda_p t + c\left(1 - exp\left(-\frac{t}{\tau_w}\right)\right) \tag{4}$$

where, λ_{init}, λ_p, c, and τ_w are regression parameters depending on the envelope and the core material. The parameters used in (Kim, 2017) are given in Table 3 as the reference model. In this research, the mentioned parameters (λ_{init}, λ_p, c, and τ_w) are derived from experimental result using Python curve fitting libraries. These unknown parameters are estimated such that the difference between the measured data and the model output is minimum. Table 3 lists these parameters for each sample and parameters in (Kim, 2017) as the reference.

Table 3. Parameters measured for samples under test and reference data proposed by Kim (2017).

Parameters	λ_{init} (mW/m K)	λ_p (mW/m.K.year)	c (mW/m K)	τ_w (year)
Reference Model (Kim 2017)	3.9 to 4.8	0.07	3.2	35.6
Type 1	3.20	0.17	1.30	35.6
Type 2	4.20	0.07	2.20	20.0
Type 3	4.00	0.05	0.66	35.6
Type 4	4.00	0.05	0.66	35.6
Type *5*	4.08	0.019	0.02	35.6

Figure 3 shows the thermal conductivity behaviour of these samples over 25 years. As it can be seen from this figure, overall, the thermal conductivity shows a linear trend over time for these samples. For Type 1, thermal conductivity measurements follow the reference model very well. The trend starts from 0.003 W/mK and uniformly increases to 0.008 W/mK, with a slope of 0.0002 W/mK per year. The thermal conductivity in this sample approximately increases by

160% over 25 years. In this type of sample, based on Table 3, the effect of λ_p is dominant. For Type 3, the thermal conductivity value increases by about 70% over 25 years, as thermal conductivity begins with 0.0041 W/mK and slowly reaches 0.0045 W/mK. Figure 3 shows a small increase for Type 4 thermal conductivity measurement over time, where thermal conductivity starts from 0.0041 W/mK and reaches to 0.0055 W/mK and it shows 34% of thermal conductivity increase. This thermal conductivity shows a linear trend with a slope of 0.00006 W/mK per year. Type 5 has a trend with a thermal conductivity raises up to 10%, and based on Table 3, it has a low gas thermal conductivity.

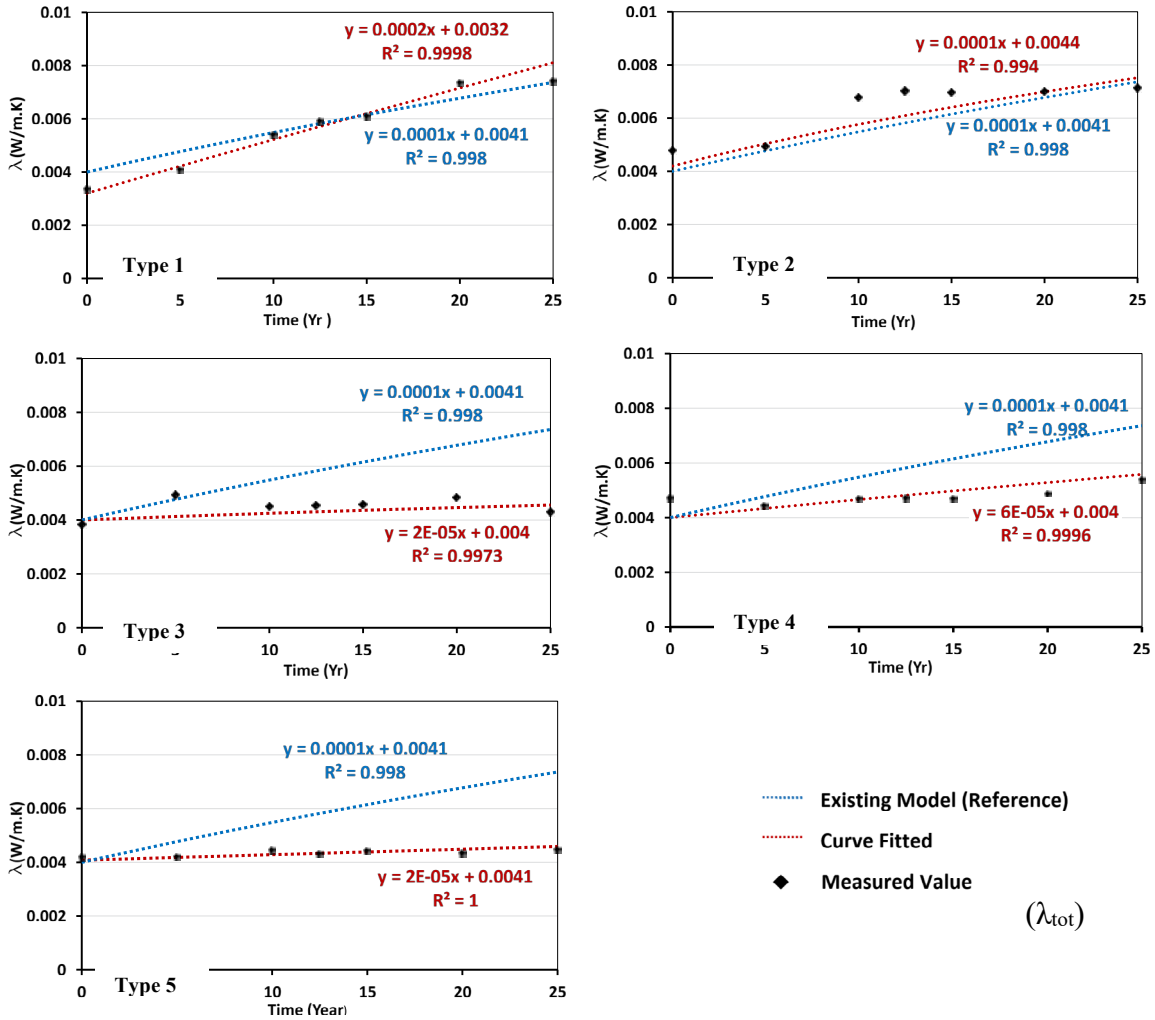

Figure 3. Thermal conductivity trend for different VIPs over time.

4 Discussion and Conclusions

Service life is one of the main characteristics of VIP assessment. The threshold value for the first definition of service life (ASTM C1484) is assumed to be 0.008 W/mK and 0.011 W/mK based on different references (Tenpierik *et al.*, 2010).

The threshold limitation and the service life of each specimen are reported in Table . Types 3 and 5 have the most extended service life among other types, formerly it followed by Types 4, 2, and 1 respectively.

Table 4. Service life of VIPs samples under test.

	Sample 1	Sample 2	Sample 3	Sample 4	Sample 5
Service life for 0.008 W/mK	25 years	30 years	> 100 years	70 years	> 100 years
Service life for 0.011 W/mK	40 years	65 years	> 100 years	> 100 years	> 100 years

The primary variables which define the quality of VIPs are the density of the core, the transmission rates of gas, and water vapor through the film barrier. Here, the test results collected from thermal conductivity measurements show that the thermal performance of the samples is mainly affected by temperature and, the amount of effect by moisture is minimal as they were also exposed to different levels of humidity without any appreciable results.

The analysis of the collected results represents that gas permeance is the factor that has the most considerable influence on VIP performance. The obtained results of Sample 1, 2 prove that the thermal resistance of the vacuum insulation panels reduces over time because of their higher gas and moisture transmittance. The thermal performances of Types 3, 4 and 5 are more stable. By comparing Types 1 and 3, it is obvious that the core materials with lower pore sizes have longer life spans due to less gas concentration. More results are reported in the paper Berardi *et al.*(2020).

Overall, the experimental analysis shows that:

- The thermal conductivity increases about 1%-2.5%, 2%, and 5%-11% a year, on average for compressed microporous silica-based, for compressed microporous silica with cellulose fiber, and for compressed microporous silica with cellulose fiber respectively.
- A small variation of thermal conductivity for compressed microporous silica and fiberglass-based cores was observed at temperatures below 0 ºC. However, since their core material porosity is dissimilar, they present different thermal conductivity behavior. The performance of the VIP microporous silica type is moderately better than that of the fiberglass over time.
- Although the initial thermal conductivity of VIP with fiberglass core is less than that of the compressed microporous silica one, fiberglass shows a significant increase in thermal conductivity after aging.
- The numerical reference model used by NRC is adapted for VIPs with fumed silica and fiberglass-based core material. However, a different mathematical model needs to be developed for compressed microporous silica and compressed microporous silica with cellulose. A significant mismatch is observed between the theoretical model plotted in Fig. 3, and the measurement results of these types.

Abstract. *A hailstorm has heavily damaged a glass fibre mesh reinforced mineral render of an externally insulated composite system (ETICS) of a family house. While a neighbouring house of identical design and of the same age showed only minor defects, for the house under investigation it was a total failure of the render. Material probes were taken from the damaged façade and analysed physically and chemically. Before renovation, the hail resistance of the façade was determined with a unique artificial hail impact test method: Clear ice balls were shot against the façade with the help of a launcher, where the kinetic energy of the projectile can precisely be controlled. The type of damage due to natural hail could be reproduced. The impact energy needed to cause a damage similar to the one caused by the natural hail was determined. The hail impact damage was also identical to results from hail testing performed in the laboratory on similar systems. Since the amount of rendering material on the façade was not according to standards of the Swiss Society of Engineers and Architects - it was by far too thin - specific laboratory tests were performed with specimens not only made of similar materials but also with a comparable thin render layer. By systematic variation of the projectile size and its velocity, the impact parameters were studied and correlated to the type and extent of the hail impact damage. A threshold, associated with the first appearance of full circle cracks in the render, was found to be a kinetic energy of 2.5 J. The assessment of a supposed thickness effect and an effect of doubling the reinforcement on the hail impact resistance and the effect of the age of the façade however was a challenge. The methodological limitations given by the circumstances and the approach used are discussed in this paper.*

Keywords: *ETICS, Hail Damage, Impact, Ageing, Testing.*

1 Introduction

The effect of ageing on the durability of building elements, such as façades has been addressed in the last years by the scientific community of construction engineering and materials science (Bochen, 2009; Bochen and Gil, 2009; Daniotti *et al*., 2015; Daniotti, Paolini, and Re Cecconi, 2013; Griciute, Bliudzius, and Norvaisiene, 2013; Norvaišiene, Norvaišiene, GriciutĖ, Bliudzius, and Ramanauskas, 2013). Building insurances of Germany, Austria and Switzerland have established a register of products for building elements, which are certified for resistance against hail impact (ACFI, 2020). The certification is based on an artificial hail impact test,

which classifies the product in one of five hail resistance classes. A weakness of this certification is the fact, that products are tested and classified when they are new. The certification does not cover any deterioration of the hail resistance with the age of the product. It is an open question how much a product in service loses hail resistance with its age.

On first of August 2017 a heavy thunderstorm accompanied by hail passed the region of Winterthur, Eastern Switzerland. The building insurance of Zürich was informed by a house owner of a medium sized family house, that the façade oriented to northwest, from where the hailstorm came, has been heavily damaged. In the view of the building insurance, the ETICS on that façade should have resisted such a hailstorm and therefor the heavy damage was not expected. Swiss Federal Laboratories of Materials Science and Technology (Empa), Natural Hazard Prevention of the Association of Cantonal Fire Insurance Companies (ACFI) and the Building Insurance of Zürich (GVZ) have initiated thereafter a case study to get a deeper understanding of the cause of this damage.

2 Design of the Case Study

The idea of the study was that the façade, which was 17 years old, had a reduced hail resistance due to ageing. During the course of the study additional factors have been considered, such as the thickness of the render (amount of material applied) and the reinforcement. The case study had the following parts:

1) Description of the thunderstorm
2) Detailed description of the hail impact damage on the ETICS
3) Determination of the hail resistance of the ETICS on-site; measurement of the hail resistance in the aged condition
4) Fabrication of a representative peace of the façade in order to determine the hail resistance of a new façade of the same design
5) Comparison of the hail resistance of the new façade with the aged façade

3 The Thunderstorm of August 1st 2017 in Winterthur

August 1st 2017 was a typical high summer day with a flat atmospheric pressure distribution over Europe. In the meteorological forecast for Eastern Switzerland the development of thunderstorms was expected with hail of hailstones up to 4 cm in diameter. Observations of hail in the neighborhood of the house under investigation stated hailstones of as large as 32 mm, s. Fig 1.

Figure 1. Hailstones of the thunderstorm on August 1st 2017 in Winterthur.

These observations confirmed a hailstorm of class 3, which has an occurrence probability of one in in 5 to 20 years in this region. Therefore such a hailstorm as to be considered in the design of a building, because a building should last for 30 to 40 years, (Kempton, Chap, and Alani, 2002). According to CFIA standards, the façade should be class 3 hail resistant, which means, that this specific event should have been survived undamaged. The first conclusion was, that the façade was not as strong as it should be according to CFIA regulations.

4 Damage Description of the Affected Façade

The house was exposed to Northwest. An aerial view of the house with the affected façade from West is shown in Fig. 2. A detailed visual inspection showed 147 damage locations evenly distributed over the façade's area of 70 m^2. The damages found were classified in three categories: cracks (low level damage), full circle fracture (medium level damage) and breakout of the render with uncovering of the reinforcement (high level damage). Typical representations of these three types of damage are shown in Fig. 3. 71 locations showed a low level, 51 a medium level and 21 locations a high level damage. The morphology of these damages was similar to damages found in artificial hail tests on ETICS (Steinbauer, 2016).

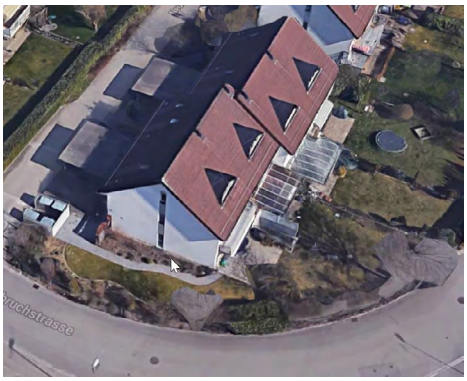

Figure 2. Aerial view of the façade from West.

Figure 3. Representations of the damage classes: crack (left), full circle fracture (center) and breakout (right).

5 Construction and Background of the Façade

The house was built in 2000. According to the drawings, the façade was based on a brick wall on which a thermal isolation of 10 cm thickness was bonded, covered by a rendering. This is a classical design of a modern ETICS. The originally used products could not be found out. Therefor 15 material probes were taken from the façade and analyzed physically and chemically.

The thermal isolation was a polystyrene foam with grain size of 2.8 mm and a density of 19.2 kg/m^3. The rendering was characterized with Thermal Gravimetric Analysis (TGA), Infrared Spectroscopy (IRS), and X-Ray Diffraction (XRD). The render was cement-bound. The main crystalline phase was calcite (aggregate, filler and carbonated binder). In addition, it contains dolomite, quartz and layer silicates as aggregates and filler. The calcium hydroxide was no longer visible from the cement, because it was carbonated (also not visible in the TGA). However, residues of the cement clinker phases were still visible. Mono-carbonate was seen as the hydration product. Some gypsum was also found. The chemical composition was as for a typical high strength mineral render bonded with Portland cement for thin layer application. The rendering was reinforced with a single or double layer of a mesh of glass fibers with an acrylic and polystyrene coating. The dimensions of the different layers were measured, s. Fig. 4. and table 1. Some those findings quality questions arose.

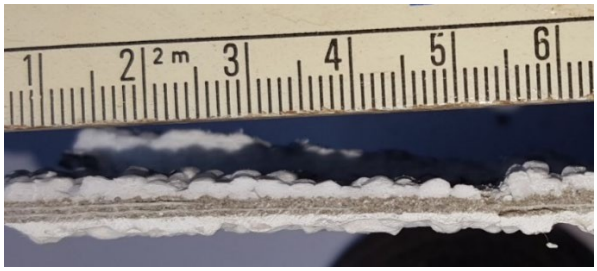

Figure 4. Cross section through the rendering (inside up – outside down): double reinforcement on the left, single reinforcement in the middle and on the right.

Table 1. Average and ranges of thickness of the different layers of the rendering of the façade.

Base coat, including the reinforcement	Finish coat, with sand grains	Paint coat	Total
mm	mm	mm	mm
1.5	1.4	0.2	3.1
1.4 – 1.6	0.4 – 1.6		2.5 – 4.5

For the strength of the rendering system, the paint coat and the finishing coat are of secondary importance. Therefore, in order to assess the quality of the rendering system, the focus was on the thickness of the base coat. According to the Swiss standard for Engineers and Architects SIA 243 (SIA, 1998), the base coat must have a thickness of 2 mm to 7 mm. Also the Austrian standard ÖNorm B 6410 specifies a minimum layer thickness of 2 mm. A new version of this standard requires an average layer thickness of 3.0 mm and a reinforcement mesh which must be covered with a minimum of 1.0 mm to a maximum of 3.0 mm of concealed render. Therefor we concluded, that the layer structure of the rendering of the façade under investigation was seriously defective and thus not carried out in accordance with the state of the art.

6 Determination of the Hail Resistance

6.1 Onsite Determination of the Hail Resistance of the Façade

6.1.1 Materials and Methods

The hail resistance was determined according to CFIA guidelines (ACFI, 2020). The test took place 8 month after the hailstorm in sunny weather (17°C / 40% r.h.). The facade was bombarded horizontally with clear ice balls at an angle of 45° with an ice ball launcher, see Fig. 5. This test equipment allows to precisely accelerating the projectiles.

Figure 5. On-site determination of the hail resistance with an ice ball launcher.

In total 19 ice balls, 15 with a diameters of 30 mm and four of 40 mm, were shot. The aim was on the one hand to determine the hail resistance class according to ACFI regulations and on the other hand to assess the energy required to provoke damage of the levels mentioned above. An energy threshold for a full circle fracture and the threshold for a breakout of the render could be determined.

6.1.2 Results

The damage caused by the artificial hail, e.g. the bombardment with ice balls, largely corresponded to the damage caused by the natural hailstorm of August 1st 2017. The shot with the lowest kinetic energy provoking a damage was 2.5 J, which corresponds to a natural hailstone of approx. 25 mm diameter in free fall. It resulted in a dent and a full circle fracture in the façade. When the façade was bombarded with 40 mm ice balls and with an energy beyond 10.0 J also breakout of the render was observed. The façade did not show a class 3 hail resistance according to the ACFI guidelines.

6.2 Determination of the Hail Resistance of Reference Specimens

6.2.1 Materials and methods

Two reference specimens representing the rendering with reinforcement built up on the thermal isolation plate were fabricated. The first was equipped with double reinforcement, as applied in the area of house edges and window cut-outs. The second reference specimen was fabricated with a single reinforcement only. Both specimen had two sections: The first section was fabricated with a base coat of only 1.5 mm thickness, representing the façade under investigation. The second section was fabricated according to SIA standards, e.g. with a base coat thickness of approx. 4 mm. For the production of the reference

specimens an equivalent rendering system was chosen which had similar chemical composition and mechanical properties. The specimens were put on the roof of the Empa laboratory for hardening under natural weathering condition for 2 and 7 month, respectively. The rendering of the reference specimens had the following dimensions:

Table 2. Average thickness of the different layers of the rendering of the reference specimens.

	Base coat, including the reinforcement	Finishing coat, with sand grains	Paint coat	Total
	mm	mm	mm	mm
Thin section 1	2.3	1.3	0.2	3.8
Standard section 1	3.8	1.8	0.2	5.8
Thin section 2	1.1	1.1	0.2	2.4
Standard section2	4.5	1.1	0.2	5.8

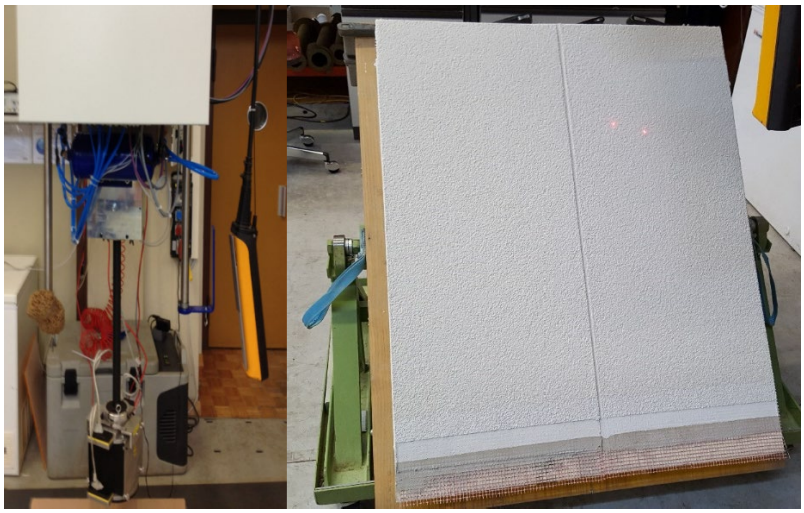

Figure 6. Air gun for artificial hail tests (left) - reference specimen before hail testing (right).

The hail tests were carried out with the Empa air gun for hail testing as well as with the ice ball launcher used onsite, see Fig. 6. The tests were carried out according to CFIA regulation No. 8 (ACFI, 2014). Both specimens were bombarded with 20 mm, 30 mm and 40 mm ice balls, which were made by the melting method from natural ice. The tests were performed at 23 °C / 50 % r.h. The aim was to reproduce the damage caused by the bombardment on the façade and to determine the threshold values for a crack, a full circle fracture and breakouts.

6.2.2 Results

A total of 67 shots were fired on the first specimen, 60 shots on the second specimen, evenly distributed over the two sections each. The results of the hail shots are summarized in table 3 and compared to the results of the shots on the façade. The façade was 17 years old and had a thin layer of base coat with a single layer of reinforcement. The reference specimens were new with a thick layer of base coat on one side and a thin layer of base coat on the other. One specimen had a single reinforcement and one a double reinforcement. Thus, the results can be analyzed with regard to a thickness effect, a reinforcement effect and an ageing effect by

comparing the values pairwise.

Table 3. Threshold for damage levels determined on the reference specimens and the façade.

base coat: reinforcement: age:	thick double new	thick single new	thin double new	thin single new	thin single aged
	J	J	J	J	J
Threshold for a crack	1.3	2.6	1.8	2.8	-
Threshold for a full circle fracture	1.9	2.9	3.3	2.8	2.5
Threshold for a breakout	15.4	11.7	12.4	11.6	10.0

No clear effect of the thickness can be seen: For double reinforcement, a thicker base coat may be favorable or unfavorable, depending on the damage level. For single reinforcement, the respective threshold values hardly differ. An effect of the reinforcement can also not be identify in the data: A double reinforcement is unfavorable for low damage level, but favorable for high damage level. An effect of ageing is weakly recognizable, both for a circle crack and a breakout: Both threshold values decrease with age, but only by approx. 15%.

7 Discussion and Conclusions

7.1 Discussion

The overlapping of three major influences makes it difficult to distinguish their individual impacts on hail resistance: For a complete investigation of all effects, not only a façade in the state "aged/too thin" would have had to be present, but also a façade "aged/standard layer". With the reference specimens the two states "new/too thin" and "new/standard layer" were available. Thus, on the one hand, the layer thickness effect could only be quantified in the "new" state and, on the other hand, the ageing effect could only be determined in the "too thin" state. The ageing effect of a rendering with standard layer thickness could not be determined with the available material. Since it was a classic mineral rendering, which was only discovered in the course of the investigation, a significant ageing effect could not have been expected. This result would probably be different if it was an organically bound rendering.

The results of the study leaves the possibility open that a thickness effect or an effect of the reinforcement only occurs in the aged state. A further possibility is that the ageing effect only occurs when the layer structure is correctly applied, but not when it is too thin. An indication that the first possibility applies is the comparison of the façade examined here with the façade of the neighboring house. Both houses have the same design and are of the same age. Assuming that the façade of the neighboring house was correctly manufactured, the thickness effect in the aged condition could be assessed by comparing these two façades. The façade of the neighboring house had only a few impact damages, which could be repaired locally. This indicates that it was not the advanced age that caused the massive damage to the façade, but the poor workmanship. The repair was a complete rebuilding of the rendering.

7.2 Conclusions

The damage to the façade by the natural hail event of August 1st 2017 could be reproduced by bombardments with ice balls of 30 mm in diameter and a kinetic energy of at least 2.5 J. Artificial hail impact with the ice ball launcher onsite as well as with the air gun in the laboratory gave similar results. Energy threshold values for typical damages were determined for a typical mineral rendering system. In the course of the study it became apparent that the structure of the façade did not meet the current standards. Thus, it had to be assumed that the damage to the façade was not only influenced by the age (17 years old), but also by a too thin rendering base coat (1.5 mm instead of at least 2.0 mm). An ageing effect is weakly discernible in the data, while an influence of the coating thickness could not be found.

Abstract. *Performance metrics serve as useful tools and indicators for many applications. For the building industry, various metrics exist; typically, these metrics do not assess the whole building performance. Instead, these represent separate components or heat transfer mechanisms of a building like R-value, U-factor/value, and airtightness. The mechanisms defined under these metrics all contribute significantly to the overall thermal performance of a building but will rarely act independently. There are metrics that account for the overall energy performance of a building, such as Energy Use Intensity (EUI). However, these metrics tend to be highly influenced by how the building is operated and used. There are also metrics which provide assessment on a relative basis. These indices are based upon comparison to a baseline, which complicates meaningful metric-based energy analyses. This paper presents a performance metric developed to account for various thermal properties and behaviors of a building. The metric accounts for all the relevant mechanisms that influence heat losses and gains in buildings and is thus directly related to the energy performance. In addition, the metric is designed to comprise air infiltration and allows users to account for workmanship quality, and imperfections of the building thermal resistance due to penetrations and other installations. This paper will describe how the metric can be applied for various building types and in different climates.*

Keywords: *BEP, Energy, Demand, Thermal Mass, Whole-Building.*

1 Introduction

The thermal performance of a building depends on various building characteristics, including outdoor climate, building usage, HVAC equipment, occupants' indoor climate preferences, etc. Due to complex interaction between these variables, describing the thermal performance of a building is difficult. Many metrics exist to describe single variables, such as *R*-value, U-factor, airtightness (ACH50/75), Solar Heat Gain Coefficient (SHGC). However, none of these indicators can fully, or even realistically, solely describe the overall thermal performance.

Several attempts have been made to define metrics which account for most variables that possess a significant impact on the energy performance (Ferrari and Zanotto, 2016). Many of these efforts focus on the building envelope thermal mass, such as the TER (Reilly and Kinnane, 2017), the M-factor (Masonry Industry Committee, 1978; Yu, 1978), and the T-value (Alterman *et al.*, 2012). Typically, the greatest hurdle to overcome is to account for solar loads and the impact it has on exterior building envelope surface temperatures and interior heat loads. The sol-air temperature (O'Callaghan and Probert, 1977) defines a fictious ambient temperature that accounts for solar induced heat transfer through the opaque building envelope, but that does not reflect solar induced interior heat gains.

There are also various simplified methods to calculate heating and cooling loads in buildings from estimating the overall thermal performance of buildings, such as CLTD/CLF (Spitler,

doi:10.23967/dbmc.2020.204

McQuiston, and Lindsey, 1993) and the RTS method (ASHRAE, 2017). These methods include all variables relevant to the energy demand in buildings, including interior loads from solar radiation through windows. However, these methodologies do not result a single indicator that represents the whole building energy performance.

This paper proposes a simplified assessment that accounts for mechanisms relevant to the heat loss and gains through the building envelope and its impact on interior loads.

2 Method

This paper presents a methodology to assess the thermal performance of building using a single-valued metric. The metric is based on the following principle.

$$\frac{Q_{HVAC}}{\eta} = Q_{net}^{env}$$
$$Q_{net}^{env} = BEP \cdot A_{tot}^{env} \tag{1}$$

The HVAC energy demand (no internal loads), Q_{HVAC} (J[Btu]), will mainly depend on the efficiency of the HVAC system η (-) and the net building envelope heat transfer Q_{net}^{env} (J[Btu]). In Eq. (1), we introduce the Building Envelope Performance metric, BEP (J/m^2[Btu/ft^2]), which is defined by the overall building envelope thermal load per building envelope area, A_{tot}^{env}. For annual heating and cooling loads, BEP is a combination of the thermal resistance of all building envelope components, $\mathcal{R}$ ((m^2·K)/W [(°F·ft^2·hr)/Btu]), and the effective cooling (c) and heating (h) degree hours, as seen in Eq (3). $\mathcal{R}$ includes heat transfer from conduction, convection and radiation:

$$BEP = \frac{eCDH}{\mathcal{R}_c} + \frac{eHDH}{\mathcal{R}_h}$$
$$\mathcal{R} = \frac{1}{\frac{1}{\sigma \cdot R_{env}} + \frac{1}{R_{air}} + \frac{1}{R_{gain}}} \tag{2}$$

where

$eCDH$ = Effective cooling degree hours (K·hr [°F·hr]),
$eHDH$ = Effective heating degree hours (K·hr [°F·hr]),
R_{env} = Conductive thermal resistance, *R*-value ((m^2·K)/W [(°F·ft^2·hr)/Btu]),
R_{air} = Air leakage resistance ((m^2·K)/W [(°F·ft^2·hr)/Btu]),
R_{gain} = Window solar and internal heat gains resistance ((m^2·K)/W [(°F·ft^2·hr)/Btu]),
σ = Opaque envelope solar and thermal radiation correction factor (-).

$eCDH$ and $eHDH$ are calculated from average outdoor and indoor temperatures during cooling and heating mode respectively.

$$eCDH = (T_{out}^{avg,c} - T_{in,cool}) \cdot t_{cool}$$
$$eHDH = (T_{in,heat} - T_{out}^{avg,h}) \cdot t_{heat} \tag{3}$$

Here,

$T_{out}^{avg,c-h}$ = Average outdoor temperature during cooling (c) or heating (h) (K [°F]),

$T_{in,cool}$ = Indoor setpoint temperature for cooling (K [°F]),

$T_{in,heat}$ = Indoor setpoint temperature for heating (K [°F]),

t_{cool} = Time for which cooling occurs (hr),

t_{heat} = Time for which heating occurs (hr).

Note that the effective cooling and heating degree hours defined in Eq. (3) are not the same as regular cooling and heating degree hours (Erbs, Klein, and Beckman, 1984). For example, because of heat loads (solar and internal), cooling may occur when the ambient outdoor temperature is below the indoor cooling setpoint temperature. Defining effective degree hours are essential to account for all loads/sinks contributing to the HVAC running cycle.

2.1 Conductive Heat Transfer

The resulting building envelope *R*-value, R_{env}, is expressed as:

$$R_{env} = \frac{A_{tot}^{env}}{\frac{A_{wall}}{R_{wall} \cdot \phi_{wall}} + \frac{A_{roof}}{R_{roof} \cdot \phi_{roof}} + \frac{A_{slab}}{R_{slab} \cdot \phi_{slab}} + \frac{U_{wind} \cdot A_{wind}}{\phi_{wind}}} \quad . \tag{4}$$

$$A_{tot}^{env} = A_{wall} + A_{roof} + A_{slab} + A_{win}$$

where

R_k = Thermal resistance (*R*-value) of envelope component k ((m^2·K)/W [(°F·ft^2·hr)/Btu]),

ϕ_k = Conductive correction factor for envelope component k, due to thermal bridges, installation quality, etc. (-). (Not validated in this study)

The opaque envelope radiation correction factor, σ, accounts for increased surface temperatures due to solar radiation and is given by:

$$\sigma = \frac{T_{out}^{avg} - T_{in}}{T_{eq} - T_{in}} \quad , \tag{5}$$

where

$$T_{eq} = \frac{T_{eq}^{roof} \cdot A_{roof} + T_{eq}^{wall} \cdot A_{wall} + T_{out}^{avg} \left(A_{win} + A_{slab} \right)}{A_{tot}^{env}}, \tag{6}$$

In which,

$$T_{eq}^{wall} = T_{out}^{avg} + R_{se,wall}\left(\alpha_{wall}\left(\frac{I_{sol,E}^{avg}\cdot A_{wall,E} + I_{sol,S}^{avg}\cdot A_{wall,S} + I_{sol,W}^{avg}\cdot A_{wall,W} + I_{sol,N}^{avg}\cdot A_{wall,N}}{A_{wall}}\right)\right.$$
$$\left. + \frac{I_{sky,E}^{avg}\cdot A_{wall,E} + I_{sky,S}^{avg}\cdot A_{wall,S} + I_{sky,W}^{avg}\cdot A_{wall,W} + I_{sky,N}^{avg}\cdot A_{wall,N}}{A_{wall}}\right) \quad (7)$$
$$T_{eq}^{roof} = T_{out}^{avg} + R_{se,roof}\left(\alpha_{roof}\cdot I_{sol,hor}^{avg} + I_{sky,hor}^{avg}\right)$$

and

T_{eq} = Equivalent building envelope surface temperature (K [°F]),

T_{out}^{avg} = Average outdoor temperature when either cooling or heating occurs (K [°F]),

$I_{sol,j}^{avg}$ = Annual average incident solar radiation on vertical surface in direction j (W/m^2[Btu/(hr·ft^2)]),

$I_{sky,j}^{avg}$ = Annual average infrared radiation on vertical surface in direction j (W/m^2[Btu/(hr·ft^2)]),

$I_{sol,vert}^{avg}$ = Annual average incident solar radiation on vertical surfaces (W/m^2[Btu/(hr·ft^2)]),

$I_{sky,vert}^{avg}$ = Annual average infrared radiation on vertical surfaces (W/m^2[Btu/(hr·ft^2)]),

α_k = Material solar absorptivity of envelope component k (-),

ε_k = Material infrared emissivity of envelope component k (-),

R_{se} = Exterior surface transfer resistance ((m^2·K)/W [(°F·ft^2·hr)/Btu]),

$E / S / W / N$ = East, South, West and North respectively (-).

The opaque envelope solar and thermal radiation correction factor seen in Eq. (5) needs to be calculated for both heating ($t_{heat} > 0$) and cooling ($t_{cool} > 0$) since T_{eq} and T_{out}^{avg} varies accordingly.

$$\sigma^c = \frac{T_{out}^{avg,c} - T_{in,cool}}{T_{eq}^c - T_{in,cool}} \text{ and } \sigma^h = \frac{T_{out}^{avg,h} - T_{in,heat}}{T_{eq}^h - T_{in,heat}} . \quad (8)$$

2.2 Convective Heat Transfer

The effective thermal resistance due to air infiltration through the building envelope, R_{air}, is defined as:

$$R_{air} = \frac{A_{tot}^{env}}{\overline{\dot{V}}\cdot\rho_{air}\cdot c_{air}}. \quad (9)$$

$$\overline{\dot{V}} = C\cdot\left(\overline{\Delta P}\right)^n \quad (10)$$

Where

$\overline{\dot{V}}$ = Annual average air flow rate through the building envelope during either cooling or

heating (m^3/hr [ft^3/hr]),
ρ_{air} = Density of air (kg/m^3 [lb/ft^3]),
c_{air} = Specific heat of air (J/(kg·K) [Btu/(lb·°F)]),
C = Air flow coefficient (m^3/(s·Pa) [cfm/Pa]),
P = Air pressure (Pa),
n = Air leakage exponent (-).

The average air pressure difference is calculated during the time of either cooling or heating. Typically, the overall pressure gradient, ΔP, around the building envelope is the sum of three components; wind loads, ΔP_w, buoyancy effect (stack), ΔP_s, and ventilation, ΔP_v.

$$\Delta P = \Delta P_w + \Delta P_s + \Delta P_v \tag{11}$$

As for all variables in Eq. (2), R_{air} is defined for either cooling or heating.

2.3 Solar, Thermal and Internal Heat Gains

Finally, an effective thermal resistance is found, due to interior heat loads. These loads consist of solar and thermal radiation through windows and all interior loads from equipment, appliances, lighting, humans, etc. The heat gain resistance, R_{gain}, is written as

$$R_{gain} = \frac{\left(T_{out}^{avg,c-h} - T_{in}\right) \cdot A_{tot}^{env}}{Q_{load,in}}. \tag{12}$$

$$Q_{load,in} = SHGC \cdot \left(I_{sol,E}^{avg} \cdot A_{win,E} + I_{sol,S}^{avg} \cdot A_{win,S} + I_{sol,W}^{avg} \cdot A_{win,W} + I_{sol,N}^{avg} \cdot A_{win,N}\right) \tag{13}$$

where
$SHGC$ = Window solar heat gain coefficient (-),
R_{gain} is a fictitious thermal resistance based on the assumption of a given temperature gradient, $\left(T_{out}^{avg,c-h} - T_{in}\right)$, which allows all thermal resistances in Eq. (2) to be lumped together.

3 Result

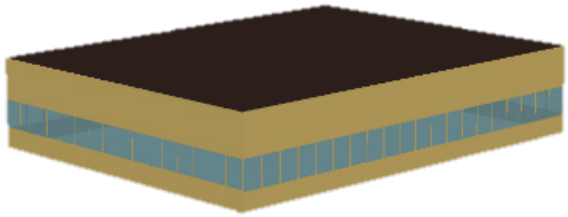
The proposed BEP metric of this paper has been validated against transient energy modelling simulation tools (EnergyPlus, 2018). The simulated building was setup as a rectangular building and with characteristics described in Table 1.

The overall heating and cooling demands were computed for 16 different U.S. climate zones (IECC, 2015) and the indoor temperature was kept at 20°C [68°F]. As seen in Eq. (2), BEP relies on the effective heating and cooling degree hours. These hours are calculated based on all loads contributing to the indoor temperature. In general, cooling and heating degree hours are calculated under the following conditions:

$$\begin{aligned} &eCDH \ when \ Q_{net}^{cool} > 0 \\ &eHDH \ when \ Q_{net}^{heat} < 0 \end{aligned} \tag{14}$$

$$Q_{net}^{cool} = \mathcal{R} \cdot \left(T_{out}^{avg,c} - T_{in,cool} \right) \cdot A_{tot}^{env}$$
$$Q_{net}^{heat} = \mathcal{R} \cdot \left(T_{in,heat} - T_{out}^{avg,h} \right) \cdot A_{tot}^{env} \quad (15)$$

Table 1. Simulation model used to validate the BEP metric.



Length x Width x Height	20 x 15 x 4 m [65.6 x 49.2 x 13.1 ft]
Window Area	84 m^2 [275.6 ft^2]
SHGC	0.352 (-)
R-value Wall/Roof/Window/Slab	1.013/3.509/0.391/adiabatic (m^2·K)/W
Solar absorptance Wall/Roof	0.92/0.7
Surface heat transfer coefficient - Interior/Exterior	8/25 W/(m^2·K)
Air tightness	Not validated

Figure 1 reveals how the cooling and heating cycle varies in the simulations for warm (Miami, FL) and a cold (Minneapolis, MN) climate respectively.

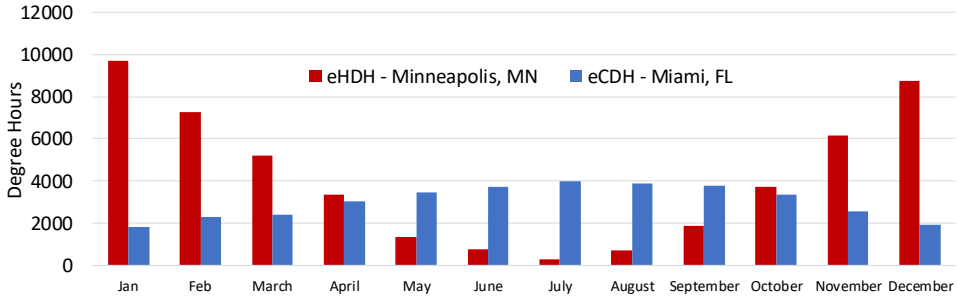


Figure 1. Variation in effective heating and cooling degree hours between a hot (Miami, FL) and cold (Minneapolis, MN) climate. $eCDH$ and $eHDH$ are calculated in accordance with Eq. (15).

A comparison was made for BEP between various comprehensive simulation models (EnergyPlus, 2018; IBP, 2019; van Dijk, Spiekman, and Hoes-van Oeffelen, 2016). Figure 2 depicts simulated cooling and heating demand for 16 locations in the U.S. According to this result, the BEP shows good agreement with more sophisticated simulation models. The main reason to the discrepancies depicted in Figure 2 for the simulated heating and cooling demand seems to be a result of dissimilar approaches to compute heat surface film coefficients.

As previously discussed, the BEP metric will account for various variables that are dependent on exterior climate conditions. **Figure 3** reveals the variation of BEP for various climates. According to the figure, colder climates tend to require an overall greater energy demand, thus a higher value of BEP.

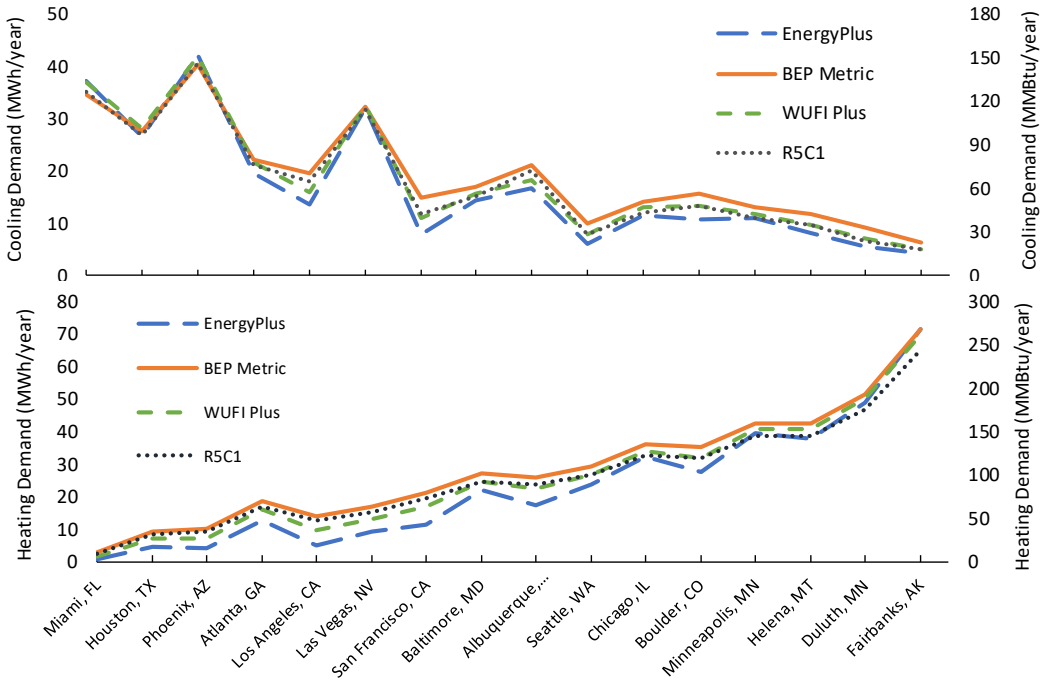

Figure 2. Validation between the proposed metric, EnergyPlus, R5C1, and finite element simulations. The proposed metric shows good agreement with more sophisticated simulation procedures.

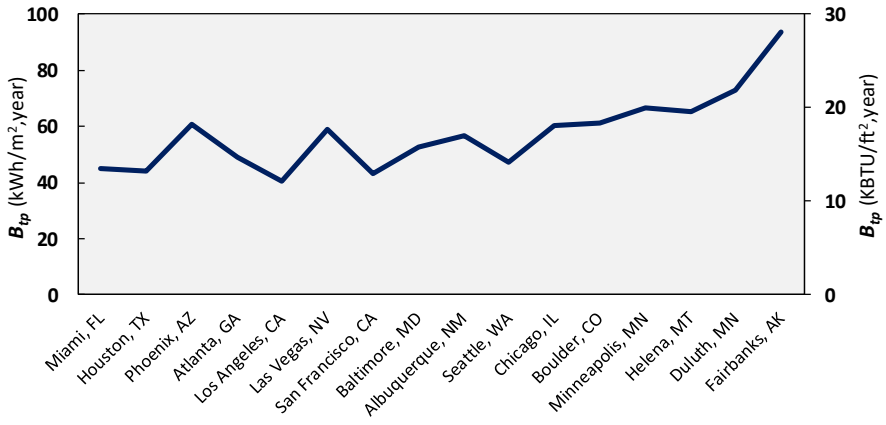

Figure 3. Variation in BEP between 16 different locations and U.S. climate zones for the validated building.

4 Conclusions

This paper introduces a new building envelope thermal performance metric, BEP. The metric accounts for all relevant heat transfer mechanisms affecting the energy demand of a building due to outdoor climate and interior thermal loads; conductive heat transfer, air infiltration, solar heat gains affecting opaque building envelope surface temperatures and indoor heat loads. This paper also presents an initial validation study by comparing simulation results from various whole building energy simulation tools. According to the comparison, BEP can predict overall energy performance similarly to existing simulation tools.

The purpose and advantage of BEP are that it does not require an iterative simulation

procedure. Instead, the proposed metric relies on input data given by the geometry of the building, thermal characteristics and outdoor climate date. This feature allows for a quick, yet accurate, thermal performance assessment of a building.

Lastly, BEP serves as an overall building envelope thermal performance metric. This allows for easy comparison of the thermal performance of buildings with varying building type, characteristics, and climate location. Additionally, the BEP allows for efficient comparison of the predicted energy performance of planned retrofits.

Abstract. *The aim of the paper is to analyze practical aspects with use of 3D Model for accurate building condition assessment. Use of fully interactive visualization methods from a technical condition assessment platform going to be, especially taking into consideration current COVID-19 scenarios, a very supportive tool for the massive inspection of building stocks, particularly in big residential areas. The authors present the approach based on high-performance images that were captured by Unmanned Aerial Vehicles (UAVs). The next step is the generation of a 3D model and orthophotos of building facades. The graphical information together with tables of attributes will allow the interactive geo-referenced management and assessment, that is proposed as a form of interactive cooperation. The idea of this approach corresponds widely with the Building Information Modeling aims. The authors introduce the methodology, stages of the inventory and follow-up process carried out within the platform requirements together with advantages of the visualization techniques, basing on a particular case study. Technical details about the information system and the analysis connected with the visualization utility will be presented and illustrated.*

Keywords: *Technical Condition, Assets Assessment, UAV, BIM, GIS.*

1 Introduction

The main aim of this paper is to introduce the further research and development of the utility previously presented by Banaszek *et al*. (2019) for the accurate assessment of the technical condition of buildings, as an efficient strategy and platform for the massive inspection of building stocks, in big residential areas. The approach is based on high-performance images captured by UAVs, and it is inspired by authors' previous works in the context of the Building Research Analysis and Information Network (Serrat *et al*., 2011, 2017).

The first successful ideas about using images taken from a model helicopter partly for the generation of a 3D-model of an historical mill we may find in Zischinsky *et al.* (2000). In recent years, there has been a growing demand in using UAVs for variety of purposes including monitoring, surveillance and information collection tasks. The application contexts and the objectives are different and diverse: natural disasters detection and monitoring, (Alexis *et al*., 2009, Neto *et al*., 2012, Popescu *et al*., 2015), marine-oceanic missions, (Rubio *et al*., 2004; Reineman *et al*., 2016; Schaub *et al*., 2018), surveillance of complex urban environments

(Semsch *et al*. 2009) among others. The specific use of multiple UAVs for a persistent surveillance aim has been also considered, and studied with optimized algorithms in (Nigam *et al*., 2012). Even taking into consideration all mentioned applications and research, the use of UAVs for collecting accurate information in a building, with purpose to assess and monitor its technical condition, has not been enough established. Few seminal studies have been developed (Eschmann *et al*., 2012; Hallerman *et al*., 2015; Banaszek *et al*., 2017) and by Serrat *et al*. (2018, 2019).

The idea presented in the article includes the full interactive visualization method for building condition assessment platform and may be considered as a part of the broadly understood Building Information Modeling (BIM). As a real-time capturing of data technology, UAV is used in the construction industry. In the recent years, the UAVs have been successfully used for different construction and operation applications of various types of construction projects (Asnafi *et al*., 2018). The topic of adapting the UAV technologies to efficiently collect information for an efficient BIM update, building management and documentation is being studied and considered in terms of systematic use by various authors (Vacanas *et al*., 2015; Chen *et al*., 2019; Grosso *et al*., 2020).

The paper is organized as follows. In Section 2 it will be presented the main methodology. Section 3 contains description of the case study and details of the procedure illustrated by a) the resulting 3D and 2D models for the building under assessment, and b) pictures of the elements, damages and severities identified by the methodology as a result of the inspection. The paper ends with a summary and the main conclusions of the conducted research.

2 Methodology

The new technologies in UAV data acquisition brings new opportunities in this field. In general, the method of visual building inspection using UAV is divided into two stages: data acquisition (in-flight) and digital post-processing (post-flight) (Eschmann *et al*., 2012). The quality and variety of data obtained from UAVs depends largely on installed sensors, the technical capabilities and good planning of photogrammetric flights. The flight mission of the UAVs has been technically protocolized in order to get the proper high-quality information about the real condition of the building. Based on that, the following methodology of a Fully Interactive Visualization is established and studied for building condition assessment.

Various research results (Mesas-Carrascosa *et al*., 2014.) proved that the UAVs orthophotos satisfactorily passed the spatial quality tests. The tested areas include urban, flat, agricultural and woods lands. Lately research have proposed building damage detection algorithms which use remote sensing technology. To estimate building damage detection and urban structural damage methods using UAV images and using 3D models' various authors described their possibilities (Torok *et al*., 2014; Fernandez *et al*., 2015; Maliki *et al*., 2016) The results shows that geometric parameters derived from the 3D point cloud can reveal damage indicators that are difficult to detect in the original imagery.

3 Case Study

The building was selected after taking into account the visible technical wear of the facade, the complicated shape and roof, and its location in a dense urban surrounding. The flight plan was established separately for each of the six facades and one for the whole roof, out in total there

were seven flights. The location in dense urban buildings required great caution during the flight. Usually during the flight there are variety of obstacles like the location of the sidewalks and the roadway next to the building caused the necessity of interrupting the flight when pedestrians or cars appeared, in particular the buses. Despite all these difficulties, the flight was carried out, which finally confirmed that the suggested solution can be used for the majority of buildings requiring a technical condition assessment.

For the experiment the DJI Inspire One lightweight quadcopter with the following specifications were used: weight: 2935g, vertical GPS accuracy: 0,5 m (accuracy determination), horizontal GPS accuracy: 2,5 m (accuracy of X, Y coordinates), Climb speed: 5 m/s, max. drop speed: 4 m s, max. cruising speed: 22m/s (ATTI mode, no wind), maximum flight height: 4500 m ASL (Above Sea Level), max. wind force:10 m/s, flight time: 18 minutes, operating temperature: -10 ° to 40 ° C, size: 438x451x301 mm. Digital camera (RGB sensor) has been used to obtain digital images with the following specifications: 12Mpix resolution (4000x3000), physical size 6.170mm x 4.628mm, focal length: 3.55mm. The flight weather condition was high humidity and transient slight rainfall, the temperature was about +5 degrees, wind at about 5 m/s (in gusts up to 10 m/s). As can be seen in Figure 1, despite the difficult weather conditions, vertical flight lines, including the assumed longitudinal and transverse overlap, have been preserved.

3.1 Digital Processing, Orthophoto Plans Generation and 3D Model

During the flight, 818 photos with a volume of 4.06 GB were made. As part of the inspection, no blurry photos were found and all of them were included in the processing process performed in the Pix4D software.

A desktop computer with the following parameters was used for processing: CPU: Intel (R) Core (TM) i7-2600 CPU @ 3.40GHz; RAM: 16GB; GPU: NVIDIA GeForce GTX 750 (Driver: 25.21.14.1694). The total processing time in the first iteration with standard processing settings was almost 7 hours:

Time for Point Cloud Densification - 3 hours. 44 min.

Time for 3D Textured Mesh Generation - 28 min.

Time for DSMGeneration - 42 min.

Time for Orthomosaic Generation - 1 hour. 42 min.

The following results of processing have been achieved:

GSD at the level of 0.36 cm / pix.

817 out of 817 images calibrated (100%), 1 image disabled.

1.93% relative difference between initial and optimized internal camera parameters.

Median of 13924.4 matches per calibrated image.

At this stage, it can be confirmed that the coating, despite the difficulties, was made correctly and the material can be used to generate the facade and roof elevation for the purpose of assessing the technical condition of the building. The final effect in the form of a 3D model generated in the 3rd iteration after cleaning the point cloud and recalculating the design is shown in Figure 2.

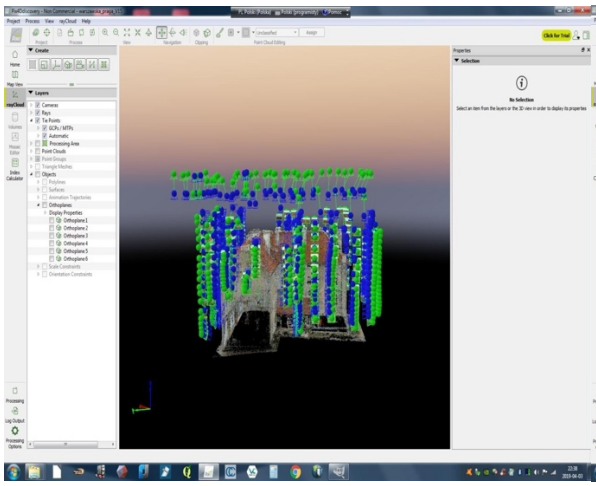

Figure 1. Location of images (view of the west facade).

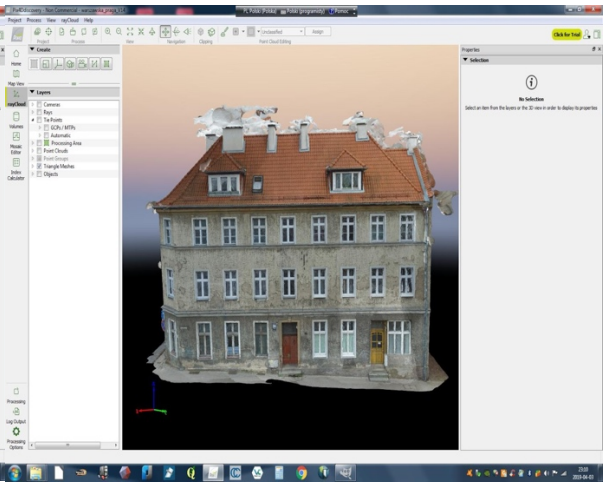

Figure 2. 3D model generated after three iterations.

Because of the GPS signal disturbances occurring during the raid, the data was processed in two blocks. Block I included the following elevations: south-west, west, north-west, north-east and a roof, and Block II included the south-eastern elevation.

On the one hand, it was necessary to enter the 11 manual tie point and reprocess the data to align the blocks. As a result, the cloud was generated in one block, and the inventoried object was characterized by the correct geometry, shape and proportions. Finally, the relative camera position and orientation of the uncertainties X, Y and Z was obtained at <0.025 for mean and <0.015 for sigma. On the other hand, it was also convenient to carry out manual cleaning and classification of the point cloud to generate a 3D model devoid of artifacts. (Figure 3 and Figure 4). This was long 6 hours process, but it resulted in the generation of a model practically free from contamination. The model allows it to be used for the visualization of selected, inventoried phenomena in 3D space in a natural way for the user. The carried-out process of cleaning the point cloud additionally influenced the quality of the generated orthophotoplanes of the facade and roof. In this stage, for each of the elevations an orthophotoplan separation was generated.

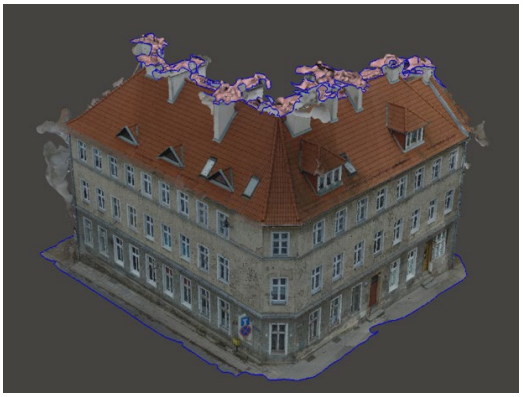

Figure 3. Visualization of the generated model in 3D space.

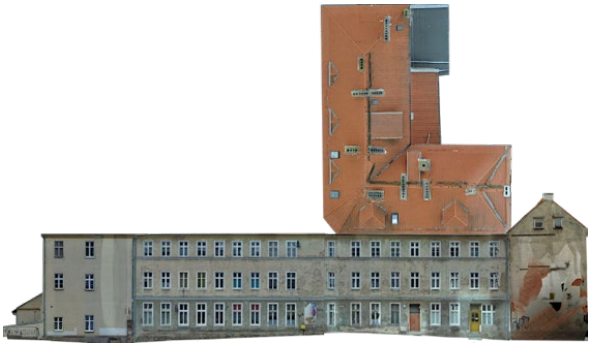

Figure 4. 3D model of an inventoried building in a flat projection.

3.2 A Square Grid and the Classification of Building Elements

In order to additionally view the selected image directly from the GIS application by indicating its center, the above-mentioned data should be enriched with the path to the directory in which the images will be ultimately stored. Good option for it is to use batch directory inventory software that saves data most often in a .txt file. Today's spreadsheets give us possibilities that can easily combine the contents of both files and generate a .txt or .csv file with the appropriate structure. The files prepared in such manner which are imported into the GIS software, after indicating columns containing the selected coordinates, enables visualization of image centers and preview of images directly from the application without the need to know their physical location. In case of image visualization in the orthophotomap area, we use the X and Y coordinates, in the case of orthophotos of elevations vertical Z and Y. During the. experiment it was generated a file consisting of 926 records, containing 5,556 attribute values. The next step to assign specific values of selected attributes for a previously defined part of the facade is to create a matrix of squares with an appropriate size. In our case study 40cm was chosen as a convenient.

The most required elements of the facade that are classified in the manual process include, parts of the geometry of the facade and the roof, window and the door joinery and architectural details. In further research with various assumed accuracy of the final inventory of all basic elements of the building one can be subjected to classic polygon vectorization (for the most accurate inventories) or indicated by assigning individual mesh squares a value corresponding to the inventoried elements (for the parts of inventory which requiring less accuracy). In case of this experiment, we used the second method and 5 classes of elements were defined: 1 - wall, 2 - molding, 3 - window, 4 - plinth, 5 - door (see Figure 5). Figure 6 shows the colorful identification of the elements.

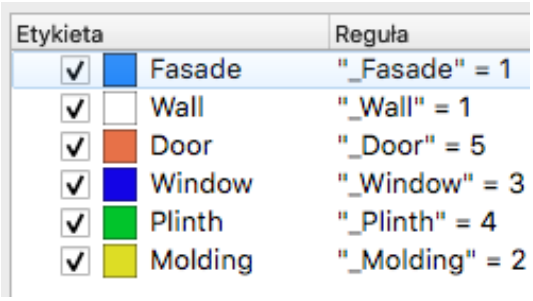

Figure 7. List of classes of identified facade elements.

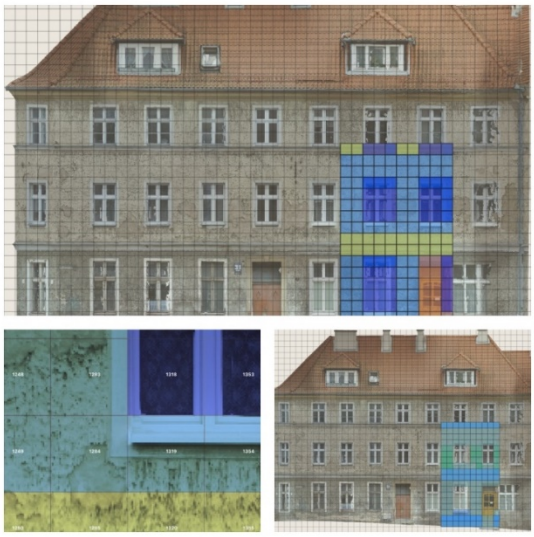

Figure 6. Ortophotoplan with completed qualification of inventoried elements.

3.3 The Visual Inventory of the Building

In the last stage, inspector carries out a visual assessment of the technical condition of the facade and determines the degree and type of damage on the basis of orthophotoplanes, looking at the square grid and classification table. Such implementation enables the automatic visualization of the technical condition in accordance with the indicated criteria and the determination of the area and position of each type of defects in the asset under inspection (Figure 7).

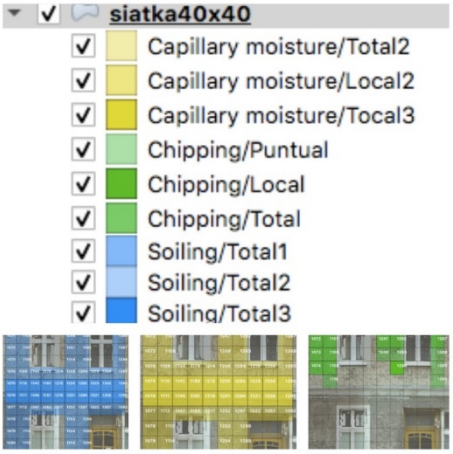

Figure 7. Visualization of different elements and damages identification.

4 Conclusions

The Full Interactive Visualization Method for Building Condition Assessment introduced in this paper, which is based primarily on high-quality digital information obtained from the deck of an unmanned aerial vehicle and good knowledge of inspector, proves to be the appropiate tool for the assessment of the technical condition of assets in residential areas. Digital images together with geoinformation data (photos, 3D model, orthophotos) with substantive data (facade element classification tables, damage classification tables) create a platform that allows intuitive access to view, to classificate, to edit and to perform the analysis of selected data, in two different modules:

- The 3D module enables the visualization of selected inventoried elements or characteristics of the asset under inspection in a 3D space in a natural way for the user and is most often used to carry out inspections and move around the model.
- The 2D module allows the technician to visualize selected inventoried elements or characteristics of the asset under inspection in a 2D space in a way that enables a more accurate and reliable identification, location, measurement and assessment.

The proposed platform provides to the users with a modern and efficient utility enabling full integration of the construction inventory process with BIM. In times when it is becoming difficult to arrange all work in a traditional form, due to the COVID-19 pandemic constraints, this tool optimizes the tasks of the different working groups. A proposal that makes feasible the situation in which the inspector's work can be efficiently carried out completely online.

Identification of Defects and Hazards in Structures Based on the Point Cloud Using the OptD Method

Joanna Janicka and Wioleta Błaszczak-Bąk

University of Warmia and Mazury in Olsztyn, Institute of Geodesy, ul. Oczapowskiego 1, 10-719 Olsztyn, Poland, joanna.janicka@uwm.edu.pl, wioleta.blaszczak@uwm.edu.pl

Abstract. *Structural changes taking place in buildings and structures due to the passage of time are a normal phenomenon. However, the building objects are also adversely affected by atmospheric conditions or violent natural phenomena. Every year, our surroundings are increasingly attacked by extreme weather phenomena such as: floods, hurricanes, heavy storms with rain or extreme heat. Such phenomena are natural elements of nature, however they significantly interfere in the technical condition of the building. They often cause measurable economic losses: flooding, cracks, construction displacements and even their total destruction. At the time of estimating losses, calculating the costs of repair, and then making decisions about the method of restoration, a helpful tool can be laser scanning: terrestrial, airborne or mobile, depending on the character of the object and the size of the disaster. The paper presents an identification of defects and hazards in structures based on the point cloud using the OptD method.*

Keywords: *Buildings, TLS, OptD, Defects, Hazards.*

1 Introduction

Building objects are subject of the influence of various factors that affect their technical condition. Every day various types of atmospheric conditions and weather phenomena occurs (wind, snow, rain, sun) but there are also such as violent phenomena that are usually extreme (hurricanes, floods, earthquakes, etc.). Either way, when the technical condition deteriorates, engineering objects should be monitoring periodically or due to the impact of a sudden phenomenon.

Traditional methods of checking the condition of buildings are extensively time consuming, laborious, and expensive and pose health and safety threats to surveyors. They rely on the employment of building inspectors, who assess the technical condition. Inspections take a long time because they require many photos, drawings and notes. It sometimes happens that inspector has to return to the inspection site many times because not all relevant information has been registered. Therefore, further suggestions are being made to solve this problem, such as the use of wireless sensor networks or smartphone sensors (Noel A.B. *et al*.,2017), (Kong Q. *et al*., 2018). In addition, classic inventory may pose a threat to building inspectors, especially in hard to reach places or at heights (Perez H. Taha J.H.M and Mosavi A. 2019). Another factor that is important is the timing of inventory taking. In the manuscript authors (Perez H. Tahy J.H.M and Mosavi A. 2019) also noticed that clients are increasingly looking for fast and effective means to quickly and frequently survey and communicate the condition of their buildings. Therefore, the search for new ways to obtain a large amount of data in the shortest possible time is also a topic that appears in the area of conducting building monitoring.

Terrestrial laser scanning has been widely used for many years, especially when creating various types of architectural documentation. It can be also used to monitor various types of objects for example: buildings (Przyborski and Tysiąc 2018), forests (Liang X. *et al*., 2016), power lines (Maikainen, L. *et al*., 2016) etc.

It allows to collect a large dataset saved as a three-dimensional coordinates and intensity parameter. Having access to this type of data, one can conduct various types of analyses, simulations, calculations, etc. About effective use of both terrestrial laser scanning and the OptD method used to identify various defects in buildings one can read in manuscripts (Suchocki and Blaszczak-Bak 2019), (Sochocki *et al*., 2019).

2 OptD Method Description

TLS measurement technology is relatively simple, fast and effective technique for obtaining data, which one can then develop according to your preferences. The biggest problem for the operator is the size of the datasets. Many times, these are multi GB files. Data can be recorded with different resolutions ranging from tens of centimeters to single millimeters. The resolution and range of the measurement has an impact on the time of measurement but also on the final results.

Thus, obtaining data is only part of the task associated with the use of point clouds to identify defects and hazards in building constructions. If the object is scanned with high resolution, the acquired point cloud is a huge data set. Usually its original size is difficult to process because it requires high performance hardware. The solution to this problem is to reduce the point cloud by eliminating some points. Commercial programs usually contain basic methods of data reduction: random or with an assumed interval, etc. The disadvantage of doing so is that as a result of random reduction one can lose many valuable points associated with the geometrical features of the object. The proposal presented in this paper is to use the OptD method during data processing.

The OptD method has been already presented in papers (Błaszczak-Bąk 2016), (Błaszczak-Bąk *et al*., 2017), (Błaszczak-Bąk *et al*., 2018). This method was developed to reduce the dataset without losing the information that is necessary for the correct implementation of the planned task. It allows to reduce the dataset significantly, but preserving the characteristics of the object, and in particular, to obtain points representing the study object. The OptD method is carried out in the following stages by Suchocki and Błaszczak-Bąk (2019).

The diagram showing the principle of operation of the OptD method that was used during the tests is shown in Figure 1.

3 Description of Sample Objects

As it was mentioned at the beginning, one can distinguish construction objects that should be inventoried because they are deteriorating due to the passage of time or those whose technical condition has deteriorated due to an event related to the operation of nature. Regardless of the reason of the inventory, it happens that staying inside the inventoried object can be dangerous for the inspector, or there are uncomfortable conditions for longer staying. It may also happens that direct access to the defect is difficult or not available. The paper present selected cases that were the subject of measurement and with which the authors have personally encountered.

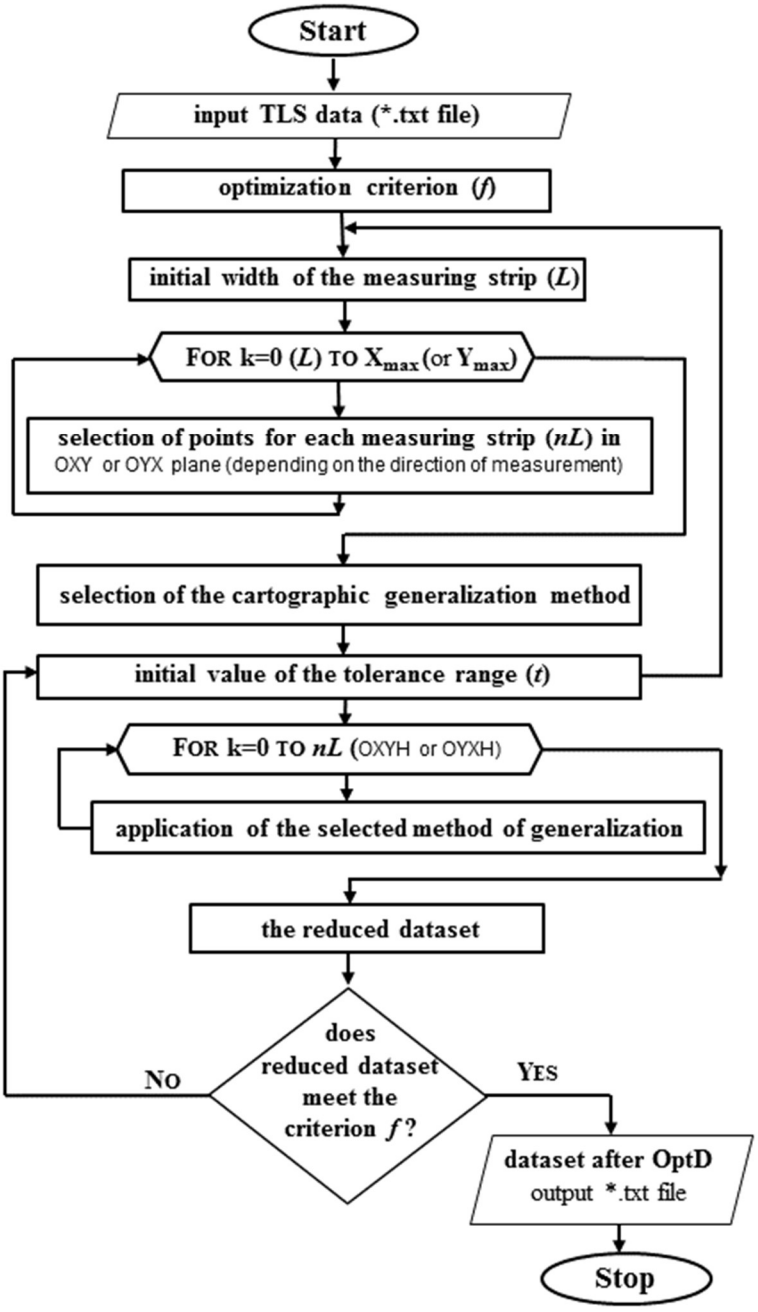

Figure 1. The scheme of the OptD reduction method.

Figure 2 presents the ruins of historic tower. In case of this tower's ruin important is to keep the fragments that are still in a quite good condition. Besides, in the underground of these

buildings there are also basements with no access to daylight. Due to the fact that there is no access to daylight or even artificial light and that the above ground remains of the tower are in a very poor condition, being in its underground is very dangerous. The technical condition of the basement is periodically checked and in this case, a terrestrial laser scanner can be a great tool because it doesn't require access to light during measurement**s.**

Figure 2. The ruins of historic tower.

The next object is a fragment of a retaining wall that supports the escarpment surrounding the primary school. The wall suffered because of a heavy downpour, therefore as a result of the natural phenomena The sudden and huge amount of water that fell on caused a lot of damage. Heavy rain eroded the area above the escarpment, and then the ground and water flowed down destroying the retaining wall. Figure 3 shows the fragments of the destroyed area.

Figure 3. Retaining wall destroyed as a result of heavy rain.

The last example is an object exposed to deformation due to subsidence. This is a church and monastery of Franciscan fathers in Barczewo, that was built in the 14th century. The Gothic church needs urgent renovation because its technical condition has deteriorated significantly.

The main reason is age and the unstable ground on which the church was built. As a result one of the church walls tilted significantly and cracked what is presented in Figure 4.

Figure. 4 Slanting church wall.

4 Results of the Processing Using OptD Method

Input point cloud is a very large dataset with the resolution of even single millimetres. Such a high resolution allows to present the tested object with high accuracy of details. However, it also happens that too densely distributed points on the scan, can hide some of the important information. The examples presented in this section show the advantages of reducing the output dataset using the OptD method. As a result of the reduction of the point cloud on selected objects, defects and hazards occurring on them were identified and presented in figures 5, 6 and 7.

Figure 5 shows detection of the basement brick wall defects using the OptD reduction. After the point cloud reduction with the proposed algorithm, those areas that have the greatest effects can be seen more clearly. OptD reduced the most points in areas that did not show significant changes in structure (in the middle of scanned object). In the area where the changes are larger, more points remain. This is visible at the bottom of the scan as a more intense green colour.

Figure 6 presents the second object and the result of the OptD reduction algorithm. The input point cloud (100 %) represents the measured object but it is difficult to observe this fragment of the wall that has been damaged. Reducing the data set by 95% allows to more accurately observe the area that is characterized by the largest defects in the wall.

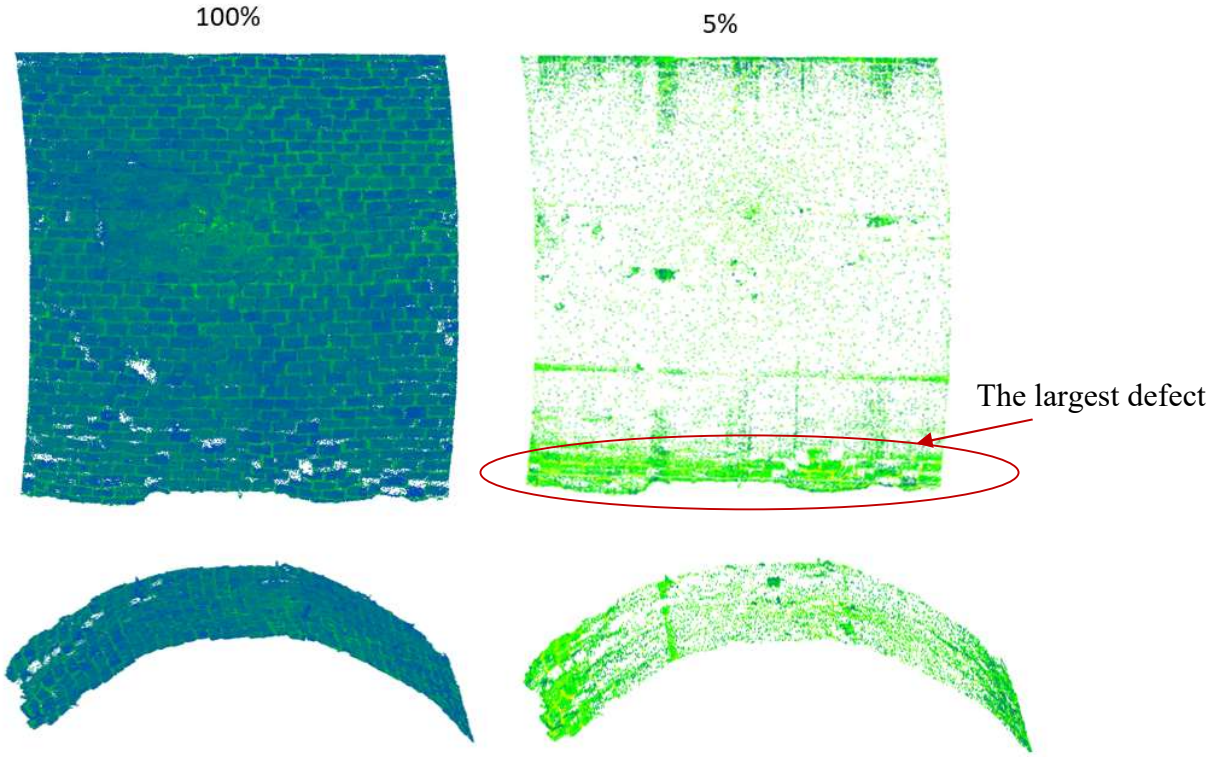

Figure 5. Detection of basement brick wall defects based on OptD: the input point cloud (100%) and the reduced dataset (5%).

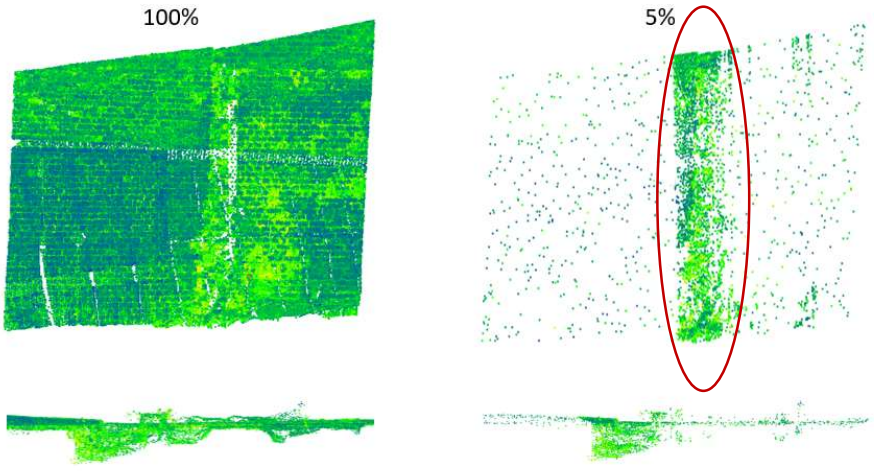

Figure 6. The retaining wall – input dataset and the reduced point cloud.

The last object is the wall of the church, which as a result of subsidence of the soil leaned out of the vertical and on its surface also formed cracks. Again, the reduction of points allowed to observe (in the form of a darker areas) the place of cracks (red line marked).

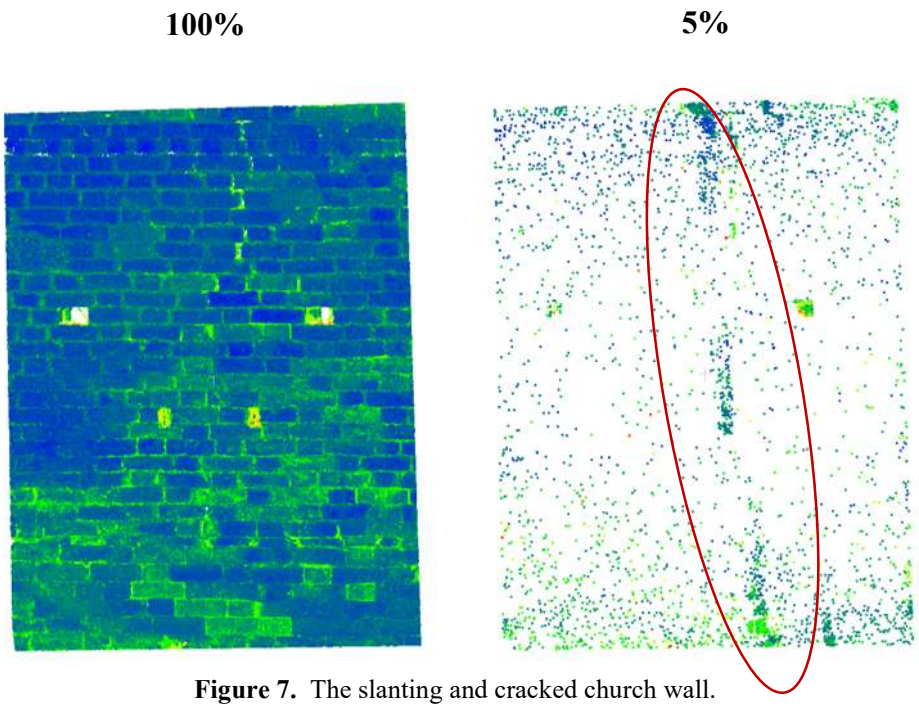

Figure 7. The slanting and cracked church wall.

5 Conclusions

Planning to measure using a terrestrial laser scanner, different approaches can be adopted. One can plan the measurement with lower resolution so that the distance between the measured points is several centimeters, and thus limit the data reduction process. Unfortunately, operator never knows exactly where the laser beam will reflect and which points will be measured and recorded. This may result in the necessity for re-measurements to udate missing information. One can also take measurements with high resolution but it takes more time, and the big dataset is obtained but a full set of information is available.

A good solution is to use the OptD reduction method in the processing of data obtained from laser scanning. The application of the OptD allows to keep more points of interest area where surface is imperfect (cracks and cavities) and reduce more points of the low interest homogeneous surface (redundant information).

Mobile Augmented Reality Application Supporting Building Facades Visualization

Michał Bednarczyk and Tomasz Templin

University of Warmia and Mazury in Olsztyn, Faculty of Geoengineering,
Institute of Geodesy and Civil Engineering

Abstract. *The use of mobile devices such as smartphones still increases over last years. Smartphone hardware capabilities are comparable with average personal computers. Thanks to the increasing computing power, their application is focused on more and more sophisticated and complex tasks. These includes among others augmented reality (AR) applications, which support precise GNSS localization and use signals from such devices like accelerometer or gyrocsope. They are able to create interactive, immersive real-time visualisation of any kind. The article presents a prototype Mobile Augmented Reality (MAR) Application for visualization of the building facades. It allows to support the original look of the building with the additional information from database. Software of this kind, can be used for overviewing, inspecting or work planning carried out on the facade of the building. As a part of the test, a prototype of the MAR application for Android has been prepared. Rest of the solution components have been presented in form of a concept, implementation of which is planned in near future. Basic technical assumptions are already developed, but details may change. The paper mentions also some important AR problems, especially positioning in urban environment and accurate registration of digital objects in the real world.*

1 Introduction

The management of building maintenance is an important topic around the world, especially in recent decades, with the incorporation of tools to automate the tracking information and potential follow-up. From the social point of view it is illogical to leave the building stock without control. (Serrat, Gibert 2011) This is the reason why many companies and institutions invest in modern IT solutions to improve the process of ongoing buildings inspection. Data collected in this process are primarily: field data, cartographic data, cadastral data as well as plot building/facade data, architectural characteristics, existing elements and materials and the state of damages at the time of inspection. (Serrat, *et al*. 2016). Data collected reliably and systematically play a special role in monitoring and analyzing the degradation of building facades. In this way, the monitoring and maintenance of valuable historic buildings and the planning of ongoing renovations are significantly supported. (Gibert *et al.* 2014). The data analysis process is automated using various IT tools, including GIS systems, which are widely known and used in many fields. They allow to combine and process spatial data and non spatial data from many sources at the same time. This gives an ability to perform analysis, plan and undertake decisions in real world.

As observed in past years, there's been a new technology developed, which is called Augmented Reality (AR). It gives the ability to present data in a new way, not available before. AR means any system that “augments”, or overlays, the real world with digital

information that seems to co-exist with the real world. (Azuma 1997) Over the past few decades, this once theoretical field has matured into a mass medium (Ahonen 2012) with applications spanning countless industries. Speaking of AR, which is used in mobile devices, many authors (Höllerer, Feiner 2004; Henrysson 2007) use the term MAR (Mobile Augmented Reality), to clarify the scope of its application. AR technology, can be understood as a special video effect or real time digital image editing. It is similar to the techniques used in film editing or television. In this way, the illusion of "extending" or "augmenting" the observed reality with additional information and images can be obtained.

Generally, the combination of digital image with the real view is obtained by the use of the digital camera and the sensors like GPS/GNSS receiver, inclinometer, magnetometer, accelerometer, compass and other, which provide information about the location and orientation of the mobile device. Siltanen (Siltanen 2012) writes that AR technology connects two fields like:

- computer graphics needed for photorealistic rendering and interactive animations,
- computer vision used for marker and feature detection and tracking, motion detection and tracking, image analysis, gesture recognition and the construction of controlled environments containing a number of different sensors.
- Taking into account other technologies needed to develop a working AR application, also should be mentioned such fields as:
- GPS/GNSS and indoor navigation which is necessary in localization purposes. While GPS/GNSS navigation is quite accurate in open space, it doesn't work inside buildings nor under obstacles. Indoor should be used other navigation methods based on such technologies like *e.g.* WiFi or Bluetooth signal or image-based localization (Janowski, Bednarczyk 2016),
- digital cartography and mapping to provide spatial data presentation and georeference,
- WWW applications technologies, Service Oriented Architecture (SOA), Database Management Systems (DBMS) and other technologies for data storage, sharing and communication.

AR starts to be widely-used and ideas for its usage can be multiplied almost indefinitely. The most obvious and popular seems to be the usage in tourism, where tourist attractions, can be observed directly on the smartphone screen, giving additional information during the tour (Kounavis *et al.* 2012). Application of this technology can be found in many other fields, where presentation of spatial data is needed. For example in architecture AR is used to present the three-dimensional models of buildings, housing estates and cities, visualization of the construction details, including installation and equipment or interior designing and decoration (Broschart *et al.* 2013; Xiangyu 2009; VTT 2013). AR is also used in spatial designing and planning for presentation of three-dimensional scale models and visualizations of projects in a real environment. Augmented reality maps, the content of which is expanded with additional information, descriptions, graphics or 3D objects, also seems to be an interesting spatial data presentation form (Moloney, Bharat 2011).

Observing such a variety of applications, the hypothesis can be formulated, that AR technology can be helpful in the building inspection process. Generally, this process is based on a comparison of the current state of the object with the state from previous years. On this

basis, conclusions may be formulated regarding further actions. An important element here is the visualization of the current and historical state in the context of the building being under study.

2 How does Augmented Reality Work

AR Glossary, document published by the AR Community, mentions that augmentation means a relationship between the real world and a digital asset (AR Community 2017). It can be said that AR mixes virtual objects like graphics, sounds, videos,3D models etc. with the view of actual world. The effect of an augmentation is a composed scene. Augmentation may be formalized through an authoring and publishing process where the relationship between real and virtual is defined and made discoverable.

There are two primary techniques for image generation which lead to obtain the AR effect (Lechner 2015; AR Community 2017), they are:

1. Geospatial based Augmented Reality.
2. Computer-vision based Augmented Reality.

Figure 1. An example of geospatial based AR application supporting searching geodetic points in the field.

To compose a scene in geospatial based AR, algorithm needs the user's location and orientation in a geographic coordinate space. Determination of location is based on geo-positioning techniques such as GPS/GNSS, WiFi or other (e.g. Bluetooth). Sometimes, location can be determined by scanning specially prepared marker for that purpose. Device's orientation parameters like rotation, slope or direction are approximated, using sensors such as a digital compass, accelerometer or gyroscope. Once approximated device's orientation may be also refined by using computer vision techniques. The virtual object can be any digital object like image or icon. To place the virtual object in the right place on the screen and compose the AR scene, the real feature's location is also needed. The augmentation occurs when user is in the vicinity of real object and points on it with a device's camera. The software will automatically determine the location and orientation of the device and display respectively generated image (virtual object) on the screen (Lechner 2015). Figure 1 demonstrates the example of augmentation performed in described way. In this case there's a database of geodetic points, which are placed in the field. AR application connects to database of points and selects these, which are in the vicinity of the device. Then the augmentation process occurs and the searched point appears on the screen (Bednarczyk 2017(b)).

In computer-vision based AR, the computer vision algorithms are used to process the image viewed by the camera, and compare it with the reference images. Augmentation is obtained when application recognizes and identifies fragments of an image and displays on this place virtual objects. Figure 2 shows the example of augmentation performed this way. In this example, the reference images are created from raster image fragments of analog map. They represent each building on the map. Each building has it's individual virtual representation in a form of automatically generated icon with basic information acquired from GIS database. Furthermore each virtual icon has an interactive button "Details". When user directs the smartphone camera to the map, application recognizes the reference image and displays a virtual icon at this place. When user touches the “Details” button on the screen, application leeds him to additional information selected from database and displayed in a form of website (Bednarczyk 2017(a)).

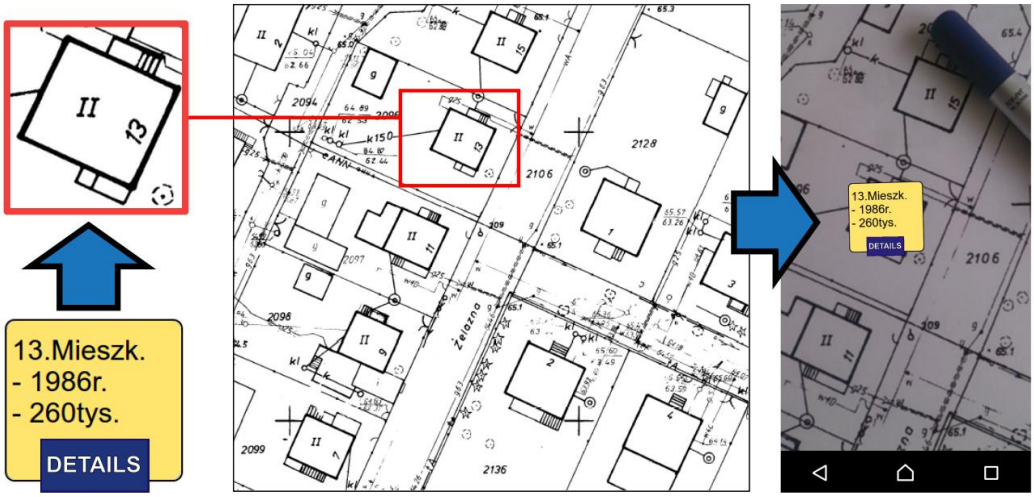

Figure 2. An example of computer-vision based AR on analog map.

3 Building Facade Visualization

As mentioned earlier, AR technology can be helpful in visualizing information about the state of the building facade during inspection. By mixing the real view of the object with the previously collected data, a direct comparison of the current and historical status can be obtained. A working prototype of the application, shown in fig. 3 uses computer-vision based AR to recognize the facade of a specific building. After that, an image (drawing) is overlayed that can contain any previously collected information related to the building, such as:

- descriptions and markings of construction elements
- descriptions and markings of defects and damages
- installation descriptions and markings
- interactive elements - to get additional information or perform an action in the application
- historical facade photos
- other useful information

Figure 3. Additional, sample information about building facade presented in AR mobile application.

At present, the application prototype is able to recognize the facade and display AR content. This software works in client-server architecture. Client application runs on a mobile device and is responsible for mixing and displaying the final image. Building the virtual "world" and sharing data is done on the server side. Further work will be focused on expanding the system's functionality.

First of all, it is needed to create an appropriate database of reference images like pictures of building facades. For the purposes of this experiment, a photo from Google Street View was used. It seems that in many cases this may be a sufficient source of images. However, this is a collection obtained automatically and, as a result, there is a risk that there may be photos taken at the wrong angle or some buildings may have been obstructed by obstacles (vegetation, people, vehicles, etc.). In addition, Street View vehicles do not visit every street or passage, but only the most important ones. Still, as of today, Street View appears to be the largest source of data of its kind.

Another important component is the inspections database of individual buildings. For testing purposes, the virtual image has been prepared manually in PNG format. It should be possible to save this data partially in vector format in a database. Thanks to this, it will be possible to generate virtual objects automatically.

To optimize performance and limit data transfer, the application should include an algorithm that allows selection of only those inspections that are closest to the observer. This can be solved by performing database queries taking into account GPS / GNSS location of the mobile device. If the proposed software is to be useful, in addition to viewing inspection data, it should be possible to edit it on site in real time. Thanks to this, inspection data could be supplemented based on the existing technical condition of the facade. All of proposed software should work under control, or be part of, more general system such as GIS or other

spatial information processing system of this kind. Schema of the conception of proposed AR system for building facades is presented in fig. 4.

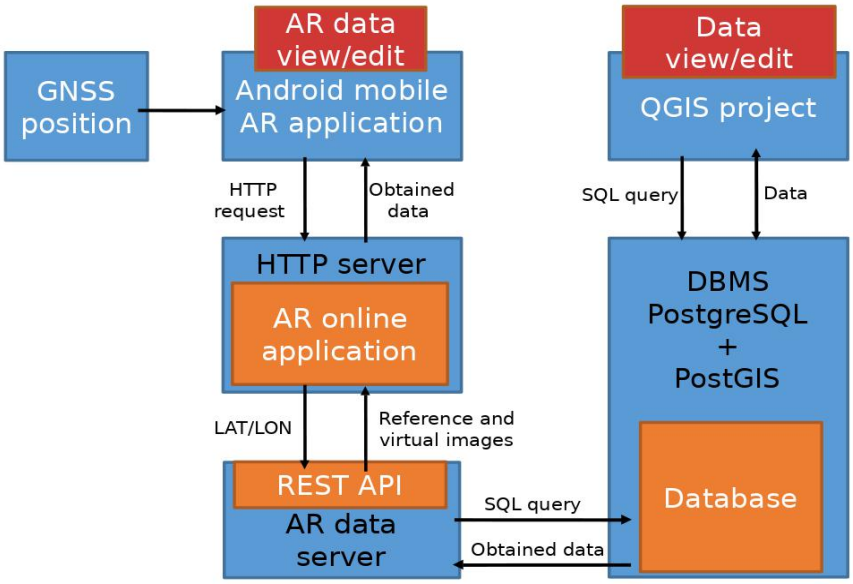

Figure 4. Components of proposed AR system for building facades.

4 Additional Observations and Results

In author's previous work on AR, some disadvantages have been observed in creating augmented reality scene (Bednarczyk 2017 (a,b)). In case of geospatial based AR, the problem is accuracy of GPS positioning, which influences quite significantly on AR virtual objects location displayed on the smartphone screen. If the GPS position error is small, AR marker indicates the destination with sufficient accuracy to identify the searched object - e.g. a geodetic point. For larger position errors, AR marker is positioned incorrectly in inappropriate place. Sometimes there is also a complete lack of GPS signal (e.g. in the forest, urban canion or while cloudy day), then the application does not work properly. This can be remedied by cutting off these observations that give too little accuracy in position determination. However, minor errors, if they occur frequently, will cause the effect of "swimming" or "jumping" virtual markers on the screen. In case of computer vision based AR, no such effects were found, but only point-oriented markers on small fragments of the analog map observed from a short distance - a few centimeters - were examined. In addition, their appearance was compact in form of an simple icon.

In this article, the virtual image covered larger area, the drawing was composed of many elements, and observation distance was several meters. In this case, it was observed that the position of the virtual image begins to deviate from the originally assumed, when changing view perspective or distance. Therefore, additional correction algorithms should be used to improve the generation of the AR scene in such cases, which will be considered in future work.

5 Conclusions

It can be assumed that visualization of building facades using AR can support the process of collecting data in the field. Using AR technology, one can display data from previous inspections, BIM, a database, or e.g. archival photos, overlaying them on the actual image of the building in real time in the field. Thanks to this, one can easily make a comparison with the existing state, make a quick view, take notes and decide whether to update the data.

However, in order to ultimately achieve the goal, further work needs to be done to refine the proposed solution. This applies above all to the system architecture, which should be expanded with appropriate components to ensure efficient and effective work, such as database of inspections and reference images. In addition, it is worth considering refining the algorithm responsible for generating the AR scene in case when observer changes the view perspective or approaches facade of the building.

Finally, considering the pros and cons of two different methods of generating an AR scene, it can be stated that, in case of facades visualization, computer vision based AR gives better results when creating an AR scene than geospatial based AR.

Abstract. *Building structures are exposed to the impact of various forces and natural phenomena. Earthquakes, heavy rains, displacements of land surrounding the building can have a significant and negative impact on the elements of buildings or entire construction objects. Terrestrial laser scanning technology can be successfully used to obtain data on changes in the structure of an object. This papier discusses the use of TLS as a measurement method for obtaining information on displacements and deformations that have occurred after heavy downpour. As a result of the rapid rain, the ground displacement occurred, which in effect led to damage to the retaining wall. The terrestrial laser scanning was used to measure the area covered by the displacements and the M-split method to model the obtained data.*

Keywords: *Buildings, TLS, M-split Estimation, Defects, Hazards.*

1 Introduction

Laser scanning technology allows to obtain a large amount of information about an object in a short time. For this reason, this technology is becoming increasingly popular also in buildings monitoring. Traditional methods of monitoring work require the involvement of building inspectors who assess the technical condition of the object. They take a series of measurements, drawings and photos and then the collected data are analysed. Sometimes it turns out that some information is missing or the inventory was not carried out correctly. In the classic approach to inventory, deficiencies in documentation require a re-visit to the site of inspection. Terrestrial laser scanning allows you to acquire data as a point cloud of varying accuracy. It is possible to measure an object with a resolution of 1 mm if such accuracy is required. Each measured point has three coordinates X, Y, Z and the intensity parameter. Thus, very detailed data about the object is obtained, that can be in the next step analyse.

Because some structures of building objects can be represented as vertices, lines, planes or others and can be described by a mathematical function. This gives the opportunity to automate the data processing what was discussed in many publication for example: Janowski and Rapiński (2013), Wang and Hsu (2007) and Zheng (2008). With this assumption it is possible to analyse for e.g. the building wall planarity, edge verticality or vertical and horizontal displacements. In the case of testing the displacement of two elements that constitute two

planes, the M_{split} estimation method can be used. The method developed by prof. Wisniewski (Wiśniewski, 2008), allows to split a functional model into two or more models, and thus identify for example two planes in the cloud of points. This paper presents the possibility of fitting planes into one cloud of points so that it is possible to identify fragments of two concrete slabs of the retaining wall that have been displaced due to ground displacement.

2 Msplit Estimation Description

The M_{split} estimation method assumes that every measurement result can be a realization of either of two or more different random variables. This estimation method was introduced by Wisniewski (Wiśniewski, 2008) and widely described in (Wiśniweski, 2009) and (Wiśniewski, 2010). Thus, based on the assumption that the functional model is split into two competitive model Y_α or Y_β each observation has its own "split potential"— the possibility to belong to one of the random variables. Therefore, the observation set $\mathbf{\Omega} = \{y_i : i = 1, 2, \ldots, n\}$ is a disordered mixture of the elements assigned to the random variables y_α or y_β in an unknown way. For that reason, each observation Y_i may have either of two competitive expected values $E_\alpha\{Y_i\} = E\{Y_\alpha\}$ or $E_\beta\{Y_i\} = E\{Y_\beta\}$. In this paper the functional model $\mathbf{V}=\mathbf{AX}+\mathbf{L}$ is split into two competitive ones which concern the same vector of observation $\mathbf{L}$:

$$\boldsymbol{split}\ (\boldsymbol{V} = \boldsymbol{AX} + \boldsymbol{L}) = \begin{cases} \boldsymbol{V_\alpha} = \boldsymbol{AX_\alpha} + \boldsymbol{L} \\ \boldsymbol{V_\beta} = \boldsymbol{AX_\beta} + \boldsymbol{L} \end{cases} \tag{1}$$

where $\mathbf{A}$ is a common coefficient matrix, $\mathbf{V}_\alpha$ and $\mathbf{V}_\beta$ are competitive vectors of random variables, $\mathbf{X}_\alpha$ and $\mathbf{X}_\beta$ are competitive parameter vectors. To achive this task the cross weighting procedure must be introduced. Estimation of competitive vectors ($\mathbf{X}_\alpha$ and $\mathbf{X}_\beta$) of parameters using the same observation vector L requires specially formulated of the objective function. The proposed method replaces function $\rho(v)$ with functions $\rho_\alpha(v_\alpha)$ and $\rho_\beta(v_\beta)$ according to the equation (2) and in compliance with the cross-weighting $\mathbf{V}_\alpha$ and $\mathbf{V}_\beta$. The weights of observations are modified according to the following equation:

$$\omega_\alpha(v_\beta) = \frac{\partial \rho_\alpha(v_\alpha)}{\partial(v_\alpha^2)}$$

$$\omega_\beta(v_\alpha) = \frac{\partial \rho_\beta(v_\beta)}{\partial(v_\beta^2)} \tag{2}$$

If $$\rho_\alpha(v_\alpha) = v_\alpha^2 v_\beta^2\,, \qquad \rho_\beta(v_\beta) = v_\beta^2 v_\alpha^2 \tag{3}$$

Then the weight functions can be written in the following form:

$$\omega_\alpha(v_\beta) = v_\beta^2, \qquad \omega_\beta(v_\alpha) = v_\alpha^2, \tag{4}$$

The idea of M_{split} estimation can be easily explained on the example presented in Figure 1.

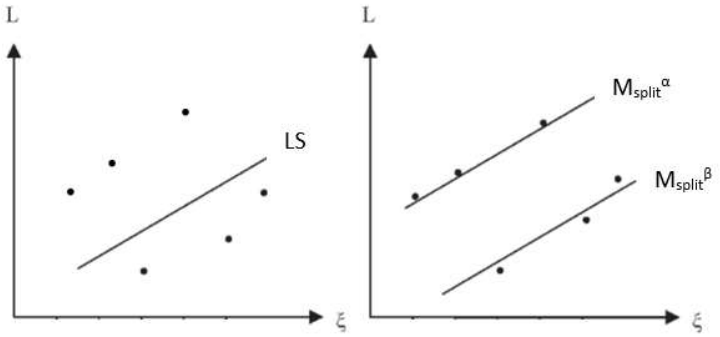

Figure 1. The idea of Msplit estimation and Least Square Method on the example of line fitting.

Figure 1 shows a line fitting using the least squares method and Msplit estimation. Similarly, one can fit two or more planes into a set of points by splitting the functional model into two or more respectively.

3 Application of M_{split} Estimation in Terrestrial Laser Scanning

Figure 2 shows the selected area of the retaining wall supporting the scarp. This scarp consists of several concrete slabs which as a result of the heavy rain were displaced and a crack was formed.

Figure 2. Two concrete slabs displaced due to ground washing.

The selected fragment shown in Figure 2 was measured using the terrestrial laser scanner. The scanning resolution set to 1mm /10 m. The crack, that formed as a result of the plates displacement is about 6-7 cm wide. The selected point cloud representing the displaced slabs and a crack is presented in Figure 3.

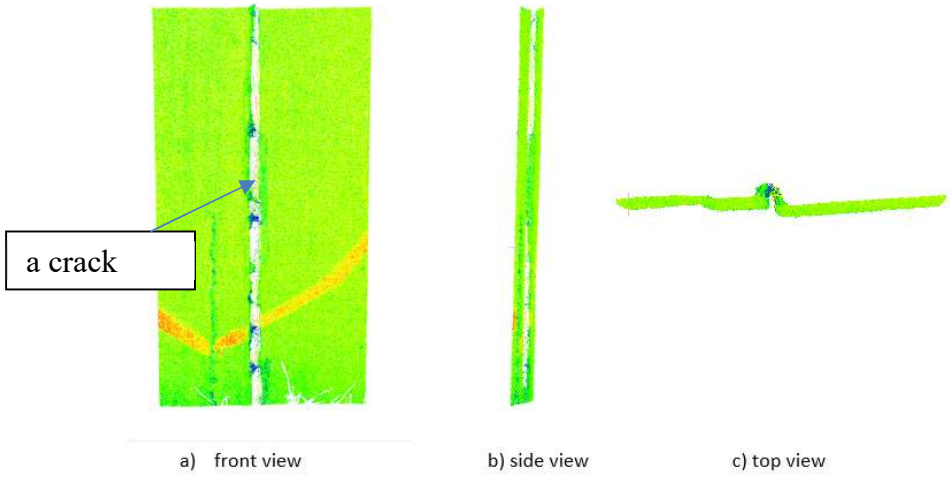

Figure 3. The selected point cloud representing two displaced slabs.

The classical approach would lead to fitting each plane separately with either manual selection of points or some search algorithm. To automate the process of fitting individual planes into the measured point cloud the M_{split} estimation method was used. The M_{split} estimation fitting results are presented in Figure 4 and Figure 5.

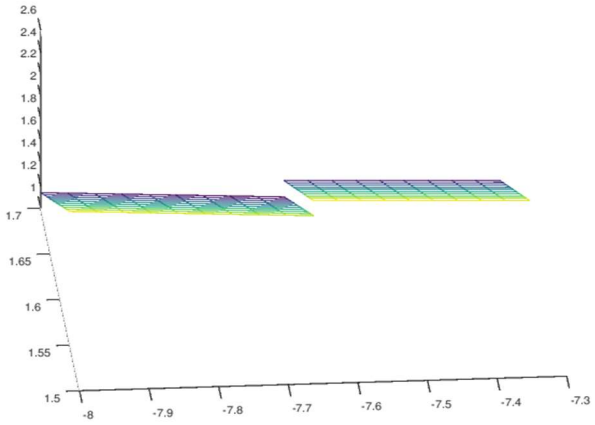

Figure 4. The result of fitting two planes into one cloud of points representing two concrete slabs of a retaining wall. Rotated view.

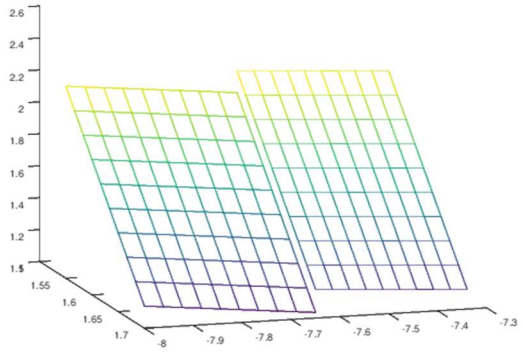

Figure 5. The result of fitting two planes into one cloud of points representing two concrete slabs of a retaining wall. Front view.

Figure 4 and Figure 5 present that the Msplit estimation can be successfully applied in two planes detection. As a result of the proposed algorithm two separate data sets were obtained. Thus, it was possible to automatically fit two planes representing displaced retaining wall slabs.

4 Conclusions

Displacements determination based on the analysis of point clouds from TLS using the M-split estimation can be successfully performed.

- The M_{split} estimation method can be successfully applied in detection of the adjacent planes.
- The M_{split} estimation method can be used assuming that the functional model is split into two models, thus it is possible to fit two planes into one point cloud.
- The possibility of fitting two planes allows for further analyzes, e.g. calculating the displacement of two plates, the distance between them and the angle of their inclination**.**

The proposed Msplit method has some disadvantages:

- as a result of TLS measuring a huge dataset (point cloud) is obtained, what affects the time-consuming data processing. So dataset should be reduced using an appropriate algorithm.
- the functional model must be selected very carefully in the terms of mathematical description of estimated model and data structure.

These topics will be the subject to further research and publications

Verification of Building Constructions Surroundings Based on Airborne Laser Scanning Data

Maja Michałowska

University of Warmia and Mazury in Olsztyn, Institute of Geodesy, ul. Oczapowskiego 1, 10-719 Olsztyn, Poland, maja.michalowska@uwm.edu.pl

Abstract. *Light Detection and Ranging, as an active Remote Sensing Technology, enables gathering accurate, three-dimensional point cloud of scanned objects. Laser scanning might be provided on the terrestrial level for specific, defined constructions, as well as on the airborne level for aerial or linear objects. Using a laser sensor mounted on a moving platform is currently the most efficient way of obtaining in a short period, accurate positions of billions of points as a representation of a scanned area. Based on this kind of dataset it is possible to perform three-dimensional analysis of the safety of scanned objects without additional measurements in the field. This article presents the analysis performed in vMatic software on data from Airborne Laser Scanning for medium voltage power line verification of obstacles with the buildings. The analysis took less than 20 seconds for the detection of buildings points that are closer than 5m from conductors for seven spans wit a total length of almost 400m. Providing distance verification on 3D point cloud data is the fastest way to obtain a hazard awareness in a short time. Once acquired by LiDAR data can be used for other various analyses for any construction, depending on current, expected and future needs.*

Keywords: *Point Cloud, Laser Scanning, LiDAR, ALS, Remote Sensing, 3D Analysis, Hazards, Obstacles, Collisions, Power Lines.*

1 Introduction

Laser scanning is the most popular technology that enables obtaining accurate, three-dimensional point cloud of scanned objects in a short time. Scanning might be provided on the terrestrial level (Terrestrial Laser Scanning - TLS) for construction like architectural heritage (Pritchard *et al*., 2017), buildings (Karagianni, 2017), bridges (Truong-Hong and Laefer, 2015), and on the airborne level (Airborne Laser Scanning - ALS) using flying platform (airplane, helicopter, unmanned aerial vehicle - UAV), for aerial objects like forests (Hyyppä *et al*., 2012), environmental heritage, as well as for linear objects: power lines (Kwoczyńska and Dobek, 2016), roads, railways (Zhu and Hyyppä, 2014), etc.

Using a multi-sensors mounted on a moving platform, as a Mobile Mapping Technology (MMT), is currently the most efficient way of obtaining in a short time, accurate positions of billions of points as a representation of a scanned area (Tao and Li, 2020). MMT is using mostly in projects for aerial and linear objects reachable from a path of the mobile platform. Choosing a type of platform that carrying all technical equipment, have to be adjusted to the kind of object that have to be scanned and the purpose of the scanning. Using a car, as a mobile platform, for power line corridor scanning while there are no roads near the power lines, is not a good idea - it would be more propriety to choose a helicopter or a plane for this purpose. It has to be noticed that Airborne Mobile Mapping using airplanes or helicopters is much more expensive than using Terrestrial Mobile Mapping with a car as a moving platform.

doi:10.23967/dbmc.2020.148

1.1 Mobile Airborne Laser Scanning system

Mobile Mapping Systems (MMS) used in the ALS technique consist of among others laser scanner, Global Positioning System (GPS) receiver and Inertial Measurement Unit (IMU). The principle of the laser sensor is to release a pulse of infrared or near-infrared light, capture returned pulses and record the length of time the pulse reaches an object and is reflected to the sensor. Based on the recorded information distance to the reflected point from a laser scanner can be calculated. It's essential to record by GPS receiver using Global Navigation Satellite System (GNSS) a position of the flying platform and parallelly precise orientation of the laser scanner by IMU. This information is the key to calculate a highly accurate position in 3D dimensions of the laser scanner and all measured by scanner points during the acquisition.

2 Materials and Methods

2.1 Field Data

Vimap company, that provides MMT services for the energy sector, provided for research purposes a sample of a point cloud data acquired by Airborne Laser Scanning. Data was acquired in 2016, in Poland, near Ostróda city, for the MV power line corridor, as a test data for test flights before launching a commercial power lines ALS project. The sample test flight was done for about 400 m of power line in an urban area, which includes seven spans, from pole with a number of 14 to pole with a number of 19.

Vimap Mapping System was consisted of among other Riegl laser scanner, VUX1-UAV model, Trimble GPS receiver and IMU. All sensors were mounted on a helicopter. A mobile mapping platform with a mounted system presents Figure 2. The average flight altitude of the flying unit was approximately 40-50 m from ground level. Components of the system and flight parameters were set to fulfill requirements for the acquisition of 3D point cloud data of MV power line infrastructure and corridor of right-of-way.

Figure 2. Mobile platform with the measuring system.

Laser scanner that was used in the measuring system, Riegl VUX1-UAV, is dedicated to agriculture, forestry, archaeology, cultural heritage documentation, as well as corridor mapping for power lines, railway tracks, pipeline inspection, topography in open-cast mining and other.

Figure 3 presents Riegl VUX1-UAV laser scanner used in Airborne Laser Scanning (source: http://www.riegl.com/products/unmanned-scanning/riegl-vux-1uav/, 2020-04-13).

Figure 3. Laser scanner model used in ALS.

Technical parameters of the laser scanner, altitude and speed of the helicopter flight allow achievement of the density of 40 points per square meter. The technical specification of the laser scanner used in the Airborne Mobile Mapping System presents Table 1.

Table 1. Technical specification of the laser scanner used in the Airborne Mobile Mapping System.

Parameters	VUX1-UAV
Laser Pulse Repetition Rate	550 kHz
Max. Operating Flight Altitude	350m
Max. Effective Measurement Rate	500000 meas./s
Max. Scan Speed	200 ans/s

2.2 Point Cloud Data Elaboration

Acquired LiDAR data were processed in Riegl software. The accuracy of the measurement of horizontal coordinates (X, Y) RMSE = 0.05m, accuracy of point height measurement (Z) RMSE = 0.10m. The point cloud density equals 55 pts/m^2.

As the main reason for the Airborne Laser Scanning of MV power lines was to provide 3D analysis of the surroundings of the power line, two basic processes were needed - classification and power line modeling. In those steps, data was elaborated in TerraSoild and Microstation software.

2.2.1 Classification

Classifying of the LiDAR data into categorical object instances is the most critical step for further 3D analysis and modeling. It's a process of assigning a label to the points that represent a specified object, like the ground, building construction, power lines infrastructure, vegetation, etc. Classification allows us to group bunches of points into the specified representative of an object class, which helps to provide further 3D analysis. The correctness of classification has a big impact on the results of analyses that might be performed on classified data. Figure 4 presents a point cloud acquired by a laser scanner, as an input data for the classification process. Figure 5 presents the point cloud after classification.

Figure 4. Point cloud with no classification - color by point intensity.

Figure 5. Point cloud with classification.

Sample of acquired LiDAR data was classified semi-automatically - using an automatic segment-based classification strategy and manual corrections of segment-based classification. There were extracted objects of following classes: ground, building, vegetation, power line wires, power line pylons pipeline, paved road, unpaved road, water, railway and not classified. Figure 5 presents classified objects in the following colors: ground – light brown, building – red, vegetation – green, power line wires – yellow, power line pylons – blue, paved road – gray, not classified – white. Classified objects were set due to restrictions that have to be checked for a power line infrastructure on the point cloud data.

2.2.2 Objects Modeling

Poles and phase cables of the MV power line were digitized based on the point cloud and save to 3D ESRI shapefile. Visualization of the digitized 3D model in Google Earth Pro is presented in Figure 6.

Figure 6. Visualization of the digitized 3D model in Google Earth Pro.

2.3 vMatic Software

vMatic software, developed by Vimap company, enables point cloud presentation and automatic performance of three-dimensional analysis based on digitized 3D models. The user interface of vMatic software and visualization of point cloud and 3D model presents Figure 7.

Figure 7. vMatic software - visualization of ALS data.

vMatic software was designed mainly for the verification of the correctness of distances from power lines to nearby buildings, vegetation, ground and other objects that are close to the power line. The analysis in vMatic can be performed at the operating temperature of the power line, as well as at simulated, on any temperature conditions of the phase cables.

Classified LiDAR data and digitized 3D model of construction building - power line, are the basic inputs for 3D analysis in vMatic software. vMatic software allows detection of hazards to any 3D vector model. The collision searching mechanism is based on releasing a virtual cylinder with a radius specified by the user, along the course of the 3D model object and detecting whether the cylinder encounters points of the particular class.

3 Results

Based on acquired ALS data of the middle voltage power line corridor in an urban area, the detection of collisions with buildings was performed for digitized phase cables of the line for seven spans, from 14th pole to 19th pole (total length: 367m). Figure 8 shows the analyzed area on an orthophotomap, poles positions with their numbers are presented in yellow color.

Figure 8. Analyzed the MV power line corridor in the urban area.

The radius of a virtual cylinder was set at 5m. It means, that from each digitized phase cable detection of buildings point will be done in 5m distance and 360° range along the course of the conductor. The collision analysis for seven spans took 19 seconds in vMatic software.

Tool for automatic detection of building collision in 5m 3D range buffer from the power line conductors found in total 9 building obstacles. Two buildings were in a really close area to the power line, with the closest 3D distance equals 2.64m (span from 16th pole to 17th pole) and 2.77m (span from 17th a pole to 18th pole). One building was detected in 3.00 – 3.99m collision range, six buildings in a range from 4.00 m to 5.00m. The other fifteen buildings in the analyzed area weren't found due to 3D distance from power line wires to the building bigger than 5m. The results of the performed analysis with division into ranges of a 3D collision distance shows Table 2.

Figure 10 presents the visualization of buildings in the analyzed area highlighted in the range collision colors presented in Table 2. Buildings not treated as obstacles for the power line are presented in light green color.

Table 2. Results of performed buildings detections with a power line on LiDAR data.

Collision ranges distances	Found building collision	Span name with a distance of collision
0.00m - 1.99m	0	-
2.00m - 2.99m	2	16-17 2.64m 17a-18 2.77m
3.00m - 3.99m	1	15-16 3.85m
4.00m - 4.49m	2	18-19 4.12m 18-19 4.40m
4.50m - 5.00m	4	17a-18 4.56m 15-16 4.81m 15-16 4.84m 18-19 4.97m

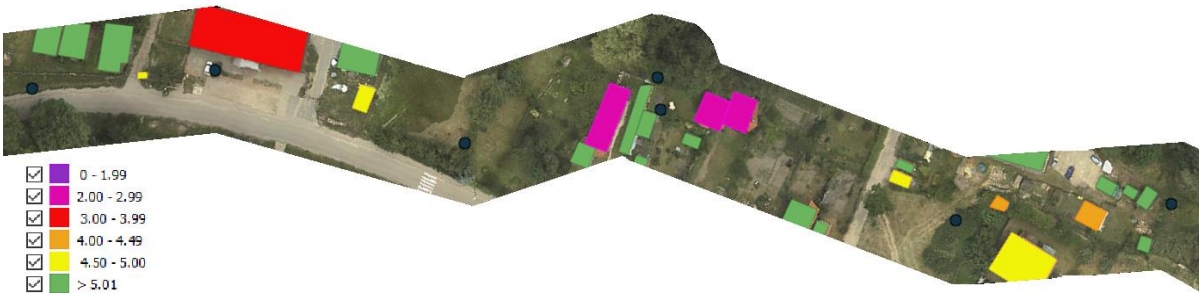

Figure 10. Buildings colored by a collision distance to the power line.

Figure 9 presents in vMatic software visualization of the closest collision from the power line wires to the building point with a distance of 2.64m (span from pole 16th to 17th). The point cloud is visualized in RGB colors, the area of collision of building points closer than 5m from power line wires is highlighted in red color.

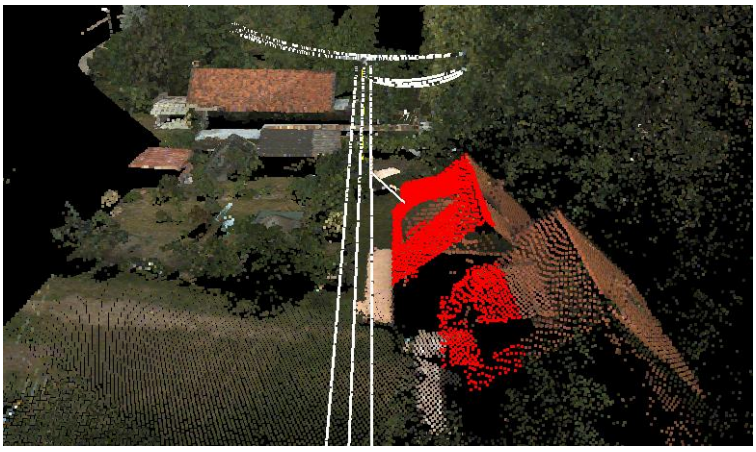

Figure 9. Found building close-up to the power line in vMatic software.

4 Conclusions

LiDAR data allows the performance of three-dimensional analysis for building constructions without any additional measurements in the field. Based on data gathered by remote sensing technology, verification of any construction surroundings can be performed in dedicated software to ensure the safety of the objects.

Performed in this article analysis of the power line obstacles were detected in vMatic software. The analysis took less than 20 seconds for the detection of buildings points (closer than 5m from conductors) for almost 400m length of the MV power line. vMatic software detected nine buildings that are too close to the power line.

Data from laser scanning, as a true representative of scanned objects/areas, might become a basic, complete product for providing 2D and 3D analysis. The results of the analysis performed on LiDAR data are reliable. Providing distance verification on 3D point cloud data is the fastest way to obtain a hazard awareness in a short time. Once acquired by LiDAR data can be used

for other various analyses for any construction, depending on current, expected and future needs.

Abstract. *Obtaining new building materials that are more environmentally friendly than the traditional and that guarantee an optimal response to the most demanding conditions, is one of the greatest challenges in the science of materials. The use of electric arc furnaces slags (EAFS) and cupola slag (CS) to produce a structural self-compacting concrete (SCC), involves the valorization of industrial by-products that often end up in landfill and avoid the extraction of a natural resource. The potential qualities of these wastes make them desirable for the production of high quality concrete. High-performance concrete mixes are designed taking advantage of the high stiffness, the peculiar geometry and the high strength of the EAFS, as well as the high pozzolanicity of the cupola slag. There are great benefits at the mechanical level with its use, but it is necessary to know more about its durability. Different mixes using basalt aggregates and silica sand are used to compare the effects of using EAFS and cupola slag admixture in mixes that have been subjected to durability tests. These tests consist of the determination of chloride ion penetration and protection against reinforcement corrosion after 10 months of exposure in tidal race. The comparisons made after subjecting the different mixes to these tests allow to conclude that chloride ions penetrate almost twice with EAFS than with natural aggregates, while no corrosion of the bars has been shown in any of the mixes.*

Keywords: *Durability, EAFS, Cupola Slag, Chloride Ions Penetration, Corrosion.*

1 Introduction

Obtaining high-performance self-compacting concrete (SCC) with EAFS is a novelty, and its durability plays an important role in its application as a structural material. As a novelty as well, it is proposed to determine its response to the chlorides penetration in a marine environment, and to check the corrosion conditions of the rebar under the same conditions.

The durability of the concrete strongly depends on the fluid circulation capacity through its microstructure, being the capillarity of the material and the paste-aggregate interfacial transition zone, the main route of penetration of external agents. One of the main causes of the deterioration of concrete are the attacks by chlorides and sulfates, and the kinetics in which the degradation mechanisms act, are related to temperature, humidity and fluid transport capacity (Ministerio de Fomento de España, 2008). Before analyzing the response of the SCC against the causes of deterioration of concrete, it is important to take into account that the microstructure of the SCC depends on factors such as the water/fines ratio, the type and content of admixtures, the type and proportion of additives or the mixing procedure (De Schutter and Audenaert, 2007).

Chlorides in concrete can come from its components, because they are totally or partially submerged in seawater or by occasional contributions on the surface, in the form of salts for thawing on roads or through salty fog due to their proximity to the coastline.

The chloride ion penetrates the concrete pore network normally dissolved in water, one part is chemically bonded with the tricalcium aluminate of the cement to form the Friedel salt, another part is immobilized by physical bonds and the rest in the form of free chlorides in the pore solution (E. Medina, 2013). Depending on the concentration of free chlorides, pitting corrosion of the reinforcing steel rebars may occur. Additionally, when the water evaporates inside the pores, the salts crystallize generating, due to the increase in volume, internal tensions in the concrete and, consequently, cracks.

The response of the SSC against the penetration of chlorides depends on the pore structure and the ionic composition thereof. Zhu and Bartos (Zhu and Bartos, 2003) conclude that the diffusion of the chloride ion depends on the type of admixture used. Additionally, they comment that the penetration of chlorides is not less for the SCC with the same strength or manufactured with the same water/cement ratio as for a conventional vibrated concrete (CVC). Other authors have observed that chloride ion penetration decreases with the use of admixtures, especially those of a pozzolanic nature (Uysal and Yilmaz, 2011).

Thus, it is considered necessary to establish the behavior of these new SCC against aggressive environments, due to the variability on which their response depends. Four SCC mixes that incorporate natural and siderurgical aggregates will be tested, in addition to traditional and siderurgical admixtures. Reinforced concrete conical specimens of 28 days of age have been submerged for 10 months, then they were sectioned and the depth of the chlorine ion and the degree of corrosion in the reinforcement have been assessed.

2 Materials and Methods

2.1 Materials

Table 1. Concrete mix proportions (kg/m^3).

Concrete mix	SCC-DC-LF	SCC-DC-FA	SCC-DC-CS	SCC-SC-CS
Diabase coarse (DC)	896	896	896	-
Slag coarse (SC)	-	-	-	1101
Diabase sand (DS)	411	411	411	-
Silica sand (SIS)	386	386	386	605
Slag sand (SLS)	-	-	-	444
Limestone filler (LF)	100	-	-	-
Fly ash (FA)	-	80	-	-
Cupola slag filler (CS)	-	-	109	109
Cement	450	450	450	450
Water	180	180	180	174
Superplasticizer additive	9	9	9	9
w/c ratio	0.40	0.40	0.40	0.39

Four concrete mixes have been manufactured, using CEM I 52.5 R, sand 0/6 (diabase and EAFS), coarse 6/12 (diabase and EAFS) and silica sand 0/2, to compare the behavior of the siderurgical aggregate with the natural aggregate. In addition, three different filler materials (limestone, fly ash and cupola slag) have been used. A SCC has been designed according to the procedure described by Dinakar et al. (Dinakar et al., 2013) with a 2% (of the cement weight) of a superplasticizer additive, in a 120 l rotating drum mixer with a kneading time of 12 min. The concrete mix proportions appear in Table 1.

2.1 Methods

2.1.1 Preparation of the Specimens

The test campaign for the characterization of the durability of hardened concrete consists of exposure to seawater of conical specimens with embedded corrugated steel bars. For the manufacture of each specimen, an Abrams cone with the face of smaller diameter as a base, has been used to facilitate filling of the specimen, following the methodology described by C. Thomas *et al*. (Thomas *et al.*, 2013). In its interior two corrugated bars of diameter 10 mm have been placed vertically, arranged in such a way that the minimum covering of one of the bars at the base of the cone is 10 mm while, in the second bar, it is 30 mm, Figure 1.
This configuration has been designed with the objective of evaluating the protection against corrosion offered by self-compacting concrete made with coating thicknesses lower than those recommended. The conical geometry of the specimens and the vertical orientation of the bars allows the penetration of the chloride ion to different coating thicknesses.

In Figure 1 can be seen that, in addition to the corrugated bars, a black metal part has been embedded in order to facilitate the manipulation of the specimens, avoiding any kind of effort in the steel that can affect the adhesion between both materials.

The mixing time has been sufficient to guarantee the homogenization of the concrete, the filling of the molds and the specimens has been done in a single step and without external vibration. A total of 8 conical specimens were manufactured, corresponding to two specimens for each mix.

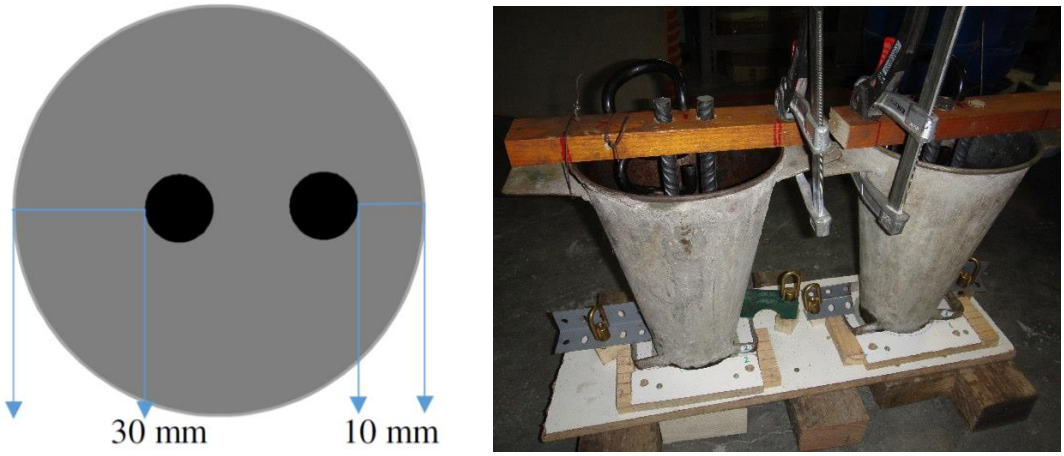

Figure 1. Arrangement of reinforcement bars on the underside of the cone and preparation of the truncated conical molds.

To ensure that the penetration of chlorides only occurs in the lateral surface of the cone, the upper and lower faces have been protected, as well as the sections of corrugated bars that protrude from the concrete with a thick layer of two-component epoxy coating, Figure 2.

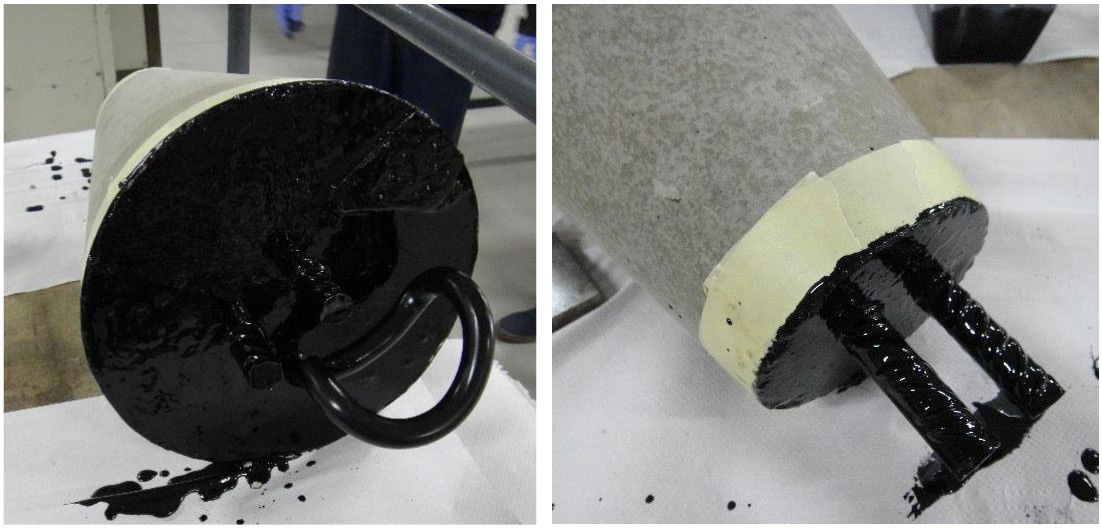

Figure 2. Detail of the application of the paint on the bases of the specimens and on the reinforcements.

After keeping the specimens in the humidity chamber for 28 days, one of each mix was transferred to the port of Bilbao. There they were distributed on two metal grids together with other specimens from other research centers (Figure 3 left). With the help of a crane, the grilles were suspended a few centimeters from the surface of the sea leaving the specimens exposed to tidal changes for 10 months, (Figure 3 right).

Figure 3. Arrangement and location of test samples in tidal race in the port of Bilbao.

2.1.2 Specimens Treatment

After 10 months, the specimens were removed and moved back to the laboratory. During the visual inspection, the abundant presence of mollusks adhered to the surface of the concrete specimens, the corrugated bars and the steel hook was observed (Figure 4). In the areas where

these colonies were not present, the formation of an organic greenish layer was observed.

Figure 4. Appearance of the specimens after exposure to the weather and tidal cycles.

With the help of a crowbar, the mollusks stuck in the concrete were removed, while those attached to the bars and the metal piece were crushed with a hammer. The surface was then rubbed with a scourer to remove the organic layer (Figure 5). Finally, they were rinsed and placed in the oven at 110 ± 5 °C until constant mass.

Figure 5. Appearance of samples before and after cleaning.

Finally, on each truncated conical specimen, two diametrically opposed longitudinal cuts were made with a radial cutter without the cutting disc reaching the corrugated bars.

2.1.3 Corrosion of the Bars and Penetration of Chlorine Ions

After breaking the truncated concrete cone into two halves, we first proceeded to observe the state of the bars mainly to assess the appearance of pitting along them. One of the halves was divided by a cross-section in order to extract a subsample with different coating thicknesses, which is used to determine, in the scanning electron microscope, the penetration depth of the chloride ion by dispersive spectroscopy of X-rays (EDX) techniques.

3 Results and Discussion

Figure 6 shows the appearance of the specimens after continued exposure to the marine environment and to the tidal race for 10 months, after cleaning the exterior faces and the longitudinal cut.

Figure 6. Exterior of conical specimens SCC-DC-LF, SCC-DC-CS, SCC-DC-FA and SCC-SC-CS after exposure to contact with seawater.

The absence of pathologies on the outside of the cone trunks can be verified as chipping or loss of material, while, in Figure 7, the intact state of the bars inside the concrete can be seen after making a longitudinal cut in the specimens. Direct exposure to seawater has not negatively affected embedded steel bars, with no deterioration observed. It should be noted that in the narrowest area of the specimens, the minimum coating thickness is only 10 mm.

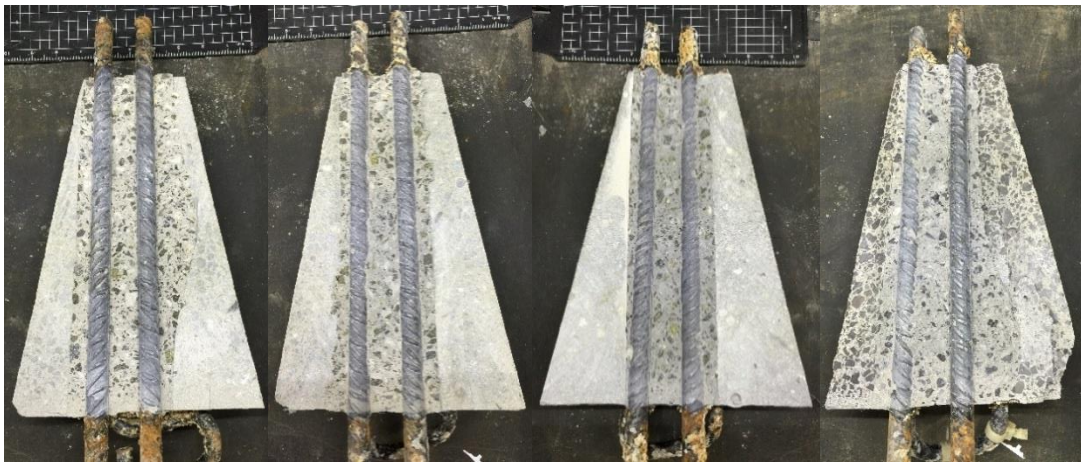

Figure 7. Inside of the SCC-DC-LF, SCC-DC-FA, SCC-DC-CS and SCC-SC-CS specimens after exposure to seawater.

Figure 8 shows in detail the appearance of the steel bars at the narrowest end of the conical specimens for the SCC-SC-CS mix. In some cases, pitting corrosion is observed in the bars, caused by the penetration of seawater from the top of the specimen as a result of the loss of the applied waterproofing paint.

Figure 8. Aspect of SCC-SC-CS and rebars after exposure to tidal race.

Due to the appearance of the steel bars inside the concrete, the cut was only made at the smaller diameter end of the cone to determine the penetration of the chloride ion in a scanning electron microscope.

Figure 9 shows the chloride concentration in the concrete obtained by microanalysis carried out from the outermost surface to the area where the steel bars are embbeded. It is observed, as expected, that the highest concentration is found on the surface. Of all the samples, the SCC-SC-CS has a much higher concentration of chlorides, while samples made with natural aggregates, despite containing different additions, have a very similar chloride content.

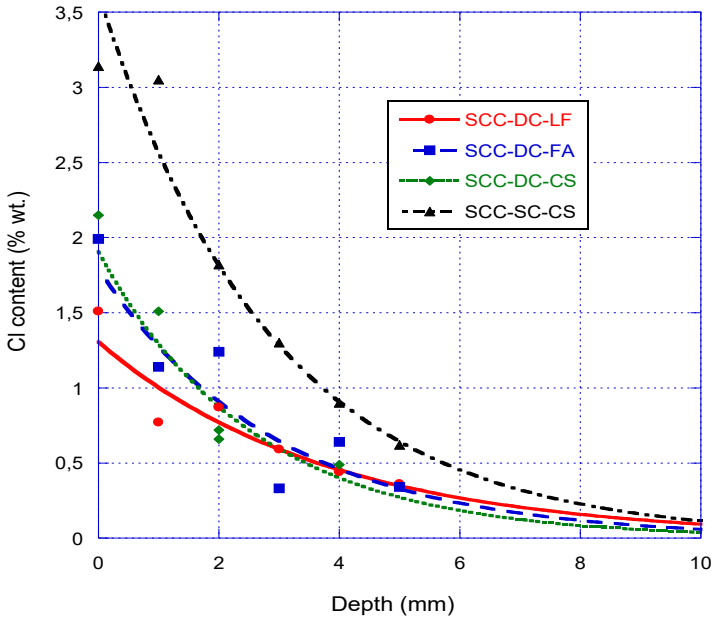

Figure 9. Penetration of chlorides in concrete.

These results agree with the oxygen permeability coefficients (Sosa et al., 2020), being able

to assume that the diffusion is carried out through the capillaries. In all the cases analyzed, it can be seen that, after 6 mm, the concentration of the Cl^- ion is less than 0.3%, which is at the limit of the detection capacity of the scanning electron microscope for this element. These results are markedly lower to those reported by C. Medina et al. for a CVC with recycled aggregates (Medina, Sánchez De Rojas, Thomas, Polanco & Frías, 2016).

4 Conclusions

In the present study, the durability of 4 concrete mixes incorporating aggregates and admixtures, both slag and natural, has been analyzed. This characterization has been carried out keeping the specimens in a tidal race, where both the marine environment and the submersion cycles can deteriorate the material prematurely. The main conclusion drawn is the following:

Exposure to seawater and the tidal race for 10 months has not affected the aesthetics, nor has it corroded steel reinforcements embedded in concrete. The concentration of chlorides in all cases is very small from 6 mm deep.

Abstract. *The structure of self-compacting concretes containing electric arc-furnace slag, their mechanical behavior, and their durability are all studied in an extensive experimental campaign, to evaluate the suitability of three concrete mixes for use in real construction works. Specimens manufactured with self-compacting electric arc-furnace slag concrete are subjected to wetting-drying and freezing-thawing test procedures, for their study in aggressive environments, especially marine environments. In general, all the test results were quite encouraging. It was once again demonstrated that the use of electric arc-furnace slag in concrete represents an opportunity to reduce both the volume of siderurgical waste generated in our society, and the consumption of fresh raw materials.*

Keywords: *Self-Compacting Concrete, Electric Arc-Furnace Slag, Durability, Marine Environment.*

1 Introduction

The future of the environment is a source of growing concern in present-day society that is calling for increasingly sustainable development. The sustainability of production processes must be carefully studied and waste-streams must wherever possible be reutilized and recycled. However, waste reduction also implies the manufacture of products of greater durability. Sustainable production processes are already dynamizing the circular economy while maintaining relevant standards and properties. Concrete products that reuse waste must therefore at the very least equal those of conventional Portland mixes.

This study is focused on the reuse of Electric Arc-furnace Slag (EAFS), a residue from the steelmaking industry, as aggregate in concrete mixtures. The reuse of slag in cement-based

material has been a recurrent topic since Motz, Geiseler and Koros (Geiseler, 1996; Koros, 2003; Motz and Geiseler, 2001) published the first studies on the reuse of slag in the construction industry.

Since those first initial studies, the mechanical behavior and the hardened properties of concretes manufactured with EAFS as aggregate have been evaluated in several studies (Abu-Eishah, El-Dieb, and Bedir, 2012; Faleschini *et al.*, 2015; Manso, Gonzalez, and Polanco, 2004). Studies have also been performed on the durability of those types of concretes (Arribas, Vegas, San-José, and Manso, 2014; Manso, Polanco, Losañez, and González, 2006). In general, most of the tests on their mechanical behavior and durability have demonstrated that EAF concretes can at least equal the behavior of natural aggregate concrete.

In some of the above works, poorer workability than natural concrete aggregate has been identified as a disadvantage of EAFS concrete. In this work it will be demonstrated that with the correct mix design, self-compacting concrete can be made using EAFS as aggregate. Its durability will also be evaluated, lending special attention to the durability of EAFS self-compacting concretes in highly saline marine environments.

There are two principal reasons for this study: on the one hand, there are few studies on the evaluation of the behavior of EAFS concrete in marine environments and, on the other hand, the mechanical and the physical characteristics of EAFS concrete point to its suitability for the construction of dykes and blocks to form protective seawalls. In fact, work is underway with this type of concrete for that same purpose in coastal areas of the Basque Country, a region of northern Spain, where the evaluation of the durability of EAFS concrete in marine environments assumes special importance. In Bilbao, the port authority is pioneering the use of electric arc-furnace slag concrete in port construction works

2 Materials and Mixes

Two different cements were used: a Portland cement type I 52,5 R and a Portland cement type IV/B-V 32.5N, which included fly ash, as per standard EN 197-1.

Water was used from the urban mains supply of the city of Bilbao, free from additional particles that might adversely affect the mixes.

The commercial limestone aggregate was of three different sizes 0-1, 0-5, and 5-12. Likewise, the Electric Arc-furnace Slag (EAFS) had aggregate fractions of 0-4 and 4-12. Finally, a superplasticizer supplied by CHRYSO was selected to adjust the workability of the mix.

Three different mixes designs, shown in Table 1, were prepared with these materials:

- A reference mix, labeled NATI, manufactured with Portland cement type I and limestone aggregates,
- A mix labeled EAFSI, in which Portland cement-type I was used, although unlike in the reference mix, EAFS was used in partial substitution by volume of the limestone aggregates. Nevertheless, proportional amounts of the different aggregate fractions were not exactly the same. The higher density and the rougher surface of the EAFS particles require higher proportions of fines, to manufacture mixes with this type of aggregate (Santamaría *et al*., 2017).
- An EAFSIV mix, with exactly the same design as the EAFSI mix, except that Portland cement-type IV, rather than Portland cement-type I, was used.

Table 1. Mix design.

	NAT I	EAFSI	EAFSIV
Cement I	330	330	
Cement IV			330
Water	165	165	165
EAFS 4-12		760	760
EAFS 0-4		550	550
Limestone fines 0-1,2	690	900	900
Limestone 0-5	560		
Limestone 5-12	730		
Superplasticizer (% cement weight)	2%	2%	2%
Density (t/m^3)	2.41	2.69	2.58
Slump flow spread. Abrams Cone (mm)	630	680	700
L-box	1	1	1

The NATI mix was manufactured in a conventional laboratory mixer and cast in different molds. An industrial concrete mixer, depicted in Figure 1, was rented to prepare the mixes for the manufacture of EAFSI and EAFSIV. From the total batch of 600 lts., two beams of each mix and several molds were precast and their mechanical and durability properties were evaluated.

Figure 1. Concrete mixer.

3 Test Method

Two tests were used to evaluate the workability of the mixes, a slump flow cone in accordance with ASTM C1611 and the L-box test, in accordance with the EFNARC standard.

The bulk density of the mixes was measured as specified in the EN 1015-10 standard. The compressive strength of the mixes was evaluated at 7, 28, 90 and 180 days, as recommended in EN-12390-3.

The Fagerlund test described in the UNE 83982 standard, based on Darcy's law, was used to analyze water absorption by capillarity.

Mix durability was evaluated with wetting-drying and freezing-thawing tests. Both tests were performed on 2 different specimens of each mix, after 90 days of curing. 148 cycles were performed for each wetting-drying test. Each cycle involved leaving each specimen in water for 16 hours, in an oven at 60°C for 6 hours placed, and at room temperature for 2 hours, to prevent thermal shock. The freezing-thawing test involved 122 cycles, in which the specimens were kept in a freezer at -15°C for 24 hours and in water, at room temperature, over the following 24 hours. The mechanical properties of the specimens were evaluated both before and after the durability test.

Three batches of specimens (100x100x100mm^3) of each mix, as shown in Figure 2, were enclosed in cages suspended from a dock wall in Pasaia Donibane port, with the purpose of analyzing EAFS concrete durability in marine environments. The cages were suspended in an intertidal zone where they would be submerged under the seawater at high tide and exposed to the atmosphere at low tide. The specimens were left in the cages for one year. After their removal, chlorine and sulphate ion infiltration was evaluated, by cutting each specimen and placing it in a vacuum chamber that was filled with nitrogen at low pressure for Scanning Electron Microscopy (SEM) analysis. Energy-dispersive X-ray spectroscopy was used to obtain the chemical composition of the first 50mm of the fracture surface and to generate backscattered electron images.

Figure 2. Specimens placed in cages at Pasaia Port.

4 Results

4.1 Workability

The workability test results of the mixes are shown in Table 1. All the mixes could be classified as self-compacting mixes. The reference mix had a lower spread than the EAFS aggregate mixes, which was a somewhat surprising result, thought to be due to the different scale of the mixes. A large number of laboratory trials had been performed before manufacturing the 600 lt. of concrete used in the mixes. The workability of the mixes with the same dosages manufactured on a small scale was worse than in the larger mixes, due in all likelihood to the

skin effect. Nevertheless, such a slight difference in workability was marginal for the purposes of this research, alongside the key aspect: the self-compacting properties of the mixes.

4.2 Density and Mechanical Strength

As might be expected, the density of the concretes manufactured with EAFS was higher than the density of the concrete manufacture with natural aggregates, with increases of around 11% in the case of EAFSI and 7% in the case of EAFSIV.

Concrete strength over time is depicted in Figure 3. The behaviors of both concretes manufactured with Portland cement type I were very similar. The EAFSI mixes gained slightly higher strengths, compensating their higher density than the other mixes. The higher strength of EAFS concretes has been explained in a previous paper (Arribas, Santamaría, Ruiz, Ortega-López, and Manso, 2015), by the denser aggregate and cement-paste interface.

The hardened strength of EAFSIV was lower than its EAFSI counterpart, reflecting the characteristics of the Portland cement type IV.

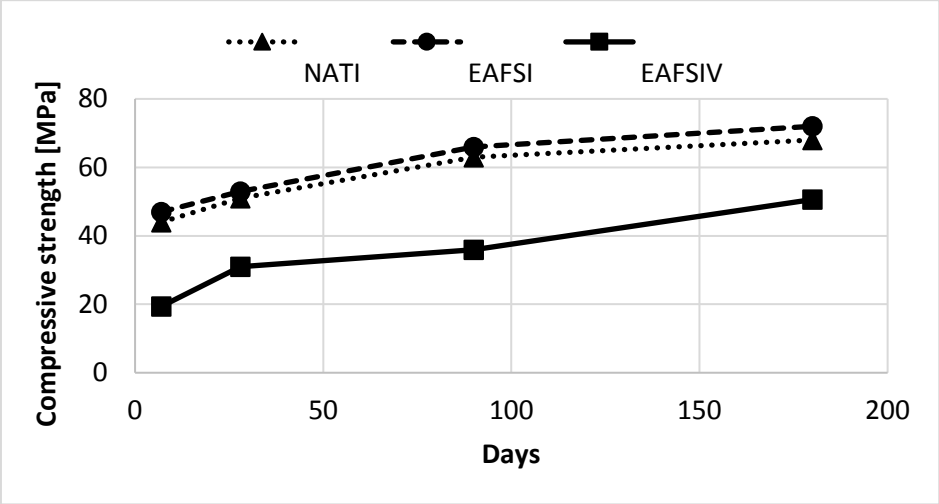

Figure 3. Compressive strength.

4.3 Capillarity Water Absorbtion

The results obtained in the capillarity water test are shown in Figure 4. The results for NATI and EAFSI were similar, unlike for EAFSIV. The curves can be divided into two zones: an initial rising zone; and, a second zone, where capillarity porosity was not evaluated as it involved other types of porosities. The less inclined slope (K coefficient 0,106 kg/m^{2}s$^{1/2}$) of the EAFSIV, in the first zone, represents low permeability. The value of the second zone shows us that the total porosity of the mix was high, which means that this mix may have a high number of single, unconnected spherical pores, which could also explain the lower density of the mix in comparison with the EAFSI mix. Both for NATI and for EAFSI, the slope of the curve was the same in the first zone (K coefficient 0,156 kg/m^{2}s$^{1/2}$), so the capillarity porosity was similar in both mixes, in the second zone, mix EAFSI achieved higher values, which might be explained by the higher porosity of the EAFS aggregate when compared with the limestone aggregate.

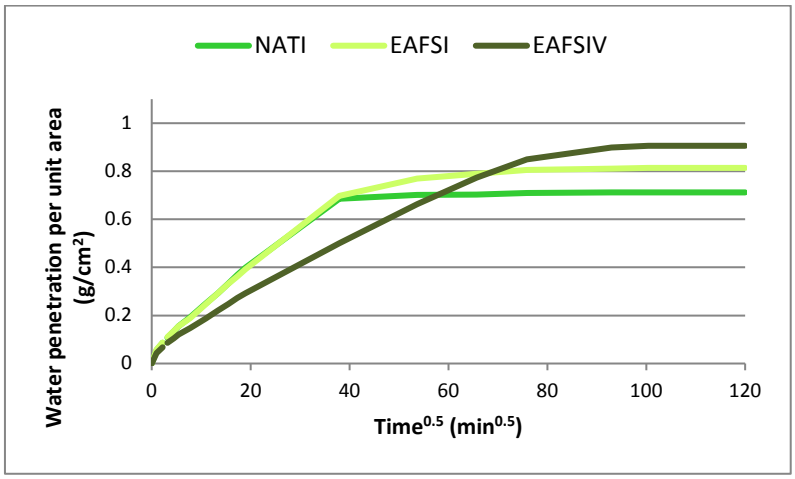

Figure 4. Capillarity test results.

4.4 Wetting-Drying and Freezing-Thawing Tests

The variation of the mechanical properties and weight of the mixes after performing durability tests are shown in Table 2. The mechanical properties of mixes NATI and EAFSI achieved similar levels. The mass loss of the EAFSI mix was higher than the mass loss of mix NATI, although if we take into account the different densities of both mixes, then their loss of volume was similar.

The behavior of mix EAFSIV during the durability test differed from the results obtained in mixes NATI and EAFSI. Strength gains were shown, rather than a loss of strength, due to the aggressive cycles. Results that are explained by the presence of fly ash associated with long-term pozzolanic reactions.

Table 2. Results of wetting-drying and freezing-thawing tests.

Mixture	Variation Strength frozen	Variation Stiffness frozen	Mass loss Frozen (g)/2500	Variation Strength wet	Variation Stiffness wet	Mass loss Wet (g)/2500
NATI	-21%	-2.8%	37.5	-2.1%	-0%	131
EAFSI	-25%	-5.1%	55.9	0%	-1.1%	158.5
EAFSIV	+6.5%	+9.4%	24	+7.5%	+13%	201.9

4.5 Marine Environment Test

In Figure 5, it is possible to see the specimens before and after exposure to a highly saline marine environment after one year. *I*t would appear, *a priori,* that this concrete has no compounds that could harm the marine ecosystem, as the specimens were teaming with mussels, oysters, and small crabs.

The behavior of EAFS concrete in marine environments was good, and even better than the behavior of natural aggregate concretes, showing slightly better strengths. The results of the analysis are in the Figure 6. No data on sulfate ions are included, as no ions of that type were found.

Figure 5. Specimens before and after the marine environment test.

Taking into account that 0.1% is a typical chlorine ion content of a cement paste, chlorine-ion penetration was around 35mm in NATI, and approximately 25mm and 15mm, in EAFSI and in EAFSIV, respectively. The higher resistance of EAFSIV to chlorine-ion penetration can be explained by looking at the results of the capillarity water test.

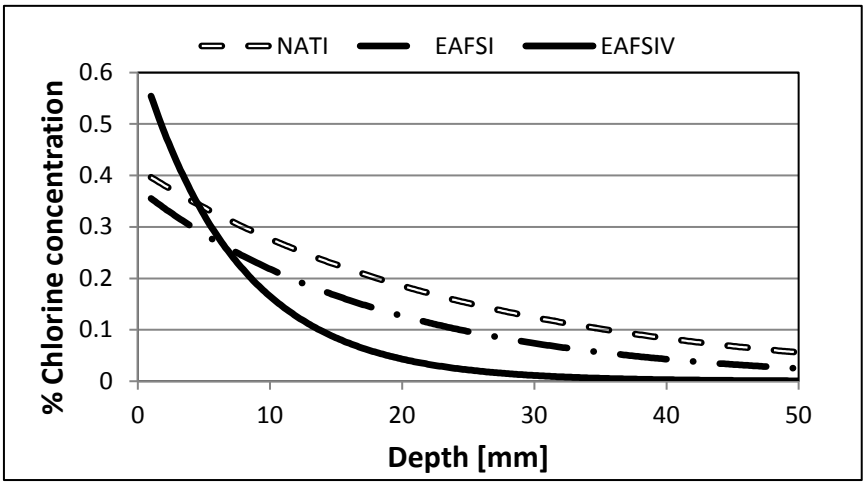

Figure 6. Specimens before and after the marine environment test.

5 Conclusion

Following the research campaign tests developed for this study, the following conclusions have been drawn:

- Mixes containing EAFS aggregate may be manufactured to the required workability, using the correct mix design. Self-compacting mixes have been successfully manufactured
- Both the mechanical behavior and the structure of the mixes manufactured with electric arc-furnace slag were fairly similar to the behavior and the structure of the mixes manufactured with natural aggregates. The main differences were observed when a different type of cement was used, in addition to the observably lower mechanical

strengths, as may be expected, in the cement type IV mixes, which also had different pore structures with larger pore volumes.

- The use of electric arc-furnace slag as a concrete aggregate was not detrimental to the durability of the concrete. The great similarities with no major differences between the natural and the EAFS aggregates were confirmed by the test results.

Abstract: The construction sector is clearly one of the most pollutant *at a global level and its consumption of natural resources is also enormous. Over recent years, heightened awareness of this issue within the construction sector has motivated changes within its working practice, seeking to reduce its environmental impacts and to mitigate the effects of climate change. The consumption of natural resources can be reduced in very different areas and special attention has been given to the substitution of Natural Aggregates (NA) in concrete design by replacing those aggregates with various waste co-products. Siderurgic concrete is the name given to concrete manufactured with siderurgical aggregate from the steel-making industry. In this paper, test results on fiber-reinforced siderurgical concrete are reported. The concrete is manufactured with approximately 50% Electric Arc Furnace Slag (EAFS) aggregate by volume, for use in pavement applications. Steel and polypropylene fibers, amounting to approximately 0.5% by volume of the concrete mass, are also added to the mix. The durability properties of this concrete type are analyzed through freeze/thaw and moist/dry tests. Furthermore, the long-term behavior of the concrete is explained through its internal structure, using Mercury Intrusion Porosity (MIP) and low-vacuum Scanning Electron Microscopy (SEM) analyses. The results add further weight to the feasibility of using EAFS in replacement of NA in fiber-reinforced concrete for pavement construction.*

Keywords: *EAFS, Freeze/Thaw, Moist/Dry, MIP, SEM.*

1 Introduction

The immense volumes of natural aggregates used for concrete production within the construction sector has motivated a search for feasible alternatives to natural resources. In consequence, several studies have over the past few decades examined the incorporation of slag from the steelmaking industry in construction and civil engineering applications (Akinmusuru, 1991; Faleschini *et al.*, 2015; Geiseler, 1996; Koros, 2003; Manso *et al.*, 2006; Motz and Geiseler, 2001; Pellegrino and Gaddo, 2009; Qasrawi, 2014; Santamaría *et al.*, 2017).

Although productive steel processes differ between plants, they may at present be divided into two types: Integral Siderurgy, in which the raw material, iron ore, is melted in a Blast Furnace, followed by a decarburization phase, usually in an Oxygen-Blow Converter, and the

Electric Cycle, in which scrap is melted in Electric Arc Furnaces (EAF). After this "primary metallurgy", a secondary refining phase usually takes place in a Ladle Furnace for carbon steels, and in a special converter for stainless steels.

Around 30% of European steel is produced with EAF technology. In the EU steel sector, a total of 47.8 Mt of steel slag were produced in 2018, of which Electric Arc Furnace Slag (EAFS) and secondary slags amounted to 7.9 Mt and 2.8 Mt, respectively, according to the EUROSLAG report "The European Association representing metallurgical slag producers and processors" (EUROSLAG, 2018), data from which are reproduced in Figure 1.

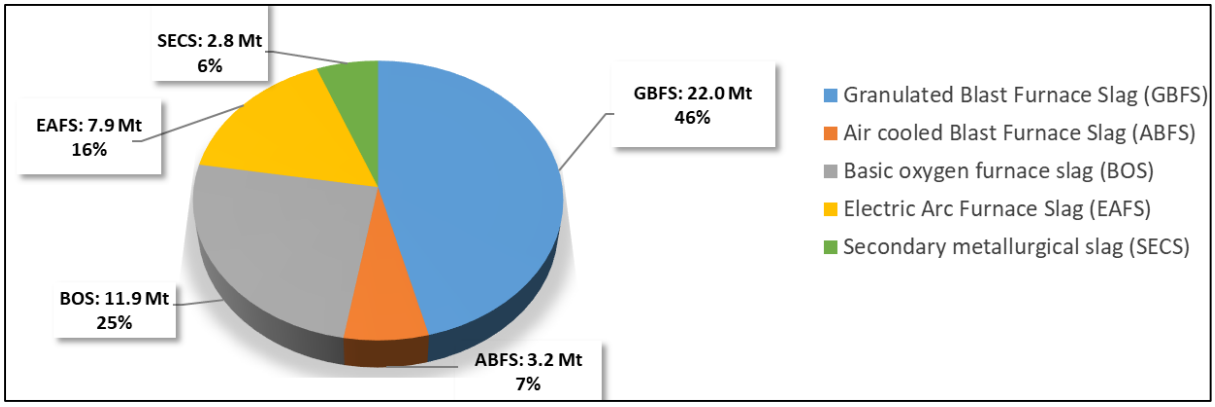

Figure 1. Slag production in the EU (% and Mt.).

Spain is the third largest producer of electric steel in the EU, after Germany and Italy, with production levels of around 10 MT of electric steel, together with more than 1 MT of EAFS and 0.5 MT of LFS by-products (Yearbook, 2019).

Taking into account the benefits of slag recycling, the viability of using Electric Arc Furnace Slags (EAFS) in fiber-reinforced concrete (FRC) is examined in this paper, for the subsequent manufacture of rigid pavements and industrial slabs. To do so, siderurgic concrete was prepared with approximately 50% EAFS and 0.5% (metallic or synthetic) fibers, in both cases by volume. The main mechanical properties of these siderurgic concretes will be analyzed and their long-term behavior examined in relation to their internal structure in the following sections, leading up to a discussion of the most significant results and relevant conclusions.

2 Materials and Methodology

The materials used in this research were: Ordinary Portland Cement (OPC) CEM I 42,5R, water, natural siliceous aggregates provided in three granulometric sizes of 0/4, 4/12 and 12/25 mm, superplasticizers (polycarboxylate modified with water), EAFS aggregates provided in three granulometric sizes of 0/4, 4/10 and 10/20 mm, metallic fibers (steel, RL-45/50-BN) and synthetic Fibers (polypropylene, M-48).

The main physical characteristics of the EAFS were: specific gravity of 3500 kg/m^3, high water absorption, low fines content, and 24% Los Angeles abrasion loss. The main chemical components were oxides of Fe, Ca and Si.

The methodology was based on the use of EAFS as coarse and medium aggregate in the concrete mix and the fine aggregate was prepared with 50% fine slag and 50% siliceous sand, in order to compensate for the lack of the fines in the EAFS.

Two reference mixtures were designed: mixture P, manufactured entirely with siliceous aggregates, and mixture E, manufactured with EAFS in coarse and medium gravel and 50%-50% of siliceous-EAFS in sand. Their mix design is shown in Table 1.

Taking the dosage of mixture E as a reference, two experimental mixtures reinforced with around 0.5% by volume of steel fibers identified as EM and with polypropylene fibers identified as ES were manufactured.

Table 1. Mix design of the reference mixtures (kg/m^3).

Mix design kg/m^3	Cement	Water	Siliceous aggregates			EAFS aggregates			Admixture
			0/4	4/12	12/20	0/4	4/10	10/20	
P	360	180	800	575	465	-	-	-	3.63
E	360	180	500	-	-	515	670	550	5.44

3 Results and Discussion

3.1 Mechanical Properties

The main mechanical properties of the siderurgic concretes are shown in Table 2.

Table 2. Mechanical properties of the experimental siderurgic concretes.

Property	standard	P	E	EM	ES
Compressive Strength at 28 days (MPa)	UNE 83507	46.3	66.1	72.6	74.0
Flexural Strength at 28 days (MPa)	UNE 83509	5.2	6.8	7.0	7.1
Splitting Tensile Strength at 28 days (MPa)	UNE 12390-6	4.3	4.2	5.5	5.2
Maximum depth of water penetration (mm)	UNE EN 12390-8	24.0	13.0	13.5	20.5
Flexural toughness (N·m)	UNE 83510	-	8.74	39.2	35.0
LOP (CMOD ≤ 0.05 mm) (MPa)	EN-14651	-	6.1	6.4	6.2
Blows until breakage in impact strength test	UNE 83514	-	13	155	88

The compressive strength of the siderurgic concrete E (66.1 MPa) was 43% higher than that of natural aggregates P (46.3 MPa), even reaching values of 72 and 74 MPa for mixtures EM and ES, respectively.

The flexural strength of the siderurgic concrete E (6.8 MPa) was also higher than that of conventional concrete P (5.2 MPa); mixtures EM and ES reaching values of around 7 MPa. This fact is attributable to the good (dense and not very porous) quality of the Interfacial Transition Zone (ITZ) of the siderurgic concretes (Arribas *et al.*, 2015) and to high adhesion between all the (aggregate, cement paste and fiber) components of the mixtures.

As regards the splitting tensile strength, little difference was observed between the reference concretes P (4.3 MPa, with fibers) and E (4.2 MPa, no fibers). An important improvement in the mixtures with fibers was once again observed, especially concretes EM (5.5 MPa) and ES (5.2 MPa).

All the mixes with EAFS showed better resistance to water penetration than the conventional concrete with natural aggregates. Likewise, they met the requirements of the EHE standard (2008), which specifies the maximum depth of water penetration under 30 mm. The impermeable nature of these concretes was therefore considered sufficient for pavement applications.

The toughness by flexion value of the fiber-reinforced mixes was close to 40 N.mm in the mix with steel fibers and was slightly lower in the mix with polypropylene fibers (35 N.mm), which in both cases are good values.

The Limit of Proportionality (LOP) tested in samples with a notch of 5 mm was similar in all the mixtures and was slightly higher in the mixtures with steel fibers (6.4 MPa).

Finally, the fiber-reinforced siderurgic concretes clearly had much a better impact strength until breakage (EM: 155 blows and ES: 88 blows) than the equivalent with non-reinforced concrete E (13 hits).

In view of these initial results, it can be concluded that the siderurgic concretes have the mechanical properties that are needed in industrial pavement slabs.

3.2 Long-Term Behavior and Durability

3.2.1 Freeze/thaw and moist/dry tests

The durability of a concrete pavement is determined by its permeability and its resistance to the very influential factors, such as the presence of water and temperature variance in its immediate environment. The freeze/thaw and moist/dry tests of the concretes under are especially interesting, given the very adverse climatic conditions of the Spanish region under study.

In this study, both the weight and the compressive strength of the mixes varied, following 56 freeze/thaw cycles and 30 moist/dry cycles, as per the UNE-CEN/TS 12390-9 and the ASTM D-559 standards("Annual Book of ASTM Standars, ASTM International, West Conshohocken, 19429-2959. PA, USA, 2008,"), respectively. The results are shown below, in Table 3.

Table 3. Freeze/thaw and moist/dry results of the siderurgic concretes.

Property	E	EM	ES
Weight variation after 56 freeze/thaw cycles (%)	-62.41	-2.92	-4.49
Variation of compressive strength after 56 freeze/thaw cycles (%)	-	-3.45	0.93
Weight variation after 30 moist/dry cycles (%)	0.23	0.14	0.34
Variation of compressive strength after 30 moist/dry cycles (%)	-15.2	-1.12	12.16

In the freeze/thaw test, cubic specimens, in duplicate, were introduced into a container filled with a solution of 3% sodium chloride (NaCl). These containers were placed in a freezer over 16 hours, at a temperature of -29ºC±1ºC, and in a container with water circulation at 20ºC±1ºC for 8 hours, and those test cycles were repeated 56 times throughout the duration of the test. Figure 2 shows the arrangement of the freeze/thaw test.

Figure 2. Arrangement of the freeze/thaw test: a) freezer at -29ºC; b) container with water at 20ºC.

After 56 freeze/thaw cycles, mix E lost a significant amount of material (-62.41%), while the results obtained for concrete mix ES (-4.49%) were good and even better for concrete mix EM (-2.92%), which maintained its cube shape. The compressive strength test at the end of all the cycles was only performed on the EM and ES specimens, due to the total deterioration of the E specimens during the freeze/thaw test. Slight damage to the EM specimens led to a decrease of 3.45% in their compressive strength, while the ES specimen showed a compressive strength that was slightly higher (+0.93 %) than before the freeze/thaw cycles. A fact also observed by other authors, which was probably caused by further hydration of the cement that came into direct contact with the water permeating through the frozen saturated surface due to its microporosity (Pellegrino and Gaddo, 2009).

The moist/dry test was also performed on cubic specimens, in duplicate. Each of the 24-hour cycles, repeated 30 times, consisted of 16 hours of immersion in fresh water at room temperature and 8 hours in an oven at 60 °C.

After the moist/dry test, all the concrete specimens showed good surface appearance and slight weight gains. The concrete with no fibers, E, showed an appreciable loss of compressive strength (-15.20%), unlike the concrete with metallic fibers, EM, that lost little strength (-1.12%) and the mix with synthetic fibers, ES, the strength of which increased (+12.16%). Similar results for concretes manufactured with EAFS were also found by other authors (Arribas *et al.*, 2014). These satisfactory results point to the good internal cohesiveness of the aggregates and fibers within the matrix of this fiber-reinforced slag concrete.

3.2.2 MIP analysis

Concrete-matrix porosity is a determining factor, in both the mechanical properties and the durability of cement-based materials, and was measured with Mercury Intrusion Porosimetry (MIP) analysis. The porosity values were as follows: 12.3% for mix E; 10.3 % for mix EM; and, 11.5% for mix ES; common values for well-performed concretes (Ortega-López *et al.*, 2018).

The lower porosity of the fiber-reinforced concretes with respect to the mix E, means that both the EM and the ES mixes were more compacted, which may also explain their higher compressive strength and the lower weight variation after the freeze/thaw and the moist/dry tests. The pore size frequency, shown in Figure 3, rises to an significant peak at around 100 nm,

higher in concrete E, with no fibers, which could be one cause of the worse behavior of this concrete against physical and chemical agents.

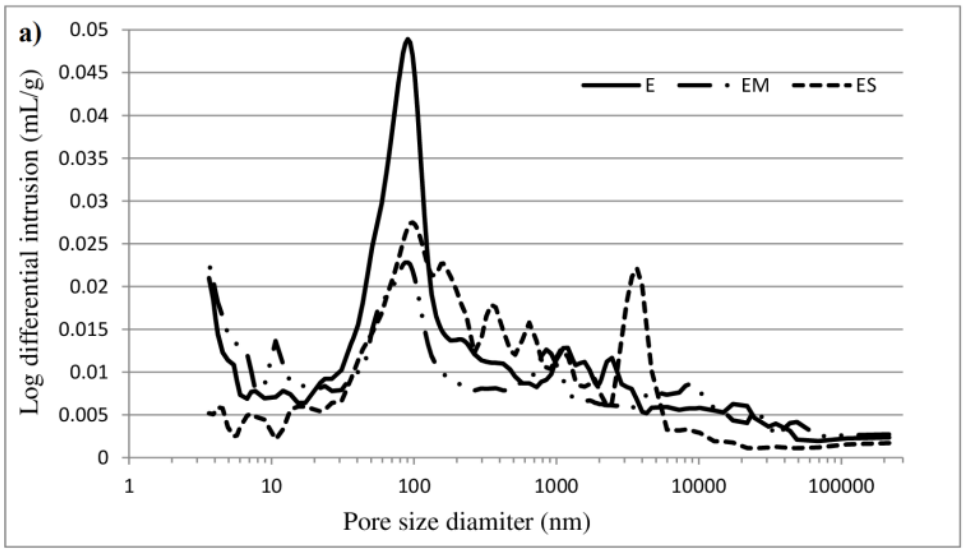

Figure 3. MIP analysis of siderurgic concretes: differential intrusion.

3.2.3 SEM observations

Low-vacuum scanning electron microscopy (SEM), with the backscattered electrons technique was used for analyzing the quality of the Interfacial Transition Zone (ITZ) and adherence between the concrete components.

Figure 4 shows three SEM images, one of each siderurgic concrete under study. In these images, it can be observed that the EAFS particles are of a lighter grey color, the siliceous particles are darker grey and, Figure 4b and Figure 4c clearly show the fibers, steel and polypropylene fibers, respectively.

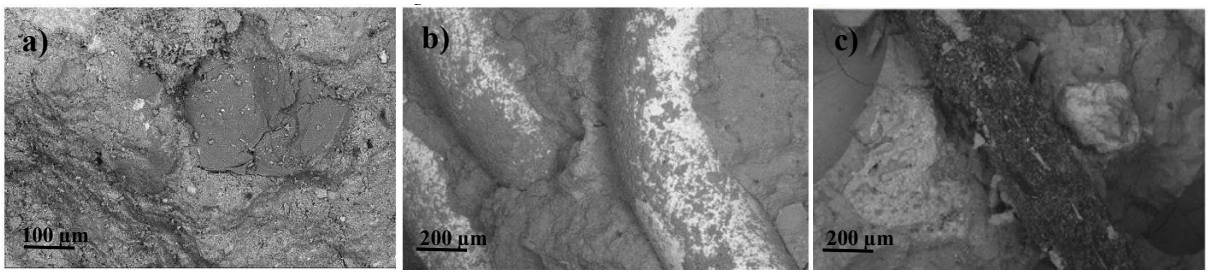

Figure 4. SEM images of concretes: a) concrete E; b) concrete EM; c) concrete ES.

All the SEM images support the conclusion that the cementitious matrices are of good quality, with excellent adherence of aggregates and fibers, which favors the durability of these concretes.

4 Conclusions

The conclusions of this work can be summarized as follows:

- The fiber-reinforced siderurgic concrete mixtures showed good mechanical properties. The results of the concretes reinforced with steel fibers were in general better than those for the concretes reinforced with polypropylene fibers.
- Durability tests delivered good results for the fiber-reinforced siderurgic concretes, yielding smaller variations of weight and strength after several conditions.
- MIP and SEM analyses revealed the good internal cohesiveness of both aggregates and fibers within the cement matrix, which favored their durability.

Mechanical and Environmental Behavior of Cement Mortars Containing Ladle Furnace Slag

Diego Aponte and Marilda Barra

Department of Civil and Environmental Engineering (DECA), Universitat Politècnica de Catalunya-BarcelonaTECH, Campus Nord UPC, 08034-Barcelona, Spain, diego.fernando.aponte@upc.edu

Abstract. *At present, steel production is mainly done in basic oxygen furnaces (BOF) and electric arc furnaces (EAF) (Pauliuk, S. et al, 2013, Morfeldt, J. et al, 2015). According to the statistics, it is expected that the use of electric arc furnaces to supply the demand for steel will prevail. In 2017, in Europe, 41% of steel was produced in electric arc furnaces, while in Spain, according to the Union of Steel Companies (UNESID, 2016), the percentage was almost 66% in 2016. In 2016 the European Union generated approximately 18.4 Mt of slag (black and white), of which 1.5 Mt was produced in Spain. In other words, the amount of white slag produced was about 286 thousand tons, approximately between 20 and 30 kg of slag per ton of steel (UNESID, 2016, Euroslag, 2016). Refining slag (white slag) is the second most abundant waste in steel production, and, to date, its final destination is still the landfill. This study has used ladle slag from refined steelworks, as a replacement for cement in different proportions (0, 25, 50 and 75%), for the manufacture of mortars. A broad characterization of the ladle slag has been carried out, as well as determining the mechanical, durable, and environmental properties of the manufactured mortars. The results show that using the ladle slag as a replacement for cement produces a decrease in compressive strength, but the expansion behavior remains below the stability limit. It also has been seen that the slag incorporated into mortars, evaluated by leaching test at 28 days, shows inert material behavior.*

Keywords: *Ladle Furnace Slag, Cement Mortars, Durability, and Environmental Impact.*

1 Introduction

Steel slag is waste that to date has no integral solution, since its properties depend on the raw materials, Steel manufacturing process and the recovery processes carried out. Slags from steel manufacturing can be either from melting or refining processes. The first ones have been subject to more research, as well as regulation. This is because, in 2016, more than 18 Mt of slag (black and white) was generated in the European Union, but they were mostly black slag (UNESID, 2016; Euroslag, 2016).

To date, different studies have been carried out on the possibility of the use of refining slag (white slag) in civil works. Some of the topics studied are: ladle slag as a filler in self-compacting concretes (Anastasiou, E. *et al.*, 2014, Sideris, K. K. *et al.*, 2018), ladle slag as a cementitious agent in concretes and mortars (Adolfsson, D. *et al.*, 2011, Herrero, T. *et al.*, 2016), ladle slag as a binder in soil stabilization (Manso, J. M. *et al.*, 2005, Ortega-López, V. *et al.*, 2014) and ladle slag as a filler in asphalt mixtures (Skaf, M. *et al.*, 2016). In the studies mentioned above, the durability problems due to the expansion of white slag are present, and it is an aspect that does not have an easy resolution. On the other hand, there are few works related to the environmental impact of slag in cement-based materials (Loncnar, M. *et al.*, 2016, Pantazopoulou, E. *et al.*, 2018).

doi:10.23967/dbmc.2020.191

Therefore, more research is still necessary to clarify the effect of ladle furnace slag when used in cement-based materials, due to its expansive behavior and its problems with the release of contaminant elements. In this context, the main goal of this study is to analyze the incorporation of fine ladle FURNACE slag in mortars in different rates (0, 25%, 50%, and 75%), and its influence in mechanical properties, expansion behavior and environmental impact (leaching test).

2 Materials and Testing Methods

The materials used for the experimental campaign are basically: (i) CEM I 52.5R Portland Cement, (ii) slag from the refining process of an electric arc furnace Steel plant, and (iii) limestone sand with a particle size between 0 to 5mm. Potable water is used for the manufacture of mortars, and MiliQ water (obtained by filtering distilled water through a Synergy water purification system-Merck) is used for all leaching tests.

Regarding the characterization tests, the size distribution of the sand is carried out in accordance with standard UNE EN 933-1, the determination of the apparent density of the cement and white slag is done in line with standard UNE EN 80103. The chemical composition is determined using the X-Ray fluorescent technique, using a Philips PW 2400 Spectrometer, and the Powder Diffraction technique for the mineralogical composition, using an Analytical X´pert PRO MPD Alpha 1 (diffractometer in Bragg Brentano $\theta/2\theta$ geometry of 240 mm of radius Cu Kα1 radiation λ = 1.5406 Å). Cement and slag size distribution is performed using a Beckman Coulter LS particle size analyzer, while a Scanning Electron Microscopy (SEM-EDS) is used to study the surface structure and perform microanalysis.

The mortars are manufactured in accordance with standard UNE EN 196-1, with a water to cement ratio of 0.5 in all cases. The nomenclature and dosage of the mortars are shown in Table 1.

Table 1. Dosage and nomenclature of mortars.

Mortar type	L. Slag (g)	Cement (g)	Sand (g)	Water (g)
Control	0	450	1350	225
M75/25	337.5	112.5	1350	225
M50/50	225	225	1350	225
M25/75	112.5	337.5	1350	225

At the ages of 7 and 28 days of curing, density and absorption are determined according to the standard ASTM C642, and the compressive strength according to standard UNE EN 196-1. A length comparator is used to measure the expansion/shrinkage of the mortars over time, which is fitted to the metal points that adhere to the mortars 24 hours after manufacture.

Finally, for the environmental impact tests, standard UNE EN 12457-2 is used for all mortars at the age of 28 days, as well as for white slag. In the case of mortars, they are dried in an oven at 40 ºC to a constant mass, at which point they are ground in a jaw crusher until all the material passes through the 4 mm sieve. It is then quartered to obtain representative samples. The results of this test are compared with the Decree on waste acceptance criteria in landfills (Council Decision 2003/33/EC of 19 December 2000) to classify mortars as an inert, non-hazardous, or

dangerous material.

3 Results and Discussion

In the following sections, the results obtained from the experimental campaign are analyzed, with emphasis on expansion behavior (durability) and environmental behavior (leaching).

3.1 Particle Size Distribution and Specific Gravity

White slag, used in this study, consists of particles between 0.1 microns to 75 microns approximately, granulometry obtained due to a process of grinding the material in a ball mill. Figure 1 shows the size distribution and compares it with the cement used (CEM I 52.5R). It can be seen that the cement has greater fineness from 2 microns to 60 microns, while the slag presents a slightly higher percentage of particles in the range 0.1 to 2 microns.

In Table 2, it can be seen that the density of the slag is lower than the density of the cement (approximately 9%). This situation will generate a change in the total volumes of mortars manufactured. But for this study, it is assumed that the influence will not change the behavioral trends if the dosage of the mortars is done in weight or volume. In Table 2, it is also observed that sand has an absorption of 1.65%, so it was decided to use this material in the condition of dry saturated surface at the time of manufacturing the mortars.

Table 2. Properties of raw materials.

Property	L. Slag	Cement	Sand
Apparent density (g/cm^3)	2.75	3.02	2.73
Dry density (g/cm^3)	--	--	2.55
Absorption (%)	--	--	1.65

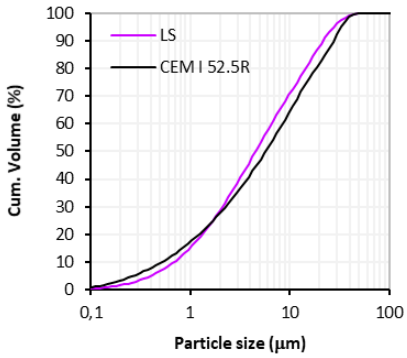

Figure 1. Particle size distribution for Ladle slag and Cement Portland.

3.2 Chemical and Mineralogical Composition

Slag and cement basically contain Calcium, Silica, Aluminium, and Iron. White slag has high magnesium content, and some of it may be present as Periclase, which will create expansion problems. Table 3 shows the compounds present in both the slag and the cement.

Table 3. Chemical composition for Ladle slag and Cement portland.

Element	Cement (%)	L. Slag (%)
CaO	63.21	46.78
SiO_2	18.65	18.60
Al_2O_3	3.98	6.62
Fe_2O_3	3.32	5.36
SO_3	2.94	1.51
MgO	1.42	10.85
Others	1.47	1.69
LOI	5.01	8.59

The phases identified in the cement used are: calcium silicates (C_3S, β-C_2S), calcium aluminate (C_3A), calcium ferroaluminate (C_4AF). Anhydrous gypsum ($CaSO_4$) and calcite ($CaCO_3$) have also been determined. It should be mentioned that the used slag contains a part of amorphous material, together with crystalline phases, such as: calcium silicates (α-C2S, β-C_2S), calcium aluminate (C_3A), gehlenite ($Ca_2Al((AlSi)O_7)$), wustite (FeO), and periclase (MgO). In addition, calcite ($CaCO_3$) and in low proportion portlandite ($Ca(OH)_2$) and lime (CaO) have been identified.

3.3 Particle Morphology and Microanalysis

Figure 2 and Figure 3 show different particles that make up the slag, and by performing micro-analysis, the compounds identified by XRD are confirmed. It is important to note that, for example, the calcium silicate compounds show a high variation in their proportions, so that it is not possible to speak of compounds with an exact composition. The presence of compounds from the gehlenite family has also been observed, which present greater or lesser amounts of aluminum in their composition.

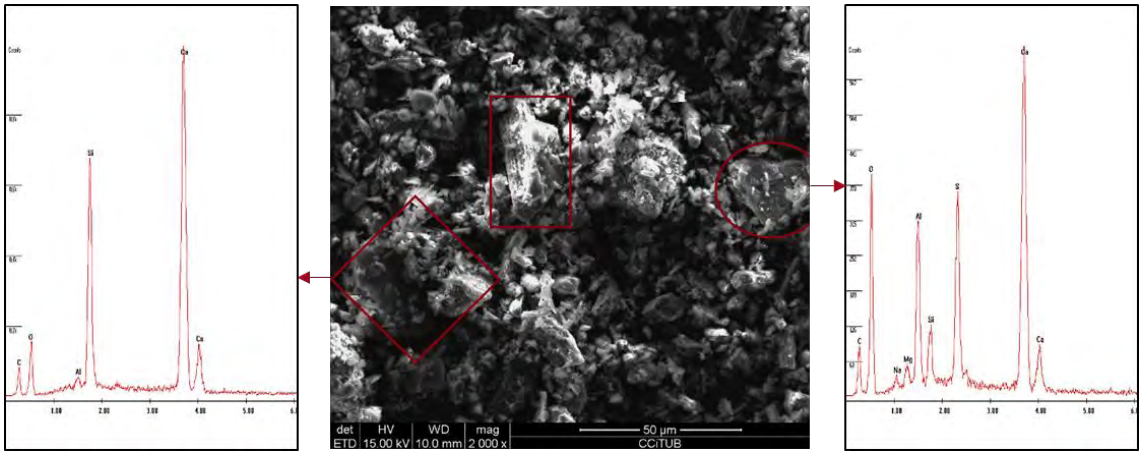

Figure 2. Chemical composition of different Calcium Silicates and Gehlenite of the particle of ladle slag.

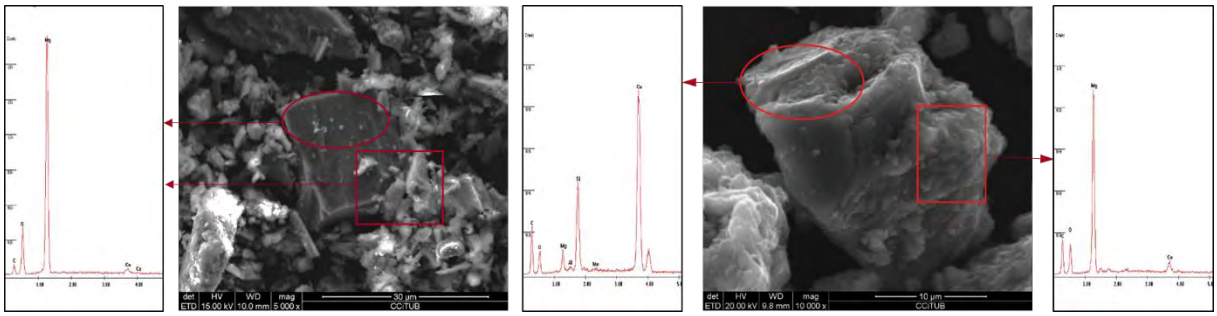

Figure 3. Periclase compound (left) and Calcium Silicate (right) in the Ladle slag.

In the samples analyzed by SEM-EDS, it was possible to find MgO particles, as shown in Figure 4. Again, the complexity of the mineralogical composition of the slag should be pointed out, since, as shown in Figure 4 right, in the same particle can be found compounds of calcium silicate and magnesium oxide.

3.4 Physical and Mechanical Properties of Mortars

As reported in the literature, fine slag has cementitious properties, but with low cementitious activity. This fact has been proved by XRD analyses, where the cementitious compounds are some slow reacting calcium silicates and possibly some gehlenites. Therefore, the particle size of the slag plays an important role in the development of mechanical properties, as it can act as a filler material.

Figure 4 shows the effect of incorporating slag into mortars and curing time (7 and 28 days) in compressive strength. It can be seen that as the amount of slag increases, the strength decreases, and this decrease is almost proportional. When 25% of the cement is replaced by slag, the strength falls by 20%, indicating that the material has a medium strength activity. However, when 50% is replaced, the compressive strength falls by 62%, and when 75% is replaced, the strength falls by 90%, clearly indicating that it is a material with medium-low cementing activity. It should be noted that with replacements from 50% cement, the strength achieved is almost 20 MPa, which means that there is a wide variety of materials that could be developed with these properties.

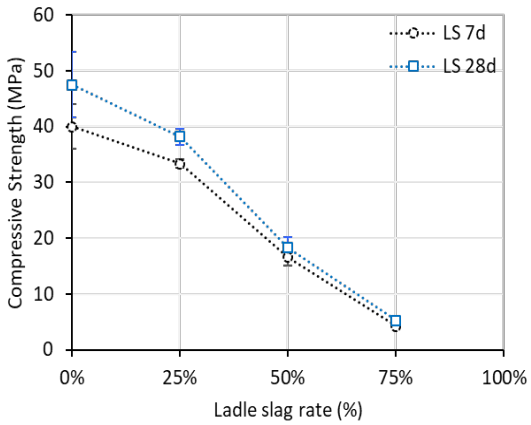

Figure 4. Compressive strength of mortar with different rates of ladle slag.

3.5 Expansion Behavior of Mortars

The volumetric stability behavior has been measured over time up to an age of approximately 400 days. The samples after manufacturing have been kept in a wet chamber (20°C and 95%R.H.), in order to have water availability and to facilitate the reactions of the expansive compounds.

Figure 5 shows the behavior for the different types of mortars (control = 0% L.S, M25/75 = 75% L.S, M50/50 = 50% L.S, and M75/25 = 75% L.S.). For the control mortar, a linear increase can be observed up to 100 days, and then the behavior is constant up to 0.02% linear expansion. For mortars containing slag, it can be seen that after 100 days, linear expansion continues to increase over time, possibly with greater expansion as the slag content increases.

The limit expansion value has been taken as 0.04%, which is used for aggregates with alkali-silica reactivity problems (Velasco, 2014). This is due to the fact that there is no regulation regarding the minimum or maximum expansion that can be accepted when using slags in rigid matrices.

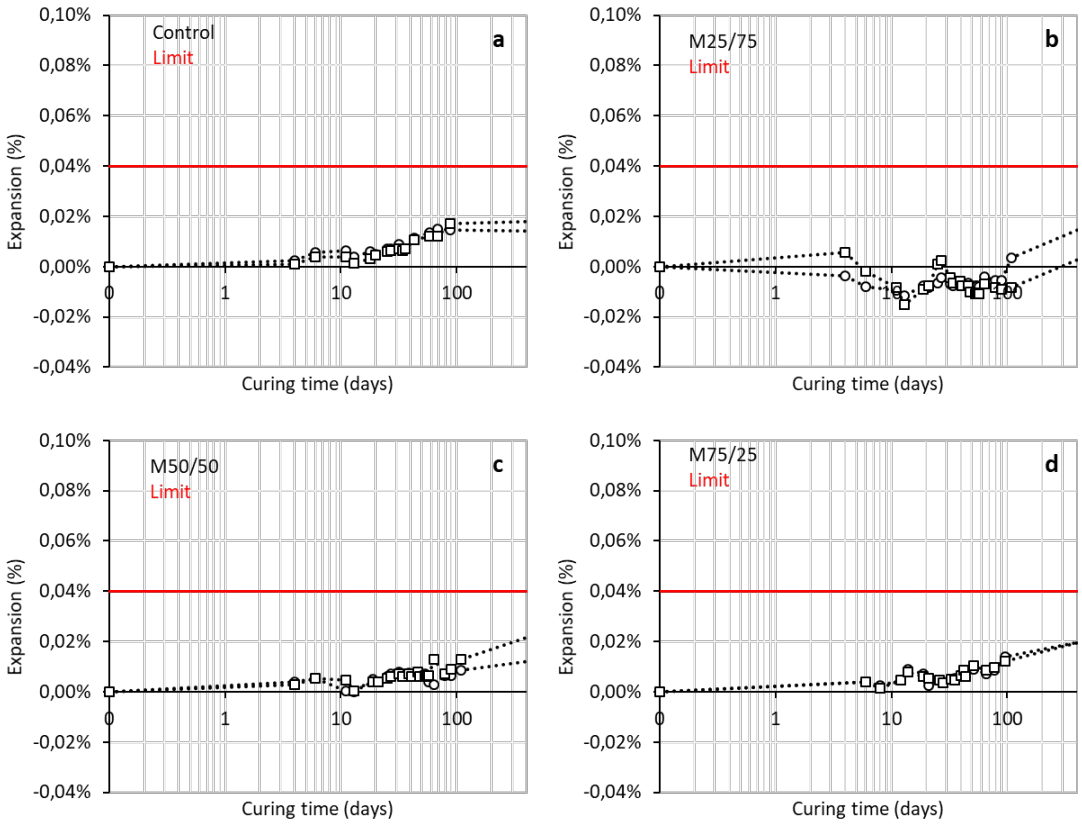

Figure 5. Expansion over time for control mortars (a), 25% ladle slag mortars(b), 50% ladle slag mortars (c) and 75% ladle slag mortars (d).

3.6 Environmental Behavior of Mortars with Ladle Slag

In general terms, in Spain and other European countries, slag is classified as an inert waste (REF). However, the classification is open and, in some cases, does not specify whether it is

black slag or white slag. In this context, some regulations have stated that the classification is only for black slag.

By carrying out leaching tests on the white slag, it can be verified that it is a material that can be in the range of non-hazardous material or hazardous material (Council Decision 2003/33/EC of 19 December 2000), depending on each manufacturing plant. In this study, the white slag analyzed present releases of some elements higher than those accepted for inert materials, such as Barium and Nickel (Fig. 7). However, it can be seen that once incorporated into the mortars, in all proportions, the release is below the limits. Figure 7 shows the quantities released for the elements Chromium, Copper, Molybdenum, Lead, and Zinc, which are below the limits for inert material.

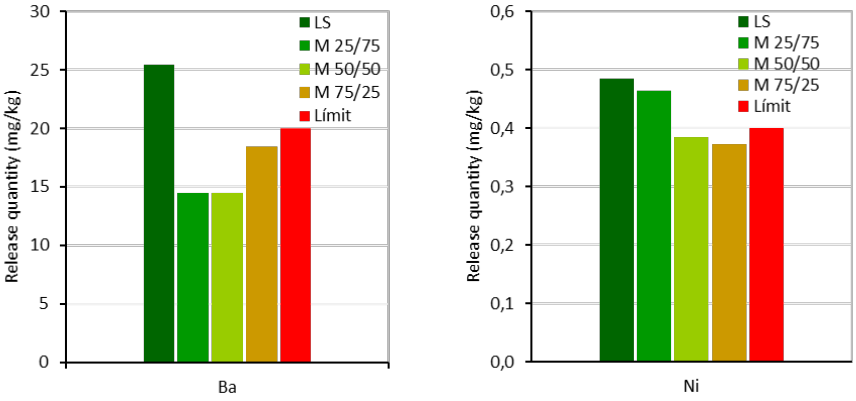

Figure 6. Release of Barium (left) and Niquel (right) of ladle slag and mortar.

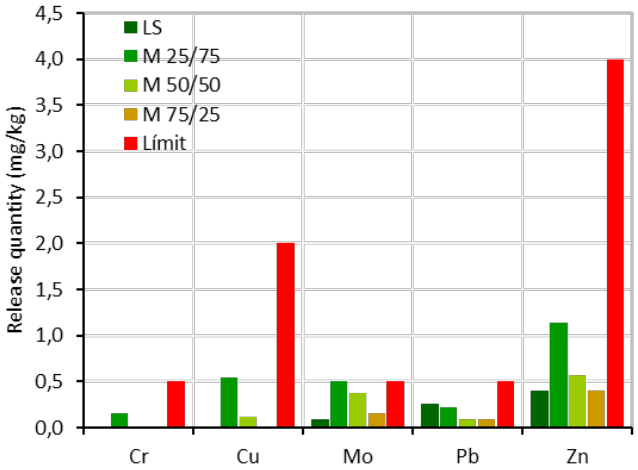

Figure 7. Release of Cr, Cu, Mo, Pb, and Zn of ladle slag and mortar.

4 Conclusions

According to the work done, the following conclusions can be drawn:

- The white slag studied presents phases that can generate cementing behavior. However, it is observed that its activity index is low (80%), and it is only working as a filler.

- Replacement of cement by slag in percentages from 50% generate materials with a compressive strength between 20 and 5 MPa. These values may be thought to be low, but they would allow the use of slag in a wide variety of applications, from low strength fluid fillers (< 2 MPa) to low mechanical stress pavement concretes (15 to 20 MPa).
- The expansive behavior of mortars has shown a tendency to increase over time, which can be a problem in terms of stability. However, linear expansions obtained up to 400 days of curing are below the 0.04% limit, which raises the possibility of their use in short-life materials.
- The white slag in this study is classified as non-hazardous materials, but when it is incorporated into mortars, it behaves like an inert material. Therefore, at the end of the lifespan of the material, it can be treated without further problems.

Pore Refinement Action of GGBFS and Fly Ash on the Primary and Secondary Capillary Imbibition Rates of Concrete

Natalia M. Alderete[1], Yury A. Villagrán-Zaccardi[2] and Nele De Belie[1]

[1] Magnel Laboratory for Concrete Research, Ghent University, Technologiepark-Zwijnaarde 60, 9052-Gent, Belgium, nataliamariel.alderete@ugent.be, nele.debelie@ugent.be

Abstract. *Capillary imbibition is a transport phenomenon occurring in concrete structures exposed to weathering, frequently in direct connection with the resistance against different deterioration processes. This property depends on the volume and connectivity of pores. For ground granulated blast-furnace slag (GGBFS) and fly ash blended concrete mixes, the pore refining action of these supplementary cementitious materials plays a positive role in the disconnection of the capillary porosity and consequent reduction of the capillary imbibition rate. Moreover, for this particular transport process, primary and secondary transport rates can be defined in connection with different driving mechanisms. This allows a complementary description of the pore structure of concrete. In this paper, blended concrete mixes were prepared by substituting 20, 40 and 60 % of OPC by GGBFS, and 20, 30 and 40 % of OPC by fly ash. The pore structure of these concretes is assessed by water absorption under vacuum and mercury intrusion porosimetry after curing periods of 28 and 90 days. Long-term capillary imbibition tests were also performed and primary and secondary imbibition rates are computed by a novel approach that considers their linear evolution with the fourth root of time. Results show the refinement action of GGBFS and fly ash by a softening in the transition stage between the primary and secondary imbibition periods. A low water flow rate is consequently correlated with the increased tortuosity of samples.*

Keywords: *Sorptivity, Supplementary Cementitious Materials, Pore Structure, Imbibition.*

1 Introduction

Sorptivity is a widely used durability index of concrete. The quantification of the rate of water imbibition by capillarity in concrete describes the pore connectivity of cementitious materials. Previous work has shown that primary and secondary imbibition rates can be used for describing the pore structure on the basis of their corresponding driving mechanism.

The most usual assessment method considers the relation between water uptake and the square root of time, but it faces the significant difficulty of the lack of linearity of this relationship for the case of cementitious materials. This is usually referred as anomalous sorptivity (Hall, 2007; Küntz and Lavallée, 2001; Lockington and Parlange, 2003; Villagrán Zaccardi *et al.*, 2017). A comprehensive analysis of this analomaly led to the proposal of a new approach considering the fourth root of time, which was validated with experimental data in the short term (Villagrán Zaccardi *et al.*, 2017). The new model considers the swelling of the C-S-H gel as the main cause for the anomalous behaviour. Physical evidence of this swelling was recently presented in (Alderete *et al.*, 2019b), where the volumetric stability of mortar and concrete samples was registered using strain gauges.

During long-term exposure of samples, water uptake further continues at a very low rate even after the capillary rise has covered the full height of samples (Alderete *et al.*, 2019a; Bentz *et al.*, 2001; Castro *et al.*, 2011; Hall and Hoff, 2009; Kaufmann and Studer, 1995; Spragg *et al.*, 2011). A secondary imbibition period for the water ingress driven by diffusion into the finest pores of the cementitious matrix can be therefore defined. Allegedly, this process starts as soon as the material makes contact with water, but it is initially masked by the capillary action which dominates the water flow during the primary imbibition. The secondary capillary imbibition has been presented as a convenient complementary descriptor of the transport properties of cementitious materials (Henkensiefken *et al.*, 2009; Kurtis *et al.*, 2016; Liu and Hansen, 2016; Wei *et al.*, 2017). Both primary and secondary mechanisms should be considered for describing the whole moisture transport during imbibition.

In this paper, capillary imbibition tests were conducted for 17 weeks on concrete mixes with and without ground granulated blast furnace slag and fly ash to determine the primary and secondary capillary imbibition rates. These transport parameters are compared with the pore size distribution obtained by mercury intrusion porosimetry (MIP).

2 Materials and Methods

Concrete mixes were designed with a water to binder ratio (w/b) of 0.45. OPC type CEM I 42.5 N, ground granulated blast furnace slag (SB), and fly ash (FA) were used supplementary cementitious materials (SCMs) in partial replacement of OPC in proportions of 20, 40 and 60, and 20, 30 and 40%, respectively. A reference mix with only OPC as binder was also made. Table 1 displays the properties of the binders, including composition, density, and particle size distribution (obtained by laser diffractometry with optimal optical parameters chosen as suggested in (Alderete *et al.*, 2016)). Mix proportions, slump, air content, and compressive strength are provided in Table 2. The mixes were named based on the binder (OPC for control, SB, and FA for the blends) and the weight percentage of cement replacement. To improve the workability, a commercially available polycarboxylic ether-based superplasticiser was added to the concrete during mixing. In addition to five concrete cylinders with 10 cm in diameter, three 10 cm cubes for compressive strength were also cast for each mix and cured in a conditioned room at 20 °C ± 2 °C and 95 % ± 5 % RH for 28 and 90 days.

Table 1. Properties of OPC, SB, and FA.(nd = not determined, LOI = loss on ignition).

Properties	OPC				SB				FA

The top halves of the five cylinders were used to determine water absorption by immersion. First, samples were submitted to vacuum for 2 h and then water was drawn into the vacuum chamber until the sample became fully immersed. After 24 h samples were removed and the saturated weight was registered. Then, samples were subjected to drying in an oven at 105 °C. Finally, water absorption was calculated from the difference between the saturated weight and the dry weight, relative to the dry weight.

The samples for MIP were approximately 125 mm^3, obtained from the core of one cylinder per mix. Microstructural damage during pre-conditioning was minimised by first drying samples at 40 °C for 24 h, and then vacuum-drying them at (20 ± 2) °C for two weeks at 0.1 bar (Snoeck *et al.*, 2014; Zhang and Scherer, 2011). The maximum applied pressure was 200 MPa in order to avoid massive cracking induced by the pressure (Beaudoin and Marchand, 2001). Measurements were corrected with a blank to disregard differential mercury compression. The intruding volume of mercury into the sample is a function of the pressure increase. Results are interpreted with the theoretical simplified model of cylindrical pores and translated into pore 'diameters' upon the application of the Lucas-Washburn equation. The surface tension and contact angle considered for these computations were 0.482 N/m and 142° (Ma, 2014), respectively. Qualitative contrasts are finally possible by comparing the threshold diameter (d_{th}) and intrudable pore volume (ϕ_{in}) (Ma, 2014). The calculation of d_{th} was made by the tangent method, and therefore denoted as d_{tg} (Liu and Winslow, 1995), corresponding to the intersection of tangent lines on the cumulative distribution curve at the smallest diameter that did not exhibit significant intrusion and the largest diameter that did. The range of the points to be fitted was determined by the analysis of the second derivative in the differential curve. Furthermore, according to the cumulative curve shape obtained, it is possible to make inferences about the presence of choke points.

The tested samples for the long-term capillary imbibition tests were obtained by sawing the section between 3 and 8 cm from the base of the five cylinders. Samples were laterally covered with aluminum-butyl tape to ensure one dimensional flow. The preconditioning procedure consisted in 72 h immersion in water and then drying in an oven at 50 °C until mass decrease was lower than a mass fraction of 0.1 % within 24 h. The capillary imbibition test consisted in putting the samples in contact with water, with an immersion depth of (3 ± 1) mm. Water evaporation was avoided by putting a lid on top of the water container. The water

level was checked regularly and the immersion depth was kept at (3 ± 1) mm during the whole testing period. Samples of OPCc and FA20c mixes with 28 days of curing were the first ones to be tested, with testing periods up to 10 weeks. Based on these results, it was decided to continue the measurements for the capillary imbibition tests on the rest of samples up to 17 weeks to obtain a larger amount of data for the secondary period than for the first data series. In this manner, a more complete description of the secondary period was achieved in those cases. Measurements were performed after exposure periods of 0.5 h, 1 h, 2 h, 3 h, 4 h, 5 h, 6 h, and 24 h and after that every 24 h during the first week, once a week during the first two months, and once a month until 4 months.

3 Results and Discussion

Figure 1 displays the results of relative water absorption of the mixes at 28 and 90 days. At 28 days, values of water absorption of all SB mixes are higher than the OPCc mix. However, at 90 days, mixes SB20c and SB40c had lower water absorption than OPCc at 90 days. Values of water absorption at 28 days increased slightly with the FA content. At 90 days, FA20c and FA30c show similar results as OPCc, but the higher replacement in FA40c does not allow to compensate the dilution effect.

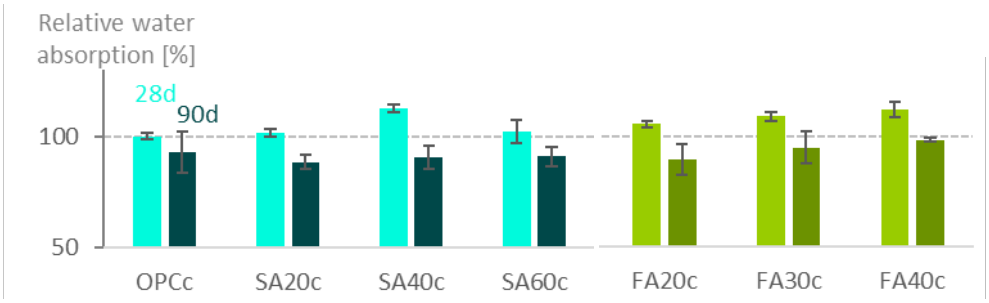

Figure 1. Relative open porosity and relative water absorption of OPCc, SB and FA concrete mixes at 28 and 90 days.

The cumulative mercury intruded volume curves of SB and FA mixes at 28 and 90 days are presented in Figure 2, with the indication of the ϕ_{in} and d_{tg} of each mix. Results reveal the refinement action of SB with time. All mixes had a reduction of ϕ_{in} between 16 % and 26 % after 90 days. Accordingly, d_{tg} values were reduced from 28 to 90 days. For FA mixes, results indicate the slower reaction of FA in comparison with SB, as indicated by reactivity tests (Alderete, 2018). Although all FA mixes have a lower ϕ_{in} at 90 days than at 28 days, the reduction is around half of that found for concrete mixes with SB. In fact, FA40c at 90 days displays a higher value than SB60c at 28 days. This shows that even with a lower amount of replacement ($40 < 60$) and with more time to react ($90 > 28$), FA does not compensate the clinker dilution as well as SB. Values of d_{tg} are in agreement with this as well, as they are higher for FA concrete mixes than SB mixes at 90 days.

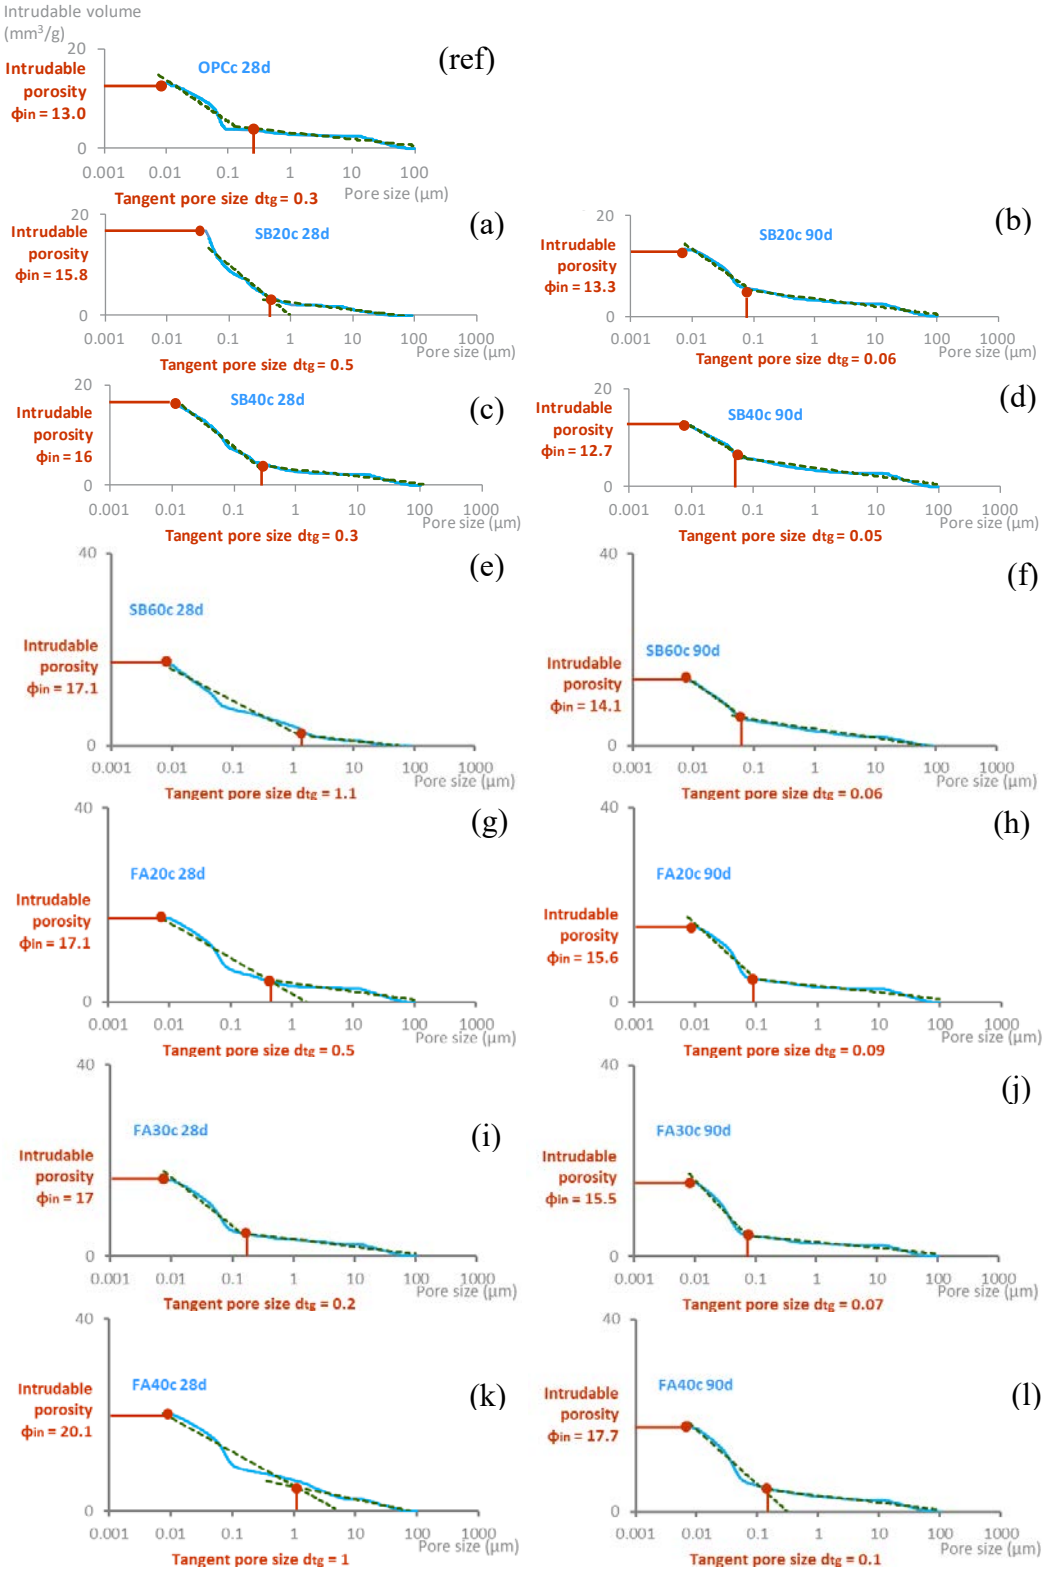

Figure 2. MIP curves of OPCc at 28 (ref), SB20c at 28 (a) and 90 (b), SB40c at 28 (c) and 90 (d), SB60c at 28 (e) and 90 (f), FA20c at 28 (g) and 90 (h), FA30c at 28 (i) and 90 (j), and FA40c at 28 (k) and 90 (l) days.

Results for the capillary imbibition of the mixes are shown in Figure 3. Two periods, primary and secondary, and a transition period in between, are observed. The primary imbibition period takes place within 1 and 3 weeks, for samples tested at 28 days and 90 days, respectively. Error bars represent the standard deviation (n = 5) and are marked in all graphs, but, as the variability was very small, some error bars are not visible because they are smaller than the marker. The capillary imbibition rate (CIR) is computed as the slope of the fitting line during the first week: CIR_{1w} (for 28 days); and during the first 3 weeks: CIR_{3w} (for 90 days). The secondary capillary imbibition rate is computed as the slope of the fitting line after the transition period: $sCIR_{1w}$ (for 28 days); and $sCIR_{3w}$ (for 90 days). The corresponding coefficients of determination are shown in the graphs. The transition period is highlighted in the graphs, where the difference between the primary and the secondary periods is less marked for blended than control concrete.

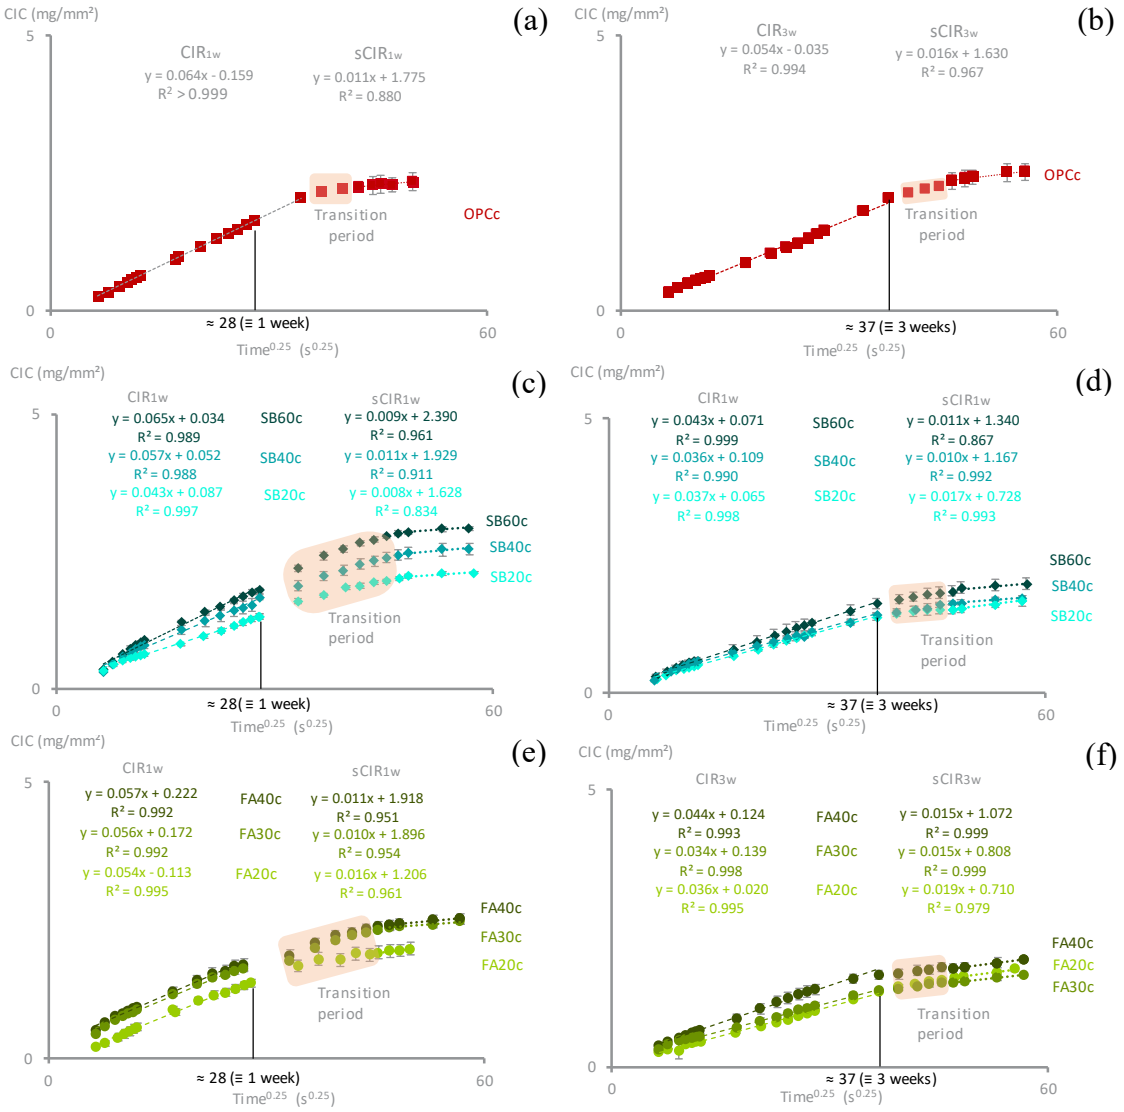

Figure 3. Long-term capillary water uptake results of OPCc at 28 (a) and 90 (b), SB at 28 (c) and 90 (d), and FA at 28 (e) and 90 (f) days.

Pore refinement due to the action of the SCMs led to a decrease in d_{tg} in the range of 0.2 to 1 μm at 28 days, to the range of 0.05 to 0.1 μm at 90 days, which corresponds to a decrease in the CIR from the range of 0.048 to 0.065 $mg \cdot mm^{-2} \cdot s^{-0.25}$ to the range of 0.034 to 0.044 $mg \cdot mm^{-2} \cdot s^{-0.25}$. This correlation is in contrast with the values of ϕ_{in}, which are not reflecting so well the refinement action of the SCMs. Contrarily, the sCIR does not show a clear connection with the MIP parameters, and this transport parameter is likely linked with the content of C-S-H in each mix and the gel pores. Additional research in this regard seems valuable. Furthermore, blended concrete mixes had a more marked transition period and lower imbibition rate at 90 days in comparison with 28 days, which indicates a lower flow rate due to their increased tortuosity.

4 Conclusions

The long-term exposure of unsaturated samples involves additional water uptake after the capillary rise has covered the total height of samples. This is a process that occurs at a much slower rate than the short-term capillary imbibition, and it can be related to a secondary transport through the finest range of pores. Long-term capillary imbibition tests in blended concretes manifested the existence of primary and secondary periods. Both periods display increasing water uptake proportional to $t^{0.25}$.

The pore refinement action of ground granulated blast-furnace slag and fly ash was reflected in the comparable reduction of the CIR and d_{tg} parameters. In second term, ϕ_{in} values were reduced from 28 to 90 days, but the correlation is not very good with the capillary imbibition. The likely reason is that pore refinement causes an increase in tortuosity more than a reduction in porosity. Lastly, sCIR does not reflect so well the refinement action of the SCMs. In this case, the transport parameter could be phenomelogically linked to the C-S-H content and its characteristic porosity.

Seismic Performance of RC Moment Frame Structures Made with EAF Slag Aggregates

Flora Faleschini, Mariano A. Zanini and Klajdi Toska

Dept. of Civil, Environmental and Architectural Engineering, University of Padova, Via Marzolo 9 35131-Padova, Italy, flora.faleschini@dicea.unipd.it, marianoangelo.zanini@dicea.unipd.it, klajdi.toska@dicea.unipd.it

Abstract. *Sustainability in the construction industry is becoming everyday more a major issue in todays world. To accomplish sustainability goals, adopted also by the Agenda 2030 of the United Nations, wide research has been carried out in the past years. Among this, the use of recycled aggregates has been proven to be promising both in terms of sustainability and material properties. Electric Arc Furnace (EAF) concrete has demonstrated a significant increase in mechanical properties when compared to natural aggregates (NA) ones. However, the mechanical properties enhancement is accompanied by an increase of its specific weight and the overall effects of its use in RC structures subjected to dynamic loads, has not been investigated yet. The present study aims to investigate the seismic reliability of reinforced concrete frame buildings made with EAF in comparison to the same structural configurations made with NA concrete, considering three different configurations (3-, 6- and 9- story building type) designed considering ordinary concretes made with natural aggregates.*

Keywords: *EAF Slag, Reinforced Concrete, Seismic Fragility, Seismic Reliability.*

1 Introduction

Sustainability is one of the global challenges that the construction industry must face in the near future. The 2030 Agenda of the United Nations sets as one of its main goals waste generation reduction and promotes policies of prevention, reduction, reuse, and recycling. Lately great effort has been made by the research community on the promotion of recycling and reuse opportunities of waste materials in the construction industry. One of the most remarkable cases of recycling is the Recycled Aggregates (RAs) production by Construction and Demolition Waste (C&DW) and their use is now regulated in most countries around the world (FHWA,1997; EN 12620:2008; NTC, 2018). More recently, waste originating from industrial processes, have been object of research to evaluate their possible use to produce RAs or so-called industrial aggregates. Among other industrial waste or by-products, those coming from steelmaking industry, particularly electric arc furnace (EAF) slag, offer great performance when used in structural concrete. In previous research has been observed that EAF slag use in concrete mixtures improves both mechanical strength (Pellegrino *et al.*, 2009; Arribas *et al.*, 2015; Rondi *et al*., 2016; Liapis *et al.*, 2018; Qasrawi, 2014) (i.e compressive strength, tensile strength and elastic properties) and durability (Faleschini *et al.*, 2015; Pellegrino *et al.*, 2012; Ortega-López *et al.*, 2018) when compared to concrete mixtures with ordinary ones. In addition, heavy-weight metals present in the EAF slag composition give to EAF concrete mixtures a higher specific weight with respect to NA mixtures.

Experimental work on the behavior of EAF concrete has been carried out also at the element scale. They have shown that reinforced concrete (RC) elements with EAF slag aggregates manifest better flexural and shear capacity with respect to ordinary RC when tested to

monotonic loading under four-point bending (Pellegrino *et al.*, 2013; De Domenico *et al.*, 2018). Axially loaded columns have shown a similar ductility to that of NA mixtures (Lee *et al.*, 2018) while a higher shear capacity of exterior beam-column joint is observed (Faleschini *et al.*, 2017). Laboratory tests on real scale EAF concrete joints under cyclic loading have shown gain with respect to NA ones in terms of ductility, dissipated energy and reduced cracking patter. Similar results were observed also for joints with lower cement content (Faleschini *et al.*, 2017). The use of EAF slag has shown enhanced ultimate and frictional bond strength with respect to conventional concrete (Faleschini *et al.*, 2017). Other beam-column joint conditions (i.e., strong beam – weak column and strong column – weak beam situations) have been numerically investigated (Faleschini *et al.*, 2017).

The results of the research work reported above have shown that EAF concrete can be suitably applied in gravity structures and in special facilities that require shielding from radiations where its high specific weight and high strength can be better exploited (Pomaro *et al.*, 2019). However, its efficiency is not so obvious when applied in elevation RC structures that are located in seismic regions where an important change of the building mass and stiffness can lead to a significant increase of the seismic loads in the structure. The present paper aims to study this topic, analyzing the seismic behavior of code conforming RC frame buildings built with ordinary concrete then replaced with three different classes of EAF concrete characterized by increasing aggregates replacement ratio. A dataset of experimental tests based on two previous research works of the same authors is used to define the mechanical properties of EAF concrete mixtures (Pellegrino *et al.*, 2016; Zanini, 2019). Via statistical analysis, ratios of variation of the main mechanical properties (i.e. compressive and tensile strength, and elastic moduli) and of the specific weight were defined for three EAF concrete classes (C1, C2, A) with respect to a benchmark mixture made with NAs. Three different geometrical configurations of regular RC frame structures with three, six and nine stories were designed according to the current Italian code for Constructions for a medium-to-high seismic hazard site. Fragility functions were then computed from the seismic responses of the analyzed configurations under a set of non-linear time history analysis (NLTHAs) and a seismic reliability assessment was carried out for all 12 resulting combinations (combining 3 structural configurations and 4 concrete mixes), investigating the variation of structural safety margins related to the use EAF concrete mixtures in replacement to a conventional NA concrete.

2 EAF Slag Concrete and RC Frame Case Studies

EAF slag is a by-product of the steelmaking industry which, after cooling from temperatures up to 1300 °C to ambient conditions, becomes a dark-grey stony material. EAF slag properties depend on the type of steel to be produced, scrap composition, slag cooling method and speed, and further weathering process. EAF aggregates present a rough texture and angular shape which influences bond development in the cement matrix since crushed stones present higher surface-to-volume ratio and require more cement paste to obtain a workable mixture in respect to NAs. The main physical properties of the slag for two size fractions, compared to a dolomitic aggregate, are reported in Table 1.

Generally, when used to replace NAs, EAF slag has a positive effect on the mechanical properties. However, the properties of the mixture strongly depend on type and amount of substitution. It has been experimentally proven that coarse aggregates have a beneficial effect,

while when fine fraction is used the beneficial effect is more limited (Pellegrino *et al.*, 2012). Compared to standard NA concrete, the EAF mixtures have higher specific weight about 3.3 – 4.0*t/m*3 against 2.7*t/m*3 of normal ones. Particular attention must be paid to the segregation phenomena. High specific weight can result in insufficient viscosity of the cement paste causing the migration of the two phases. Elastic modulus is also enhanced when using EAF slag. This is mainly because concrete elastic modulus depends mainly on the aggregates elastic modulus. The overall property improvements are also due to the interfacial transition zone (ITZ) between EAF aggregate and cementitious matrix that results denser and less porous than conventional concretes. However, if a bad quality cementitious matrix or a high water/cement ratio is employed property enhancements are less important.

Table 1. Physical properties of EAF slag compared to dolomitic aggregate (NA).

	Apparent density (kg/m^3)	Water absorption (%)	Porosity (%)	Shape
EAF slag 0-4 mm	3800	1.0 – 1.5	2.0	Crushed
EAF slag 4-16 mm	3950	<1.0	0.5 – 2-7	Crushed
NA 0-4 mm	2760	1.0 1.5	< 2.0	Roundish
NA 4-16 mm	2790	<0.5	0.9 – 1.8	Roundish

To analyze the structural response of buildings built with different concrete mixtures, three-moment frame RC structures with 3-, 6- and 9- stories were considered. The structures are characterized by a regular rectangular shape with five spans in the longitudinal direction and three in the transversal one. Spacing between consecutive bays is equal to 5 m.

The structures were supposed to be located in a moderate-to-high seismic hazard site (Municipality of Pordenone, Northeast Italy) and designed in accordance with the Italian Building Code considering a low ductility class (Class B). Seismic forces were computed from a dynamic linear analysis while beams and columns were sized accordingly, using Reference C25/30 strength class.

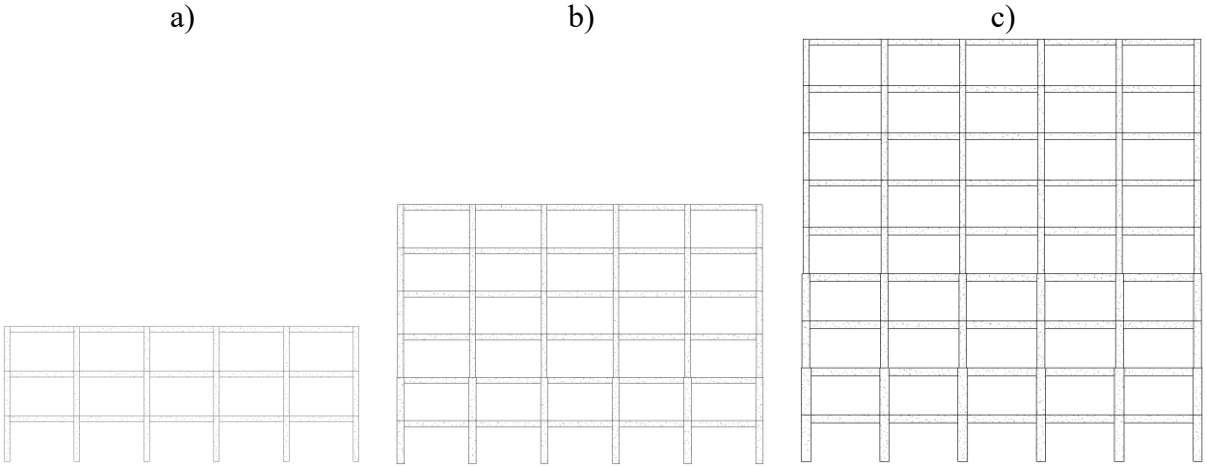

Figure 1. RC frame layouts analyzed: floor plan (a), 3- (b), 6- (c) and 9-story (d) building archetypes.

3 Seismic Reliability Analysis

For the Performance-Based Earthquake Engineering (PBEE) framework (Cornell *et al.*, 2000) the occurrence of mainshock events at a given site is assumed to be a Homogenous Poisson Process. Neglecting damage accumulation on structure, the process of events causing the structural failure is also represented by an HPP, whose unique parameter, the failure rate λ_f, can be used for computing the failure probability in any time interval. Particularly, it depends on the hazard curve (λ_{im}), representing the seismicity on a specific site, and on fragility curve ($P[f|im]$) being the probabilistic structural behavior of a specific structure. λ_f can be computed by applying the Total Probability Theorem in the following way:

$$\lambda_f = \int_{im} P[f|im] \cdot |d\lambda_{im}| \tag{1}$$

Once estimated the failure rate, based on the HPP assumption it is possible to quantify the probability of failure for a given time window of interest *t* due to earthquake occurrences:

$$P_{E,f} = 1 - e^{-\lambda_f t} \tag{2}$$

and further, derive the seismic reliability index ($\beta_{E,t}$) in accordance with the reliability analysis theory with the following transformation:

$$\beta_{E,t} = -\Phi^{-1}(P_{E,f}) \tag{3}$$

3.1 Seismic hazard and fragility estimation

To compute λ_{im}, seismic hazard map for Italy, provided by the National Institute of Geology and Volcanology (INGV), was used. To compute the failure rate a continuous hazard function is needed. Since INGV provides hazard data (values of the 16th, 50th and 84th percentile) only for nine return times, median values were fitted with a quadratic function in logarithmic space:

$$\lambda(s) = k_0\, e^{(-k_1 \ln(s) - k_2 ln^2(s))} \tag{4}$$

In assessing seismic reliability, instead of the median hazard curve, it is more suitable to refer to the mean one which is possible to derive with the following equation:

$$\bar{\lambda}(s) = \lambda(s)\, e^{(\frac{1}{2}\beta_H^2)} \tag{5}$$

Where β_H can be estimated as:

$$\beta_H = \frac{\ln(S_{84\%}) - \ln(S_{16\%})}{2} \tag{6}$$

The fragility function ($P[f|im]$) represents the probability to reach and exceed a certain damage state given a specific intensity im. In this work, Cloud Analysis method (Jalayer&Cornell, 2003) is adopted. The fragility parameters are estimated starting from a set of n natural ground motion records and the fragility function is computed as follows:

$$[f|im] = P\left[EDP > \overline{edp}|im\right] = 1 - P\left[EDP \leq \overline{edp}|im\right] = 1 - \Phi\left[\frac{ln(\overline{edp}) - ln(edp)}{\beta}\right] \tag{7}$$

$\overline{edp}$ is the median threshold value of the assumed structural limit state, and edp represents the median estimate of the demand that can be computed with a ln-linear regression model, as:

$$ln(edp) = a + b \cdot ln(im) \tag{8}$$

β is the standard deviation of the demand conditioned on im and can be estimated from the regression of the seismic demands as:

$$\beta_H = \frac{\ln(S_{84\%}) - \ln(S_{16\%})}{2} \tag{9}$$

4 Seismic Reliability Assessment of the EAF RC Frame Archetypes

For the NLTHAs a diffused plasticity model, using a fiber section discretization, was adopted to consider material non-linearities. Unconfined and confined concrete was modeled via the Mander *et al.* (1988) model whereas the Menegotto-Pinto (1973) steel model was used for the non-linear behavior of rebars. Simulations were carried out via SeismoStruct software and a set of 30 natural unscaled ground motion records were adopted using all three components of the seismic wave. EAF concrete characteristics are computed using the ratio coefficients in Table 2 and the reference concrete material (C25/30) characteristics.

Table 2. Ratios between EAF and Reference concrete properties.

	Class EAF-C1	Class EAF-C2	Class EAF-A
$\rho_{c,EAF} / \rho_{c,Ref}$	1.166	1.166	1.154
$f_{c,EAF} / f_{c,Ref}$	1.395	1.404	0.915
$f_{ct,EAF} / f_{ct,Ref}$	1.280	1.100	1.080
$E_{c,EAF} / E_{c,Ref}$	1.330	1.100	1.040

In the present paper, the chosen Engineering Demand Parameter (EDP) parameter is the maximum inter-story drift ratio (IDR) while the peak ground acceleration (PGA) is used as Intensity Measure (IM). Four damage states: Slight, Moderate, Extensive and Complete, with corresponding EPD threshold of 0.4%, 0.8%, 1.5% and 3%, were defined. Threshold values result similar to those proposed for ductile RC moment frame structures by Ghobarah (2004) and were defined from non-linear static analysis. For the mid-rise and high-rise buildings, a reduction factor of respectively 2/3 and 1/2 as proposed by FEMA (2012) was considered to account for higher mode effects and differences between average computed in non-linear static analysis and maximum individual IDR from NLTHAs.

5 Results and Discussion

Structural response was evaluated with respect to the four damage states previously defined, varying from Slight to Complete. Fragility functions were computed for each of the 12 cases, resulting from different geometrical and material combinations, using the Cloud Method described in Section 3.1 (Figure 2). A comparison of the seismic performance of structures built with the reference concrete and EAF concrete is given in Figure 2 with the fragility curves and the reliability index in Figure 3.

It can be noted that the overall performance of EAF concrete structures is close to the performance of the reference material one. The 6- story model has shown almost the same response for all considered materials, proven by overlapping fragility curves, while the 3- and 9- story curves tend to vary more when considering different materials.

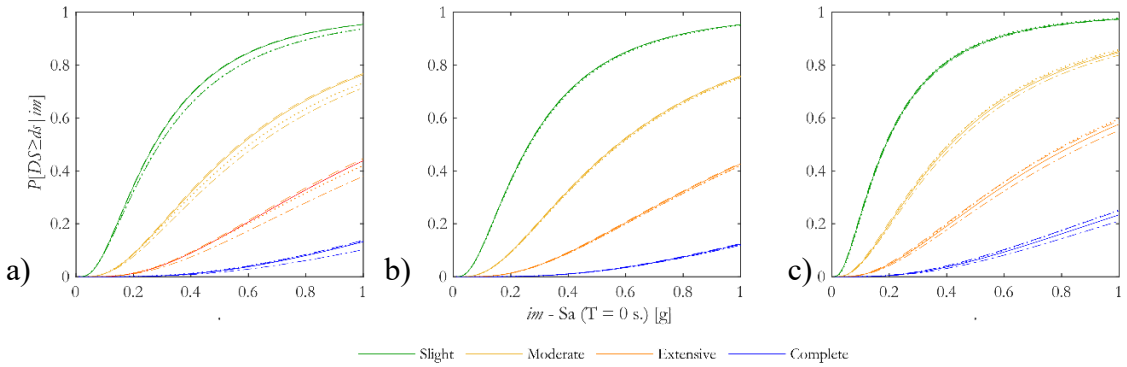

Figure 2. Slight, Moderate, Extensive and Complete DS fragility curves for 3- (a), 6- (b) and 9- (c) story RC frame archetypes (Solid - reference (C25/30); Dotted - EAF-C1; Dashed - EAF-C2; Dash-dot – EAF-A).

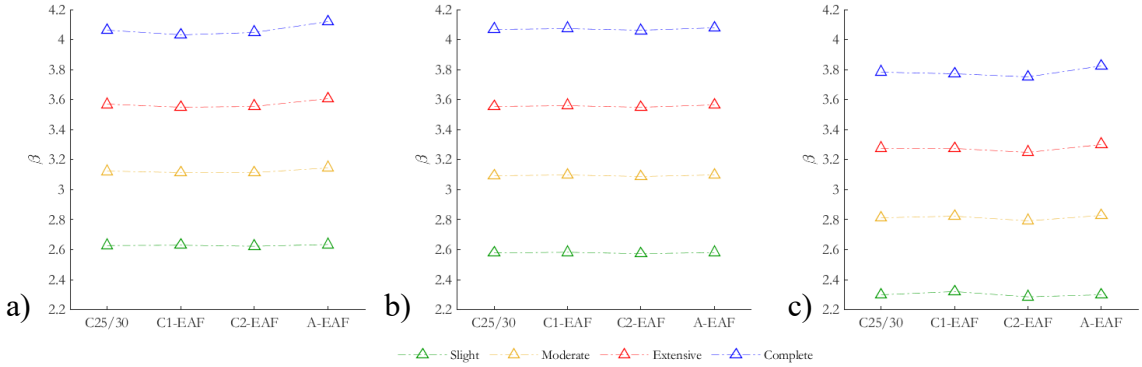

Figure 3. Reliability index for 3- (a), 6- (b) and 9- (c) story RC frame archetypes.

Mean failure rates and reliability indexes were also reported for all building frames (Table 3). When compared to the reference material, EAF concrete buildings report similar reliability indexes. This confirms that in terms of safety margins with respect to seismic actions, buildings designed with ordinary concrete but built with EAF aggregates are exposed to almost the same risk as those built with NAs ones.

This highlights that NAs replacement with EAF aggregates, in the same structural system, has a small impact in terms of seismic reliability levels achieved. The difference in the mean failure rate of the 9-story building and those of the 3- and 6-story ones may be due to the reduced damage states EDP threshold adopted for the 9- story by considering it a high-rise building. It also points out that current code recommendations do not guarantee building design characterized by the same level of seismic reliability but often some differences can be observed, especially when comparing different rise buildings.

Table 3. Comparison between mean failure rates and reliability indexes (β) derived for 3-, 6- and 9-story RC frame archetypes.

DS	Story	C25/30		C1-EAF		C2-EAF		A-EAF

6 Conclusions

The main goal of this paper was to investigate the effect of concrete mixtures with EAF slag in the seismic performance of different code conforming RC-frame structures (3-, 6- and 9-stories). The impact of EAG slag in mass and stiffness variation can lead to different seismic loads and global response of the building. A seismic reliability assessment was carried out and fragility functions, mean failure rates, and reliability indexes were computed for each combination of geometrical configuration and material. Based on the results of the present study the following conclusions can be highlighted:

- Using materials that were proved to have higher mechanical strength than the reference one, might not improve the global seismic behavior of the structure.
- When replacing NAs of ordinary concrete with EAF ones the seismic safety levels achieved are comparable to those of the same structural configuration built with ordinary concrete.
- For the low- and mid-rise buildings considered (3- and 6- stories) results showed similar reliability levels, while a more significant variation was observed for the high-rise case (9-story). This marks out how current building codes may not ensure the same seismic reliability level for all the designed structures.

Abstract. *In the last three decades the soft computing methods were used by the research community in almost every branch of construction, providing successful and convenient solutions for different problems in civil engineering. This paper presents some of the applications of these methods – especially neural networks (NN) and support vector machine (SVM) - in sustainable construction, i.e. its economic, social and environmental aspects. Soft computing applications were made in the last several years by our research team at the Faculty of Civil Engineering in Skopje, N. Macedonia, in collaboration with other authors from our and other countries. Several predictive models were developed using: general regression neural network (GRNN), support vector machine (SVM) and radial basis function neural network (RBF NN), using predictive modelling software DTREG. Applications of these models cover most of the aspects of sustainability in construction. Models were focused on predicting: road structure construction costs, bidding price in construction, sustainability assessment at early facilities design phase, predicting construction cost and construction time and predicting consumption of energy in buildings. Some of the mentioned developed predictive models are hybrid, composed of process-based and data driven models which contributed very much to the improvement of the accuracy of the predicting. The general conclusion is that the soft computing methods are a useful tool for developing models in the area of all aspects of sustainability and their application can lead to increasing sustainability in construction.*

Keywords: *Sustainable Construction, Soft Computing Methods, Predictive Modelling.*

1 Introduction

The construction industry creates conditions for the whole development of the country, but it can have some negative impact on the sustainability aspects: environmental, social or economic aspect. In that regard, balancing society's needs with environmental and economical demands, the construction industry should fulfil the present society needs, but with respect to its future needs (Chendo, 2013; Rafandadi *et al.,* 2014).

The implementation of sustainable construction procedures is a slow process, mostly due to the widely spread opinion that they are time, effort and cost more demanding than traditional ones (Dobson *et al.,* 2013). Hence, meeting the sustainable aims has become a construction project participants' challenge and researches' focus worldwide. They have researched different sustainable aspects using various of techniques and methods. Some of them are soft computing methods (SCMs). SCMs are noted as useful for developing models for different sustainable problems in construction (Polat *et al.,* 2014; Ahmad *et al.,* 2014; Arida *et al.,* 2016). Therefore, the aim of this paper is to present a brief review of the authors' research on several construction

sustainability issues by using SCMs. The models were focused on predicting: sustainability assessment, bidding price, construction time, construction cost and energy consumption of buildings.

Sustainability assessment: Facilities construction is globally noted as having large consequences on sustainability aspects. Thus, in spite of the existence of numerous obstacles, balancing sustainable issues and their incorporating in facilities construction and maintaining is a challenge for all participants in the construction projects (Aksorn and Charoenngam, 2015). Therefore, the early design phase is seen as a phase with high impact on facilities sustainability due to its providing drawings and specifications for the facility in accordance with the clients' wishes and needs (Crawford, 2013). Facility design which integrates the sustainability issues provides benefits for the project participants, the facility users and the whole society (Adeyeye *et al.,* 2013). But that is a complex process which puts designers under pressure. Therefore, construction project managers can support the inclusion of sustainability aspects in the facility's design which will lead to increasing the money value of the facility, while providing satisfied customers and construction of eco-friendly facility.

Bidding price: Construction companies usually acquire their work by winning a tender. Hence, choosing the bidding price that will win the tender is of particular interest for each construction company. But the decision what price to bid is a responsible, time and effort-consuming process which is influenced by a set of factors (Watt *et al.,* 2009). Therefore, having a model for predicting the price in order to win the bid is useful and it facilitates the decision making process.

Construction time and cost are elements that are included in each contract regarding facilities construction. Hence, they have influence on the contract signer's work and reaching the contracted time and cost is signer's challenge. That leads to a number of investigations regarding construction cost and time, such as: their prediction, their overrun, the time-cost relation, their influencing factors, etc. (Abu Hammad *et al.,* 2008).

Energy consumption of buildings has an impact, not only on the comfort, costs and other social and economic aspects of users, but also on the environmental aspect. In fact, buildings are among the biggest users of energy, thus prediction of their energy consumption is of particular interest. During the stage of selecting the optimal design of the new building or old building reconstruction/renovation, numerous measures/solutions can be used for reducing the building's energy consumption. Some of them are: system with heat pump from ground source (Michopoulos *et al.,* 2016); renewable energy systems usage and their combination or combination of systems for heating, power and cooling; system installation for energy management, etc. (Farhat *et al.,* 2014; Rasool *et al.,* 2015; Kialashaki, 2018). Thus, of particular interest is to have models for energy consumption forecasting.

2 Literature Review

Sustainability outcomes and environment protection are in a significant positive relation (Smith and Rootman, 2013), so for owners the sustainability has impact on their portfolio (Warren-Myers, 2012). Rafindadi *et al.,* (2014) stated that there is no significant difference among project stakeholders on sustainable projects risks, so for Babawale and Oyalowo (2011) the real estate valuers should have more knowledge about sustainability aspects of properties in order to effectively assess their value. For Dobson *et al.,* (2013) there is perception that capital costs

for sustainability are high, which can be an obstacle for the construction.

Bidding price in construction – There are different categories of bidding-price models, such as: models that are directed towards maximization of the expected; models based on systems for decision support; models based on artificial intelligence, etc. (Polat *et al.,* 2014). For example: a bidding model that uses generic software for probability estimating of the success is presented by Kitchenham *et al.,* (2005).

Construction time and cost relation and their overruns are researched worldwide. Zhang and Ng (2012) solved time-cost optimization problems using evolutionary-based optimization algorithm. Similarly, Afshar and Fathi (2009) used Fuzzy-sets theory for accounting the uncertainness in each activity direct cost, in order to determine the financing cost and required credit. They developed a model for searching the solutions that are non-dominated for the construction objectives: total time, financing cost and required credit.

Energy consumption of buildings is among issues that are highly researched, from different aspects and using different methods and techniques. Widely used are: traditional numerical methods, statistical methods and intelligent methods. Promised results were given by: Ekici and Aksoy (2009) using backpropagation ANN; Holcomb *et al.,* (2009) with support vector regression, ANN and multilinear regression; Ahmad *et al*., (2014) with support vector machine and ANN concluding that hybridization of these methods is suitable for more accurate prediction; Arida *et al.,* (2016) using ANN, particular non-linear auto-regression ANN; Amber *et al.,* (2017) using the Multiple Regression technique; Li *et al.,* (2017) using extreme deep learning approach, etc.

3 Methods

There are generally two types of methods for analysing data: traditional hard-computing and modern soft computing methods. The hard computing methods use an accurately stated analytical model of the process that should be modelled, while the soft computing methods do not need analytical model of the process. The soft computing methods have been developed as an alternative solution for solving the contemporary problems. The two most important constituents of soft computing are learning from experimental data (neural networks and support vector machine) and fuzzy logic methods, but in recent years there are also other: probabilistic reasoning, genetic algorithms, chaos theories, fractals (Kecman, 2001). There are many different types of NNs developed for solving different problems, some of them being: GRNN, RBF NN, polynomial NN, probabilistic NN, multilayer perceptron (MLP), cascade correlation NN. In our research we have used only the first two.

3.1 Data-Driven Soft Computing Methods

Soft computing methods try to transfer the human knowledge into mathematical, analytical models by finding methods for learning from experimental data.

NNs and SVMs are mathematical computing models that implement the idea of learning from experimental data, and FL systems implement structured human knowledge into effective computing algorithms (Kecman, 2001).

3.1.1 Artificial neural networks (ANNs)

NNs implement the functioning of the human neurons. The three most important aspects of the NNs are: implementation of biological neural networks, the concept of parallel distributing processing and the concept of learning and self-organizing (Haykin, 2005). NNs can approximate multivariable nonlinear functions, identifying the interactions between input and output data easily, minimizing some error function which expresses the difference between actual output values and the predicted values by the NN. In our research most often used NNs were: GRNN and RBF NN.

Radial basis function neural network (RBF NN) is a 3 layered feed forward network (Figure 1 (Sherrod, 2013b)). The values from the input neurons are fed to the neurons from the next hidden layer, which has mutable number of neurons determined by the algorithm for the training process. RBF NN can have one or several outputs, depending on the task which is solved; if it is used for forecasting then RBF NN has only one output, but if it is used for classification, then it may have several outputs, equal to the number of categories of the target variable.

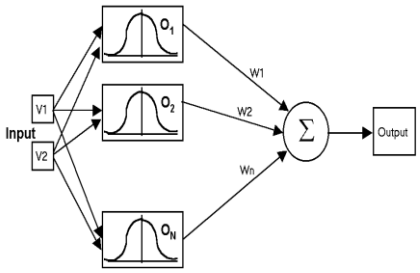

Figure 1. RBF NN architecture.

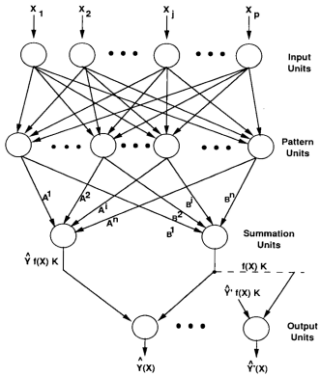

Figure 2. GRNN architecture.

General regression neural network (GRNN) is most often used NN in our research. This NN is in most of the cases very accurate and is used for forecasting, control problems, mapping (Specht, 1991). The most attractive characteristic of GRNN is its ability to converge to the optimal solution very quickly, requiring only several samples. GRNN has 4 layers (Figure 2) (Sherrod, 2013b).

3.1.2 Support vector machine (SVM)

SVM models have been developed to solve the contemporary problems that have appeared with the standard classical statistical modelling. SVMs can successfully work with standard contemporary multidimensional data sets and also with small training data sets (Kecman, 2001). SVMs have similar architecture as classical NNs. In fact, a two - layer feed forward NN is equivalent to a SVM model which uses sigmoid kernel function.

3.2 Bromilow Process-Based Model and Hybrid Modelling

The soft computing methods that were described above are *data-driven methods*, and they do not use any knowledge about the process which should be modelled in a form of some mathematical formula. *Process-based methods* describe the process by some mathematical formulae. The *hybrid modelling* is a relatively new field of investigation and very promising results have been reported.

The process-based model used in our research was the well-known Bromilow "time-cost" model which gives the relation between construction time and construction cost. This model is given by the equation (1):

$$T = aC^b \tag{1}$$

T is a construction time, C is a construction cost (price), *a* is a model parameter which expresses the average time needed for construction of a monetary value, and *b* is parameter which expresses the dependence of the time on cost change (Bromilow, 1969).

4 Results and Discussions

Using the methods described above, in the last several years predictive models applied for solving different problems in civil engineering have been developed by the research team from our country and also with collaboration with authors from other countries. The software used for developing the models was predictive modelling software DTREG (Sherrod, 2013a, 2013b). The developed models were applied for forecasting: sustainability assessment, bidding price, construction time, construction cost and energy consumption of buildings. Part of the available data for developing the models was used for training and part of them for validation of the model. The most used methods for validation were k-fold cross validation and random percent. The accuracy of the models has been estimated by the standard estimators: MAPE (mean absolute percentage error), and the coefficient of determination R^2 which measures the global fit of the model.

Sustainability assessment: 112 project managers from construction firms in R. Macedonia were participants in an anonymous survey, whose goal was to determine their opinion about the factors that mostly affect the sustainability assessment of the facilities' preliminary design. The questionnaire developed by the authors consisted of 72 questions, seen as factors that influence the sustainability of the facilities preliminary design. 27 of them were chosen as most representative for building the model. The participants were asked to answer the questions on a 6 point Likert scale (from 1 – unimportant, to 6 – extremely important). The questions were considered as predictors for the model. One of them was considered as target variable – the question: sustainability assessment of the preliminary design. GRNN from DTREG predictive modelling software was used for modelling. DTREG also computes the most important factors that impact the target variable, and the 6 most influential of them reported by DTREG were: 1) work experience, 2) work on several outline design proposals, 3) resolving issues between stakeholders, 4) prioritization of participants in the design phase, 5) procurement management and 6) defining project program and goals. The conclusion from this modelling is the finding that the project managers assessed the social aspects more influencing sustainability and economic and environmental issues less influential. The accuracy of the model was: MAPE= 2.6% and the coefficient of determination was R^2=0.84 (Zileska *et al*., 2017).

Bidding price: A model for forecasting bidding price was developed using SVM method for prediction. Data from 26 tenders were used for modelling out of 54 tenders that were collected from construction firms. Two variables were used as predictors (time for preparation and the price offered) and the target variable was price obtained. The accuracy of the model was with MAPE 2.5%, and $R^2 = 89.8\%$, (Petruseva *et al*., 2016).

Construction time: Several hybrid models were developed for predicting time of construction using Bromilow time-cost model (BTC model) as process-based model. One of them was hybrid, composed of BTC model and GRNN model and it was modelled with data for 116 different types of structures: road structures, petrol stations, bridges, education facilities, business buildings, and other. The data was about purpose of the structure, year of construction, region of location, contracted time and cost and also realized time and cost. Target variable was real time of construction, and as predictors were chosen: purpose of the structure, real and contracted cost and contracted time. The accuracy of the model was: MAPE=3.3% and $R^2 = 93.2\%$, using purpose of construction (as string variable), and contracted time, contracted cost and real cost of construction as predictors, and target variable was real time of construction. The input values of real and contracted time of construction and real and contracted cost of construction were not their actual values, but logarithm of their values, because of the application of the BTC model (eq. 1). This equation was applied for the relation of the real time and real cost of construction, and also for the contracted time and cost, and these two equations were logaritmized and summarized and the obtained equation was a relationship between their logarithmic values. We shall stress here the importance of the hybrid model which drastically improved the accuracy of the model, because without using BTC model as part of the hybrid model, the accuracy of the model was drastically decreased: MAPE = 31.8%, and R^2 =75,6% (Petruseva, Car-Pusic and Zileska, 2019).

Construction cost: One of the developed models for predicting construction cost was hybrid model, composed of RBF NN and BTC model with accuracy: MAPE = 0.64%, R^2=99.2%. The data were for 65 objects. Target variable was the real cost of construction, and predictors: contracted cost of construction and real and contracted time of construction, but here also as input values for these variables logarithms of their actual values were used because of the application of the BTC model. Without BTC model as part of the hybrid model, using only RBF NN, the accuracy of the model was: MAPE around 54% and R^2 around 44% (Zileska and Petruseva, 2017).

Energy consumption of buildings: The model developed for predicting building energy consumptions used data for real energy consumption for 55 residential buildings in R. Macedonia, constructed/reconstructed from 2013 to 2018. The accuracy of the model, using GRNN was: MAPE=3.12% and R^2=91.7%. The target variable was building energy consumption Q [kwh/m^2/year], and from all available data, 10 were chosen as most representative predictors, which were related to: 1) thermal transmittances (in W/m^2) of: walls, windows, floors, roofs, and also: 2) their corresponding geometries and areas (in m^2) – areas of the floors, walls and roofs (Zileska, Petruseva and Samardzioska, 2018).

5 Conclusions

Sustainability aspects are complex and inter-connected, so their researching and incorporating in construction is an effortful process. Furthermore, there are many sustainability influencing

factors, so it's useful to have prediction models for sustainable aspects. Recently, the most popular soft computing methods used for predictive modelling have been SVMs and NNs (GRNN, RBF NN, MLP, polynomial NN, cascade correlation NN, probabilistic NN). In the last several years we have developed several predictive models using mostly GRNN, SVM, RBF NN, and several hybrid models composed of data-driven and process-based model. The developed models gave a satisfied accuracy in prediction of: manager's assessment of the sustainability in early design phase for the facility, building energy usage, bidding price, construction time, construction cost, etc.

The models presented in this paper showed that the usage of SCMs facilitates the decision making process and leads to increasing the sustainability in construction.

Decision Support to Identification of Road Infrastructure Segments With Poor Conditions

Nikša Jajac

Faculty of Civil Engineering, Architecture and Geodesy, University of Split, Matice hrvatske 15, 21214 Split, Croatia, niksa.jajac@gradst.hr

Abstract. *Planning of maintenance activities (an integral approach) on ever growing system such as urban road infrastructure requires decision makers to take into account large number of different data and usually conflicted criteria, derived from several aspects of analysed problem. This systematic approach to planning is based on the main three steps: identification of alternatives, their validation and selection for inclusion into a maintenance plan. Most of authors are dealing with the last two steps however, focus of this research is on the first step. This step is a critical phase of planning because it is important to identify road infrastructure segments that need to be improved. Meaning, those with poor condition. The condition of a segment must be expressed as simple as possible (by unique Condition Assessment Value) and by usage of few but most relevant criteria (such as level of service, safety, time period passed form the last renovation and stability). Another important issue is provision of relevant, relatively quick and consistent expert assessment of segment condition according to above mentioned criteria and for large number of segment. To insure such assessment with high quality of segments identification this paper propose an decision support concept/expert system based on combination of trained and tested Artificial Neural Networks (ANN) and Simple Additive Weighting (SAW) method. The concept is validated on urban road infrastructure of city centre of Split, Croatia and it proved to be useful for determining a set of road infrastructure segments where maintenance activities should be undertaken.*

Keywords: *Decision Support Concept, Road Infrastructure Segments, Planning, Artificial Neural Networks.*

1 Introduction

In the field of urban road infrastructure systems, planning process of maintenance activities is highly complex and ill structured problem. This complexity is defined by several factors: lots of stakeholders with different opinions, huge amount of information quantities, multidisciplinary character of the problem, conflicts among goals and criteria, budget restrictions, etc. These factors indicate that the decision-making to maintaining activities of the road infrastructure planning are burdened with complex and socially sensitive problems, especially for the long-term planning. For that reason, long-term planning tasks should be supported by decision making tools such are multicriteria methods that can contribute to a more efficient realization of the tasks. In order to manage such complexity, a decision support approach is proposed, aimed at improving decision making to planning of maintain activates at the road infrastructure system. This concept represents a multicriteria decision-making approach, and is based on multicriteria analysis. Three main steps are crucial for a realization of planning: identification of alternatives, their validation and selection for inclusion into a maintenance plan. In this research, focus is given to the first step where road infrastructure

segments are identified and need to be improved because of their poor condition. These conditions are express by Condition Assessment Value (CAV), using few the most relevant criteria (such as level of service, safety and time period passed form the last renovation, etc.).

Expert assessment of segments conditions according to defined criteria are given and to achieve the most precise assessment this paper propose an decision support concept and expert system based on combination of trained and tested Artificial Neural Networks (ANN) and Simple Additive Weighting (SAW) method. There are many studies dealing with possibilities of generating decision support tools for maintaining road infrastructure segments. Zavdskas, Liias and Turskis (2008) gave a review of international and national practices in investment decision support tools in bridges and road quality management. He, Song and Chaudhry (2013) in their paper, explored the integration problem of service-oriented system and intelligence technology through the use of a group decision support system, applied on transportation management. Petty and Mahoney (2008) gave enhancements and refinements associated with winter maintenance decisions that the United States Federal Highway Administration initiated in a project aimed at developing a winter road Maintenance Decision Support System (MDSS).

The goals of the MDSS project were to construct a functional prototype MDSS that can provide objective guidance to winter road maintenance decision makers concerning the appropriate treatment strategies These strategies are used to control roadway snow and ice during adverse winter weather events, and develop a prototype that will also serve as a catalyst for additional research and development by the private sector. Dunkel *et al*. (2011) proposed a reference architecture for event-driven traffic management systems, which enables the analysis and processing of complex event streams in real-time and is therefore well-suited for decision support in sensor-based traffic control systems. Zhou et al. (2010) presented a research effort undertaken to explore the applicability of data mining and knowledge discovery (DMKD) in combination with Geographic Information System (GIS) technology to pavement management to better decide maintenance strategies, set rehabilitation priorities, and make investment decisions. Bielli (1992) presented a decision support system to urban-traffic management to achieve maximum efficiency and productivity for the entire urban-traffic system, including the urban road infrastructure. Guisseppi and Forgione (2002) and Jajac, Knezić and Marović (2009) in their papers gave a cost and benefit aspect of potential infrastructure investments, showing that several decision-support models can be generated. Quintero, Konaré and Pierre (2005) described an improved decision support system named Intelligent Decision Support System that coordinates management of several urban infrastructure systems, such as the sewage and waterworks. Proposed Intelligent Decision Support System was a solution for the future urban infrastructure management. Similar approaches were given by Pomerol, Roy and Rosenthal-Sabroux (1996), Turban and Aronson (1995) and Leclerc *et al.* (2001). Sayers, Jessop and Hills (2003) used SAW method (Hwang and Yoon, 1981) to present a multicriteria evaluation of transport infrastructure for ranking transport investments. These investments aim was to improve infrastructure in small towns, analysing three solutions: minimum interventions on the existing network, upgrading the existing route, and building a bypass. A simplified transport project ranking methodology with an integrated multicriteria decision making process that prioritizes transport projects in cases when multiple stakeholders present various different opinions was given by Shelton and Medina (2010) and Jajac, Marovic and Baucic (2014). Jajac (2010) made a research on the development and maintenance of urban road infrastructure by implementing and using multicriteria analysis and ANN at strategic, tactical and operating

decision making levels, in urban areas. To improve a decision making process in such complex circumstances, it is important to develop new tools aimed at raising the level of transparency and objectivity in the solution-selection process (Jajac, 2010). This research is focused on decision support concept to maintenance activities panning of improving road infrastructure segments in urban areas. It is based on the multicriteria methods AHP and SAW, and expert systems, using ANN, to support project management. The concept is validated on the urban road infrastructure of the city centre of Split, Croatia, and proved to be useful for determining a set of road infrastructure segments where maintenance activities should be undertaken.

2 Decision Support to Improve Maintenance Planning of Road Infrastructure Segments

Using architecture of the DSS for urban-infrastructure management (Jajac, 2010), a decision support to planning of maintenance activates improvement of road infrastructure segments is developed. The model for improving urban road infrastructure segments maintenance planning is proposed in Figure 1. The process of decision-making starts at the strategic and tactical levels, where with the case study is determined and stakeholders are selected. The main characteristics of each segment of infrastructure are collected and stored in database, they are accessible for entering periodically new inputs at the operational level during the continuous maintenance process. These main characteristics of segments are important for defining criteria and their weights. Firstly, stakeholder are selected and gathered together through subjective assessment of their influence and legitimacy. They are divided into three groups:

Local government - deputy mayor who is responsible for utility affairs, and principals of several administrative offices (*e.g.* Office for Strategic Planning and Development, Office for Finance, Office for Physical Planning, etc.);

Experts - civil engineering, transport engineering, environmental, and economics experts of both academic and practical backgrounds;

Users - the representatives of city districts or similar city formations.

After the identification of stakeholders, goals, criteria, and weighting factors are defined. The goal analysis is given in the form of hierarchical structure of goals and criteria. The criteria are defined by local government and experts group, while criteria weights are determined by all stakeholder groups. Using the AHP method (Saaty, 1982) and interviewing all stakeholders, weights can easily be assigned through a group decision-making process. The decision-making process of each stakeholder group must be repeated until consistency of each group' criteria weights determination is achieved. Furthermore, having determined the hierarchy of goals and stakeholder groups, three scenarios are developed, while the final (fourth) scenario is determined as the compromise opinion of all groups. Values of the compromise opinion are introduced as weights for the SAW method, which is used to set priority of selected road segments according to their improvement requirements. After the goal hierarchy is defined, all segments are analyzed, and those with conditions that need to be improved are identified using ANN. This way the condition assessment for all segments is provided within the study area. Only those segments with the condition assessed as poor, unsuitable and worn-out are selected for further analysis and priority-setting. Moreover, the segments are then ranked according to defined criteria. The local-government representatives, as strategic decision-makers, assisted to the group of experts in selecting the most convenient solution based on the present policies and

multicriteria analysis. The selected solution establishes a strategic plan of the road infrastructure segments conditions improvement. The proposed concept was tested on the road infrastructure segments maintenance planning in the city of Split, Croatia.

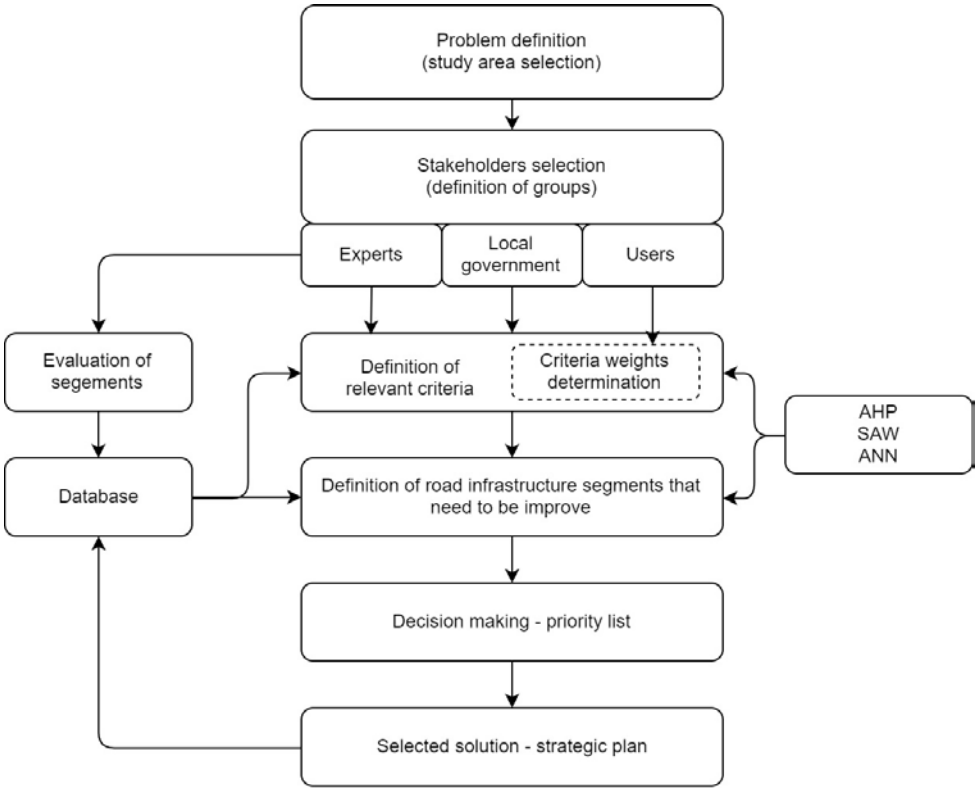

Figure 1. Decision support to road infrastructure segments improvement.

3 Road Infrastructure Segments Improvement Planning

The city of Split is taken as a study area. It has a high concentration of public facilities and pedestrian flows. There were 236 identified infrastructure segments, divided into 10 types: street, street section, crossroad, garage, parking, bus station, bus terminal, petrol station, overpass and tunnel. To evaluate each of the elements 13 criteria are defined. Each group of stakeholders defined criteria in their field of expertise. These criteria are grouped in social, technical, economic and ecologic group, as is shown in Table 1. Three scenarios are created, one for each stakeholders' groups and each for each scenario criteria weights are determined using AHP method. Compromise scenario is calculated as average value of each criterion weight by each scenario. Using compromise scenario, opinions of all three groups are equally taken into account.

Table 1. Criteria definition with weights and scenarios.

Group of criteria	Criteria name	Criteria label	Scenario 1	Scenario 2	Scenario 3	Compromise scenario
Social	Population density	C1	0.05	0.03	0.06	0.05
	Density of business facilities	C2	0.06	0.04	0.04	0.05
	Area of business facilities	C3	0.04	0.01	0.02	0.03
	Density of public facilities	C4	0.03	0.02	0.05	0.03
Technical	Constructability	C5	0.06	0.09	0.08	0.08
	Fitting into plans	C6	0.09	0.08	0.09	0.09
	Maintenance-segment improvement	C7	0.10	0.12	0.08	0.10
	Functionality improvement	C8	0.09	0.12	0.08	0.09
Economic	The amount of investment	C9	0.08	0.10	0.11	0.10
	The ability of land buying	C10	0.09	0.09	0.11	0.10
	The existence of investor	C11	0.09	0.09	0.10	0.09
Ecologic	The amount of noise	C12	0.10	0.11	0.08	0.10
	The amount of combustion gasses	C13	0.11	0.11	0.10	0.10

Criterion C7 (Maintenance – segment improvement) is divided into four subcriteria: level of service, safety, time period passed form the last renovation and stability. Using these four subcriteria and methodology of ANN, the unique Condition Assessment Value (CAV) is obtained. This value also presents an assessment of condition of segment.

4 Results

Using methodology of ANN, road-infrastructure segments in poor conditions are identified, by including four input variables and only one output variable. The four input variables are four criteria defined in previous section: level of service, safety, time period passed form the last renovation and stability. This ANN is trained by the back-propagation algorithm using the training set consisting of 200 cases, each case with four input variables (collected during the monitoring cycle), and 200 output variables, provided by experts' assessment. The output variable is CAV. Input values for 236 segments are collected during the second monitoring

cycle. Applying ANN methodology, conditions of segments are obtained. However, only segments assessed as inadequate and poor were selected for further analysis. If the CAV is less then 1, condition is classified as bad (0-worst condition, 1-the best condition). Segments with CAV values are shown in Table 2. There are 18 segments with poor condition, and the best one is segment Sg13 (crossroad), while the worst is Sg8 (street section).

Table 2. Road infrastructure segments with poor condition.

Infrastructure segment	Label of segment	CAV
Street section (Pojišanska1)	Sg1	0.458
Street section (Pojišanska 2)	Sg2	0.634
Crossroad (Pojišanska i Zvonimirova)	Sg3	0.556
Street (Put Stinica)	Sg4	0.543
Street section (Sukoišanska)	Sg5	0.687
Crossroad (Meštrovićeva, Sustipanskog P. and Ulica Dražanac)	Sg6	0.731
Crossroad (Spinčićeva, Zajčeva and Put Firula)	Sg7	0.476
Street section (Ulica slobode)	Sg8	0.437
Garage (Varoš 4)	Sg9	0.489
Crossroad (Hercegovačka, Put suplava and Put stinica)	Sg10	0.685
Crossroad (Sukoišanska and Starčevićeva)	Sg11	0.577
Street section (Domovinskog rata)	Sg12	0.496
Crossroad (Kavanjinova, Manđerova)	Sg13	0.832
Garage (Spinut North 4)	Sg14	0.747
Bus station (Pojišanska 2)	Sg15	0.659
Garage (Lovret North 1)	Sg16	0.671
Crossroad (Mažuranićevo Š., Dom. rata and Gundulićeva)	Sg17	0.681
Crossroad (Vukovarska, Bihaćka, Zagrebačka and Dom. rata)	Sg18	0.729

Table 3 shows the ranking of the infrastructure segments. Criteria weights values are calculate from the compromise scenario. These weight values are then used in the SAW method. Segments are evaluated by experts. Evaluations are normalized and transformed, and then SAW is included in further process. All of 13 criteria are used for evaluation of 18 infrastructure segments. Table 3 shows the ranking of 18 segments. The segment evaluation with higher score value means that the segment is considered as prior to improvement. In this case segment Sg10 (76.87) has the highest value, while the Sg8 (25.88) has the lowest.

Table 3. Ranking of segments.

Segment label	Score	Rank position	Segment label	Score	Rank position
Sg1	70.32	7.	Sg10	76.87	1.
Sg2	72.75	4.	Sg11	54.12	11.
Sg3	71.58	6.	Sg12	49.16	14.
Sg4	44.35	15.	Sg13	38.67	17.
Sg5	73.28	3.	Sg14	66.57	8.
Sg6	58.21	10.	Sg15	53.41	12.
Sg7	40.13	16.	Sg16	63.18	9.
Sg8	25.88	18.	Sg17	72.45	5.
Sg9	73.31	2.	Sg18	49.82	13.

With proposed model of decision support, ranking list for the priority of improvement of infrastructure segments is obtained as is shown in Table 3. Then local-government representatives selected the most appropriate solution, according to the results of the ranking and present policies. The selected solution must be in consent with financials available in the budget of city of Split. Finally, eight top-ranked segments are included in the maintenance plan, in the next investment period.

5 Conclusions

- In this paper an approach of decision support for the road infrastructure segments maintenance planning is proposed. With this approach, support to final decision maker, in this case to local government of city of Split, can be very useful and practical, especially in making decisions for the compound and ill-structured problem such is maintenance planning of the road infrastructure segments. One of the main characteristics of the approach is analysis of required data and selection of appropriate methods.
- The proposed approach is used for obtaining the priority ranking of the infrastructure segments. Relevant stakeholders are identified and gathered together to determined criteria that are used for segments evaluation. Stakeholders were divided into three groups: local government, experts, and users, and were directly involved in the decision-making process, expressing their opinions through criteria weights, using AHP and SAW method.
- This approach is a combination of multicriteria analysis and ANN. Monitoring the infrastructure segments using relevant criteria such are level of service, safety, time period passed form the last renovation and stability, data were collected that were further introduced into the ANN methodology. This way, condition evaluations of infrastructure segments are obtained as values of CAV. Involving ANN methodology as a knowledge-based system, substitution of experts can be achieved.
- The presented approach of decision support is an adequate tool for decision makers in the field of the improvement of maintenance planning of road-infrastructure segments.

Abstract. *Construction project costs often reach values higher than planned. Accuracy in project cost estimation is one of the most important criteria for project success, even for its sustainability.*
The main idea of this research is to examine the relationship between realized cost and contracted cost values for residential buildings. The aim of the research is to determine the mathematical relationship between realized and planned costs in the project implementation phase by using a few mathematical methods and some machine learning methods in comparison to linear regression. This would enable validation of methods themselves by comparing and evaluating the obtained relevant parameters. Comparison would be performed on two levels, based on its general characteristics, as well as on the results of their application on the basis of 24 building reconstructions and new buildings by comparing the mean absolute percentage error (MAPE) and the determination coefficient (R^2) using Predictive Modelling Software DTREG (pronounced D-T-Reg). The relationship of realized and planned costs will be determined for the building as a whole and for certain types of construction works. That relationship would enable more realistic budget planning of similar future projects. Cost overrun factors will be analysed for particular types of construction works, as well as the probability of their occurrence, and what measures should be undertaken to prevent or reduce them in similar future projects. The phenomenon known in project planning as "optimism bias" will be analysed in the context of research focus of exceeding the construction cost.

Keywords: *Building Construction, Contracted Cost, Realized Cost, Predictive Modelling Software, Machine Learning.*

1 Introduction

In the construction practice, the contracted construction cost overrun is a very common occurrence, which is a very frequent and undesired situation. The goal is to avoid or minimize cost overruns, which can be achieved by accurately estimating costs during project preparation, before signing a construction contract. This can be achieved by using scientifically based models obtained by applying adequate mathematical methods and by browsing the finished projects database. In contrast, experience shows that costs are usually calculated by method of unit price calculations and calculated quantities, but also estimated on a flat-rate basis, on the basis of experience, that is, without adequate scientifically or experientially based budgets. This often happens under deadline pressure as the cost information must be provided so that further project activities can continue. Thus, inherent uncertainties and risks, which are characteristic for all construction projects to a greater or lesser extent, are neglected, resulting in possible generation of higher costs of those estimated in the project.

Project cost estimation is a complex and challenging task, as evidenced by the cost overruns of numerous projects all over the world (Flyvbjerg *et al.*, 2002, Le-Hoai *et al.*, 2008; Žujo, 2008, Le-Hoai and Lee, 2009, Car-Pušić and Radujković, 2009; Žujo *et al*., 2010,). Scientific knowledge (Nikić, 1998, Radujković, 1999, Flyvbjerg *et al.*, 2002, Žujo, 2008; Le-Hoai *et.al.*, 2008, Žujo *et al.,* 2010; Car-Pušić and Radujković, 2009; Alshamrani, 2017, Petrusheva *et al.,* 2017, Juszczyk *et al.*, 2018) and experience show that the successful cost estimation requires:

1. Monitoring and registering data on constructed structures
2. Sufficient information about the new project
3. Application of multiple assessment methods and selection of the most accurate one.

Due to the diversity of projects, numerous risks involved and the complexity of cost estimation, researchers have often addressed this problem and developed a number of linear regression models to analyze costs depending on different variables, e.g. construction time (Žujo *et al.*, 2010) structure type, building area, number of floors, floor height (Alshamrani, 2017), geotechnical and construction variables (Petroutsatou *et al.*, 2006). Linear regression models using construction time, which is the most common independent variable, as a predictor (Žujo *et al.*, 2010) could be considered an inverse problem compared to the well-known "time-cost" ("TC") model used in the 1960s and founded by Bromilow (1969). Although this approach may be tempered by over-simplification because only one predictor is considered, numerous further studies have been conducted, which resulted in establishing of country-specific models, because the specific economic circumstances determine the parameters (Chan and Kumaraswamy, 1999; A.P.C. Chan, 1999; Car-Pušić, 2004). In some studies, this model has been used as the basis for the development of hybrid cost estimation models, which combine regression and neural networks (Petrusheva *et al*., 2017; Petrusheva *et al.*, 2019).

The application of artificial neural networks for cost estimation with one independent variable, the construction time, has been researched by some authors (Petrusheva *et al.,* 2017, Juszczyk *et al.*, 2018; Tijanić and Car-Pušić, 2019; Tijanić *et al*., 2019).

This research analyzes construction projects of building construction structures in a manner deviation from the usual one (Mlađen, 2017). The relationship between the realized and contracted costs is investigated. As these costs most often vary, the previous thesis is confirmed stating that often flat-rate and superficial assessment without applying scientifically proven methods and without considering the possible risks are employed. The difference in costs, expressed relatively, is known in the literature as "optimism bias". Available data are data on contracted and realized cost values and data on years of construction/reconstruction (Mlađen, 2017). Different methods seek to obtain the most accurate estimation model for this type of structure. Since these are the projects implemented in the territory of the Republic of Croatia in the County of Istria, the model is best applied for future projects in the area. This methodology can be applied to any type of facility and area. The cost difference obtained in this way can be considered a risk response measure.

2 The Main Research Goals

The main research goal is to define relation between the real and the contracted investment cost in building construction applying mathematical methods – linear regression and artificial neural

networks. The goal is to identify the model that provides the most accurate cost estimate and implementation guidelines.

3 Methodology

The set research hypothesis will be tested by applying linear regression and neural networks on data on constructed or reconstructed structures and by comparing the model accuracy.
The conditions of application for the most accurate cost estimation model will be analyzed.

3.1 Research Hypothesys

The value of construction works in building construction (reconstructions and new constructions) is not contracted in real terms, but usually below real values. The contracted value of works is the total value of works from the accepted best offer, which is usually obtained by method of unit price calculations and calculated quantities. The thesis is that the real value of the works most often exceeds the contracted value. There is a dependence between these values, which can be mathematically determined with satisfactory accuracy.

4 Research Methods, Data Base and Data Processing

Using the documentation review and analysis, data on contracted and realized prices of public and private building construction structures (new construction, reconstruction and rehabilitation), 24 in total, built on the territory of the County of Istria in the Republic of Croatia were obtained. (Mlađen, 2017).The investments were realized in the period from 2006 to 2017. The average overrun of the realized project values is 12.15%. The minimum overrun is 1.61% and the maximum is 41.49%. The standard deviation is 11.87%.

Predictive Modelling Software DTREG is used for data processing and modelling, which supports a wide range of models (regression models, decision trees for regression, neural networks, support vector machine, etc.). The database must be an ASCII file in Comma Separated Value (CSV) format with values for one case per row and one column for each variable. One of the variables is the target variable, while one or more other variables are predictors. DTREG analyzes the data and generates a model that gives the best estimate of the target variable based on the available predictor values. The software allows you to select model parameters from the multiple options offered. Moreover, the iteration offers the expected optimal parameters (Sherrod, 2014). In this research, the target variable is the value of the real construction cost C_R, and the predictor is the value of the expected, planned and contracted construction costs.

Considering the research goals and scientific hypothesis, the following methodological procedure is applied:

1. Application of linear regression
2. Application of neural networks and Support Vector Machine (SVM) model
3. Comparison of results for the validation data, discussion, application proposal.

4.1 Linear Regression

First, the simple regression analysis method was applied as a common and simple, well-understood, widely used method (Sherrod, 2014), and the adequacy and accuracy of the model

obtained was determined by appropriate indicators. The general form of the applied regression function is:

$$y = \beta_0 + \beta_1 x \tag{1}$$

4.1.1 Output generated for linear regression

The following parameters were obtained using simple regression analysis using DTREG software:

Table 1. Results for linear regression.

Variable	Coefficient	Std. Error	t	Prob.(t)
C_C	1.128	0.0137	82.22	<0.00001
Constant	14.877,5	1.532e+004	0.97	0.34209

The regression function is:

$$C_R = 1{,}128 C_C + 14877{,}5 \tag{2}$$

The t Statistic value is 82.22 with a probability <0.00001. The coefficient R^2 as a proportion of variance explained by the model is 0.98849 (98.849%). The correlation coefficient R between actual and predicted values is 0.99684 (99.684%). Mean Absolute Percentage Error (MAPE) is 13.824% for validation data.

4.2 Neural Networks and SVM Model

In an attempt to obtain a more accurate cost estimation model, i.e. a lower value of the MAPE parameter, the next step includes the application of General Regression Neural Network (GRNN), Radial Basis Function (RBF) and Support Vector Machine (SVM). These models were selected because they are suitable for continuous variables and for smaller databases. The Multilayer Perceptron (MLP) network has proven to be inappropriate due to too little data was excluded from further consideration.

4.2.1 Output generated for GRNN, SVM, RBF

For all models, the expected optimal initial parameters provided by the software were used.

For GRNN, the Gaussian kernel function was applied, σ values were calculated for each predictor variable (min σ 0,0001 and max σ 10, with 20 search steps) and Leave One Out (LOO) validation method of evaluating σ values during the optimization process was used. Each training model is built with all training rows except one and then, the error was evaluated. This was repeated for all rows, and the error was averaged (Sherrod, 2014).

The model has been reduced to 7 neurons when the minimum error occurred. Despite the small number of retained neurons, the reduction of neurons should be performed because it significantly contributes to the accuracy of the model. In this case, the MAPE was reduced from 75.488% to 35.130%. The coefficients R^2 and R are shown in Table 2.

The initially defined type of SVM model Epsilon-SVR model was used for the SVM. Another possible option is the V-SVR model. The differences that may arise are small and the other model has not been applied. Radial Basis Function (RBF) has been implemented as the kernel function, which in most cases produces the best results. Kernel function transforms the

input data into an n-dimensional space where a hyperplane can be constructed to partition the data (Sherrod, 2014). The optimal approximation linear function will be obtained in the new space (Petrusheva *et al.,* 2017).

Using the RBF, the SVM model generates the RBF network architecture. The difference is in the number and position of nodes. At SVM, their position is on the support vectors (Sherrod, 2014). 24 support vectors are used by the model.

Model validation is performed by Cross validation method with 10 cross-validation folds. At SVM, low values were obtained for R and R^2 as well as for MAPE 14.814% (Table 2).

After three iterations, the three-neuron RBF network gave the best result of 10.976% for MAPE, but lower values of R^2 and R (Table 2). The Cross validation method with 10 cross-validation folds was also applied as the validation method.

Table 2. Results for linear regression and neural networks for source data.

Parameter	LR	GRNN	SVM	RBF
R^2	0.988	0.605	0.345	0.556
R	0.997	0.919	0.644	0.796
MAPE /%/	13.824	35.130	14.814	10.976

4.3 Application of Input Variable Natural Algorithms

Following the time-cost model, the following model is assumed:

$$C_R = E \times C_C^F \tag{3}$$

$C_R =$ realized price
$C_C =$ contracted price
$E =$ model parameter that shows the average real price for monetary value construction
$F =$ model parameter that shows real cost dependence of contracted cost changes

The model can be expressed as a logarithm to obtain the following form:

$$lnC_R = lnE + FlnC_C \tag{4}$$

It means:

$$\left.\begin{array}{rcl} lnE & = & \beta_0 \\ E & = & e^{\beta_0} \end{array}\right\} \tag{5}$$

$$F = \beta_1 \tag{6}$$

4.3.1 Output generated for linear regression for logharitmized data

The natural logarithms of C_C predictors and the target variables C_R were calculated. Applying regression analysis on natural logarithms using DTREG software, the following parameters were obtained:

Table 3. Results for linear regression.

Variable	Coefficient β_1	Std. Error	t	Prob.(t)
lnC_C	1.03367	0.0165	62.64	<0.00001
Constant β_0	0.0700096	0.02752	2.54	0.01849

Using the information in the previous table (Table 3), the regression function reads:

$$lnC_R = 0{,}07 + 1{,}03367 lnC_C \tag{7}$$

$$lnE = 0{,}07$$

$$E = 1{,}07$$

$$F = 1{,}03367$$

The model which is obtained is:

$$C_R = 1{,}07 \cdot C_C^{1{,}03367} \tag{8}$$

The value of t Statistic is 62.64 with a probability of p (t) <0.00001. The values of R^2 and R are 0.993 and 0.997 respectively. These values confirm the regression dependence. The MAPE is 11.816%. (Table 4).

4.3.2 Output generated for GRNN, SVM, RBF for logharitmized data

The Gaussian kernel function was applied for GRNN, σ values were calculated for each predictor variable (min σ 0.0001 and max σ 10, with 20 search steps) and Leave one out (LOO) validation method was used. The model has been reduced to 18 neurons when the minimum error occurred. In this case, the MAPE is 12.291%. The coefficients R^2 and R are shown in Table 4.

After four iterations, the three-neuron RBF network earns the MAPE value of 23.810%, and the R^2 and R values shown in Table 4. As a validation method, the Cross validation method with 10 cross-validation folds was also applied.

The initially defined Epsilon-SVR model was used for the SVM. Radial Basis Function (RBF) was applied as the kernel function. 24 support vectors are used by the model. Model validation was performed by Cross validation method with 10 cross-validation folds.

Table 4. Results for linear regression and neural networks for logharitmized data.

Parameter	LR	GRNN	SVM	RBF
R^2	0.993	0.962	0.995	0.693
R	0.997	0.985	0.997	0.839
MAPE /%/	11.816	12.291	6.469	23.810

MAPE is 6.469 %, R^2 and R values are 0.995 and 0.997 respectively. By applying the SVM model to logarithmic values, the lowest model error value is obtained.

5 Discussion of Results

By applying the linear regression model to the original data, a MAPE of 13.824% was obtained. In order to obtain a more accurate cost estimation model, the neural network models GRNN and RBF and the SVM model were applied. RBF gives a more favorable MAPE of 10.976%.

By applying the linear regression and RBF, GRNN and SVM to the natural logarithms of the input data (following the Bromilow "time-cost" model), (Bromilow, 1969) the lowest MAPE was obtained using SVM. The MAPE is 6.469%. Compared to the lowest MAPE obtained by processing the original data, this one is lower by 4.507%.

6 Conclusions

- The real costs of new constructions and reconstructions of structures in building construction field often exceed contracted values. The accepted tender price, obtained from the bill of quantities and unit prices (C_C) is taken as the contracted price. The aim of the research was to obtain a model that accurately defines the functional dependence of the real price C_R and the planned price C_C. Thus obtained real price should be taken as the contract price. This would reduce the risk of the contract price being exceeded. Although the database consists of a relatively small amount of data, the possibility of applying linear regression models, neural networks and SVM models to estimate the real cost of construction and reconstruction of high-rise buildings is presented. These models were applied to the original values C_R and C_C as well as to the values of natural logarithms. Namely, following the Bromilow "time-cost" model, the model $C_R = E \times C_C^F$ was established and tested. By expressing it in logarithms, the linear regression function is obtained.
- By applying linear regression and neural networks to the values of the natural logarithms of the variables, it was found that more accurate results can be obtained compared to models with original data. The best results, i.e. the lowest MAPE of 6.469%, are obtained by the SVM model applied to natural logarithm values of the predictor and the target variable.
- Despite the small database, the obtained insight could be relevant to solving the real cost prediction problem when working with larger databases. The results should also be investigated for civil engineering databases.

Possible Applications of Neural Networks in Managing Urban Road Networks

Ivan Marović[1]

[1] Faculty of Civil Engineering, University of Rijeka, Radmile Matejčić 3, HR-51000 Rijeka, Croatia, ivan.marovic@uniri.hr

Abstract. *Life-cycle management of urban road networks as a part of an urban system is a very complex process from the management standpoint of social, technical and economic aspects. The complexity and multidisciplinarity of such a problem suggest the need for using soft computing tools as well as multi-criteria analysis and group decision-making. Recently, there is a significant increase in using various soft computing tools, especially neural networks, for different prediction purposes in the field of road construction planning and management. Along with known advantages of such a prediction method, yet some applications showed the shortcomings. In that sense, the focus of this research is on possible applications of neural networks related to the life-cycle phases during the management of urban road projects. This is done in both horizontal (projects' life-cycle phases) and vertical (hierarchical decision-making levels) approach. The final aim of the research is to compare and highlight the possible applications of neural networks as a prediction tool and support for decision-making in urban road management.*

Keywords: *Decision Support, Neural Networks, Project Management, Strategic Planning.*

1 Introduction

Urban development and management especially the management of urban road networks, as a part of the urban infrastructure system, is a highly complex process from the management standpoint of social, technical and economic aspects. The development of urban road infrastructure is an integral part of any urban expansion processes and often considered as a dominant transport asset. The World Road Association (2014) reported that the average length of public roads in OECD countries is more than 500,000 km with a strong tendency of increasing, and is often the largest publicly owned national asset. Therefore, in urban areas where road infrastructure covers over 20% of the whole city area (Deluka-Tibljaš *et al.*, 2013) it's quality and strategic development directly influence the citizens' quality of life (Hanak *et al.*, 2014). Developing management practices that effectively integrate the processes of urban infrastructure management is a challenging goal that many cities are struggling with nowadays, but is an important necessity to achieve desired long-term sustainability.

Public management of urban road networks is a highly complex and socially sensitive as the city governments encounter different problems during the decision-making phase when it is necessary to find a solution that would meet the requirements of all stakeholders. All solutions must be strategically aligned and be a part of the desired development concept. Initially, the different views are provided by stakeholders and experts regarding the scope, scale, and potential solutions. Such happens during the whole life-cycle of the urban road network as each municipality has a certain annual budget for its construction, maintenance, and remedial activities. Therefore, planning activities altogether with project prioritization emerges as one of

the most important and most difficult issues to be resolved.

The evaluation of such investments requires explicit consideration of multiple, conflicting and incommensurate criteria that have an important social, economic, and environmental influence on various stakeholders in different ways (Jajac et *al.*, 2015). The complexity and multidisciplinarity of such a problem suggest the need for using soft computing tools, such as artificial neural networks (ANN), as well as multi-criteria analysis and various decision-making methods. The use of ANNs in solving pavement engineering problems and road management has a long history as well. Since the 1990s, ANNs have been frequently used for solving various complex problems, mostly for operational purposes, such as automatic pavement evaluation (Kaseko and Ritchie, 1993), pavement performance prediction (Banan and Hjelmstad, 1996), rutting (Simpson *et al.*, 1995), and maintenance (Fwa and Chan, 1993). A very few stressed out the importance and possibilities of their application in decision-making processes as a part of a decision support system *i.e.* DSS (Turban, 1993; Turban and Aronson, 1995).

In the 2000s, researchers followed the scientific contribution from previous decade and enhance the efficacy of ANNs in assisting asphalt mixture design and evaluation (Sundin and Braban-Ledoux, 2002; Yang *et al.*, 2003; Tarefder *et al.*, 2005; Ceylan *et al.*, 2007; Terzi, 2007; Commuri and Zaman, 2008; Ozsahin and Oruc, 2008; Tapkin *et al.*, 2009; Tušar and Novič, 2009). All these aspects were evolved to efficiently solve technical problems that occur on the operational management levels. A very few gave another insight of ANNs to be used on higher management levels such as tactical and strategic. Researches such as Loia *et al.* (2000), Quintero *et al.* (2005), Šelih *et al.* (2008), and Jajac *et al.* (2009) can be highlighted as the one where ANNs were used for solving problems on both tactical and strategic management levels based upon Turban's DSS concept. Such approach bloomed in 2010s when more and more researchers very efficiently applied ANNs for solving structured problems that occur on operational level (Gesoglu *et al.*, 2010; Xiao *et al.*, 2010; Ozgan, 2011; Ciresan *et al.*, 2012; Singh *et al.*, 2013; Ozturk and Kutay, 2014; Zavratnik *et al.*, 2016; Androjić and Marović, 2017; Zhang *et al.*, 2018; Gong *et al.*, 2019) as well as for solving semi-structured and unstructured problems that occur on tactical and strategic levels as a part of various DSS'es (Durduran, 2010; Coutinho-Rodrigues *et al.*, 2011; Dahal *et al.*, 2013; Du *et al.*, 2014; Jajac *et al.*, 2014; Jajac *et al.*, 2015; Han *et al.*, 2016; Marović *et al.*, 2018).

The main objective of this paper is to summarize the findings of up-to-date research articles concerning the application of artificial intelligence, specifically neural networks, related to the life-cycle phases during the management of urban road networks as a part of an urban system. Some of the other objectives were also assessed, such as to: (i) identify specific problems that are solved by the aid of neural networks during life-cycle management of urban road networks, (ii) evaluate and highlight the possible applications of neural networks as a prediction tool and support for decision-making on different management levels.

2 Systematic Review

Studies about neural networks and urban infrastructure management, especially road networks, were surveyed. The review reflects on papers published in peer-reviewed journals preferably articles and review papers. Researches related to neural networks in managing urban road networks published from 2000 to 2019 was reviewed. The survey was conducted using selected keywords (artificial neural network, decision support, infrastructure, multi-criteria analysis, and

road management) that resulted in 1703 publications (1014 in Web of Science and 689 in Scopus) which were selected by the following criteria: year of publication (from year 2000); document type (only journal articles were taken into consideration); repetitions (duplicate between Web of Science and Scopus); and relevance and relation to the topic. This resulted in 73 selected articles. The number of publications considered in this paper and their corresponding year of publication is summarized in Figure 1. Only the papers that solely highlight the use of ANNs for solving various structured problems (operational level) and/or various semi-structured and unstructured problems (tactical and strategic level) are referred to.

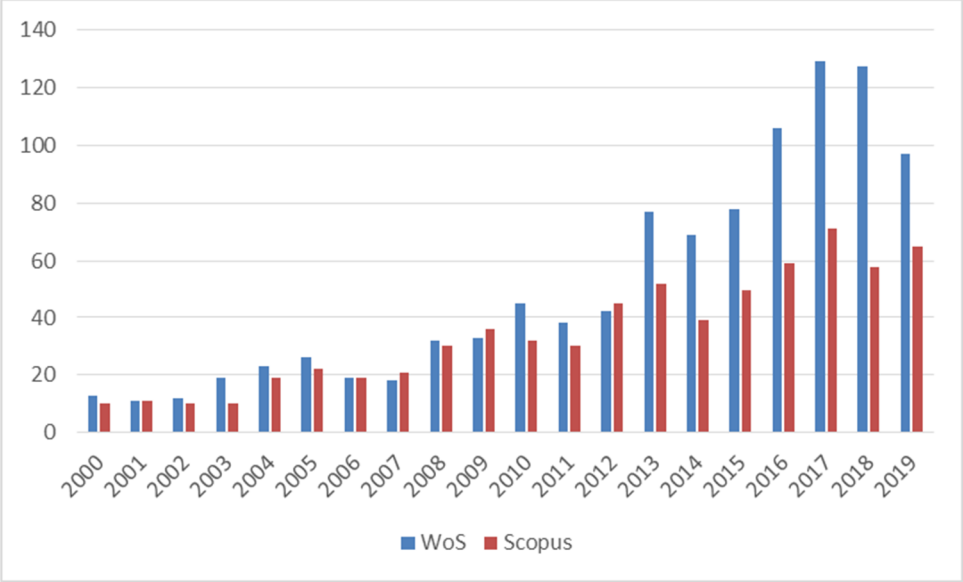

Figure 1. Number of publications and corresponding year of publication.

Collected data (Figure 1) shows the increasing interest and published papers on this topic by the research community from 2013 until now. Such is more evident regarding Web of Science than the Scopus database. For 2019, it should be noted that other papers may appear in the databases during October 2019 and later.

3 Urban Infrastructure Management

Life-cycle management of urban road networks, in general, can be seen through the interaction of horizontal and vertical aspects of urban road management (Figure 2) to achieve previously defined sustainable goals. The horizontal aspect takes into account the project management approach through four cyclically connected phases (*e.g.* initiation, planning, execution, and closure phase) thus represent the life-cycle phases. These phases do not change whether the project is managed traditionally or agile. Sure, it is obvious that projects do not appear and are not managed solely horizontally. Therefore, a vertical management component should not be forgotten and must be considered with all the difficulties that it brings. Such is observed throughout the vertical aspect of urban road management that takes into account the hierarchical management levels (operational, tactical and strategic).

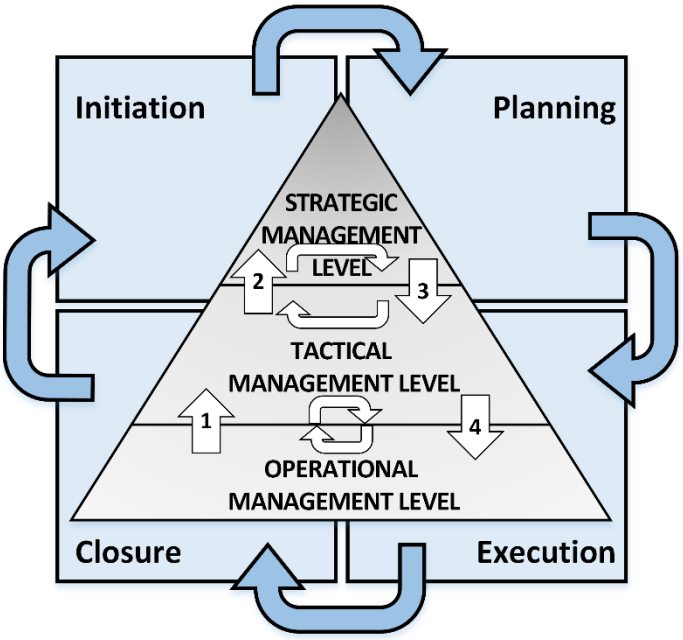

Figure 2. The horizontal and vertical aspects of urban road management.

The first management level supports decision-makers at the lowest operational management level. Besides its general function of supporting decision-making processes at the operational level, it is a meeting point of data and information where the problems are well defined and structured. This management level exclusively deals with structured problems that can be characterized as specified, detailed and narrow, clearly scheduled and internal. Additionally, it provides information flows towards higher decision levels (arrow 1 in Figure 2). A circular arrow between two management levels symbolizes interactions between the levels for purposes of solving specific problems. The decision-makers at the second management level (*i.e.,* tactical management level) deal with less-defined i.e. semi-structured problems and unstructured problems. At this level, tactical decisions are delivered, and it is a place where information basis and solutions are created. Problems that occur on this level can be characterized as broader than on lower level but still very focused and specified, clearly scheduled and internal. Based on applied models and methods, it gives alternatives and a basis for future decisions on the strategic management level (arrow 2 in Figure 2), which deals with even less-defined and unstructured problems. At the third management level, based on the expert deliverables from the tactical level, future development of the system is carried out. Strategies are formed, and they serve as frameworks for lower decision and management levels (arrows 3 and 4 in Figure 2). Problems that occur on this level are general and with a broad scope, both internal and external, and often ad hoc.

Depending on the management level and type of the occurred problem, various tools and methods could be used such as soft computing tools (for example, ANNs) as well as multi-criteria analysis and group decision-making. Many authors have studied possibilities for generating decision support tools for urban infrastructure management that convergence toward some type of decision framework is more or less similar to a basic DSS structure. According to Turban (1993; 1995), DSS's basic structure consists of three modules: database, model base, and dialog. In 2005, Quintero et al. introduced an improved DSS named IDSS (Intelligent

Decision Support System) as a solution for the future needs of urban infrastructure management. Later, Jajac *et al.* (2009) introduced the new architecture of DSS for urban infrastructure management that places the management levels in the core of the DSS structure. Such provided that the interactions between DSS modules are realized through decision-making processes at all management levels, which serve as meeting points of adequate models (from the model base) and data (from the database). The new architecture provided that complex and sensitive decision-making processes can be correctly supported if appropriate methods and data are properly organized and used. Gudac *et al.* (2014) highlighted the utter importance when decisions must be quickly made based upon real-time information, while Tijanić *et al.* (2019) proposed ANN based models to accurately estimate road construction costs.

3.1 Application of Neural Networks at the Operational Management Level

During the years various researches made a significant contribution with ANNs to efficiently solve technical problems that occur on the operational management levels in managing urban road networks. They were mostly focused on various asphalt mixtures and predictions of their properties during material production as well as during the exploitation period when the mixtures became part of the road network. In that sense, Xiao and Amirkhanian (2009) explored the application of ANN in predicting the stiffness behavior of asphalt mixtures and reported that the ANNs are more effective in predicting the fatigue life of the mixture than the traditional models. Ceylan *et al.* (2007) also reported the higher prediction accuracy of ANN compared to the existing regression models. Tušar and Novič (2009) analyzed the impact of various factors by using several models, multiple linear regression (MLR), partial least squares regression (PLS) and artificial neural networks (ANN), in the prediction process of the monitored hot mix asphalt properties. They reported that the use of MLR and PLS models show a better predictive ability that the ANN models. In 2016, Zavratnik *et al.* (2016) showed the application of ANN and MLR in the process of forecasting air void content with different used parameters on 5 types of asphalt mixtures. The authors concluded that the use of MLR models is better than ANN in the prediction of certain mixtures, but such is not the case for all asphalt mixtures together. In 2019, Androjić and Marović developed ANN and MLR models to predict the hot mix asphalt properties (air void and binder content) produced in a laboratory. The performed research on 6 types of asphalt mixtures indicates that it is possible and desirable to apply neural networks in the prediction process of the required properties of hot mix asphalt, wherein it is necessary to use a substantial set of input data. Gong *et al.* (2019) approach the fatigue cracking prediction problem in pavements by using the highly flexible ANNs through the deep learning framework. They reported that the difference between prediction performances of fatigue cracking transfer function concerning the proposed framework is 30% in favor of ANNs.

3.2 Application of Neural Networks at the Tactical Management Level

To improve conditions of road elements, as a part of sustainable development of the road infrastructure in the city of Split, Jajac *et al.* (2015) introduced the ANN that was trained and tested on road infrastructure data that come out of 236 city's road projects during the two years. Only road elements with insufficient conditions were assessed, while four network input variables were used: level of service (LOS), safety, savings on vehicle maintenance, and maintenance quality. In 2018, based on the decision support concept (Jajac *et al.*, 2009),

Marović et al. showed that complex and sensitive decision-making processes, such as the ones for road maintenance planning, can correctly be supported if appropriate methods and data are properly organized and used. They designed and developed an ANN model to achieve a successful prediction of road deterioration as a tool for maintenance planning activities. Recently with drastic improvements in computing capacity, fast optimization algorithms, and new network topology enabled researchers to explore considerably more complex models such as crack detection on asphalt surfaces (Zhang *et al.*, 2018) during maintenance phases, and to actively estimate and manage cost overruns (Tijanić *et al.*, 2019). Also, there is a strong tendency for optimizing ANNs for the evaluation of asphalt pavement structural performance (Bosurgi *et al.*, 2019) to improve the efficiency of pavement management systems.

3.3 Application of Neural Networks at the Strategic Management Level

The use of ANNs for solving problems at the strategic management level is closely connected with the ones previously stated at the tactical management level. It is important to note that at this management level ANN is used as one of the models out of the model base of the DSS for urban infrastructure management as a core management framework. This is the management level where all project phases are strategically managed. A specific decision support concept focused on the planning phase was proposed by Jajac *et al.* (2014), as a part of the decision support framework for the management of urban transport projects (Jajac *et al.*, 2015). Marović *et al.* (2018) highlighted the importance of the maintenance planning aspect of DSS that is based on real-time collected and processed data by the means of ANN. As road management is a spatial problem, Coutinho-Rodrigues *et al.* (2011) proposed a spatial DSS where they highlight the importance of implementing Geographic Information Systems (GIS) for planning and decision-making purposes. Such is helpful not only for a static view of road networks, such as planning and maintenance activities but also could provide additional dynamic benefits such as traffic accidents (Durduran, 2010), all as a part of sustainable urban infrastructure management framework (Torres-Machi *et al.*, 2018).

4 Conclusions

This paper has presented a literature review concerning the applications of neural networks in managing urban road networks. In recent years, an understanding and application of neural networks have been significantly increased as they have been applied in a variety of matters. The conducted literature review gave insight in ways that the neural networks have been used in different life-cycle phases during the management of urban road networks for solving structured, technical problems that occur on the operational management levels, but also as one of the methods for solving semi-structured and unstructured problems that occur on tactical and strategic levels as a part of various decision support systems.

At the operational level, neural networks are mostly used for predictions of various asphalt mixtures properties during material production as well as during the exploitation period when the mixtures became part of the road network. At tactical and strategic levels, neural networks are often used as one of the methods for improving conditions or road elements, maintenance planning activities, projects prioritization, all as a part of a decision support framework.

Abstract. *This paper presents a systematic way to consider the uncertainties of the building elements' service lives within a stochastic framework, by defining the corresponding probability density functions, based on a service life database. This methodology is appropriate for screening and detailed building LCA, since the service life database offers the possibility to define the probability density functions of the service lives, in different level of details.*

Keywords: *Service Life, Screening and Detailed LCA, Uncertainty, Global Sensitivity Analysis.*

1 Introduction

Designing sustainable buildings consists a key issue in order to reduce the environmental impacts of the building sector. It is important, thus, to identify the stages of the building life cycle and consequently the materials that are the main contributors to the building's *e.g.* greenhouse gas emissions. The evaluation of the environmental impacts is performed using the LCA methodology, which can successfully define the direct and indirect environmental impacts of products, goods, services and consequently buildings.

According to EN-15978:2011 (SN EN 15978:2011, 2011) the conventional life cycle stages of a building are the production and construction stage (A1-A3 and A4-A5, respectively), the use stage with the maintenance (B2), replacement (B4), operational energy (B6), water use (B7) and other processes, as well as the disposal at the end of life (C1-C4). Performing a building LCA is followed by many assumptions for several of the parameters included in the different LCA stages. Consequently, reliability and consistency issues derive from the uncertainty and variability of the input data, as already discussed in Huijebregts (Huijbregts, 1998).

One important parameter that contributes to the replacement stage (module B4) of a building LCA is the service life of the building elements. Different studies have shown that the service life calculation is governed by high uncertainty, as summarized in Grant (Grant, 2010), since it is influenced by a variety of uncertain factors, not necessarily technical, which cannot be defined objectively. Cooper (Cooper, 2004) summarizes different studies that identified parameters, such as *'the design, the technological change, the cost of repair and the availability of parts, the household affluence, the residual and resale values, the aesthetic and the functional quality, fashion, advertising and social pressure',* among the ones that influence the service life.

doi:10.23967/dbmc.2020.143

Furthermore, another uncertainty of the building elements' service life is linked to insufficient information, concerning the material choices, during the early design stages of the building process. The LCA in the early design stages can be used as a comparative tool for choosing the most sustainable building concept and lately, there is an increasing interest of the scientific community to conduct a building LCA in the early design stages (Azzouz *et al.*, 2017; Cavalliere *et al.*, 2018). However, the significant uncertainty in this design stage restricts the use of LCA calculations, (Röck *et al.*, 2018). Thus, LCA is generally applied in late design stages, when possible changes in the building design are not economically cost effective (Hollberg and Ruth, 2016).

A systematic way to consider the uncertainties (technical and other) in LCA is by using a stochastic approach. Hence, reliability issues in LCA calculations can be mitigated. Treating probabilistically the service lives has been already proposed by Aktas (Aktas and Bilec, 2012), Pannier (Pannier *et al.*, 2018) and Hoxha (Hoxha *et al.*, 2014). However, Aktas used only a limited number of materials, while the latter (Pannier and Hoxha) defined the probability density function, based on theoretical assumptions.

In this study, the service life of building elements is considered stochastically in order to include their uncertainty in the whole building LCA result and consequently enhance our confidence in the latter. The probability density functions of the service lives of building elements were defined with a consistent way, using input data from an international data collection. Finally, it was examined how the uncertainty of the LCA result can be allocated to the different sources (different building elements) of the input uncertainty using a sensitivity analysis (Saltelli, 2004).

2 Methodology

The general probabilistic framework, followed in the current study, has been already proposed by Padey (Padey *et al.*, 2013) and Cucurachi (Cucurachi *et al*, 2016). It consists of the following four steps: (1) definition of the LCA model, (2) determination of the probability density function (PDF) of the building elements' service life, (3) uncertainty analysis and (4) sensitivity analysis.

The building LCA model was calculated, using Eq. 1. The environmental impact of the materials and technical systems ($LCA_{Manufacturing}$ and $LCA_{disposal}$) were calculated for the greenhouse gas (GHG) emissions, using the *KBOB* database (Frischknecht and Büsser Knöpfel, 2013). The environmental impact of the operational energy was based on heating demand calculations according to SIA 380/1:2016 (SIA 380/1:2016, 2016), while the efficiency factor for heating and DHW was based on SIA 2040 (SIA 2040, 2017) and the impact values of the energy carrier were calculated using the KBOB database.

$$LCA_{tot}=LCA_{Manufacturing}+LCA_{Replacement}+LCA_{Disposal}+LCA_{Operational\ Energy} \quad (1)$$

The LCA of the replacement stage, was calculated, using Eq. 2,

$$LCA_{Replacement}=(LCA_{Manufacturing}+ LCA_{Disposal})*k \quad (2)$$

Where, k is the replacement rate that defines the number of replacements that occurs during the reference study period of the building. It was calculated for each building element, as a fractional number, according to SIA 2032 (SIA 2032, 2010), as shown in Eq. 3,

$$k=(RSP/SL)-1 \quad (3)$$

Where, RSP is the reference study period of the building, i.e. 60 years, according to SN EN 15978 (SN EN 15978:2011, 2011) and SL is the service life of the building element in years.

The probability density functions of the building elements were derived with a systematic way, from the DUREE Database, using a lognormal distribution (Goulouti *et al.*, 2020). This database includes international service life data from different sources. The database was structured, using the building decomposition of the Swiss construction costs, classified according to the Swiss Standard, *i.e.* eBKP-H – SN 506 511 (CRB, 2012). This building decomposition includes five main construction categories, *i.e.* structural work (C), technical systems (D), façade elements and coatings (E), roof elements (F) and internal layout (G). These main categories are further decomposed into two sub-categories, according to the SN 506511 nomenclature (*e.g.* the intermediate element level and the detailed element level). Five more sub-categories were added to this decomposition, in order to cover lower levels for more detailed components. Consequently, the service lives of the building elements can be assigned either to the main categories for screening LCA, or to the sub-categories in order to proceed to a detailed LCA. Table 1 presents the main categories and some of the subcategories of the database that were considered to the current study, as well.

Table 1. Building decomposition and building elements considered in the study.

	G4. Ceiling coverings			X

After the definition of the model and the identification of the input distributions, the uncertainty analysis followed and 40’000 Monte Carlo simulations were computed, in order to

achieve convergence. Based on these simulations, the Probability Density Function (PDF) of the LCA was calculated. In addition, a sensitivity analysis was conducted in order to define the building elements whose service life uncertainty mostly influences the LCA output. The variance-based global sensitivity analysis was chosen, which decomposes the variance of the model (LCA) into fractions, that can be attributed to the inputs, here the building elements (Saltelli, 2004). This method is used in order to rank variables, fix unessential variables and decrease problem dimensionality (Kucherenko and Song, 2017), (Sobol′, 2001). Hence, the first and the total Sobol' Indices (main and total effect, respectively) were calculated, which represent the unique contribution of the parameters or the joint one with other parameters, respectively.

3 Results

The methodology was applied to a building case study that represents a single family house (SFH) in Switzerland and its energy performance level complies with the SIA 380/1 Swiss Standard (SIA 380/1:2016, 2016). The case study was decomposed according to Table 1 for the screening LCA and the service lives of the building elements were attributed to the main group categories. The uncertainty analysis was conducted and the probabilistic LCA was calculated for the GHG emissions [expressed in $\mathrm{kg\,CO_{2-eq}\,/(m^2y)}$]. Figure 1(left) presents the PDF of the probabilistic LCA [$\mu = 23.20\ \mathrm{kg\,CO_{2-eq}\,/(m^2y)}$, $(\sigma^2 = 5.5^2)$], along with the deterministic LCA of the SIA 2032 [19.2 kg $CO_{2\text{-}eq}/(m^2y)$] and CRB [min=28.1 kg $CO_{2\text{-}eq}/(m^2y)$, mean=18.9 kg $CO_{2\text{-}eq}/(m^2y)$ and max= 15.1 kg $CO_{2\text{-}eq}/(m^2y)$]. The three CRB values (min – mean – max) correspond to the minimum, mean and maximum service lives, which mean maximum, mean and minimum replacement rates, respectively. Furthermore, the 95% confidence interval of the mean is narrow [$\mu = 23.22\ \mathrm{kg\,CO_{2-eq}\,/(m^2y)} \pm 0.05$], revealing the accuracy of the simulations. The most probable value of the LCA, *i.e.*, the mode of the distribution, *i.e.* $x_m = 20\ \mathrm{kg\,CO_{2-eq}\,/(m^2y)}$ is slightly higher than the deterministic SIA 2032 and CRB–mean (4% and 6% respectively).

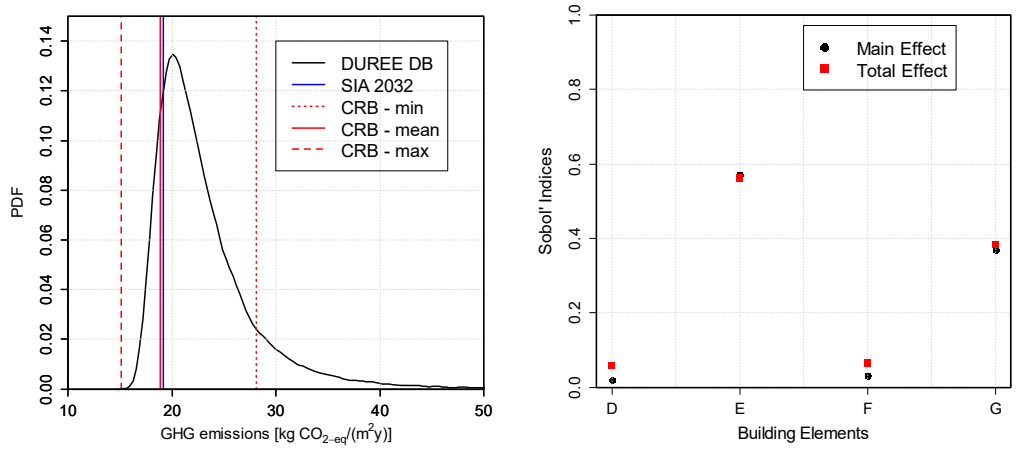

Figure 1. PDF of the probabilistic LCA (left) and Sobol' Indices for the screening LCA (right – *D: Technical systems, E: Façade coatings, F: Roof elements, G: Interior layout*).

Figure 1 (right) presents the sensitivity indices, which show the building elements whose uncertainty mostly influences the LCA uncertainty. Both the first order index (main effect) along with the total index (total effect, which includes the interactions between the parameters) are plotted. It is found that the individual effects and not the interactions among the building elements, explain the LCA uncertainty. This result proves that the initial hypothesis, according to which the replacement of a specific element does not interact with another element's replacement is valid. Furthermore, in order to verify the accuracy of the indices, a bootstrapping with 500 replicates was used (Archer, Saltelli and Sobol, 1997). The 95% confidence intervals of the indices remained narrow (*e.g.* for the G2 category, $S_{iG} = 0.38 \pm 0.05$) and of the same magnitude. Hence, we can be sure about their order, which determines the elements, with the highest impact on the LCA uncertainty (Cucurachi *et al.*, 2016). It can be concluded, that the E (façade) and G (interior finishes) building elements have the highest impact on the LCA uncertainty. The result is quite straightforward, since the LCA uncertainty is mostly influenced by the building elements that have the highest environmental impact (first the external façade – E and then the interior finishes – G) and the highest coefficients of variation, ($cv_E = \frac{sd}{mean} = 1.2$ and $cv_G = 1.4$) of the replacement rate probability distribution.

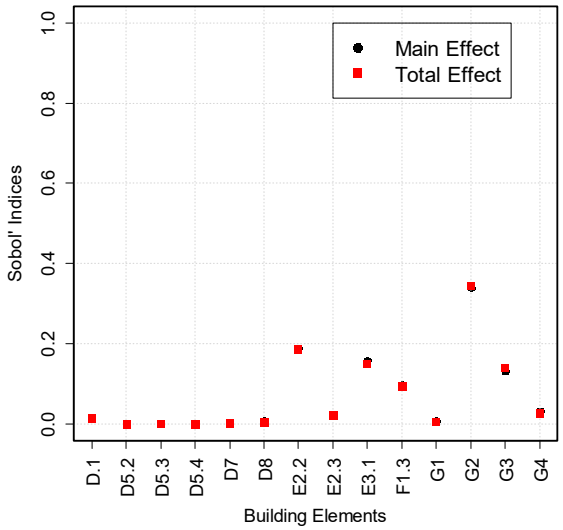
4 Discussion

As already mentioned the results of the sensitivity analysis can be used in order to rank the unimportant variables and thus simplify the model. The Sobol' Indices revealed that the service life uncertainty of the façade elements and the interior finishes have higher influence on the probabilistic LCA. On the contrary, the uncertainty on the service lives of the technical systems and the roof elements have no influence on the uncertainty of the building LCA. Thus, in further screening LCA, the service lives of the technical systems and the roof elements can be treated deterministically, by using current data from the standards. However, the prevailing Sobol' Indices of the façade elements and the interior finishes indicate that special attention is needed for determining their service life. This result derived, also, by the fact that different building components and layers are grouped together.

Hence, in order to explore the influence of the level of details of the building decomposition, a detailed LCA was conducted for which the service lives of the building elements were attributed in lower level of details, as it is shown in Table 1. Figure 2 presents the main and the total effects for this decomposition. The same validation procedure was followed, concerning the order of the indices, as already described. It is derived that, for this level of details too, the individual effects and not the interactions among the building elements explain the LCA uncertainty. The uncertainty of the LCA, expressed in GHG emissions can be mainly explained by five building elements, *i.e.* the E2.2 (compact façade), E3.1 (windows), F1.3 (sloping roof), G2 (flooring) and G3 (wall covering). Among the elements with the highest GHG emissions (first E2.2, followed by F1.3 and G2), it is the replacement rate of G2 that presents the highest coefficient of variation ($cv = 1.25$), followed by E2.2, ($cv = 1.01$), and F1.3 ($cv = 0.98$). The E3.1 and G3 building elements, present lower GHG emissions than F1.3, but the coefficient of variation of their replacement rate is more significant, which explains the higher relative sensitivity indices. The Sobol' Indices of the technical systems are found to be close to zero, proving that their service live uncertainty does not affect the GHG emissions uncertainty.

The same conclusions, concerning the service lives of the technical systems were derived

both by the screening and detailed LCA. However, as far as the roof elements are concerned, they exhibited a higher impact on the detailed LCA uncertainty, than in the screening LCA. In addition, by decomposing the building using a lower level of details, it can be seen that there is a prioritization concerning the façade elements and the interior finishes.



Names of building elements			
D1. Electrical installations	D7. Ventilation	E3.1 Windows	G3. Wall coverings
D5.2 Heat production	D8. Sanitary installations	F1.3 Sloping roof	G4. Ceiling coverings
D5.3 Heat distribution	E2.2 Compact façade	G1. Internal partitions	
D5.4 Heat diffusion	E2.3 Ventilated façade	G2. Flooring	

Figure 2. Sobol' Indices for the detailed LCA.

5 Conclusions

The current study presented a systematic way to treat probabilistically the replacement rate of the building elements and quantified the impact of the service lives' uncertainty on the LCA output. The main outcomes and recommendations derived are the following:

- A screening and a detailed LCA was conducted using the DUREE service life database. The results of the sensitivity analyses were similar. The façade elements and the interior layout explain mainly the LCA uncertainty;
- The screening and the detailed LCA revealed that the uncertainty of the technical systems service lives (D building element) present low impact on the LCA uncertainty. In further probabilistic LCA analysis, the LCA model could be simplified and conventional deterministic values from the standards (SIA 2032, CRB) could be used for this building element, instead;
- By conducting a detailed LCA, if a threshold is defined at 0.10 for the Sobol' Indices, only five building elements out of fourteen are the most influential on the LCA uncertainty, i.e. E2.2 (compact façade), the E3.1 (windows), the F1.3 (sloping roof), the G2 (flooring) and G3 (wall covering). This means that special attention should be given when defining the service lives for these element types in further LCA calculations.

Use of Machine Learning in the Function of Sustainability of Wastewater Treatment Plants

Goran Volf

Faculty for Civil Engineering, University of Rijeka, Radmile Matejčić 3, 51000 Rijeka, Croatia, goran.volf@uniri.hr

Abstract. *Wastewater treatment plants (WWTP) are complex and dynamic systems whose management and sustainability can be improved by using different modelling and prediction approaches of their work. A machine learning tool for development of model trees was used in this paper in order to develop a model for chemical oxygen demand (COD) in the wastewater effluent from the WWTP with activated sludge to increase its sustainability and helps in its management purposes. Measured data, both in influent and effluent of the WWTP were used for modelling. For the COD model, machine learning tool Weka and algorithm for development of model trees M5P were used. Obtained model has a high descriptive power and correlation coefficient and thus can be used for prediction and modelling purposes, which can help in management and sustainability of the WWTP. Also, the purpose of this paper is to show the benefits of using machine learning tools for developing WWTP models.*

Keywords: *Wastewater Treatment Plant, Machine Learning, Model Trees, Function of Sustainability, Management.*

1 Introduction

There is a need for wastewater treatment plants (WWTP) to adapt to a rise in water and energy demands, prolonged periods of droughts, climate variability, and resource scarcity (Cornejo 2015).

As population increases, minimizing the carbon and energy footprints of wastewater treatment, while properly managing nutrients (mainly nitrogen and phosphorous) is crucial to improving the sustainability of WWTP. Integrated resource recovery can also mitigate the environmental impact of wastewater treatment systems, however, mitigation potentially depends on various factors such as: a) treatment technology, b) resource recovery strategy, and c) size of system (Cornejo 2015).

Today, the biological treatment of wastewater with activated sludge is one of the most widely used technological processes in WWTP, because of its capabilities, economy and efficiency. The two main components of this process are aeration basin, e.g. the bioreactor and the secondary clarifier (Henze *et al.*, 2002).

Biological treatment of wastewater consists of complex physical, chemical and biological processes through which organic matter, nitrogen and phosphorus are removed from the wastewater. Successful wastewater treatment requires appropriate concentrations and conditions for the growth of microorganisms that must be achieved in the bioreactor (Henze *et al.*, 2002).

Due to the complexity and sensitivity of the treatment process, it is difficult to continuously maintain optimal operating conditions within the WWTP. Because of this,

modelling becomes very useful tool that is often used to simulate and control the operation of the WWTP. Mathematical models (e.g, Activated Sludge Models (ASM), IWA task group, 2000) are commonly used to model WWTP. In this paper, machine learning tool Weka (Witten and Frank, 2000), e.g. the algorithm M5P for induction of model trees, is used to model the WWTP e.g. chemical oxygen demand (COD) concentration in the effluent of the WWTP.

Today, various tools and methods are used to model WWTP, such as, for example, statistical models (Čurlin *et al*., 2008; Dürrenmatt and Gujer 2011; Razifa *et al*., 2014), expert systems (Dürrenmatt and Gujer 2011; Baeza *et al*., 1999; Roda *et al*., 1999), knowledge-based approaches (Comas *et al*., 2003), neural networks (Dürrenmatt and Gujer 2011; Belanche *et al*., 1999; Zhao *et al*., 1999; Hong *et al*., 2015; Mjalli *et al*., 2007), hybrid approaches (Sànches-Marré *et al*., 1996; Grieu *et al*., 2005; Picioreanu *et al*., 2004; Picioreanu *et al*., 2003) and various types of machine learning (Dürrenmatt and Gujer 2011; Hong *et al*., 2015; Comas *et al*., 2001; Atanasova and Kompare 2002; Kompare *et al*., 2006; Manu *et al*., 2017).

The purpose of the model obtained with the use of machine learning tools in this paper is to model the concentration of COD in the effluent of the WWTP. The value of the COD in the effluent is considered as the best indicator for operation quality for the WWTP, i.e. residual organic loads, which also indicated the efficiency of the treatment process (Čurlin *et al*., 2008; Henze *et al*., 2002; Tchobanoglous *et al*., 2003). For this reason, the variable specified is defined as the observed parameter, which best indicates the state of the process in the WWTP, and also, the variable whose dynamics the machine learning tool wants to explain and predict. Using the given model, it would be possible to predict the values of the COD concentration, and if it is greater than the limit value prescribed by Ordinance on emission of limit values for wastewaters (2016), a rapid response would be possible which would then ensure its reduction to an acceptable level (Čurlin *et al*., 2008).

Except the modelling the COD concentration in the effluent from the WWTP with machine learning, the aim of this paper is to demonstrate also some of the advantages and capabilities of machine learning tools.

2 Materials and Methods

2.1 Description of the WWTP

Modeled WWTP is a second stage WWTP, with size of 9,500 population equivalent (PE). The WWTP on the water line consists of mechanical pretreatment and second stage treatment of wastewater (Figure 1). Mechanical pretreatment consists of a coarse, fine screens and aerated grit chamber. The second stage of treatment consists of selectors, aeration basins and secondary clarifiers.

The flow of water on the WWTP is: first, the wastewater enters a channel in which are located coarse and fine screens, after which the wastewater goes to the aerated grit chamber. The water is then transported to the selector, where the selection of microorganisms (contact of biomass with wastewater) takes place. After selector water is then transported to aeration basins (bioreactors), where biological treatment with activated sludge takes place. Finally, the mixture of water and activated sludge is transported to secondary clarifiers, where the activated sludge floccules are deposited and treated water is discharged into the recipient (sea)

through a submarine outlet. Part of the deposited sludge from secondary clarifiers is returned back to the selector or aeration basin in order to maintain the required concentration of activated sludge for successful biological treatment of the process in aeration basins.

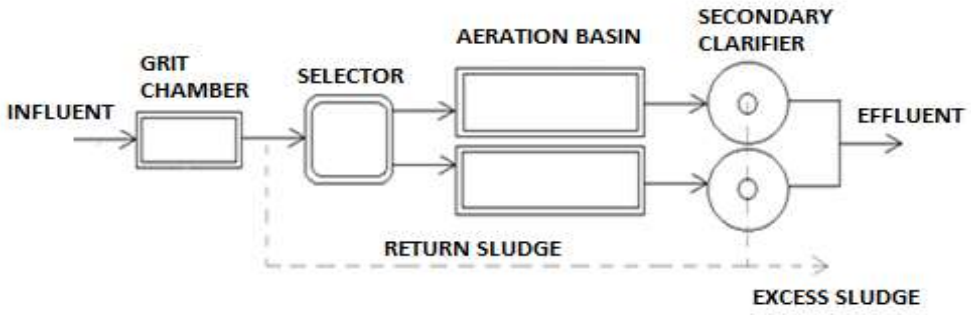

Figure 1. Water line for the WWTP.

2.2 Database

The data used for the modelling (see Table 1) were measured in influent and effluent of the WWTP. The data are presented as mean values through one day, that is, one record in the database represents the one-day situation of the WWTP operation. The database consists of total 718 situations (days).

To supplement the missing data in the total data set, the cubic spline method of interpolation between the measured values was used.

Table 1. Measured data at WWTP uded for modeling.

Data	Description	Unit
Q_{in}	Influent flow	m^3/s
Q_{out}	Effluent flow	m^3/s
T_{out}	Effluent temperature	^0C
COD_{in}	Influent Chemical Oxygen Demand	mg/l
COD_{out}	EffluentChemical Oxygen Demand	mg/l
NH_4-N_{in}	Influent Ammonium	mg/l

3 Machine Learning; Regression and Model Trees

While the simple linear regression calculates one equation (one weighing vector) for the entire data set, piecewise or tree-structured regression divides the data set into several subsets on which uniform class value or linear equation can be applied. The division to subsets is based on tests of the values of the input attributes which are put as nodes in a regression or model tree.

Thus, regression trees are hierarchical structures composed of nodes and branches, where the internal nodes contain tests on the input attributes. Each branch of an internal test corresponds to an outcome of the test and the predictions for the values of the target variable

(the class) are stored in the leaves which are the terminal nodes in the tree. If the leafs contain a single value for the class prediction, then we are talking about simple regression trees, while if a linear equation is used for prediction in the leaf, we are talking of model trees (Quinlan, 1992, Witten and Frank, 2000). Figure 2 illustrates the procedure of constructing regression and model trees.

For the experiment, a variation of the M5 algorithm was used, called M5P, implemented in the software package WEKA (Witten and Frank, 2000).

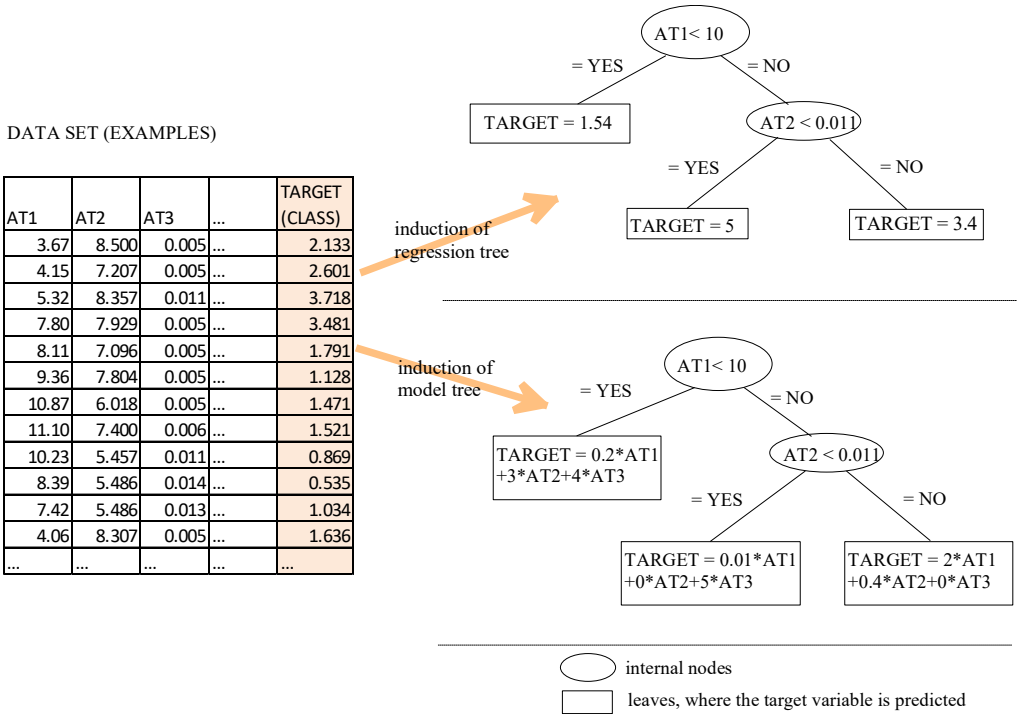

Figure 2. Induction of regression and model trees from given data set (examples).

4 Experiment Setup

The experiment was designed to produce a model of the COD concentration in the effluent of the WWTP. The COD concentration in the effluent was therefore set as the dependent variable, while the flow (Q), COD concentration, ammonium (NH_4-N) and total suspended solids (SS) in the influent of the WWTP were set as independent variables.

5 Results and Discussion

The purpose of the model obtained with machine learning tools, in this case model trees, is to predict the change in COD concentration in the effluent of the WWTP, using the measured variables in the influent of the WWTP. From the given data set (Table 1), a model of the COD concentration in the effluent of the WWTP was created (Figure 3). The model consists of a total 6 nodes and 7 leaves, which contains the values of the variables measured in the influent of the WWTP (see Table 1). Each leaf contains one equation to calculate the COD concentration in the effluent of the WWTP, depending on the structure of the tree itself. The

equations in the individual tree leaves are shown in Table 2. The correlation coefficient R for the obtained model using cross validation method is 0.64.

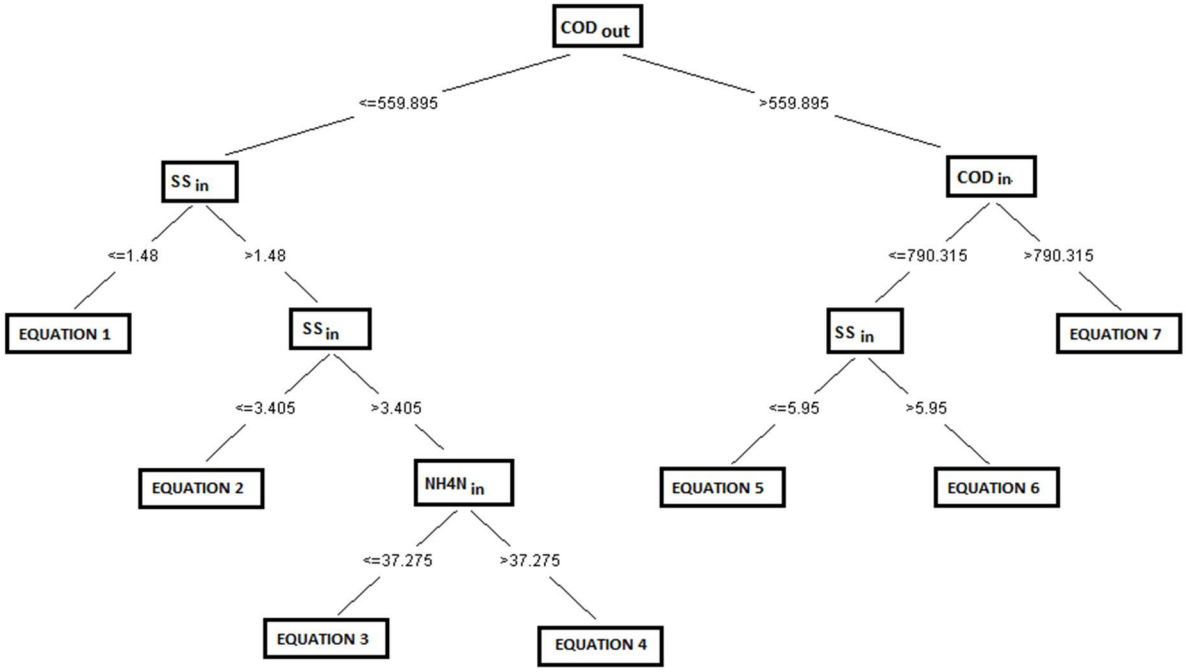

Figure 3. Obtained model for COD concentration.

Table 2. Model equations for COD concentration.

Equation number	Equation
1	COD_{out}=-0,0088*Q_{in} + 0,0954*COD_{in}-1,0529*NH_4N_{in}-0,0215*SS_{in}+45,669
2	COD_{out}=-0,0049*Q_{in}+0,038*COD_{in}-0,1132*NH_4N_{in}-0,0172*SS_{in}+20,0079
3	COD_{out}=-0,0006*Q_{in}+0,0016*COD_{in}-0,0016*NH_4N_{in}-0,0153*SS_{in}+20,1564
4	COD_{out}=-0,0006*Q_{in}+0,0016*COD_{in}-0,0034*NH_4N_{in}-0,0153*SS_{in}+23,1117
5	COD_{out}=-0,0009*Q_{in} +0,0046*COD_{in}+0,1559*NH_4N_{in}-0,0957*SS_{in}+24,0748
6	COD_{out} =-0,0009*Q_{in}+0,0046*COD_{in}+0,1559*NH_4N_{in}-0,0818*SS_{in}+17,0162
7	COD_{out}=-0,0009*Q_{in}+0,005*COD_{in}+1,3378*NH_4N_{in}-0,3479*SS_{in}-7,1299

To predict the COD concentration in the effluent of the WWTP, it is necessary to select from the model shown in Figure 3 the appropriate linear equation depending on the values of the individual attributes in the tree nodes. From Figure 3 can be seen that the COD concentration in the effluent depends mostly on the COD concentration at the inflow (initial

node), then SS and NH_4-N, while the flow (Q) do not appear in the tree at all, but only in single leaves equations. Interpreting the model results, the larger COD values in the effluent are given by the right side of the model tree, that is, the tree shown in Figure 3, and the smaller values by the left side of the model tree. Therefore, lower values of COD concentration in the effluent are associated with nodes in which SS and NH_4N are located, while the higher values are associated with nodes in which COD and SS are located.

A comparison of the time series of measured and modeled COD concentration values can be seen in Figure 5. From Figure 5, can also be seen a good adaptation of the measured and modeled COD concentration values, and also by visual inspection it can be concluded that the peak points values are satisfactorily matched.

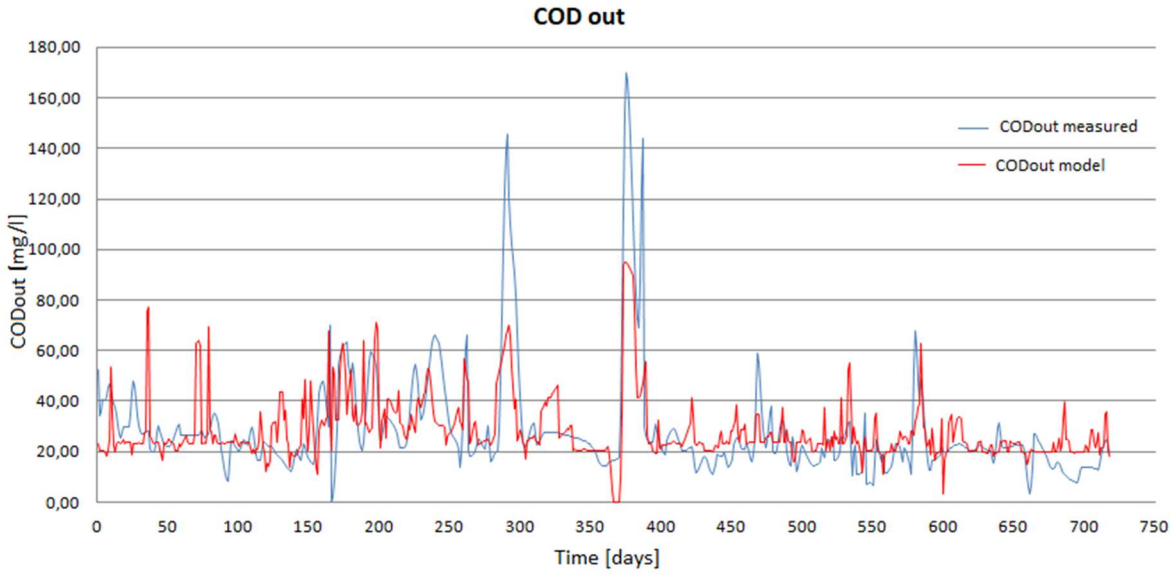

Figure 4. Time series comparison of measured and modeled values of COD concentrations in the effluent.

The results of the experiment show that it is useful to use different approaches when modeling WWTP. As for any method of modeling which use measured data, it is essential that the database consists of sufficiently different situations from which, in this case a machine learning algorithm can learn to predict a dependent variable. Also, for better model results, it would be useful to have more measured parameters in the influent of the WWTP affecting the dependent variable, such as water temperature, pH, chloride concentration (if it is a WWTP in the coastal area such as discussed in this paper), sludge age, sludge return, dissolved oxygen concentration in the aeration bioreactor, food to mass ratio (F/M), etc., which over a longer period can have a greater and significant impact on the COD concentrations (Henze *et al*., 2002). Therefore, as the database used in this paper contains relatively few input parameters, a more accurate prediction of the COD concentrations from the WWTP cannot be expected. However, the resulting model behaves as expected and produces satisfactory results.

7 Conclusions

Use of machine learning tools to create model from database, in this case model trees have been successfully applied to model WWTP, that is, the COD concentration in the effluent of the WWTP which can help in management and sustainability of the modeled WWTP. Obtained model is simple, understandable, and relatively accurate in predicting COD concentrations in the effluent of the WWTP. Before starting modelling procedure, it is important to note that the database contains the actual attribute values and that it has information about the time when the data was collected so that the dynamics of the system being modeled can be incorporated into the model.

Therefore, some of the advantages of using machine learning tools in modeling can be marked, firstly, the construction of descriptive, or white box models, which make it much easier to interpret the obtained models. Models are more comprehensible, thus providing insight into their functioning, that is, the functioning of the modeled system.

Also, it is especially important to emphasize the use of machine learning tools for simpler and more efficient management and sustainability of the WWTP, as shown in this paper.

Future work is recommended to focus on increasing the database so that model accuracy can be increased and other parameters such as nutrients, e.g. nitrogen and phosphorus can be modeled with the enlarged database, where properly managing of nutrients is crucial to improving the sustainability of the WWTP. Thus, new links and patterns among the data could be revealed.

Abstract. *Nowadays, low-cost sensors and acquisition devices have been emerging as an obvious solution to many innovative applications such as Structural Health Monitoring (SHM) systems. In this paper, issues regarding dynamic data acquisition, as well as their respective solutions, are presented. Moreover, a comprehensive description through-out an inexpensive sensor network system using open-source hardware for a real-time acceleration data acquisition has been presented. The platform consists of an accelerometer, an Arduino board, and a computer as a data recorder and presenter. Data is recorded through an efficient microcontroller code that can provide a considerable reading frequency (up to 300Hz). Using Python, instant acceleration recording for all the three axes has been done. It is shown how the performance of the proposed system is efficient for the field of SHM systems.*

Keywords: *Arduino Due, Structural Health Monitoring (SHM), Mpu9250, Internet Of Things (IoT).*

1 Introduction

While low-cost sensors are getting significant attention from scientists, how to use them correctly is another matter. Here, by using an Arduino Due and an accelerometer and a raspberry pi, a wireless application has been presented. The nobility of this application would be the chance to observe data capturing in real-time from any place with any device. Firstly here, an introduction through Arduino due, raspberry pi, MPU9250 (the accelerometer) has been presented. Secondly, a brief presentation regarding the coding of the Arduino and the raspberry pi has been given. Finally, the methodology and the result of this application has been shown.

2 State of the Art

In this section, a brief review of the used sensors and a microcontroller in the project has been given together with their technical descriptions.

2.1 Arduino Due

Arduino is an open-source electronics platform based on easy-to-use hardware and software. The Arduino Due (Fig.1) is a microcontroller board based on the Atmel SAM3X8E ARM

doi:10.23967/dbmc.2020.200

Cortex-M3 CPU. It is the first Arduino board based on a 32-bit ARM core microcontroller. It has 54 digital input/output pins (of which 12 can be used as PWM outputs), 12 analog inputs, 4 UARTs (hardware serial ports), an 84 MHz clock, an USB OTG capable connection, 2 DAC (digital to analog), 2 TWI, a power jack, an SPI header, a JTAG header, a reset button and an erase button. Unlike most Arduino boards, the Arduino Due board runs at 3.3V. The maximum voltage that the I/O pins can tolerate is 3.3V. Applying voltages higher than 3.3V to any I/O pin could damage the board (Blum, 2013).

Figure 1. Schematic of an Arduino Due.

2.2 MPU9250

The MPU-9250 (Fig.2), delivered in a 3x3x1mm QFN package, is the world's smallest 9-axis MotionTracking device and incorporates the latest InvenSense design innovations, enabling dramatically reduced chip size and power consumption, while at the same time improving performance and cost. The MPU-9250 MotionTracking device sets a new benchmark for 9-axis performance with a power consumption of only 9.3μA and a size that is 44% smaller than the company's first-generation device. Gyro noise performance is three times better, and full-scale compass range is over four times better than competitive offerings. The MPU-9250 is a System in Package (SiP) that combines two chips: the MPU-6500, which contains a 3-axis gyroscope, a 3-axis accelerometer, and an onboard Digital Motion Processor™ (DMP™) capable of processing complex MotionFusion algorithms; and the AK8963, the market-leading 3-axis digital compass. Improvements include supporting the accelerometer low power mode with as little as 6.4μA of, and it provides improved compass data resolution of 16-bits (0.15 μT per LSB). (InvenSense, 2014).

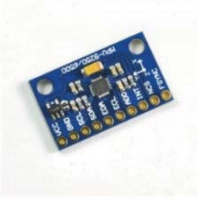

Figure2. Schematic of MPU9250 sensor.

3 Communication Ways

While many sensors use digital and Analog ports to provide the microcontroller the information which they have measured, some sensors use the inter-integrated circuit (I2C) protocol. This is a protocol that allows multiple "slave" digital integrated circuits (Sensors) to communicate with one or more "master" chips (Arduino). Like the Serial Peripheral Interface (SPI), which is only intended for short-distance communications within a single device(Ozdagli et al., 2018). The accelerometer sensor had to be connected to the I2C port (SCL, SDA) on the board. The code was written on the Arduino platform and uploaded to the board via a USB cable. For getting the main characteristics of these sensors, few tests have been done (Mobaraki et al., 2020) (Mobaraki and Vaghefi, 2016).

4 Methodology

After installing the last version of Python on the Computer. For communication of the computer with the Arduino, a library entitled pyserial had to be installed. With this done, the Arduino port could have been introduced to Python to show the captured data. With a python code, the received data were given their time of capture. For being able to use the exact time from the internet another library had to be added and used. The name of that library was DateTime.The given time to the received data had a resolution of 1 microsecond. For illustrating the data wirelessly, the computer had to be connected to the internet. The only power supply that this application needed was hocking up the computer. The Arduino gets its power from the USB port of the computer and initiates the accelerometer. In order to make this project wireless, another free application had to be installed on this computer (Komarizadehasl et al., 2020a) (Komarizadehasl et al., 2020b). The VNC is a remote application that lets users control their devices over the internet. By having the VCN application on any other internet-connected device, the functionality of this device would be observable. The written python code would save the data at the same time as it is illustrating them.

5 Experiment

For testing this sensor and its reliability, an experiment has been implemented. With a dynamic jack, a sinus signal has been programmed, and the vibrations had been saved by the accelerometer. In Fig.3, a picture of the jack can be seen. This jack can shake its bottom plate as was programmed. The instructions to the hydraulic jack were to make a wave with a fixed frequency of 5 hertz (5 complete waves in one second). The movement of the jack was to go up to 0.1 millimeters up and -0.1 millimeter down from its null axis to make a sinus wave. With a very simple two time differential, the acceleration equation could be calculated.

$$y = d * \sin(\omega * t + \varphi) \quad (1)$$

$$\omega = 2 * \pi * f \quad (2)$$

In the above equation, **y** is the displacement in time **t**, d is the maximum allowed movement of the jack in each cycle, $\boldsymbol{\omega}$ is the angular frequency, and $\boldsymbol{f}$ is the set frequency, which equals to 5Hz, and $\boldsymbol{\varphi}$ is the phase constant. On the equ.3, acceleration has been calculated from the Eq.1. This was done by getting the second-order derivative of the Eq.1. By putting all the data

in the Eq.3, the maximum acceleration was calculated as 10.4352 g*10^{-3} m/s^2.

$$a = \frac{d^2 * y}{dt^2} = \ddot{y} = -d * \omega^2 * \sin(\omega * t + \varphi) \quad (3)$$

Figure 3. The hydraulic jack subjected to the experiment.

6 Analysis

The very first faced problem in this experiment was that the sensor could not record data or, if recorded, the data were messy. It was deducted that the sensor had to be glued to the bottom plate of the jack for getting accurate information. The second problem was that the written python code could save only 120 data per second while the sensor was reporting more than 300 data per second. Although, by using serial port commercial software on the computer, it could have been possible to save data at the same speed as their production. Since here, getting the accurate time of capture was vital, it was obligatory to use Python to attach the provided data with their corresponding time. To tackle this problem, the speed of data capture had to be dialed down, so the Python could get and save them. To be on the safe side, the speed of capture had been set on 84Hz.

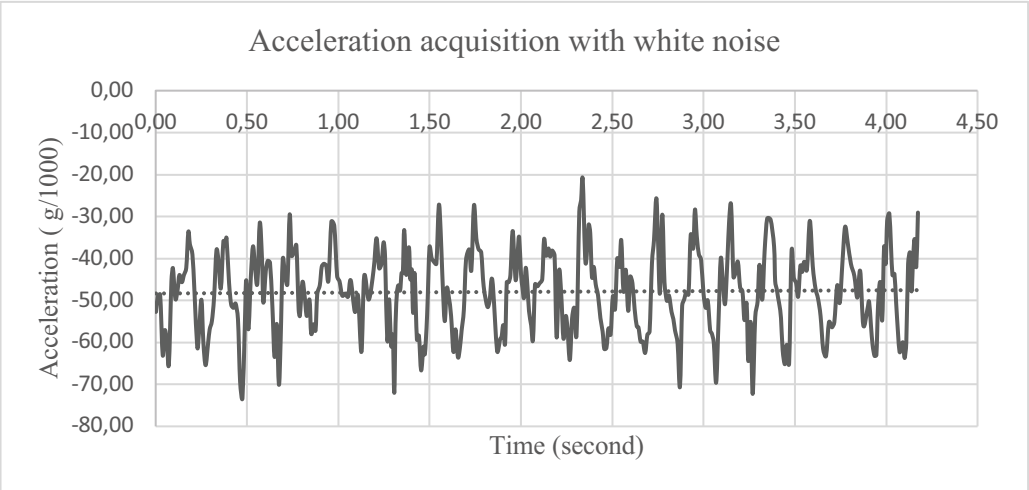

Figure 4. Acceleration, Time diagram with white noise.

The other unexpected issue that this project faced was that, though this sensor had been calibrated in the company, it had a constant number added to all provided data, which from nowhere it would be named as the white noise. As in the Fig.4, it has been illustrated, and the averaged data is around -50milli-g while they had to fluctuate around zero. This -50milli-g was considered as the white noise of this sensor. In order to measure this correctly, the average of 10000 sets of data in a vibration-free test has been calculated. For this sensor, the white noise had been calculated as -49.8535 milli-g.

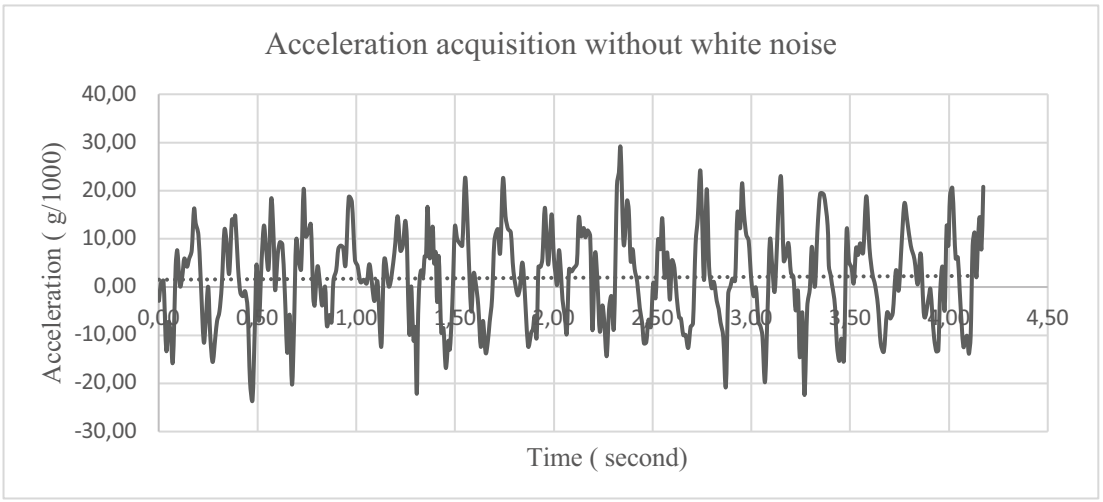

Figure 5. Acceleration, Time diagram without the white noise.

By removing this amount from the provided accelerations, the values had been pulled up where they needed to be. The data were clearer and more understandable when this white noise had been removed (Fig.5). Different accelerometer boards had been tested, and it was concluded that each circuit has its own different amount of white noise that must be dealt with. It should have been assured that this white noise is constant. Moreover, the circumstances and time

cannot change it. For this reason, the jack was programmed with many more different frequencies and displacements. In all of those experiments, the white noise stayed the same.

7 Conclusions

As in Fig.5, it is visible the sinus wave conducted from the accelerometer is quite close to the expected behavior. As it is observable, the sinus wave is fluctuating about 10.5 milli-g from its average as it was calculated in the last section, the graph should have had a 10.453 milli-g fluctuation. It is quite notable to see that they have worked out almost the same. In Fig.5, the filtered data from the 5Hz experiment has been shown. As can be seen, the result is not so accurate, for the fluctuation has other unexpected data or noises as well. In the future works, filters must be applied to delete the unwanted data and ambient noises that may have entered into this experiment unwantedly.

Acknowledgments

The authors are indebted to the Spanish Ministry of Economy and Competitiveness for the funding provided through the research project BIA2017-86811-C2-1-R directed by José Turmo and BIA2017-86811-C2-2-R, directed by Jose Antonio Lozano-Galant. Abstract. *Product installation during the construction process impacts the overall performance and durability of a building. However, when the building construction industry fails to address installation quality the product performance is affected. This research explores the importance of optimized product installation and how it affects product performance. During the installation period, standard product performance can be affected by the information known about the product and the amount of time put into the assembly of the product. The building products can vary from insulation, A/C units, water heaters, etc. An installers' workmanship can impact standard product performance if they have limited knowledge about the product and its operational functionality. The products' prescribed functionality could be altered due to less than standardized installation practices. Improper installation of a product can lead to major deviations in performance that can increase maintenance costs over the lifetime of the product in addition to adverse effects of the product during its normal life cycle. Labor sensitivity is an underrepresented aspect of building construction that contributes to the problem of energy inefficiency. The goal of this work is to develop a metric that can quantify how relatively sensitive a building product and overall building performance is to the efforts of time and knowledge, specifically during the installation process. From this metric, the impact of installation on performance for different products can be compared through numerical values, highlighting products that require special care during the installation process to ensure desired performance.*

Keywords: *Building Performance, Sustainability, Product Installation, Installation Cost.*

1 Introduction

In terms of product performance there are theoretical and practical benchmarks in place to evaluate standard operation and procedures. Manufacturers design a product with certain achievement expectations in mind during the product development process. Before production begins, prototypes are designed with the goal of meeting this desired performance set forth by the manufacturer. As Murthy and Rausand (2008) has classified that the prototype specifications are manipulated and changed until the desired performance is reached by the product. Essentially, the performance set by the manufacturer becomes the expected level of performance the product should reach after its usage. A perspective to consider when analyzing overall building performance, "achieving the expected performance requires that the factors
that the design concept is based on fulfils certain standards and are within expected ranges. Hagentoft (2017) suggest that these factors could for instance be workmanship, interior and exterior climate, maintenance and/or material properties.

There are several factors that contribute to inefficient building performance, we intend to focus on the impact of workmanship during the installation process. Individual product performance and energy usages contribute to the overall performance and efficiency of the building. Considering this approach to building performance leads us to focus on individual products and

how their performances measure on smaller scales within the performance gap. Frei (2017) considers the term "Performance Gap" used to denote deviations between a buildings' planned and actual performances. Comparatively so, the previous definition of a building performance gap is the framework for the gap between the actual and individual product performances; the expected performance would not be met if it varies from the actual performance. In this paper we focused on building products that are extremely sensitive to performance issues that occurred during the installation process as a result of workmanship.

Most specialized products and their installation within a building is dependent upon the workmanship of skilled laborers. Some of the products include HVAC systems and heat pumps, which are particularly susceptible to poor performance due to installation errors. Residential heat pump installations and the vocational education of technicians have a dynamic impact on the successfulness of the job completed by the installer. As Gleeson (2016) stated, the lack of broader educational content and deficiencies in engineering knowledge will have profound negative impacts on both the performance and market acceptance of heat pumps. Domanski (2014) conducted a sensitivity analysis on heap pump installation faults and its skewed performance as a result in five different climatic zones. Simulations were run for faults including duct leakage and refrigerant undercharge to determine the effects on energy performance. The study concluded that installation faults could be responsible for a 30% increase in energy usage. The findings in this study can be further validated by the energy reports from the American Council for Energy Efficient Economy. According to the ACEEE (2018), energy savings from high efficiency air conditioners and heat pumps can be negated by a 20-40% loss in energy efficiency due to poor installation. Additional performances of other building products were reviewed to contribute to the argument of unsatisfactory workmanship affecting standard functionality. According to Langmans (2017), the insulation installed in building cavity walls provides a thermal barrier for reducing energy consumption. A performance analysis of these building components illustrated that the thermal performance of especially rigid board insulated cavity walls were highly depending on the installation quality of the insulation layer.

The product used as an example throughout this framework is building insulation. Zero Carbon Hub (2014) acknowledged that faulty installation of insulation is the main contributor to the building performance gap. In their study, two groups of houses were constructed to simulate good and bad workmanship to measure the impacts. Some of the test houses were constructed carefully in a manner that could be described as good workmanship while others were constructed in such a way as to mimic poor workmanship…features associated with poor workmanship could in some cases cause the U-value to rise by as much as 310%. Other investigations related to similar issues performed by Doran (2008) included a thermographic test and visual inspection which found that the quality of installation of insulation can be very important. Essentially areas where insulation is poorly fitted can incur high levels of heat loss. From these results it can be concluded that the poor installation can be a contributor to poor product performance.

2 Methods

The proposed framework emphasizes the effects of installation and its importance for reducing energy consumption. Continual reduction of energy consumption will result in lower cost throughout the lifetime of the product. The overall goal of this paper is to produce a Probabilistic Investment Return (PIR) that includes cost and energy performance of any given product. Consumers can gain an understanding of how the installation cost of a product and its energy savings per year combined can provide information on how it will pay for itself over a span of time. The PIR is based on the installation and performance aspects of building products. In Figure 1, the development of this end goal is displayed in a concept map.

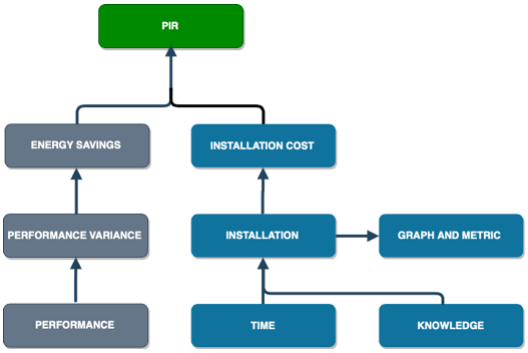

Figure 1. Probabilistic Investment Return Flow Map.

The proposed performance metric is based on the cost of installation and its potential energy savings. The Probabilistic Investment Return value is representative of the return on an investment of any given product in regard to its performance and installation cost. Apart from the installation process, this section will discuss how performance can be used to the estimate the returns on product investments. This figure is a representation of the developmental process and breakdown of each section in the overall framework.

The methods provided in this framework consider the difficulty of installation, variance in product performance, energy consumption as a result of performance, and a resulting probabilistic investment return. A conceptual map reflects the process of how each part within the developmental process of the PIR value was considered in the overall framework. A graphical representation of how an installer's performance is dependent on their contributions of time and knowledge is presented in Graph 1, representing a trade-off between an installer's knowledge and time spent on installation in relation to how a product performs.

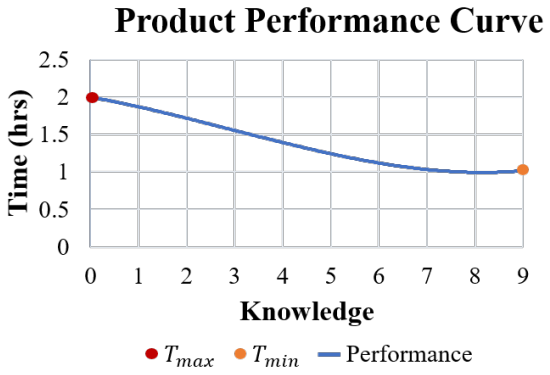

Figure 2. Product Performance Curve.

The above graphic is an example of the performance output of various products throughout a building system. Whether the product is a HVAC unit, heat pump, or roof/wall insulation there are apparent sensitivities to the installation process which require both time and knowledge. The time variable of this analysis was defined to be highly fluctuating due to the innate behavior of the installation process. There is no definite maximum on the time scale to measure the installation time. Depending on the installers' knowledge level different products will require varying time allotments to complete the installation. For this reason, time was treated as a relative variable that could be applied to all products. Knowledge proves to be more difficult to classify when

considering unskilled and skilled persons. This framework focuses on the comprehensive ability of an installer based on their knowledge and experience, so it requires a scale to measure that ability. In the UK, the NVQs, or national vocational qualifications, consists of a system for understanding vocational skill sets in terms of a ranking system. Gann and Senker (1998) suggest that different qualification levels can be met through performance-based assessments of vocational skills within specialized fields. A ranking system was developed in **Table 1** for an individual to place themselves on the knowledge scale. Intuitively, an installer would have a better gauge of their experience and to what extent it can be applied. The scale is also a rubric to help categorize and differentiate between areas of workmanship and understanding, which helps defines an individual's competency level.

Total Knowledge Score (0-9): *K*	

Table 1. Installer Knowledge Level Conditions.

Guo *et. al*., (2012) determined a knowledge worker's human capital scale to include the dimensions of education, work experience, learning ability, and training. The Knowledge Score (K) represents an individual's knowledge within a product installation context.

3 Installation Metric

The graphical representation presented above provides a visual understanding of the relationship between time, knowledge, and performance, but a metric is desired in order to fully understand the magnitude of the relationships. The metric proposed comes in two parts which together describe the installation effort and the variability in that effort.

$$\text{Metric} = \text{Area under Performance Curve} \tag{1}$$

$$\text{Area} = \frac{T_{max} - T_{min}}{T_{max}} \text{ X } 100\%$$

The first portion is determined from the area underneath the performance curve. Each unique product will have its own curve and therefore its own area. In this case, the area is a combination of time and knowledge which together are a representation of the effort required to reach expected performance. In order to perform the installation, the installer spends the necessary amount of time put forth time during the installation process. This time can be considered a portion of the effort required to install the product. The second contributor to this effort comes from the installer's knowledge level. To have met their current knowledge level, an installer must have invested in their understanding, training, and experience. Products which require the installation be completed by knowledgeable installers are considered effort intensive in terms of its underlying training and experience required to complete the process. The combination of time

and knowledge required to perform an installation describe the overall effort of installing the product.

The second portion of the metric intends to describe the variation in time and knowledge across the performance curve. A ratio is created by subtracting the minimum installation time from the maximum installation time and then dividing by the max installation time. This percentage gives an indicator of how much time and knowledge vary in relation to performance. From this percentage we can gain insight on the installation of a product. If this value is high, then the time required for a knowledgeable installer to perform the installation will be significantly less when compared to an unknowledgeable installer. If the percentage is low, then an installer with a high knowledge level will not receive a significant decrease in installation time when compared to unknowledgeable installer. This would indicate that the installation may take a similar amount of 'effort' in terms of time for all knowledge levels. This is particularly useful when determining who should install a product. Installers with greater knowledge levels typically have a higher hourly wage due to their experience and skill. An individual may choose to hire an installer with minimum knowledge if they can pay them less money but still have the job done correctly and on time. Generally, this percentage provides a depiction of the shape and steepness of the curve from start to finish. Both values can provide information on the visualization of the graph. For example, the area represents the space under the curve in units of time and knowledge combined (K-hrs). The percentage represents the time differential between the highest and lowest recorded times throughout the data. Both parameters are essential for providing the bounds of the graph. An example is provided below.

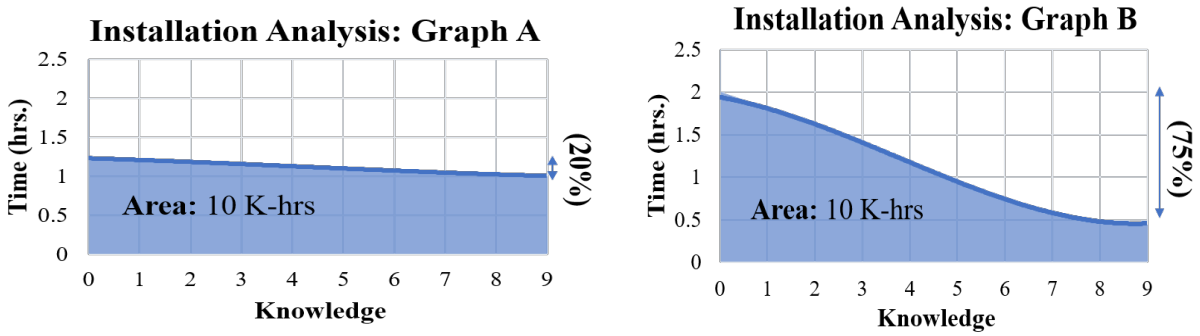

Figure 3. Installation Analysis of Two Performance Curves.

The two graphs shown in Figure 3 above represent possible curves for a product installation. Notably, both curves have a similar area meaning that on average, their installations require similar effort. However, the second graph has a 75% change in time while the first graph has a 20% change in time. This portion of the metric represents the variability of the installation effort across the performance curve. The graph with a 20% change in time is less variable across the curve. An installer with minimal knowledge would not spend a significant amount of time more on the installation than an installer with maximum knowledge. On the other hand, the graph with a 75% change in time has a greater variability in effort across the performance curve. An installer with maximum knowledge will take a significantly less amount of time to perform the installation than an installer with minimum knowledge.

4 Installation Cost

This framework also seeks to understand the costs associated with installation and performance; the installation analysis curve can be adapted to reflect installation costs. Because the knowledge and skills of a laborer are often reflected in their hourly pay, the knowledge scale on the x-axis is

adapted to represent hourly wages of installers. From this change, the cost of installation can be determined.

In Figure 3, the current performance curve is a representation of either the data collected through sampling installations or from the manufacturer questionnaire. The individual data points are a combination of the laborer's wage, W_n, and the installation time T_i. Together these can provide the total installation cost for each installation, C_i. Each individual installation will have its own cost depending on the labor hired to perform the installation. This cost adaptation can then be used to find the current average installation cost for the product being analyzed.

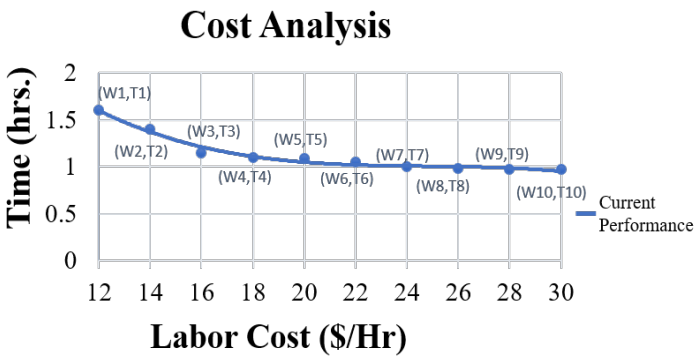

Figure 4. Cost Analysis of Installation.

Installation Cost ($) = Installation Time (hr) x Labor Wage ($\frac{\$}{hr}$)

$$C_i = T_i \text{ x } W_n \tag{2}$$

5 Probabilistic Investment Return

Together, the cost of installation, the cost of the product, and the energy savings for a performance level can provide a general return on investment in terms of years required for the product to pay for itself. We describe this in terms of Probabilistic Investment Return or PIR. The cost of each installation along with the product material cost is then divided by the yearly energy savings of each performance to determine the number of years required to break even on the investment. This is represented as

$$\text{PIR} = \frac{P(C_i) + C_P}{C_E \cdot P(\Delta\,\xi)} \tag{3}$$

where

$P(C_i) = P(T_i * C_w)$; $Probability\ of\ Installation\ Cost$ ($)

$T_i = Installation\ Time\ (hrs)$

$C_w = Installer\ Wage\ (\frac{\$}{hr})$

C_P: $Product\ Cost$ ($)

C_E: $Energy\ Cost\ (\frac{\$}{BTU \times yr})$

$P(\Delta\,\xi)$: $Probability\ of\ Change\ in\ Energy\ Consumption$ (BTU)

6 Conclusion

Throughout this research, we have provided evidence that specialized building products such as HVAC systems and heat pumps are impacted by installation. More specifically, the installers' knowledge is related to how well the product performs. Poor installation of products can result in energy waste in regard to the entire building and its envelope. We have provided a framework for analyzing the impact of installation building performance and its corresponding energy and cost factors. These methods have quantified the contributions of installers to performance levels, the extent of product performance gaps, and the probabilistic return on investment for installing a product. These efforts can then be considered a framework for a holistic understanding of the product installation process and its far-reaching effects on building performance. From this framework, products can be evaluated on an installation basis to determine their effects on building performance and to move toward overall reduced energy consumption in current buildings, retrofit projects, and future constructions.

Abstract. *The paper deals with the first results of the activities of BIG Building Innovative Governance srl, Academic Spin-Off and Innovative Start Up, which provides smart services for Building Maintenance and Facility Management also launching circular R&D actions in the relative reference areas. The contribution introduces some actions actually in progress geared to upgrading the Maintenance Management Model, M3, specifically aimed at managing the life cycle of buildings.*
The current stage of development corresponds to a TRL 4. TRL 8 is that expected by the end of 2020. Characterized by interconnectivity and scalability, the Maintenance Management Model is a dynamic, collaborative and implementable system, whose architecture consists of three separated but strongly interconnected devices: an information interface system, a collaborative platform, a remote cloud. An ICT network infrastructure able to activate using BIM models (IFC and COBie standards) circular information workflows between all operators and/or users involved in Maintenance and Facility Management processes. It allows the development and/or implementation of information management and sharing models based on Open Data and Semantic Web. Its use will also promote shared lexicons and the circulation of knowledge within a holistic process of managing information from and for Maintenance. The use of BIM models and the possibility of collecting and managing a large amount of data will be oriented to the structuring of information feedback databases according to ISO 15686 guidelines. In this way, available information can be usefully transferred in life cycle assessments and service life prediction of materials and components.

Keywords: *Facility Management, Information System, Maintenance Management Model, Operation&Maintenance, Service Life Planning.*

1 Introduction

BIG srl is a spin-off of the *Mediterranean* University of Reggio Calabria, as well as an enterprise registered in the list of innovative Startups.

It operates in the field of technological innovation exploiting, in line with the operational trend of Industry 4.0 and the potentials of Information Communication Technology, ICT; also provides Innovative Integrated Services characterized by technical-scientific nature and high technological value oriented to the construction market and in particular to the Facility Management, FM; develops R&D actions in the sectors focused on Smart Building and Smart Cities drivers. To implement its mission, it assumes as central the interactions between technological capital (infrastructure and technology), human capital (researchers, companies, professionals, users, etc.), administration (institutions, universities, managers, etc.) and real estate (public and/or private heritage).

BIG srl is currently engaged in the experimentation of an innovative governance system for real estate assets, *Maintenance Management Model*, M3.

The service offered through the proposed Maintenance Management Model answer for a primary need of the construction sector as well as of the research one: to increase the effectiveness, efficiency, circulation of information and communication between the operators involved in the management and operation & maintenance practices whose activities presuppose multidisciplinary approaches and great structured data availability.

This primary need is today perceived as immanent criticality for the construction sector. Its effects are felt with concern by technicians and workers, and at the same time, shape a crucial issue that manifests itself in all its severity due to the unexpectedly increasing costs - economic and social – connected with the lack of maintenance of infrastructures, buildings and plants. (World Economic Forum, 2016)

O&M operating and maintenance costs, which are generally neglected during the design phase, generally amount to more than half of the total costs of the building's life cycle (Becerik-Gerber *et al.*, 2012). However, more and more often they represent cost items linked to the inefficiency of choices in the design phase or to mistakes made during the construction phase.

The authors of the paper are among the founders of BIG srl and have been working on the issue for a long time in the scientific and academic field. (Lauria, 2003, Azzalin *et al*. 2005, Lauria and Azzalin, 2006, Azzalin, 2007, Lauria and Azzalin, 2007, Lauria *at al.* 2015, Lauria and Azzalin, 2019, Azzalin, 2019)

In addition to the skills of each founding members, BIG srl avails itself of the expertise recognized to the two industrial partners:

- ACCA software S.p.A. (Https://www.acca.it). Established in 1989, the company is today the Italian leader in the construction software market and a reference point for the sector. For BIG srl provides its expertise and its products with reference to the management of databases, information security, information systems through the implementation and use of collaborative platforms for maintenance and Facility Management purposes.
- BimCo (https://www.bim-co.com), an innovative Startup Enterprise specialized in the use of IT methods and tools for interoperability such as BIM, Building Information Modeling. For BIG srl, BimCo provides the skills related to the production, implementation and management of digital models.

2 Background

The service life and management of a building in its life cycle always combines the terms "costs", "efficiency", "maintainability" and "sustainability" with the planning activity. In this context, Facility Management is defined as an integrated approach oriented to the operation, maintenance, improvement and adaptation of real estate and infrastructure in order to meet the primary objectives of the occupants, owners and managers (Atkin and Brooks, 2009).

Its importance and relevance, assumed by BIG srl as a corporate policy, refers to and is framed, in numerous regulatory actions, scientific research, market trends, both internationally and nationally. The FM involves a relevant field of interest, requires numerous data and information and presupposes multidisciplinary approaches.

The available information and data, whether they concern new or existing construction, are almost never structured to be effectively used in the O&M activities, and not sufficient.

In practice, inefficiencies, disconnected processes and different degrees of dysfunction correspond to this gap.

In the recent past, and even today, data and information for FM are organized and managed by Computerized Maintenance Management System and Computer Aided Facility Management (CMMS and CAFM), Electronic Document Management Systems (EDMS), Building Automation Systems (BAS), etc.

However, these processes are subject to errors (Becerik-Gerber *et al*., 2012).

Today, in general, in the face of still limited use of open standards for structuring and transfer of information, the specific need for open systems and standardized data libraries and specifically declined is added (BIFM, 2012). The availability of open standards, Industrial Foundation Classes, IFC (ISO 16739-1:2018) and data specifications, Construction Operations Building information exchange (COBie-NBIMS-US-V3.4:2015), the diffusion of Building Information Modeling (BIM) methodologies and the adaptation of legacy systems represent the new frontier for the research and standardization challenges. (Kassem *et al.*, 2015a). Several countries, including the United Kingdom in the first place, have introduced and prescribed the use of interoperability tools based on open data, open standards (IFC) and data specifications (COBie) as formats and information exchange methods between the project delivery phases and the use phase of the building (Kassem et al., 2013).

As part of the aforementioned policies, in the United Kingdom the PAS 1192-3:2014 standard (BSI 2014a) is a reference for the structuring of data aimed at the management phase. It introduced an information management methodology based on openBIM standards and data specifications (COBie) connected with BS 8544:2013 (BSI 2013), relating to life cycle costs during the maintenance phase of buildings.

Currently, BuildingSMART deals with the open standards (BIM, IFC and COBie) with the aim of defining languages shared between the various operators and for each of the phases of the building process and the life cycle of the assets. (Atkin and Brooks, 2009).

Further research areas concern the COBie data exchange (Cabinet Office, 2012) for which the British industrial standard BS 1192-4:2014 (BSI 2014b) is the reference.

IFC and COBie are also employed in the context of standardization actions relating to Service Life Planning, ISO 15686 Series. In this sense ISO 15686-4:2014 is a specific reference. The standard proposes "IFC property sets" (IFC4) to support service life planning, including information on the durability of materials, semi-finished products and components. Moreover, the factors that affect durability as introduced in ISO 15686-2:2012, environmental impacts in ISO 15686-6:2004 (at now withdrawn), and Life Cycle Costing (LCC) according to the contents of ISO 15686-5:2017. This thus confirms a strong interrelationship between the LCC assessments, the costs in the usage phase of the building and the decision-making processes aimed at optimizing the Operation & Maintenance phase (Fu *et al.*, 2007, BSRIA, 2009). In other words, in a general context of life cycle management, the BIM based interoperability systems based on open data (IFC standards and COBie) can provide the information needed for planning, execution and management of maintenance actions allowing this information to be structured and kept in an organized management system (CIC, 2012). This system, which can be implemented and accessed over time, will be both a repository and a source of feedback information available at the design stage (Volk *et al.*, 2014).

In short, the essential background introduced above and, more specifically, OpenBIM for FM, the interactions between IFC and COBie and their applications for the management of FM processes and the service life planning (Maxwell, 2005, Kassem *et al.*, 2015b) configure the assumptions from which the R&D actions of BIG srl and the Upgrading of M3 start.

3 Upgrading M3

Currently the upgrade of the Maintenance Management Model, M3 specifically aimed at managing the life cycle of buildings is being implemented thanks to a public financing from the Calabria Region according to the Public Call of POR Calabria ERDF 2014/2020 Action 1.4.1 Support for the creation of innovative micro-enterprises Startup and Spinoff of research.

M3 is aimed at the assistance and smart accompaniment for building maintenance and real estate assets Facility Management activities.

Developed starting from a PhD research (Melchini, 2015), the subsequent definition and implementation of M3 has received significant validation resulting in being the winner and finalist of some contests for innovative business ideas (Coopstartup Calabria Ricomincio da T (r)E, 2016; StartcupCalabria, 2016, national finalist of Startup Europe Awards, 2017).

M3 is an ICT network infrastructure that will allow the development and/or implementation of information management and sharing models based on Open Data, as well as the definition and continuous verification of operational requirements (BSRIA, 2009) among the various operators involved in the whole cycle of life of a building. From the design phase (clients, designers, structural engineers, installers, etc.) and construction (companies and producers / suppliers of materials and components) to management (maintenance personnel, etc.) and disposal phases; and between all operators and the final users themselves (Figure 1).

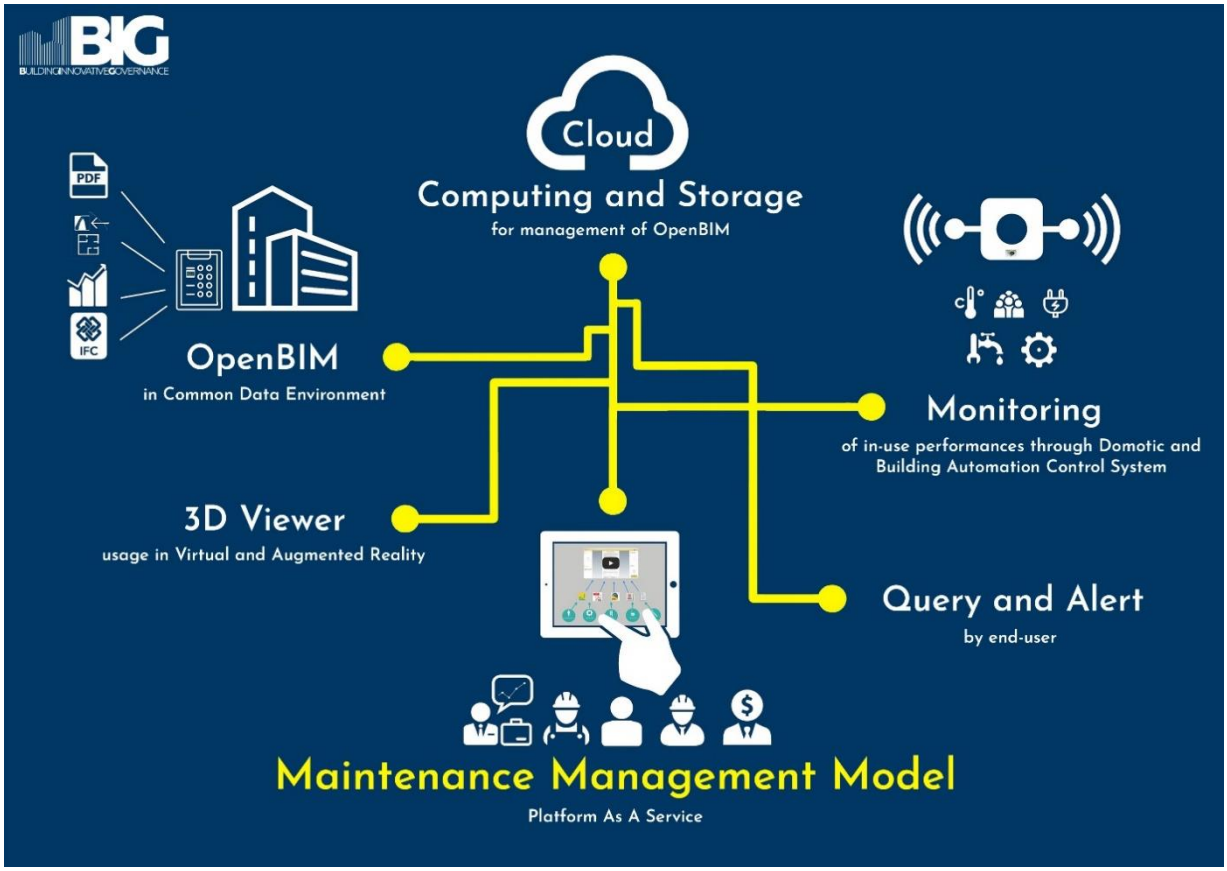

Figure 1. M3 Maintenance Management Model Architecture.

The objective is to support the decision-making process relating to the building management phase through an Information Modeling Asset (AIM) based on openBIM standards (IFC) and specifications on the data structure (COBie).

The structuring of the requirements that allow the definition of the AIM is based on the use of the ISO methodology, Information Delivery Manual (IDM) in ISO 29481-1:2016. A general methodology for defining the requirements of the FM format. In particular, IDM makes possible mapping and describing information processes throughout the life cycle of a building, maintaining links with each of the different phases in which information has been generated, exchanged, controlled and used.

Assumed as an initial development stage of the Management Model, a TRL 4 "low reliability prototype that can be built to demonstrate the technology and its function in the laboratory", a specific Business Development Plan and R&D is being implemented to allow:

- The realization of the engineering functioning model, corresponding to a TRL 6. In the specific case, the expected result is equivalent to an engineering prototype whose technology realizes a first connection level of the three apparatuses that make up the architecture of the Maintenance Management Model: an Information System (AIM); a collaborative platform (usBIM.platform by ACCA Software spa); a Cloud Computing.
- The upgrade to TRL 8 corresponding to a complete prototype system.
- Its experimentation, verification and validation (O.R.R., Operational Readness Review).
- Its marketing.

On a technical level, the availability of all the documentation, information and administrative management relating to the building/s appropriately collected and systematized in digital dossiers will allow, through an integrated system of alphanumeric and graphic databases (IFC and COBie format), the management of complex data concerning localization, use, security, accessibility, employment conditions, usability of spaces.

The availability of a digital twin in OpenBIM format will therefore allow, through a viewer and the interaction in Virtual and Augmented Reality modes, the following visualization:

- information on the current state of construction;
- the behavior of component and sistem transmitted by monitoring system (Building Automation home automation systems);
- the location and degree of severity of active fault and possible operational scenarios for the purpose of the intervention.

The partner ACCA spa, leader in the OpenBIM at national level, has made the usBIM.platform collaborative platform technology available for implementation in the direction described. With usBIM.platform is possible to manage the OpenBIM models (IFC standards and COBie specifications) of each type (architecture, plants, energy, structures, construction site and maintenance) in a single Data Sharing Environment (ACDat) or Common Data Environment (CDE). The related plug-in is being tested through a pilot application to the case study identified in a portion of the building asset of *Mediterranean* University of Reggio Calabria. In particular, the "usage scenario" of the system is the evaluation of IFC4 and COBie 2.4 and some of their enabling technologies.

The ongoing experimentation and the subsequent M3 implementation prefigure some main expected results. Evaluating IFC and COBie support in meeting the information requirements for the creation of the management activity register and proposing ways to implement and extract maintenance requirements respectively in and from BIM models.

The actions undertaken also promote shared lexicons and the circulation of knowledge within an interdisciplinary process of managing information from and for Maintenance.

The use of BIM models and the possibility of collecting and managing a large amount of data will be used as a source of information for service life planning. In particular, they will be oriented to the structuring of information feedback databases according to ISO 15686-7:2017 guidelines related to service life prediction of materials and components.

4 Conclusions

Although the results of the research in these areas refer to experiments that bring to the identification of some general OpenBIM requirements capable of supporting building maintenance activities (Hallberg and Tarandi, 2011, Becerik-Gerber *et al*., 2012, CIC, 2012, Motamedi *et al.*, 2014). To date, detailed studies and systematic evaluations of the IFC and COBie standards applied to FM are still lacking. In fact, it emerges from the literature that these, together with the available software support tools, are still inadequate for the management of the life cycle during the maintenance phase. (Kassem *et al.*, 2015a)

Furthermore, there are no widespread studies on the development of OpenBIM for FM and in particular research aimed at understanding "how" and "if" IFC and COBie can be effectively integrated to support FM processes.

Limits and criticalities that represent the areas of development and implementation of research in general and that related to the upgrade phase of M3 in particular but also of future commitments in the world of standardization and ICT.

In a perspective that embraces a holistic view of the life cycle of an artifact, which considers together: quality, duration, environmental, social and economic costs, the Maintenance Management Model, M3 takes on a dual meaning.

On the one hand, a tool to support the management of real estate assets through the activation of innovative information sharing processes (Open Data and Semantic Web).

On the other hand, it is evident that to effectively support decision-making processes in the development and execution of maintenance strategies, information on the useful life of building components is fundamental (Hovde and Moser, 2004) and should be taken into consideration from the earliest stages of planning (Marteinsson, 2005).

According to this vision M3 is beginning to look as a privileged "observatory" of the phenomena that characterize building systems over time, their operation and their use. Therefore, it appears functional for oriented collection of feedback data relating to the behavior of materials and components in specific contexts according to ISO 15686-7:2017 and as clearly expressed by the same ISO 15686-4:2014.

Abstract. *In the context of the existing buildings, along the recent years the concept of maintenance has changed from corrective maintenance to preventive maintenance, which is based in part on periodic inspections. There is ample evidence that preventive maintenance is more efficient than corrective maintenance, since severe deteriorations that may represent danger to people are avoided, and also money is saved. To make periodic inspections of the buildings is useful to quantify the extent to which deficiencies are severe or not, in order to facilitate decision making and prioritize therapeutic interventions. To this purpose many scales have been used and are used to assess the degree of gravity of the damages in constructive elements. But it is important to say that there is no common consensus and these scales are different between them according to the study to which they belong. Thus, the main goal of this article is to propose a methodology for calculating the degree of severity of damages in buildings, which is of widespread use. This calculation method, which is in distribution and in scalar, lets to calculate the severity index of systems and of the entire building, and it is easy to use and flexible.*

Keywords: *Scale, Severity Index, Damages, Direct Assignment Method, Quartiles.*

1 Introduction

The rapid industrialization and population migration of the last 30 years, has led to a fast growing urbanization, doubling the building and partially the infrastructure stocks in very short periods (20-30 years) (Yang, 2006). In this context, the crucial indicator is the state of degradation of the different components of the stock (Kohler and Yang, 2007). Likewise, "What is not defined can not be measured. What is not measured can not be improved. What is not improved, it is always degraded". This phrase is from Sir William Thomson, Baron Kelvin of Largs. Although the phrase is from the nineteenth century, it is fully in force, and we are well aware of the importance of performing preventive maintenance in buildings in order to prevent their degradation and the appearance of severe deteriorations. In the framework of maintenance is true that to make periodic inspections of buildings, is useful to quantify the extent to which deteriorations are severe or not, in order to facilitate decision making and prioritize therapeutic interventions. In fact many scales have been used and are used to assess the degree of gravity of the constructive elements. But there is no common consensus and these scales are different from each other according to the study to which they belong (Ruiz, 2014).

All the referred shows the need to propose and validate a scale, in order to assess the severity index of constructive elements in buildings, which is of widespread use. Thus, the main goal of this article is to propose a calculation method, in distribution and in scalar, to calculate the degree of severity of systems and of the entire building, easy to use and flexible.

doi:10.23967/dbmc.2020.236

2 Methodology

In most of the known scales, there is not any method to calculate the degree of severity of a system or of the entire building. In the few scales where there is a method, the output values are scalars, which do not show the variability of the distribution of severities. The proposed methodology in this paper aims to add the variability of the distribution of severities in the resulting vector scale. It is also remarkable to highlight that unlike what happens in other areas of science where there are scales widely used and commonly accepted, in the field of the buildings there is not a common scale for assessing the degree of severity of the constructive elements, and there are many different scales. There is no doubt that in building engineering would be very useful to have a common scale and a methodology widely used to assess the degree of severity of the buildings.

2.1 Application Levels

In this section the proposed methodology for calculating the degree of severity of damages in buildings as a whole (biggest proposed unit) or parts thereof, which will be called systems (S) is introduced. It is considered appropriate to propose a reasonable division of building into systems, which is presented in Table 1. In order to provide flexibility to the methodology it allows that the total number of systems and the definition of them can be chosen by the technician that develops the study of the building, thus the proposed method is of general application. Therefore, the building as a whole is the sum of the systems that constitute it, as indicated in Equation (1):

$$Building\text{: } (B) = \sum_{i=1}^{n} (S)_i \tag{1}$$

Table 1. Proposal of building systems.

System	Description	Main constituent parts
1	Façades	Claddings, base material, cantilevers, cornices, windows and other practicable openings, railings, balustrades, ornamental elements, etc.
2	Vertical structure	Pillars, load walls, foundation, etc.
3	Horizontal structure	Beams, beam filling, vaults, arches, etc.
4	Roofs and inner courtyards	Roof tiles, pavements in flat roofs, waterproofing, thermal insulations, skylights, walls and practicable openings for inner courtyards, etc.
5	Interior building elements	Partitions, interior walls, practicable openings, pavements, interior claddings, etc.
6	Staircases	Walls, stair structure, steps, railings, etc.
7	Sewer facilities	Downpipes, drains, gutters, etc.
8	Other facilities	Electricity, water, gas, elevators, etc.

Each system can be divided into zones which constitute the last and smallest proposed unit to value. A zone is defined as a specific part of a constructive element, as for example an area of a wood beams floor, an area of a façade, an area of a reinforced concrete beam floor, an area of a balcony, etc. Figure 1 shows some images that represent what is named zone.

Figure 1. Images of four zones of construction elements.

Thus, the set of zones into which the system has been divided (p), constitutes the entire system, as shown in Equation (2):

$$System: (S)_i = \sum_{j=1}^{p} (Z)_j \tag{2}$$

One important point is that this methodology can be applied to any kind of existing scale of severity of damages in buildings, regardless they are based in direct assignment method (DA) or application of mathematical functions or algorithms method, or in both.

The proposed scale in this paper ranges from value 0 (zero gravity and the constructive element is in perfect condition) to value 10 (extreme gravity; it is not conceivable a greater gravity; pathology in terminal phase; collapse may occur at any time). Due to the scale is applicable to any type of constructive element (walls, beams, columns, bearing walls, façades, etc.), definitions are necessarily generic. These definitions can be seen in Ruiz *et al*. (2019).

2.2 A Vector Scale of Severity of Damages in Buildings

The proposed methodology, which is schematically presented in Figure 2, it is initiated by the direct assignment method (DA) based on the generic definitions of the reference scale, through which the grade or index of severity, G, is assigned to zones, j, of the building. In the variant called (a), the process ends at this level, which is in cases where the object of study is assessing the gravity of different zones of the building, but it is not necessary to evaluate the overall gravity of a system or of the whole building.

The next step of the methodology, when required, is to assess the severity of one or more systems, for which there are the variants called (b) and (c). In variant (b) DA method based on the generic definitions of the proposed scale is used, through which the degree of severity of

the considered system is assigned. In variant (c) the calculation method that it is proposed in the next subsection is used, applying it to the G_j values comprising the zones of the system, which allows to calculate the degree of severity of the considered system.

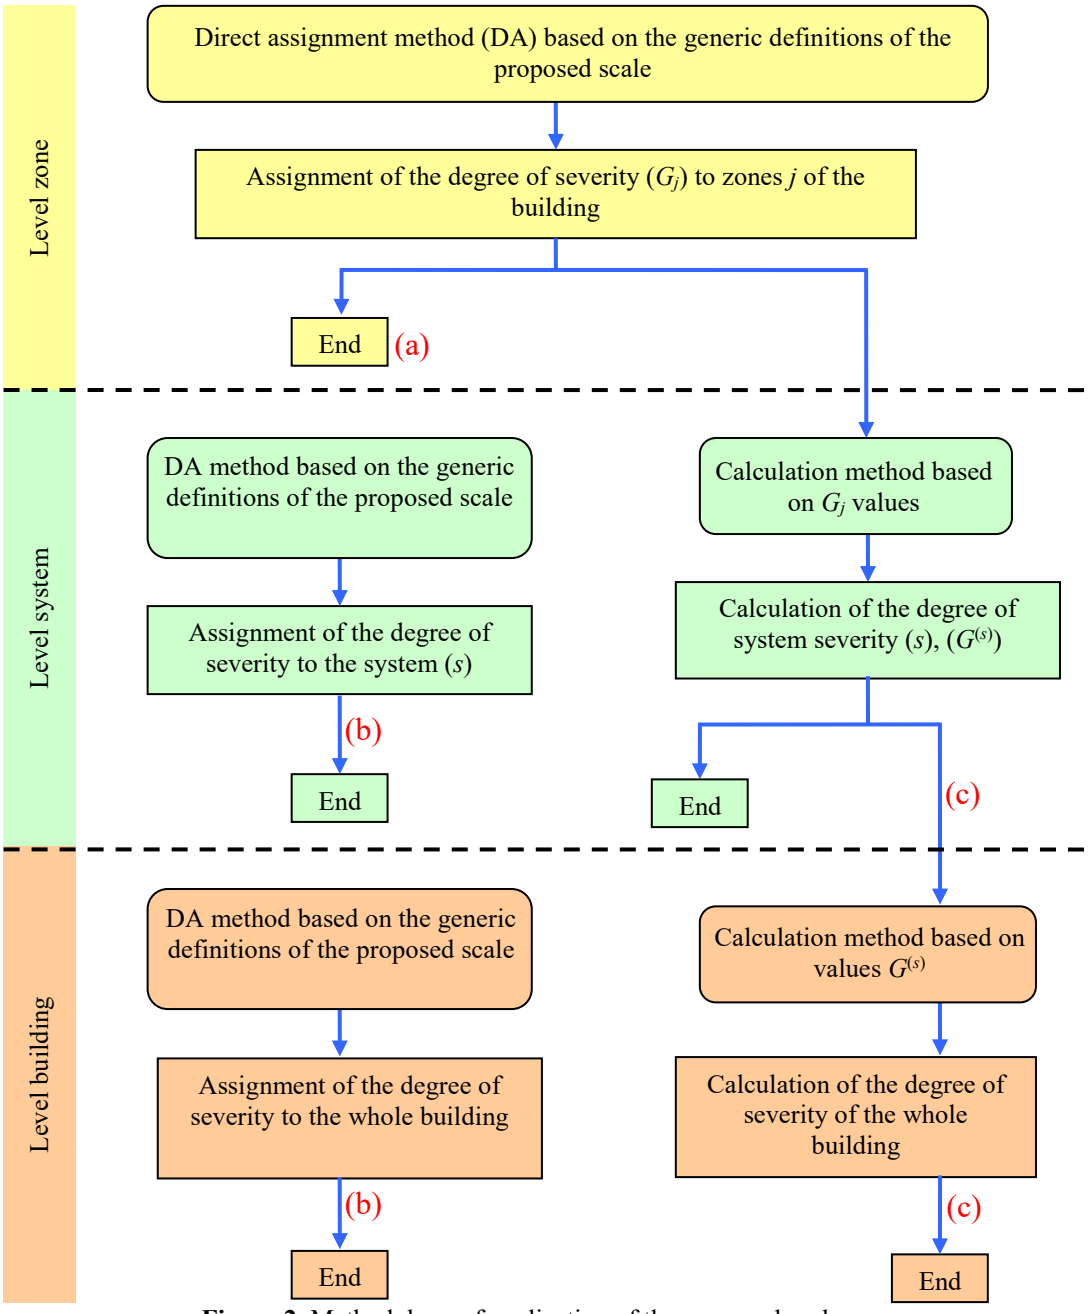

Figure 2. Methodology of application of the proposed scale

The variant (b) is of application in cases where the object of the study is such that it is necessary to spend a short time. Some of these cases may be the following: i) Global study of an urban area, in which it is necessary to assess the grade of gravity of hundreds or thousands of façades; ii) Emergency interventions, such as civil service technicians or firemen in cases of sever

deteriorations with potential risk for people. The variant (c) will be of application in the remaining cases in which is required to determine the grade of gravity of a system or building.

2.2.1 Definitions and computations at system level

Within the framework of variant (c) in Figure 2, first it should be said that to obtain the resultant severity of a system based on the summation of the G_j values of that system, applying a weight w_j that is based on the area or proportion of the zone j (A_j) regarding the area or whole unit (A_T) of the considered system, gives adequate results only for cases that severity of the system is homogeneous, for example if the entire system is heavily degraded or everything is in good condition. However, it gives inadequate results in cases where there is a significant variability of severity in the system, especially in cases of extreme dispersion.

For this reason, after discarding the previous method of calculation for being inadequate, in order to calculate the resulting severity of a system s it is proposed a method based on statistical quantiles. In this case quartiles are used as well as the minimum and maximum values of G_j of the analyzed system, allowing to define the distribution of severity of system s, $G_d^{(s)}$, as follows in Equation (3):

$$G_d^{(s)} = (q_0^{(s)} , q_{0.25}^{(s)} , q_{0.50}^{(s)} , q_{0.75}^{(s)} , q_{1.00}^{(s)}) \tag{3}$$

where, $q_0^{(s)}$ and $q_{1.00}^{(s)}$ are the minimum and maximum value, respectively, of G_j of the system s, and $q_{0.25}^{(s)}$, $q_{0.50}^{(s)}$ and $q_{0.75}^{(s)}$ are the maximum value of G_j corresponding to the 25%, 50%, 75% less degraded, respectively, of the system s.

With this methodology can be directly observed the highest value of G_j of each of the evaluated systems of the building ($q_{1.00}^{(s)}$). Similarly can be directly establish whether the extension of the pathologies is generalized or localized in function of the G_j values, which are derived from analyzing the 25%, 50% or 75% of the system.

The resulting vector of a system s allows to determine the priority of intervention of the system s, which is determined by the value of G_{max}, corresponding to the last value of the vector. $G_d^{(s)}$ also allows to establish the extension of the corresponding dysfunction to G_{max} , extension that it is denoted by $e(.,G_{\max})$, that evaluates the position of the minimum quartile in which the G_{max} value appears. Formally, it is defined in Equation (4):

$$e\left(G_d^{(s)}, G_{\max}\right) = q, \text{ where } q \text{ is the smallest } q_k \text{ such that } q_k = G_{max} \tag{4}$$

Thus, it should be emphasized that the proposed vector $G_d^{(s)} = \left(q_0^{(s)}, q_{0.2}^{(s)}, q_{0.5}^{(s)}, q_{0.7}^{(s)}, q_{1.0}^{(s)}\right)$ gives a lot of information about the severity of the system s, since besides it shows the minimum and maximum severity of the system, it shows the distribution of severities thereof. It must be said that while the vector $G_d^{(s)}$ describes numerically the grade of gravity of a system with sufficient accuracy, the distribution can be interesting to be summarized in a single value. To this end, we propose a method that transforms the vector $G_d^{(s)} \in \{0, \ldots, 10\}^5$ into a scalar $G_r^{(s)} \in [0, 10]$, which it is named resulting severity of the system, and it is denoted by $G_r^{(s)}$.

To estimate the mean value of the distribution and using the relationship $E(X) = \int R(g)dg$ that calculates the expectancy of a positive random variable X (in our case between 0 and 10) as the area under the complementary function of the distribution function ($R(g)$ = 1-$F(g)$), where F denotes the distribution function, it is proposed that $G_r^{(s)}$ is obtained as the first order approximation of the area under the empirical distribution of R from the distribution $G_d^{(s)}$. By construction it takes the values $R(q_0) = 1 - 0 = 1$; $R(q_{0.25}) = 1 - 0{,}25 = 0{,}75$; $R(q_{0.50}) = 1 - 0{,}50 = 0{,}50$; $R(q_{0.75}) = 1 - 0{,}75 = 0{,}25$ y $R(q_{1.00}) = 1 - 1 = 0$. Figure 3 illustrates this calculation for the numerical example $G_d^{(1)} = (0, 2, 5, 5, 8)$.

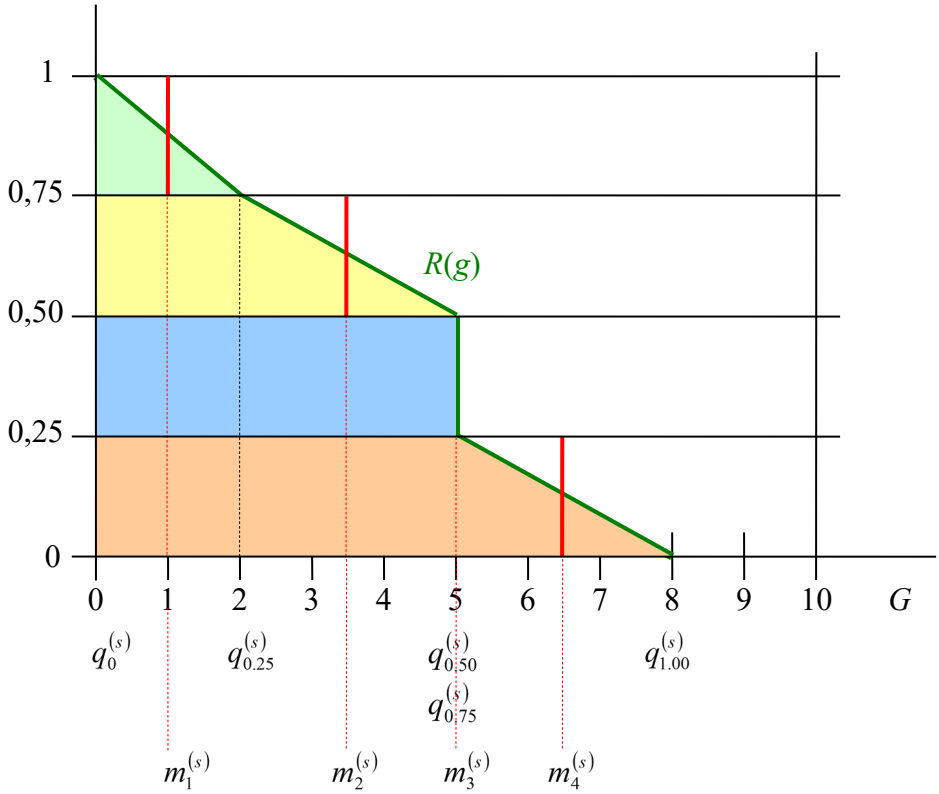

Figure 3. Function to determine the $G_r^{(s)}$ value.

So,

$$G_r^{(s)} = \left(\frac{q_0^{(s)} + q_{0.25}^{(s)}}{2}\right)\cdot 0{,}25 + \left(\frac{q_{0.25}^{(s)} + q_{0.50}^{(s)}}{2}\right)\cdot 0{,}25 + \left(\frac{q_{0.50}^{(s)} + q_{0.75}^{(s)}}{2}\right)\cdot 0{,}25 + \left(\frac{q_{0.75}^{(s)} + q_{1.00}^{(s)}}{2}\right)\cdot 0{,}25 =$$

$$= \frac{q_0^{(s)} + 2q_{0.25}^{(s)} + 2q_{0.50}^{(s)} + 2q_{0.75}^{(s)} + q_{1.00}^{(s)}}{8}, \quad (5)$$

or equivalently

$$G_r^{(s)} = \sum_{i=1}^{4} \frac{m_i^{(s)}}{4}, \quad (6)$$

where $m_i^{(s)}$ are the midpoints between the components of $G_d^{(s)}$.

In order to have a greater sensitivity over the parts of the building with greater severity, it is proposed to generalize the Equation (6), so it could be applied a set of coefficients $w_i^{(s)}$, which allows, among other possibilities, give more weight to the components on the right, which are those corresponding to the highest values G_j of the system. In order to provide flexibility to the methodology, it is proposed that the technician can determine the relative weights $w_i^{(s)}$ to give to each coefficient, under the condition that $\sum_{i=1}^{4} w_i^{(s)} = 1$. These coefficients act on the midpoints $m_i^{(s)}$ between components $q_k^{(s)}$, which allows to obtain $G_{rw}^{(s)}$ ($G_r^{(s)}$ weighted) defined as

$$G_{rw}^{(s)} = \sum_{i=1}^{4} w_i^{(s)} \cdot m_i^{(s)} \tag{7}$$

2.2.2 Definitions and computations at building level

After obtaining vectors $G_d^{(s)}$, s = 1,..., S, representing the distribution of the gravity of each system s, it is defined the distribution of severity of the building (G_d^*), as follows:

$$G_d^* = \begin{pmatrix} G_d^{(1)} \\ G_d^{(2)} \\ \dots \\ G_d^{(S)} \end{pmatrix} = \begin{pmatrix} q_0^{(1)} & q_{0.25}^{(1)} & q_{0.50}^{(1)} & q_{0.75}^{(1)} & q_{1.00}^{(1)} \\ q_0^{(2)} & q_{0.25}^{(2)} & q_{0.50}^{(2)} & q_{0.75}^{(2)} & q_{1.00}^{(2)} \\ \dots & \dots & \dots & \dots & \dots \\ q_0^{(S)} & q_{0.25}^{(S)} & q_{0.50}^{(S)} & q_{0.75}^{(S)} & q_{1.00}^{(S)} \end{pmatrix} \tag{8}$$

Therefore, G_d^* is a Sx5 matrix, stacking by rows the severity distributions of each system. Similarly than before, matrix G_d^* can be summarized to a single value $G^* \in [0,10]$ by defining

$$G_w^* = \frac{\sum_{s=1}^{S} w^{(s)} \cdot G_{rw}^{(s)} \cdot w_{(\tilde{s})}}{\sum_{s=1}^{S} w^{(s)} \cdot w_{(\tilde{s})}}, \tag{9}$$

where

- $w^{(s)}$: coefficient for each of the S systems of the building, in order to give more weight to the most important systems.
- $w_{(\tilde{s})}$: coefficient for each of the S systems of the building, in order to give more weight to those systems that are in worse condition, which numerically means to give more weight to those highest values $G_{rw}^{(s)}$.

3 Conclusion

It should be noted that the proposed methodology can be easy applied by a technician. Just determining the G_j severity (through DA method) and the A_j surfaces of different areas j, it is possible to obtain automatically the resulting severities of each system $G_{rw}^{(s)}$ and the resulting severity of the building, by using a spreadsheet. Likewise, when applying the methodology to real cases, consistent results have

been obtained, confirming the validation of the proposed methodology. Finally, it has been proven that this vector scale is an efficient tool as support to the technician in decision making.

Abstract. *The evolution of the state of a structure is characterized by deterioration. This is mainly due to corrosion of the steel reinforcement and damage from mechanical solicitations. The maintenance of existing infrastructures involves a good grasp of their condition and a high level of expertise on the part of the project managers. An accurate assessment of the bridge state condition is required to plan maintenance and repair activities for better durability, and to maintain the level of service of the road network. In this paper, an effective management framework for bridge is proposed using field observations from visual inspections. Each element of the bridge was evaluated separately by a visual inspection from which were derived ratings to quantify the structural performance and the material condition. The element ratings were also combined to obtain an overall rating for the bridge considering its defects and impact on the behavior of the complete structure. The modelling approach proposed in this work can better represent the deterioration of concrete-built bridges when the defect is visible. A representative structure in Quebec was studied to illustrate how to apply the methodology for the assessment of a real structure condition at specific times.*

Keywords: *Concrete, Bridge, State, Assessment, Durability.*

1 Introduction

The main cause of deterioration of road structures in cold regions is steel rebar corrosion in concrete with the presence of chloride ions (Conciatori, *et al.,* 2018; Roelfstra, *et al.,* 2004).

However, using de-icing salts during winter, due to the microclimate, problematic for the safety of structures (Angst, 2019). For example, there are 614,387 bridges in the USA, among which 56,007 were structurally deficient in 2016. Most bridges have been designed for a 50-year service life, but nearly 40% of them are more than 50 years old. Currently, the average age of those bridges is 43 years. Around 188 million users cross a structurally deficient bridge every day. The latest estimations bring the backlog of bridge rehabilitation needs in the USA to $123 billion (ASCE, 2017). In Canada, 60% of structures in the national highway network will be

more than 40 years old in 2020. The number of bridges built more than 50 years ago, has increased by 50% since 2010 (RRN, 2010). Usually, repair works are done each 30 years period.

For the next few years, maintenance and repair needs in Quebec, Canada will reach a high level. The setting of Quebec is interesting because it is a Nordic climate where the challenges of a cold, harsh winter, de-icing, etc. are significant.

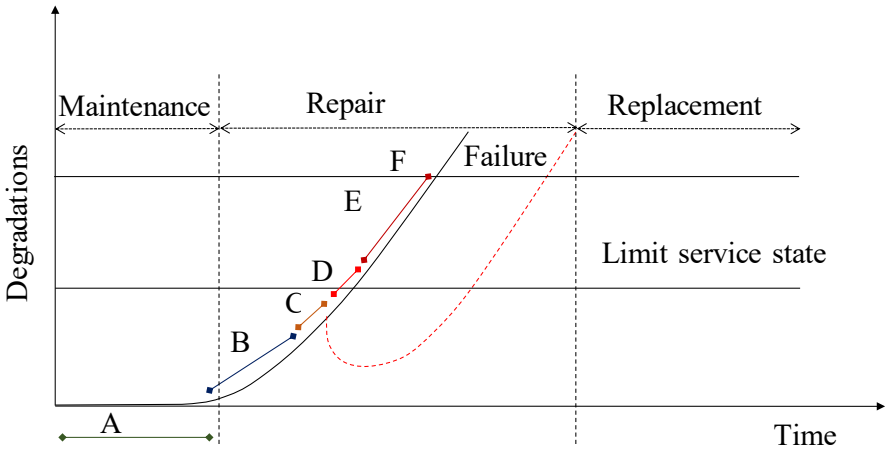

Figure 1. Evolution of the deterioration state of a reinforced concrete bridge: A: Very good; B: Good; C: Satisfactory; D: Bad; E: Very bad; F: Failure.

Monitoring the state condition of a bridge allows one to plan maintenance and repair activities. These activities, including replacement, have a considerable impact on the mobility of users and goods. Historical and current visual inspection data on bridge condition can be used to predict future bridge state conditions (Stewart, 2001). Inspectors are aware of the fast deterioration thanks to the visual inspection results and their follow-up is closer when degradation appears for the sensitive structural elements. Detailed historical inspection reports can be used to determine, during future inspections, the kinetics of degradation (CSA, 2014).

The evolution of the deterioration state of a reinforced concrete bridge and its rehabilitation can be represented with the state index indicator (Figure 1). A, B and C ratings mean very good, good and satisfactory conditions, respectively. D and E ratings are bad and very bad conditions, respectively (MTQ, 2018). The fundamental interest of a project manager is to understand perfectly the permissible service and failure limit states in order to plan appropriate repair activities (Ter Berg, *et al.,* 2019). Sustainability and resilience concepts for infrastructure systems are important for the community. Consequently, both of these concepts need to be integrated at the level of the infrastructure assessment to accurately determine the performance criteria of an infrastructure (Lounis and McAllister, 2016). This allows to consider the acceptable risk of service failure to minimize the consequences associated with the different limit states such as: accidents, interruptions of service to users and repair costs (Adey, *et al.,* 2003).

In this paper, a new approach to assess the condition of a typical structure is proposed. The methodology has been applied on a 60 year reinforced concrete bridge in Quebec (Figure 2).

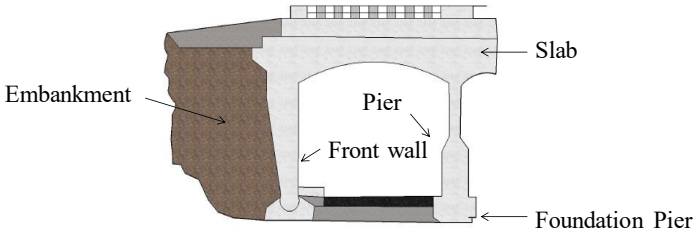

Figure 2. Half profile of the bridge (Quebec).

The bridge consists of a portico with two symmetrical spans (the free span is 11.4 m).The deck is a thick slab kind. Its thickness at the level of the supports is 1 m and its thickness at the centre is 0.60 m. The extremity supports and the central pier are continuous over the full width of the structure. It has four traffic lanes. The closure would cause significant inconvenience for the users which access to the lower four lanes under the bridge. This paper focuses on the degradation analysis process and the bridge assessment. This approach introduces a new management methodology for making an optimal and sustainable decision for bridge maintenance.

2 Degradation Analysis Process

A visual inspection of this bridge allowed us to evaluate its material and structural behavior state. The defects were identified during the visual inspection process, following the methodology in the inspection manual of the 'Ministère des Transports du Québec'(MTQ, 2017). The objective of the experimental procedure was to assess separately by the visual inspection method: (i) the material deterioration and (ii) the structural behavior of the bridge.

The purpose of material condition assessment is to provide with an assessment of the material defects detected on an element. To do this, four states ($\alpha, \beta, \gamma, \delta$) are defined, depending on the severity levels observed: no deterioration, moderate deterioration, significant deterioration, and very significant deterioration, respectively. The structural behavior evaluation rating of an element i (b_i rating) gives an indication of the impact of defects on its structural capacity, functionality, stability, user comfort and safety. The behavior rating for each bridge element is estimated with a four degradation scale: $1 \rightarrow 4$ (1 being the worst and 4 the best behavior).

Figure 3. Visual inspection of the front wall of the bridge.

The bridge was divided into elements, which were evaluated separately. As an example, the visual condition of the bridge front wall showed a reparation during the visual inspection (Figure 3).

Table 1. Visual inspection rating of material condition and behavior of the front wall of the bridge.

	Material (%)				Behavior
Ratings	α	β	γ	δ	b_i
Front wall	15	0	85	0	3

The inspection report for the front wall showed: α = 15% of the material has no deterioration and γ = 85 % has to be repaired, and the structural behavior reaches a rating of b_i = 3 because this defect affects appreciably the stability of the structure (Table 1). Similarly, the material and behavior defects for each element of the bridge were performed and presented in section 3 (Table 2).

The local rating on structural elements, as described above, allows one to identify the wrong behavior or a major deterioration on a part of the structure. This could provide the managers the idea to conduct some urgent local repair. However, structure managers are often interested to assess a global index of their structure. The global index allows managing the structure in the network scale and to plan its intervention agenda according to the whole network state, and with a minimum impact on the traffic. This global index gives an indication on the structural behavior and the material deterioration level of the entire structure, considering their impacts.

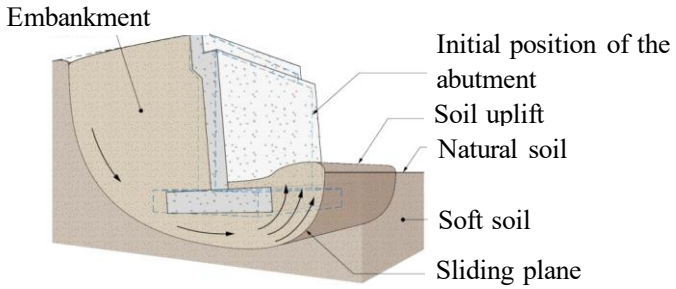

Figure 4. Example of abutment failure links (MTQ, 2017).

The following model proposes an evaluation of the global index as defects of each element (rating of each element) and the impact of the default on the structure by a decision tree analysis. The element ratings are merged considering failure assignment links to obtain the bridge global rating. For example, an abutment with a soil failure links has a repercussion on the abutment foundation (Figure 4). Additionally, the abutment foundation has a repercussion on the bridge seat, and the bridge seat has a repercussion on the slab. Let x_{ij} the defects affectation link between two elements *i* and *j*,

- x_{ij} = 1 when the degradation of an element i directly affects the adjacent element *j*;
- x_{ij} = 0 when there is no link between the defects of the adjacent elements i and *j*.

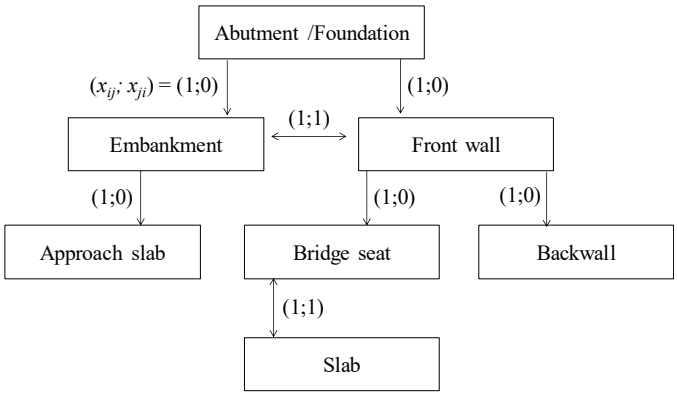

Figure 5. Failure links $(x_{ij}; x_{ji})$ for the abutment of the bridge.

In this way, $(x_{ij}; x_{ji}) = (1; 0)$ when element i is affected by element j but a defect of element j does not impact element i. Moreover, $(x_{ij}; x_{ji}) = (1; 1)$ when the defect of element i affects element j and, conversely, a defect of element j affects element i. The defect affectations of the bridge are given for the previous example with the abutment in Figure 5. This systematic approach is based on the qualitative and quantitative analysis of the visual inspection records. The parent-child principle, based on the decision tree analysis, enables to gradually identify the different links between the element failures at the local level. Thereafter, the bridge was assessed at the global level with different equations developed in the following section.

3 Bridge Assessment

For the bridge assessment, as initiated previously in section 2, two scales are developed: a local scale at the level of the structural element, and a global scale at the level of the structure. In this part, the rating of each element is calculated, and then a new model for assessing the material global index I_M and the behavior condition I_B of the bridge is proposed. A visual inspection was conducted in situ on the bridge to evaluate the material rating m_i and the behavior rating b_i of each element i. The visual inspection results for each bridge element are presented in Table 2. Some information is missing because the elements concerned were neither accessible nor visible.

Table 2. Visual inspection rating of material condition and behavior of the first span of the bridge.

Element	Material					Behavior
	α	β	σ	δ	m_i	b_i
Backfill Granular						4
Foundation Prefabricated concrete piles / abutment						4
Front Wall	15%	0	85%	0	2	3
Foundation Prefabricated concrete piles / Pier						4
Pier/Barrel	98%	0	2%	0	4	4

Running surface	80%	10%	10%	0	3	3
External side (North)	95%	0	5%	0	4	3
External side (South)	95%	0	5%	0	4	3
Deck Regular concrete slab	99%	0	1%	0	4	4
Sidewalk (North)	80%	20%	0	0	4	4
Sidewalk (South)	20%	0	80%	0	2	2
Guardrails Other Models	20%	80%	0	0	3	4

The four levels of material condition degradation (α to δ) were combined to obtain a single material rating m_i for each element i through equation (1):

$$m_i = \sum_{j=1}^{4} \frac{P_{j,i}}{P_{1,i}+\cdots+P_{4,i}}(5-j) \;\; with \;\; P_{1,i} = \alpha_i^{\exp n_{(\alpha)}}, \ldots, P_{4,i} = \delta_i^{\exp n_{(\delta)}} \tag{1}$$

P is the deterioration penalty of the bridge element i, n is the weight of the deterioration penalty, the exponential function represents a factor of the deterioration penalty, and j *is* the deterioration level. In this study, n is fixed for each level of degradation and defined such that the repair activities must be recommended for each element (Table 3) if at least one of the following conditions is true : $\delta > 1\%$; $\beta > 15\%$ and $\gamma > 13\%$; $\beta > 45\%$ and $\gamma = 13\%$; $\beta = 0$ and $\gamma \geq 15\%$. Such conditions allow to consider the moderate degradations β that are currently not considered by the traditional infrastructure managements.

Table 3. Weight of the penalty n assumed in this study.

Material state		$\boldsymbol{n}_{(.)}$
No deterioration	(α)	0
Moderate deterioration	(β)	0.15
Significant deterioration	(γ)	0.73
Very significant deterioration	(δ)	2.5

An example of the material rating calculation for the front wall of the bridge is illustrated by equation (2). m_i was evaluated using the extended visual inspection in Table 1:

$$m_i = \frac{15^{\exp 0}}{10{,}093}\cdot(5-1) + \frac{85^{\exp 0.73}}{10{,}093}\cdot(5-3) \approx 2 \tag{2}$$

Finally, the global index I_M and I_B are obtained from the rating m_i and b_i calculated for each element i and from the global assignment links (x_{ij}; x_{ji}). Intermediate equations R_M and R_B were defined to simplify the expression of I_M and I_B such as:

$$R_M = \sum_{i\epsilon W} A^{m_i} \sum_{j\epsilon W\setminus i} x_{ij} \text{ and } R_B = \sum_{i\epsilon W} A^{b_i} \sum_{j\epsilon W\setminus i} x_{ij} \tag{3}$$

where W is the global assignment links and A the factor of degradation evolution. A was assumed to be equal to 5 in this paper (W.R. de Sitter, 1984). Thus,

$$I_M(\%) = 100 * \left(1 - \left[\frac{R_M - R_{M_{best\,(\forall\, i,\ m_i=4)}}}{R_{M_{worst\,(\forall\, i,\ m_i=1)}} - R_{M_{best\,(\forall\, i,\ m_i=4)}}}\right]\right) \quad (4)$$

$$I_B\,(\%) = 100 * \left(1 - \left[\frac{R_B - R_{B_{best\,(\forall\, i,\ b_i=4)}}}{R_{B_{worse\,(\forall\, i,\ b_i=1)}} - R_{B_{best\,(\forall\, i,\ b_i=4)}}}\right]\right) \quad (5)$$

4 Results and Discussions

For the entire bridge, the results of the assessment model computations, based on the visual inspection, to assess its state condition are: I_M = 78.76 % and I_B = 79.97 % (Figure 6). The results of this model show that the deterioration level of the bridge, both in material and behavior is lower than the maximum accepted limit of 80 % defined by public sector managers. For structures in good condition, maintenance is recommended between 75 and 80 % as soon as possible. The present model allows one to provide advice for a maintenance to avoid further major repairs. However, using a model only based on visual inspection can only identified most obvious visible deteriorations (identified by C, D and E phases in Figure 1). The early signs of deteriorations, such as probable steel rebar corrosion (phase B), cannot be detected by the visual inspections to prevent the further deteriorations and anticipate preventive maintenance for cost efficiency.

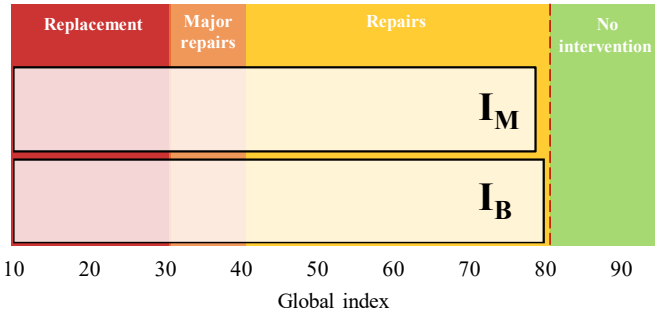

Figure 6. Bridge behavior and material condition by visual inspection.

5 Conclusion

The challenge for maintaining existing infrastructure plays an important role in a country's economical and social activities. This paper addresses the assessment of a bridge condition focusing on the resilience of each element at the local level to achieve a significant benefit at the global level of the bridge based on the visual inspection. The developed visual inspection model incorporates (in the assessment) the effects of moderate degradations, which are generally ignored by inspection managers. The consideration of those degradation levels revealed that the bridge needs maintenance. As a result, this assessment model based on visual

inspections allows to improve the degradation rating used by traditional public managers.

However, the uncertainty on the physical and chemical degradation observed by visual inspection have an important impact on the computation of the material and behavior indices. Further works in progress will improve the assessment of the bridge state condition by coupling the visual inspection model presented in this paper with a deterioration prediction model. This approach will refine the deterioration assessment to the early state phases (A and B phases in Figure 1) to forecast preventive maintenances.

Abstract. *Most of the maintenance actions in the construction sector are still reactive and sporadic, based on subjective criteria. Usually, maintenance actions are performed when the building already presents unacceptable degradation levels, and the reactive maintenance actions carried out only correct the anomalies observed, not dealing with the causes, thus leading to additional costs and risks for owners. This study establishes a condition-based maintenance model applied to natural stone claddings. This model has a stochastic nature, in order to deal with the complexity of the degradation phenomena. For that purpose, Petri nets are used, providing an efficient tool to model the deterioration process and the maintenance decisions considered for stone claddings. The maintenance model is a full life-cycle model that encompasses: (i) the stochastic assessment of the degradation condition of the stone claddings, and their expected service life; (ii) and the inspections, maintenance and renewal processes. In this study, three maintenance strategies are considered: (i) major intervention only; (ii) combination of minor and major interventions; and (iii) combination of cleaning operations, minor and major interventions. The impact of the different maintenance strategies in the future performance and remaining service life of stone claddings is analysed, also evaluating the economic impact of each maintenance plan.*

Keywords: *Degradation, Service Life, Maintenance, Natural Stone Claddings, Petri Net.*

1 Introduction

The awareness of the building managers and/or owners about the need to maintain their assets more efficiently has increased over the last years (Silva and de Brito, 2019). The maintenance of buildings' envelope elements is not yet a first concern (Forster and Kayan, 2009; Thomsen and van der Flier, 2011). Usually, maintenance actions are carried out when the buildings' envelope elements are already severely degraded, or reactive maintenance actions are performed to react to failures and do not deal with the causes (Mobley, 2014), thus leading to additional costs and risks (Dann and Cantell, 2005). Furthermore, regular inspections to assess the condition and maintenance actions on these elements are not mandatory (Shohet *et al*., 2002). The definition of the end of their service life is subjective, based on the outward appearance, owners/users' demands and the funds available for maintenance works (Emídio *et al*., 2014).

Therefore, the development of more efficient methodologies for the implementation of strategic planning of maintenance actions is important (Lacasse and Vanier, 1996; Aikivuori, 1999). The existing tools have several limitations (Ashworth, 1996; Sherwin, 2000; Forster and Kayan, 2009): scarce data about maintenance protocols; poor or non-existent implementation of strategic procedures; lack of information regarding durability and performance of buildings; insufficiently accuracy of the existing maintenance policies; and lack of infor-

doi:10.23967/dbmc.2020.026

mation about global costs associated with repairs. This information is extremely relevant to managers, insurers, owners or users, and allows the adoption of more sustainable and durable solutions at the design stage and for the definition and implementation of reliable maintenance policies, enabling a more rational management of the building stock.

The main purpose of this study is the development and implementation of a condition-based maintenance model for Natural Stone Claddings (NSC). The proposed model is implemented using a stochastic Petri Nets (PN) framework. The case study selected is composed of 203 NSC, located in Portugal. The sample was established based on the diagnosis of the degradation condition of these claddings in-service performance, through *in situ* visual inspection. In the methodology developed, three maintenance strategies are assessed: (i) major intervention only; (ii) combination of minor and major interventions; and (iii) combination of cleaning operations, minor and major interventions. The first one represents the most common solution adopted by buildings' owners. The other two are analysed in order to evaluate the impact of the different alternatives in the claddings' service life and in the whole-life maintenance costs, for the period under analysis.

2 Petri Nets (PN)

PN are a mathematical and graphical modelling tool, introduced by Carl A. Petri in 1962 (Petri, 1962), suitable for description of systems whose dynamics are characterized as being concurrent, asynchronous, distributed, parallel, nondeterministic, and/or stochastic (Murata, 1989).

In a few words, PN can be defined as a bipartite directed graph that comprises two types of nodes, places (representing a state or condition of the system, drawn by circles) and transitions (representing an action, denoted by bars and/or boxes). Both nodes are linked by directed arcs. An arc connects a place with a transition, or vice-versa. Tokens (drawn by small black dots) are stored in places and its distribution (denoted by marking, M) represents the current state of the system. Transitions are responsible for the evolution of the system from one state to another (movement of the tokens between places). A transition is enabled to fire when, in all input places, there is at least one token. Furthermore, it is possible to assign to each transition a firing rate that can be deterministic or modelled by any probabilistic distribution. Figure 1 shows an example of PN composed of three places (p_1, p_2, p_3) and one transition (t_1). In this example, the transition is not enabled to fire since place p_2 is empty.

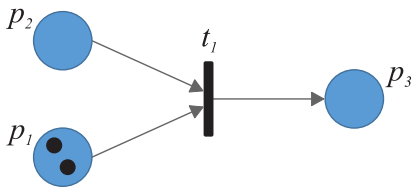

Figure 1. Example of a Petri net.

3 Maintenance Model

The maintenance model, based on the Petri nets methodology, proposed to assess the performance of NSC, is presented in Figure 2. Below, the meaning of each part of the model is briefly described. More information about the model can be seen in Ferreira *et al.* (2019).

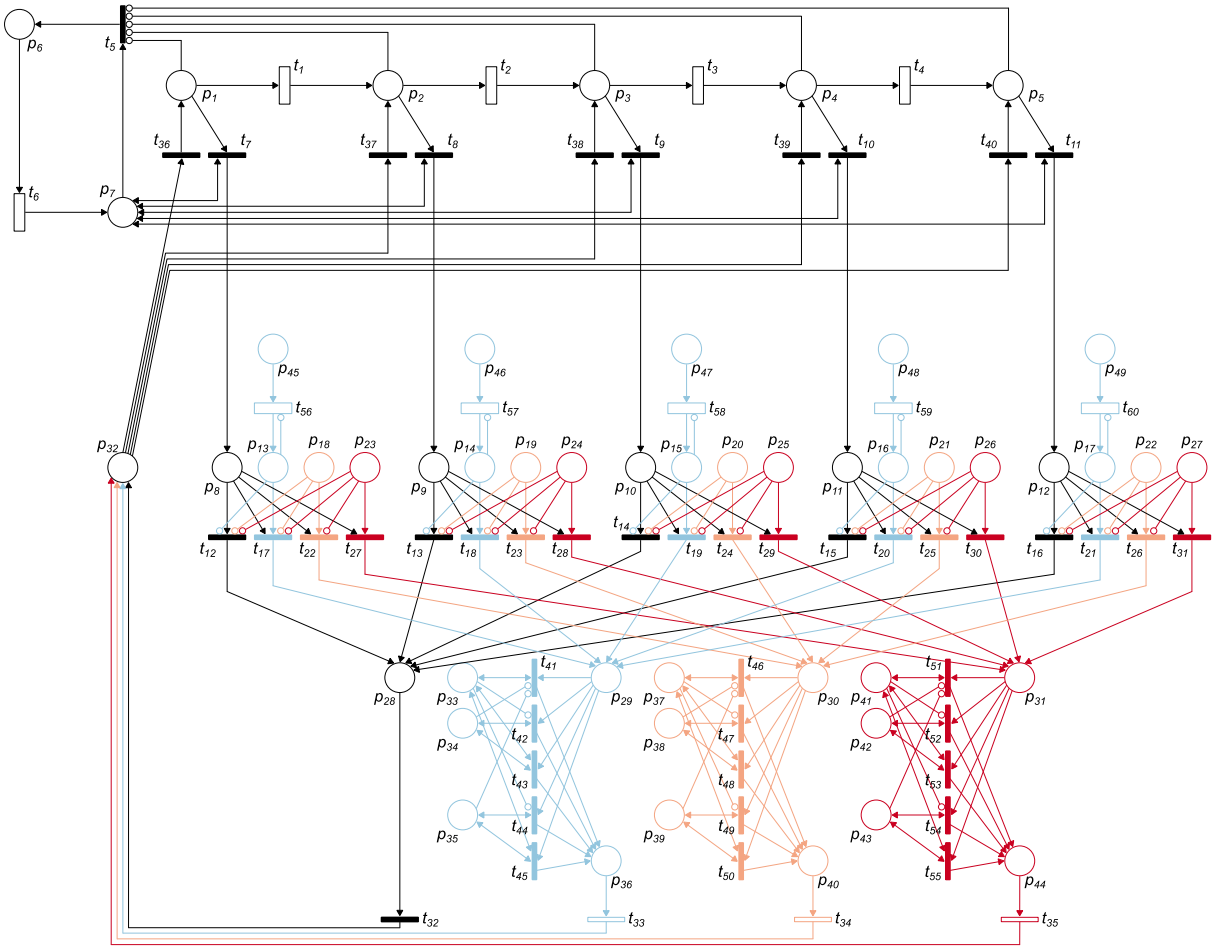

Figure 2. Petri net scheme of the maintenance model proposed.

The maintenance model implemented is a condition-based model, where it is assumed that maintenance actions are planned after the condition has been assessed through inspections. In other words, the need for a maintenance action is assessed during inspection, and then, according to the current observed degradation condition of the component under analysis, a decision on intervening is made. The model can be divided in several main parts: (i) degradation process; (ii) inspection process; (iii) maintenance process; (iv) modelling of the maintenance actions; and (v) periodicity of the cleaning operations.

In Figure 2, the degradation process is depicted by five places (p_1 to p_5) and four timed transitions (t_1 to t_4). Each place denotes a condition level defined in the classification system adopted, where places p_1 and p_5 represent, respectively, the best and worst condition level of the classification system. The timed transitions, located between places, model the transition times of moving between different condition levels. The transition times are samples from the appropriate distributions that can be obtained by studying the degradation characteristics of the NSC (Le and Andrews, 2016). The classification system adopted (Table 1), proposed by Silva *et al.* (2011), is based on visual inspections of the extent of the cladding area affected by the different anomalies. The severity of degradation index, S_w, is defined with the intent of expressing the overall degradation condition of these claddings, and is given by the ratio between the area affected by the defects

observed in a NSC, weighted according to their severity, and a reference area equivalent to the total cladding area with the highest possible level of degradation (Equation 1) (Silva *et al*., 2016).

$$S_w = \frac{\sum(A_n \times k_n \times k_{a,n})}{A \times \sum k} \quad (1)$$

where S_w represents the severity of degradation (in %), k the multiplying factor corresponding to the highest degradation condition level of the cladded area A, A_n the cladding area affected by any defect n (in m^2), k_n the multiplication factor for the defect n, in terms of their degradation condition, and A the total area of the NSC (in m^2). More information about the classification of defects and the determination of S_w can be found in Silva *et al*. (2016).

Table 1. Degradation conditions for natural stone cladding.

Degradation condition	Severity of degradation
Condition A: No visible degradation	$S_w \leq 1\%$
Condition B: Good	$1\% < S_w \leq 8\%$
Condition C: Slight degradation	$8\% < S_w \leq 20\%$
Condition D: Moderate degradation	$20\% < S_w \leq 45\%$
Condition E: Generalized degradation	$S_w \geq 45\%$

The inspection process is modelled through the cycle formed by nodes: p_6 - t_6 - p_7 - t_5 - p_6 (Andrews, 2013). A token in place p_6 means that an inspection should not be performed at that time and enables transitions t_6 that manages the time intervals between inspections, θ. A token in place p_7 means that it is time to perform an inspection, enabling several actions. First, it enables one of the transitions t_7 to t_{11}. The firing of one of these transitions allows revealing the true condition of the cladding. A token in places p_8, p_9, p_{10}, p_{11} or p_{12} means, respectively, that the true condition of the cladding is A, B, C, D or E. After that, transition t_5 is enabled, which causes the token in place p_7 to return to place p_6 to wait for the next inspection.

The maintenance process is represented by places p_{13} to p_{32} and by the transitions t_{12} to t_{40}. Here, the available types of interventions are analysed, according to the observed conditions. In the proposed methodology, three intervention levels are considered: cleaning operations, minor and major interventions. This information is introduced in the model through places p_{13} to p_{27}. Tokens in places p_{13} to p_{17} mean cleaning operations must be done, in p_{18} to p_{22} that a minor intervention is needed, and in p_{23} to p_{27} that a major intervention is required. If there is no token in these places, no interventions are performed. Otherwise, if, for the same condition, there is more than one type of intervention available, the highest impact intervention is performed. A token in places p_{28}, p_{29}, p_{30} or p_{31} indicates, respectively, that no intervention, cleaning operations, minor or major interventions are required. After that, the token returns to the degradation process by place p_{32} and transitions t_{36} to t_{40}.

In Figure 2, the cleaning operations is modelled by places p_{33} to p_{36} and by transitions t_{41} to t_{45}. The marking of places p_{33}, p_{34} or p_{35} means, respectively, that the cleaning operation, when applied, has the effect of improving the condition, supressing the degradation process or reducing the deterioration rate. Then, depending on the impact of the cleaning operation on the cladding, only one transition can be fired. For the minor (places p_{37} to p_{40} and transitions t_{46} to t_{50}) and major (places p_{41} to p_{44} and transitions t_{51} to t_{55}) interventions, the same methodology is implemented.

In this model, the periodicity of the cleaning operations is considered through places p_{45} to p_{49} and timed transitions t_{56} to t_{60}. The introduction of the information that this intervention is available in a given condition level is performed by placing tokens in places p_{45} to p_{49}. Transitions t_{56} to t_{60} are associated with a delay that allows, at the end of θ_{clean} time units, the tokens present in places p_{45} to p_{49} to be returned to places p_{13} to p_{17}, allowing cleaning operations to be performed at the next inspection time, if the imposed constrains are complied with.

4 Case Study: Natural Stone Claddings

The case study under examination is composed of 203 NSC directly adhered to the substrate, located in Portugal. The degradation condition of each cladding in the data set was analysed based on *in situ* visual inspections. The methodology described, was applied to analyse the degradation of NSC over their lifetime. A 150-year time horizon was considered and the cladding is expected to be in perfect conditions at the beginning of the analysis (in condition A).

4.1 Probabilistic Analysis of the Deterioration Process

To find the best distribution that describes the degradation characteristics of the NSC, the degradation process (without maintenance) is applied to the complete sample. Table 2 shows the optimized estimation parameters obtained for the three distribution functions (Exponential, Weibull and Lognormal) analysed, in terms of mean time in each degradation condition and standard deviation, as well as the respective log-likelihood value.

Table 2. Optimal parameters obtained using the three distributions analysed.

Distributions	Mean [years]				Standard deviation [years]				-log L
	T_A	T_B	T_C	T_D	T_A	T_B	T_C	T_D	
Exponential	5.8	51.6	84.9	1.67×10^7	5.8	51.6	84.9	1.67×10^7	161.89
Weibull	4.1	42.9	22.4	49.9	7.0	10.3	1.4	2.4	125.56
Lognormal	4.2	44.0	24.3	1.54×10^6	11.3	13.3	0.3	2.50×10^7	127.12

The parameters of the probability density function are fitted to the historic database based on the concept of maximum likelihood (Kalbfleisch and Lawless, 1985). The likelihood, L, is defined as the predicted probability of occurrence of the observed transitions (Equation 2).

$$L = \prod\prod\prod p_{ij} \Longrightarrow \log L = \sum\sum p_{ij} \tag{2}$$

where p_{ij} is the probability of transition from deterioration condition i to j.

The results allow concluding that two-parameter distributions (Weibull and Lognormal) show a better adjustment to the data set than the Exponential distribution. Since Weibull distribution is the one that shows a minor log-likelihood, log L, value and, consequently, a better fit to the historical data, this distribution is chosen to sample the transitions times that specify the movement between different conditions levels.

4.2 Maintenance Strategies and Costs

In this study, three Maintenance Strategies (MS) are considered: (i) major intervention only (MS1); (ii) combination of minor and major interventions (MS2); and (iii) combination of clean-

ing operations, minor and major interventions (MS3). The different strategies were defined based on previous works and on experts' judgement. Table 3 presents the fixed costs, application zones and impacts of the different types of interventions considered. It was assumed that an *Alpinina* marble cladding, directly adhered to the substrate, was used. For example, a cleaning operation of NSC has a cost of 31.37 €/m^2, is applied in condition B and improves it to condition A with a probability of 15% or causes no significant improvement with a probability of 85%. Regarding the inspections, a deterministic periodicity of 5 years is considered.

Table 3. Fixed costs, application zones and impacts of the different types of interventions considered.

Interventions	Cost [€/m^2]	Application zone	Impact of the maintenance actions [%]		
			P_A	P_B	P_c
Inspections	1.03	All	-	-	-
Cleaning operations	31.37	B	15.0	85.0	-
Minor interventions	68.80	C	-	80.4	19.6
Major interventions	149.51	D, E	100.0	-	-

4.3 Comparison of the Different Maintenance Strategies

Figure 3 compares the degradation curves obtained for the three MS and for the situation without interventions. The results show that the proposed MS have a significant impact on the mean severity of degradation. For all MS, the mean severity of degradation is less than 8% (condition B), with MS3 showing the greatest variation over time.

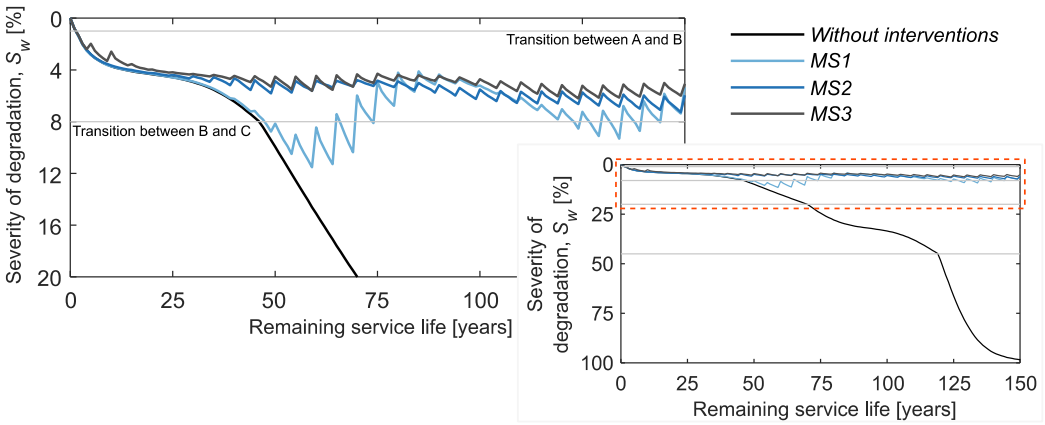

Figure 3. Comparison of the degradation curves over time for all maintenance strategies.

On the other hand, if the cumulative costs are analysed (Figure 4), MS2 has the lowest cumulative costs when the discount rate is 0% (Figure 4a) and MS1 for a discount rate of 6% (Figure 4b). For both rates, MS3 is the one with the highest cumulative maintenance costs.

The discount rate is used to balance the initial investment costs against the future maintenance cost. Since this parameter is difficult to predict, two extreme values were considered to assess the sensitivity of the results. Its choice is mainly a political decision, and the value usually ranges between 4% and 6% (van Noortwijk and Frangopol, 2004).

Finally, the number of interventions and the remaining service life for the three MS are analysed (Figure 5). According to Silva *et al*. (2016), the end of the service life of a NSC varies

between 68 and 90 years. The end of the service life occurs when a major intervention is performed. If the first major intervention is analysed (Figure 5a), for MS1, in year 85 there is a probability of 90% of NSC having been replaced at least once. The value agrees with the range suggested by Silva *et al*. (2016). On the other hand, for MS2, in year 150 there is only a 58% probability that the NSC has been replaced at least once, and, for EM3, this percentage in the same year is reduced to 28%. From this it results that combining major intervention with other intervention works, such as minor interventions and cleaning operations, increases the service life of NSC. Similar observations can be made for the minor intervention (Figure 5b). Considering cleaning operations in MS3 postpones the need of a minor intervention.

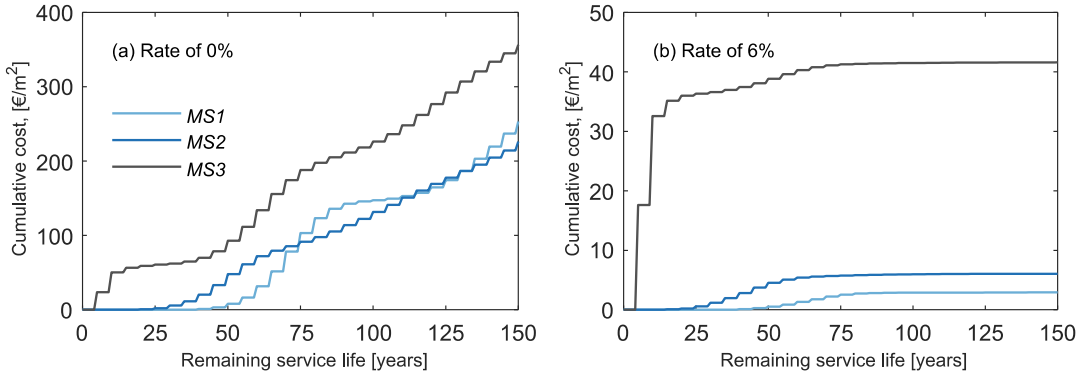

Figure 4. Comparison of the cumulative costs over time for all maintenance strategies.

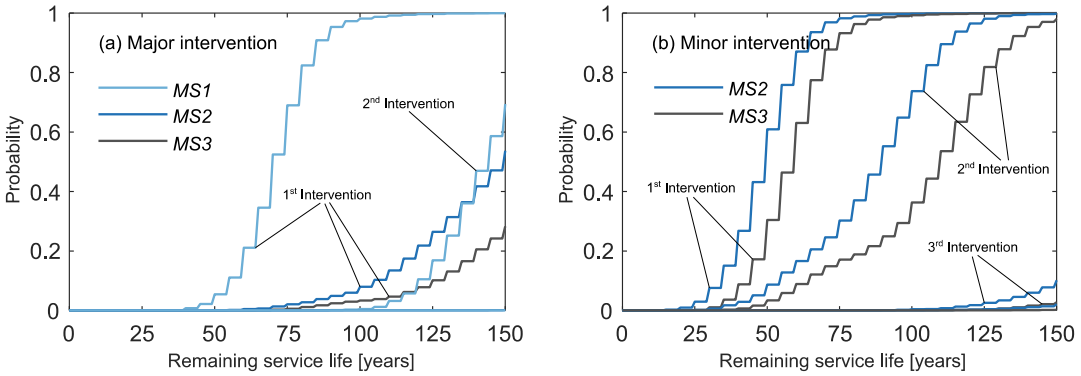

Figure 5. Comparison of the cumulative distribution function of the number of interventions.

5 Conclusions

In this study, a maintenance model, based on the PN formalism, is proposed to analyse the impact of different MS to control deterioration conditions of NSC. In the proposal methodology, three MS are analysed. These are composed by three different intervention levels: cleaning operations, minor and major interventions. The results reveal that: MS1 presents the lowest cumulative cost for a discount rate of 6%. In MS1, only replacement of the cladding is considered, which does not allow improving the condition over time, as well as its service life. MS3 shows the best degradation results but leads to the highest cumulative costs over the claddings' lifetime. MS2 seems to be the most rational and adequate solution, according to the model's assumptions, since it allows increasing the service life and the cumulative costs are competitive when compared with those of

MS1. However, in the end, the choice of the best MS is always assumed by the building managers and/or owners and depends on their budgets and target condition for the cladding.

Abstract. *This examined the performance of the iron-foil sensor in concrete and its relationship with the amount of chloride in the solution simulating concrete. The corrosion sensor reacted at a chloride ion concentration of 500 ppm. From the results, it was inferred that the sensor has a high sensitivity. Furthermore, to evaluate the performance of the sensor, it was built a wireless system using radio-frequency identification (RFID), embed it into an actual concrete structure, and subsequently initiate observation.*

Keywords: *Corrosion, Sensor, Chloride Ion, Monitoring, Solution Simulating Concrete.*

1 Introduction

Corrosion of the internal steel in reinforced concrete structures is a degradation phenomenon that causes cracks and significantly reduces structural strength. The ASTM C876-15 (2015) standard self-potential method and polarization resistance method of the CEB Working Group (1997) are widely used methods of confirming the soundness of the internal reinforcing steel. However, since those methods require running cable to the reinforcing steel, in practice they can require breaking parts of the structure. Even if the cables are installed in advance, it is difficult to ensure their long-term durability. Moreover, those methods represent a post hoc diagnostic approach that checks for corrosion for purposes of corrective maintenance. Once corrosion is confirmed, deterioration has likely already advanced.

For this reason, Lee and Shin (2003) and Takewaka and Yamamoto (2001) have been developing and studying sensors for monitoring corrosion in steel. In order to enable preventive maintenance by predicting the possibility of corrosion in advance, many of these sensors electrically identify corrosion, not in the reinforcing steel itself but in steel materials that act as a proxy for the reinforcing steel. Therefore, the sensors are able to identify corrosion with no damage to the structure. Furthermore, by identifying the risk of corrosion of the reinforcing steel at an early stage, the sensors enable a more efficient consideration of follow-up countermeasures.

We have developed a corrosion environment sensor that consists of a reinforced iron-foil. If the corrosion factors reach the sensor, the sensor itself will corrode and rupture. The sensor

doi:10.23967/dbmc.2020.029

is designed to detect the occurrence of corrosion by sensing the change in electrical resistance when the rupture occurs. To evaluate the performance of the corrosion environment sensor, we varied the concentration of chloride ions in a simulated concrete test solution and determined the point at which the sensor ruptured, thereby verifying the sensitivity of the corrosion environment sensor to the chloride concentration.

In order to develop the corrosion environment sensor into a practical system, we additionally designed a completely non-destructive monitoring system using passive radio-frequency identification (RFID), a close-proximity wireless technology, and installed it in an actual structure for use as a measurement and monitoring system.

2 Structure and Mechanism of the Corrosion Environment Sensor

The sensor consists of a circuit formed on an iron-foil positioned on top of a resin film as shown in Figure 1. The iron-foil is 0.01 mm thick and made of pure iron. The circuit is similar to a simple single conducting wire. When measured, the value of the electrical resistance between both ends is 15 Ω or less. However, if the sensor itself becomes corroded enough to disconnect, it will show a resistance of 100 Ω or more. Precious metals are deposited on the surface at the ends of the iron-foil to serve as cathode electrodes, making the film highly sensitive to corrosion. As shown in Figure 2, the iron-foil sensor is integrated into a ceramic housing and the surface is covered by mortar. This structure is designed to maintain an alkaline environment that prevents corrosion due to atmospheric factors, such as humidity.

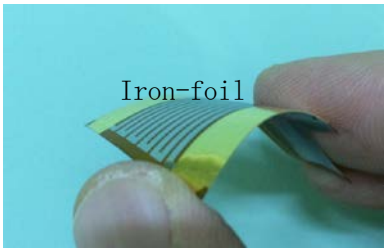

Figure 1. Appearance of the corrosion sensor.

3 Performance Testing of the Sensor

Since the sensor is made of iron, which is the main component of the reinforcing steel inside the concrete, it also suffers corrosion as corrosion factors from the environment penetrate into the concrete, increasing the risk of corrosion of the reinforcing steel. The sensor simply evaluates whether or not the iron has corroded, but cannot determine the cause of corrosion.

Although corrosion degradation of reinforcing steel is thought to occur due to multiple factors, the main factors include the rupture of the passive film due to salinity, reduction of alkali anti-corrosion protection due to carbonation, and penetration of moisture and oxygen. In Japan, the specifications of the Japan Society of Civil Engineers warn that steel corrosion occurs when the concentration of chloride ions in the concrete reaches 1.2 kg/m^3 or higher. There are also regulations in each country on the permissible chloride concentrations in the materials that make up concrete. In Japan, the concentration is generally capped at 0.30 kg/m^3.

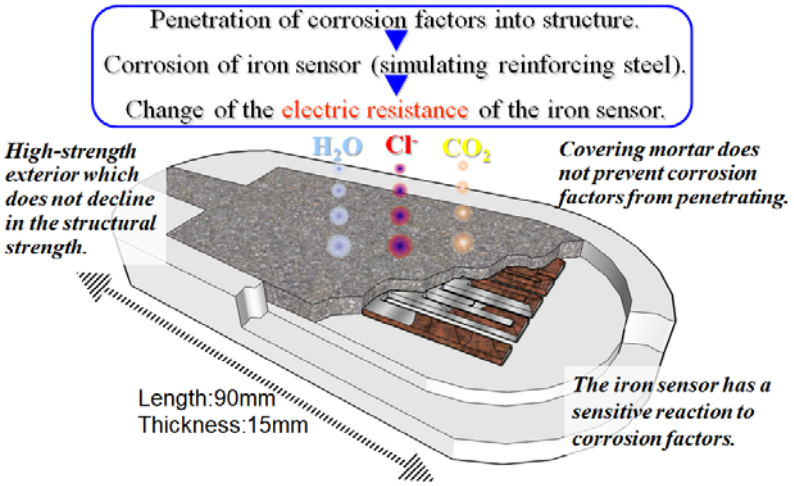

Figure 2. Overview of the corrosion sensor and its working.

From this perspective, we can evaluate the performance of the sensor by quantitatively capturing the penetration of chloride ions, which can cause degradation, and determining the relationship between the concentration of chloride ions and the detection performance of the sensor.

3.1 Overview of Performance Testing of the Corrosion Environment Sensor

Performance testing of the sensor was conducted in a saturated calcium hydroxide solution to mimic the internal environment concrete. This was done to maintain an environment of uniform pH and chloride content in the solution and to make it easy to retrieve the sensor as needed during testing to visually check the specimen (sensor) and the iron pieces used for comparison.

Figure 3 shows the configuration of the environment for performance testing of the sensor. An air pump was used to vent air into the saturated aqueous solution of calcium hydroxide. The carbon dioxide in the air reacted with the calcium hydroxide test solution, preventing the lowering of its pH, as indicated in Table 1. After the carbon dioxide was removed, the air was fed into the test tank. We periodically measured the pH of the test solution to ensure that its pH did not change.

If the sensor reached a resistance value of 100 Ω or more after the start of the test, it was considered ruptured. We tested five sensors per test level.

3.2 Verification of Corrosion Rate Using Steel

In order to understand the corrosion rate of each chloride ion concentration in the simulated concrete test solution, we immersed a sample of SS400 steel, of dimensions 20 × 80 × 2 mm, in the solution using the same test equipment configuration used to test the corrosion environment sensor.

To obtain the corrosion rate of the steel, we immersed a steel sample in each of the aqueous solutions shown in Table 1 and measured the reduction in the mass of the steel before and after the test. We tested five steel sheets per test level.

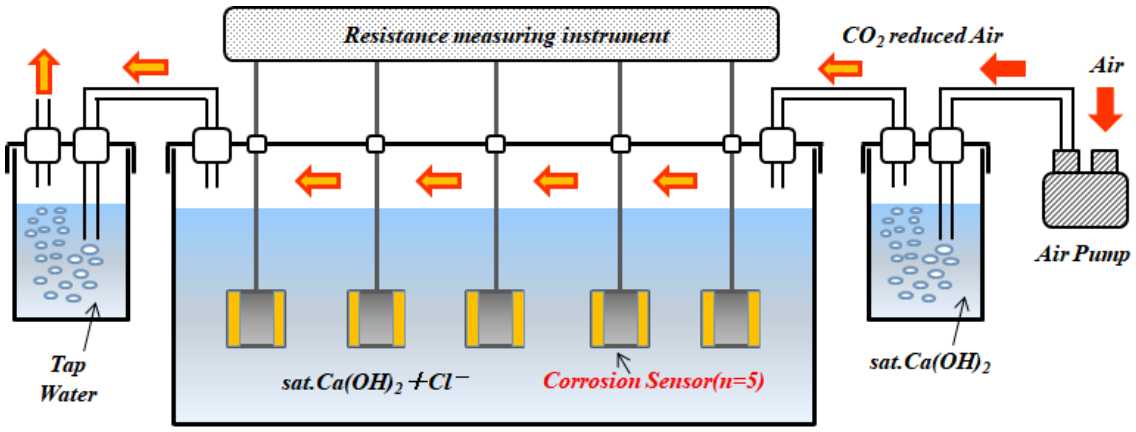

Figure 3. Configuration of the corrosion sensor evaluation experiment.

Table 1. List of aqueous solutions used to test the corrosion rate of the steel sample.

	Cl^- (ppm)
sat. $Ca(OH)_2$ pH 12.3 to 12.5	200
	500
	1000
	2000
	5000

To obtain the reduction in the mass of the steel after rust removal, we immersed the steel in a mixed solution of hydrochloric acid and corrosion inhibitors for a period of 36 days and then measured its mass. We subtracted this value from the mass of the steel measured before the test to obtain the reduction in mass.

4 Results of Performance Testing

4.1 Detection Performance of the Corrosion Environment Sensor

Figure 4 shows the time taken for each sensor to rupture. The earliest rupture occurred at the chloride ion concentration of 5000 ppm. At the chloride ion concentration of 200 ppm, no rupture was observed, even after 2500 hours. The graph shows that the sensor rupture time tends to increase as the concentration of chloride ions decreases. In particular, the chloride ion concentration of 500 ppm produced the longest rupture time, which was 1700 hours (about 70 days). The chloride ion concentrations of 500 ppm and 5000 ppm showed a difference in average rupture time of about 1000 hours.

Figure 5 shows the result of converting the horizontal axis of Figure 4 to represent the relative concentration between Cl^- and OH^- at a pH of 12.1. The sensors ruptured when Cl^-/OH^- was 0.71 or greater. There are various theories about steel corrosion thresholds based

on Cl^-/OH^-, but given that our test results are within the range of 0.6 to 1.0 reported of D. A. Hausmann (1967) in related literature, we can conclude that the sensor is able to rust and rupture with reasonable sensitivity.

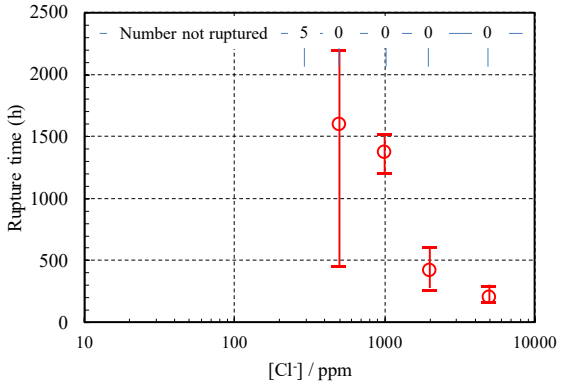

Figure 4. Rupture time of corrosion environment sensor at each chloride ion concentration.

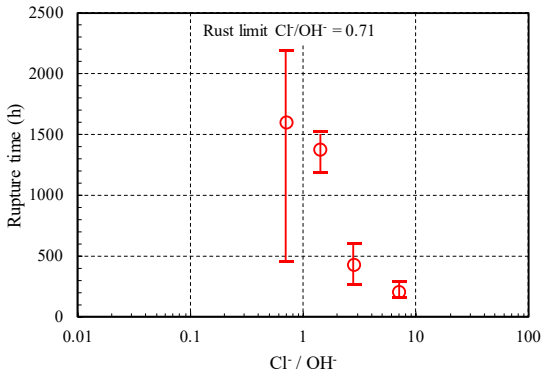

Figure 5. Relationship between sensor rupture time and Cl-/OH-.

4.2 Results of Steel Corrosion Rate Test

Figure 6 shows the corrosion rate of steel in the different aqueous solutions. In this test, the steel in the test solution with a chloride ion concentration of 200 ppm showed a corrosion rate of 0 mm/y, i.e. no corrosion. As the concentration increases from 500 ppm, the corrosion rate also increases. These results are similar to the differences in the rupture time of the sensors shown in Figure 4. At the chloride ion concentration of 500 ppm, a very small corrosion rate of 0.0001 mm/y was observed. Since the corrosion rate of steel in seawater is 0.1 mm/y, the fact that the sensor ruptures under conditions at which the corrosion rate of steel is approximately 0.001 mm/y suggests that the sensor has a highly sensitive reaction to the chloride ion concentration.

In alkaline environments, steel tends to form a passive film due to the supply of oxygen. In our testing environment, the air pump is used to inject oxygen partial pressure into the simulated concrete test solution under conditions that are close to natural. In evaluating the corrosion rate, it is important to prevent excessive increases in the oxygen partial pressure.

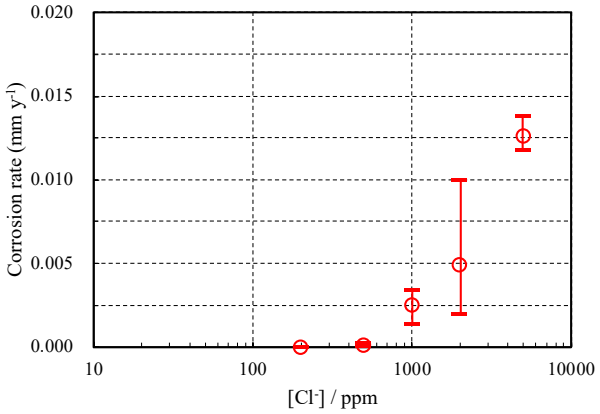

Figure 6. Corrosion rate of steel at each chloride ion concentration.

5 Measurement System of the Sensor

As explained above, the sensor detects whether the environment has become corrosive by measuring the electrical resistance in the sensor itself. This makes it easy to identify a corrosive environment by embedding the sensor in the structure and measuring the electrical resistance with a simple tester through a cable. However, to evaluate the corrosion environment inside an actual concrete structure, it is necessary to expose the cable to the outside environment for a long period of time, which may cause corrosion of the metal in the connectors or deterioration of the cable due to ultraviolet rays.

We therefore investigated ways to take sensor measurements wirelessly. We developed a wireless measurement system that uses passive RFID, a technology widely used for electronic money transfers. This system does not require a battery on the sensor itself. Figure 7 shows how the sensor is connected to the passive RFID.

The sensors and passive RFID units were connected by cable and embedded inside the structure. To measure the electrical resistance of the sensor, an electromagnetic wave was transmitted from the antenna of the RFID reader/writer to the RFID unit embedded in the concrete, and the measured output value was then returned to the RFID reader/writer. This system is powered by the electromotive force generated inside the RFID large-scale integration (LSI) chip.

This system enables completely non-destructive measurement with no need to expose the cables to the surface of the structure. To take a measurement, an electromagnetic wave is simply transmitted from the RFID reader/writer to the surface of the structure in which the RFID unit is embedded. The embedded sensors and RFID units do not require batteries, making them ideal for long-term maintenance without the hassle of battery replacement.

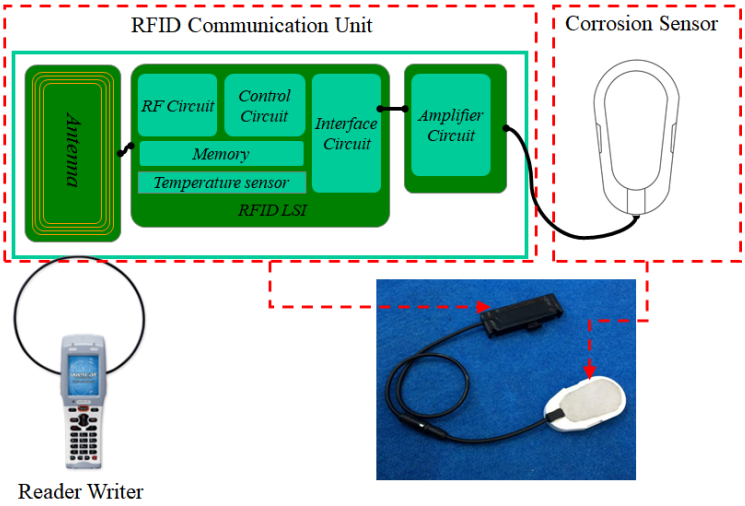

Figure 7. Configuration of the RFID corrosion sensor.

6 Examples of Application of the Sensor and Measurement System

The measurement system of the sensor is often used in concrete structures with high risk of steel corrosion. Major applications include port structures, such as lighthouses and piers, and road structures, including bridges where penetration of chloride ions from antifreeze agents is a concern.

The sensor has also been used to evaluate the repair effects of concrete structures. Figure 8 show the application of the sensor to bridge pier repairs. The subject bridge was constructed in 1973, in Hokkaido, Japan, and has undergone one round of repairs in 2007 following the occurrence of rebar corrosion-induced flaking. However, in just two years, the repaired area degraded. Therefore, we placed these sensors at six locations on the bridge following a second round of full-scale partial patching in 2011. Subsequently, corrosion was measured, once a year, for five years, followed by another measurement in the seventh year. One of the sensors detected salt-induced corrosion at a location, while the other five locations were observed to be stable. We confirmed that there was no issue with the measurement performance of the sensor, and established its durability and utility as an effective maintenance management system. Corrosion at the subject structure will be measured again in 2021 and subsequent repair plans will be made based on the measurements captured by the sensors.

Figure 8. Application of the system to bridge pier repairs.

7 Conclusions

We verified the performance of a corrosion environment sensor made of iron foil by measuring how long it took the sensor to identify corrosion under several different conditions corresponding to different chloride ion concentrations in a simulated concrete test solution. The following results were obtained:

- The corrosion environment sensor ruptured due to corrosion in environments with a chloride ion concentration of 500 ppm. The higher the chloride ion concentration, the shorter was the time to rupture.
- The fact that the sensor ruptures in an environment with a chloride ion concentration of 500 ppm, which corresponds to a corrosion rate of 0.001 mm/y, suggests that it has a highly sensitive reaction to the chloride ion concentration.
- By adopting passive RFID as the communication interface to the corrosion environment sensor, we were able to build a practical preventive maintenance system against steel corrosion.
- We were able to demonstrate the long-term durability of the sensor system based on passive RFID by applying it to repair work on real structures and maintaining it for seven years with no failures.

8 Future Work / Discussion

This sensor provides a simple way to determine whether the risk of corrosion increased in the environment around the sensor by detecting corrosion in iron as a proxy for corrosion in reinforcing steel. A variety of factors is involved in the corrosion of steel in actual structures, including the type of cement, formulation of the materials, and progress of carbonation. In this paper, we evaluated the performance of the sensor by focusing on the chloride ion concentration.

In the future, we plan to verify the performance of the sensor by focusing on other parameters, such as changes in the pH of the concrete, and to quantitatively evaluate the penetration of multiple corrosion factors into the concrete.

Abstract. *The sealant that fills the joints of an exterior walls of building is subjected to weather loads, such as sunlight, ambient temperature, and rain, as well as a movement of the joints. As a result, the sealant gradually deteriorates under the combined deterioration factors of weathering and movement. Meanwhile, the results of a 15-year outdoor dynamic exposure test conducted in Japan using the methodology of ISO 11617 showed that the progress of damage varies greatly depending on the type of sealant and the stress relaxation rate. However, the mechanism of damage progression is unclear. In the present study, we focused on the load when the sealant moves and developed a load-measuring apparatus as the first step in clarifying the relationship between the progress of damage and the load. The load was measured at −20, 23, and 40 °C for test specimens with different stress relaxation rates, and it was confirmed that the developed load-measuring apparatus was able to measure the load correctly. Furthermore, it was shown that it is difficult for the stress of the sealant with a high stress relaxation rate to relax over time at low temperature but easy at high temperature, and the load increases when switching from the compressed state to the extended state.*

Keywords: *Joint Sealant, Load Measuring Apparatus, Joint Movement, Deterioration, Durability.*

1 Introduction

The sealant used for a joint of an exterior wall is affected by various environmental factors, such as ultraviolet rays, the air temperature, and rain, and is gradually degraded by movement of the joint. In Japan, in the 15 years since 1992, dynamic outdoor exposure tests were carried out at three locations having warm, subtropical, and cold climates using a variable sealant as defined by ISO 2014: 11617. It was found that most sealants deteriorated remarkably at the subtropical location where irradiation by ultraviolet rays was strong. However, for some sealants (having a high stress relaxation rate), the damage depth (Df value) near the adherend was more remarkable at the warm and cold locations than at the subtropical location as shown in Fig. 1. It was believed that this was due to the load that the sealant received when movement occurred.

However, few studies have clarified the damage to sealants in terms of the load they are subjected to during service life. Further, commercially available accelerated testing machines are either accelerated weathering or fatigue testing machines, most studies have been limited to either of them. In the case of a material, such as a sealant, in which deterioration progresses due to the combined action of the weathering and the movement, it is desirable to verify the

durability by an acceleration test in which the weathering and the movement are simultaneously loaded.

In this study, as a first step to explain the mechanism by which deterioration is more intense in cold regions, we aim to develop an apparatus that measures the load applied to a sealant when both the weathering and the movement are combined. We fabricated prototype sealant with different stress relaxation rates and verified whether the load acting on the prototype sealant can be measured properly with a load-measuring apparatus.

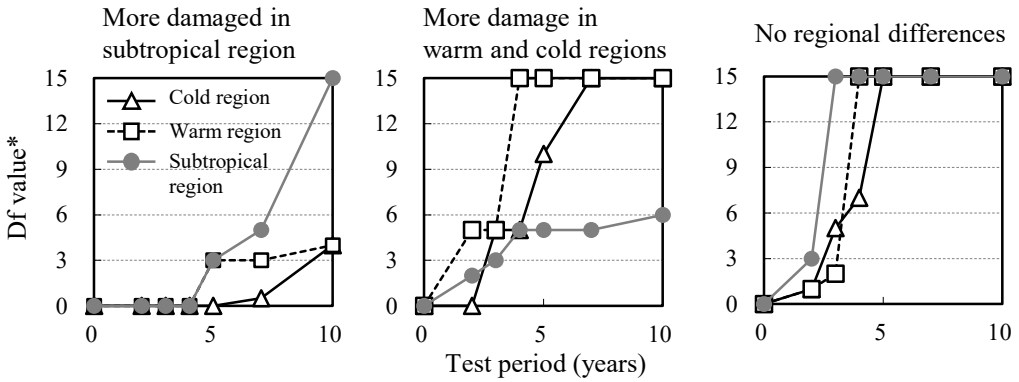

Figure 1. Example results of an outdoor dynamic exposure test.

2 Development of a Load-Measuring Apparatus

2.1 Load-Measuring Apparatus

To measure the load acting on the sealant when movement occurs, we developed a load-measuring apparatus as shown in Fig. 2. The ISO-type specimen shown in the figure is fixed to the load-measuring apparatus using a fixing jig. The portion of the specimen on the handle side is connected to a beam-type load cell, and the ball screw under the specimen portion is connected to the handle. When the handle is manually rotated, the specimen portion on the handle side moves horizontally, the sealant can be put into a compression or extension state, and the load generated in the sealant at that time can be measured by the load cell. A guide prevents displacement in the shear direction being applied to the specimen itself when movement is applied to the specimen. The dynamic outdoor exposure tests described above were carried out under various temperature conditions, and the temperature around the specimen could change. However, because the load cell is highly sensitive to temperature, the load cell is installed slightly away from the specimen so as not to be affected by temperature.

2.2 Prototype Sealant and its Stress Relaxation Ratio

As described above, sealants with high stress relaxation rates in the dynamic outdoor exposure test degraded greatly in a cold region. Two prototype sealants with different stress relaxation rates were therefore fabricated for testing in the present study.

The prototype sealants were two-component modified silicone sealants with different mixing ratios of the base material and curing agent. The sealants were intended to have almost the same moduli after standard curing but different stress relaxation rates.

To confirm that the intended sealants could be produced experimentally, test specimens of the

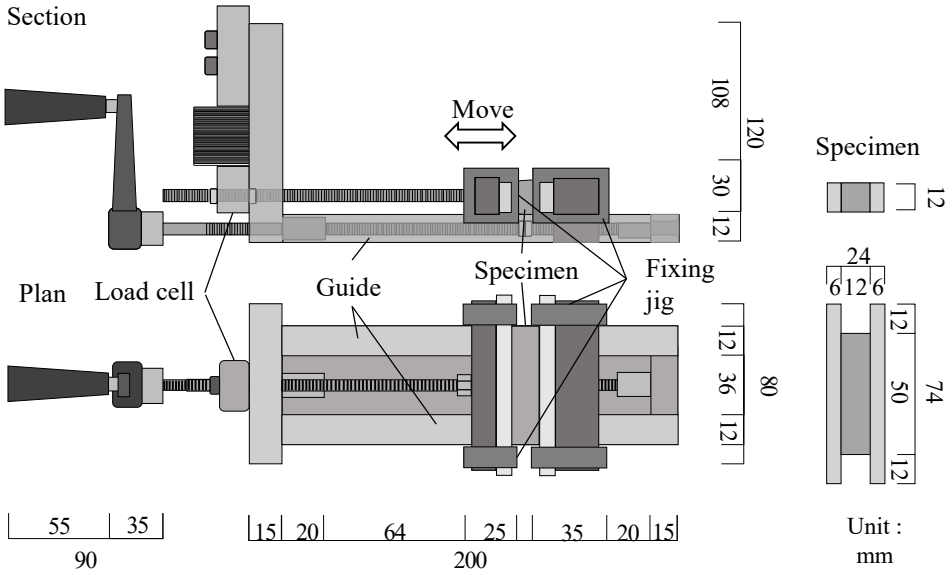

Figure 2. Load-measuring apparatus.

tensile adhesiveness test specified in JIS A 1439 were prepared using the prototype sealants (cured at 23 °C and 50% relative humidity for 7 days and at 50 °C and 50% relative humidity for 7 days, where the adherend was aluminum), and the stress relaxation rate was measured. Each specimen was attached to a tensile testing machine, the specimen width was extended by 30% (from 12 to 15.6 mm), and the stress was measured when the specimen was held for 18 hours in this state. The temperature was 23 °C and the tensile rate was 50 mm/min.

The temporal variation of stress is shown in Fig. 3 while physical properties, including the stress relaxation rate, are given in Table 1. The stress was a maximum when the specimen was extended by 30% and it lowered immediately afterwards. The stress did not decrease remarkably with time for specimen 1 having a low stress relaxation rate but lowered remarkably until 18 hours for specimen 2 having a high stress relaxation rate. Moreover, the moduli were almost the same, and it can be said that the aim of creating prototype sealants with almost the same initial modulus but different stress relaxation rates was achieved.

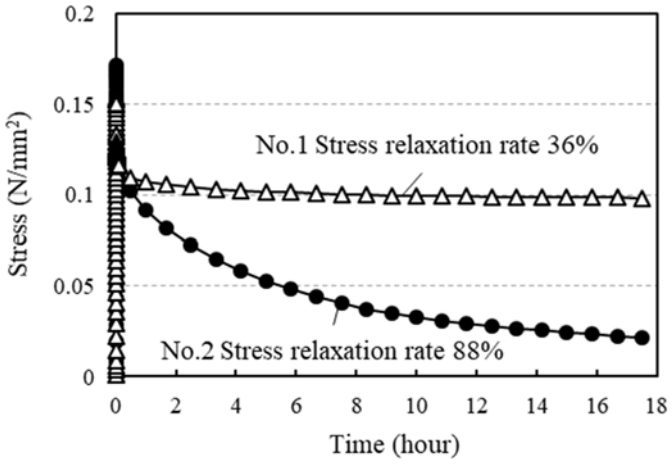

Figure 3. Temporal variation of stress.

Table 1. Physical properties of prototype sealant after standard curing.

Specimen	Stress relaxation rate*1(%)	Tensile adhesion*2		
		M_{50} (N/mm^2)	Tmax (N/mm^2)	Emax (%)
Specimen1	36	0.18	0.30	677
Specimen2	88	0.15	0.31	758

*1: Stress relaxation rate (%) = (Maximum stress -Stress after 18 hours) / MaximumStress × 100, Tensile speed 50 mm/min, Temperature of 23 ° C

*2: M 50: 50% modulus, Tmax: ultimate tensile stress, Emax: elongation at Tmax

2.3 Load-Measuring Procedure

To determine whether the load can be measured properly with the load-measuring apparatus, the joint width was compressed by 30% (from 12 to 8.4 mm) and held for 24 hours, and then extended by 30% (from 12 to 15.6 mm) and held for 24 hours, and the load was measured. The movement was realized manually as described above. The speed of movement was set to 50–100 mm/min with some variation.

As described above, there was more remarkable damage at the warm location and cold location than at the subtropical location in the dynamic outdoor exposure tests, and the present experiment was thus conducted taking the ambient temperature around the test specimen as a variable. The temperature conditions in the present experiment were set at three levels: a low temperature (−20 °C), normal temperature (23 °C), and high temperature (40 °C). The low-temperature condition was realized with a commercially available freezer, the normal-temperature condition with a constant-temperature and constant-humidity room, and the high-temperature condition with a box lined with insulating material and a planar heating element.

In cases of low and high temperature, only the temperature around the specimen was adjusted while the temperature of the load cell was kept constant. The test commenced after confirming that the internal temperature of the specimen was similar to the ambient temperature.

2.4 Test Results

Test results are shown in Fig. 4. For both specimens, the load peaked immediately upon movement but rapidly decreased immediately after and continued to decrease gradually with time. The decrease was remarkable for specimen 2 having a stress relaxation rate of 88% at normal and high temperatures. In other words, when the stress relaxation rate was high, the effect of temperature was strong, and the maximum load when switching to extension was large especially at high temperature. Furthermore, there was cohesive fracture during switching to extension at high temperature, and fracturing continued to progress even during holding in extension. The stress after 24 hours of compression had greatly relaxed, and it is thus considered that the sealant adapted to the compression state and the change due to the load generated in the next extension became large.

Table 2 shows the stress relaxation rate for extension. The stress relaxation rate at normal temperature (23 ° C) was slightly lower than that given in Table 1, which was measured by a tensile testing machine, because the specimen was extended after the compression state was

maintained. However, the difference in the stress relaxation rate was clearly well measured by Table 2 shows the stress relaxation rate for extension. The stress relaxation rate at normal temperature (23 ° C) was slightly lower than that given in Table 1, which was measured by a tensile testing machine, because the specimen was extended after the compression state was maintained. However, the difference in the stress relaxation rate was clearly well measured by the developed load-measuring apparatus, and it is considered that the change in stress with time can be appropriately measured even if the temperature of the environment changes.

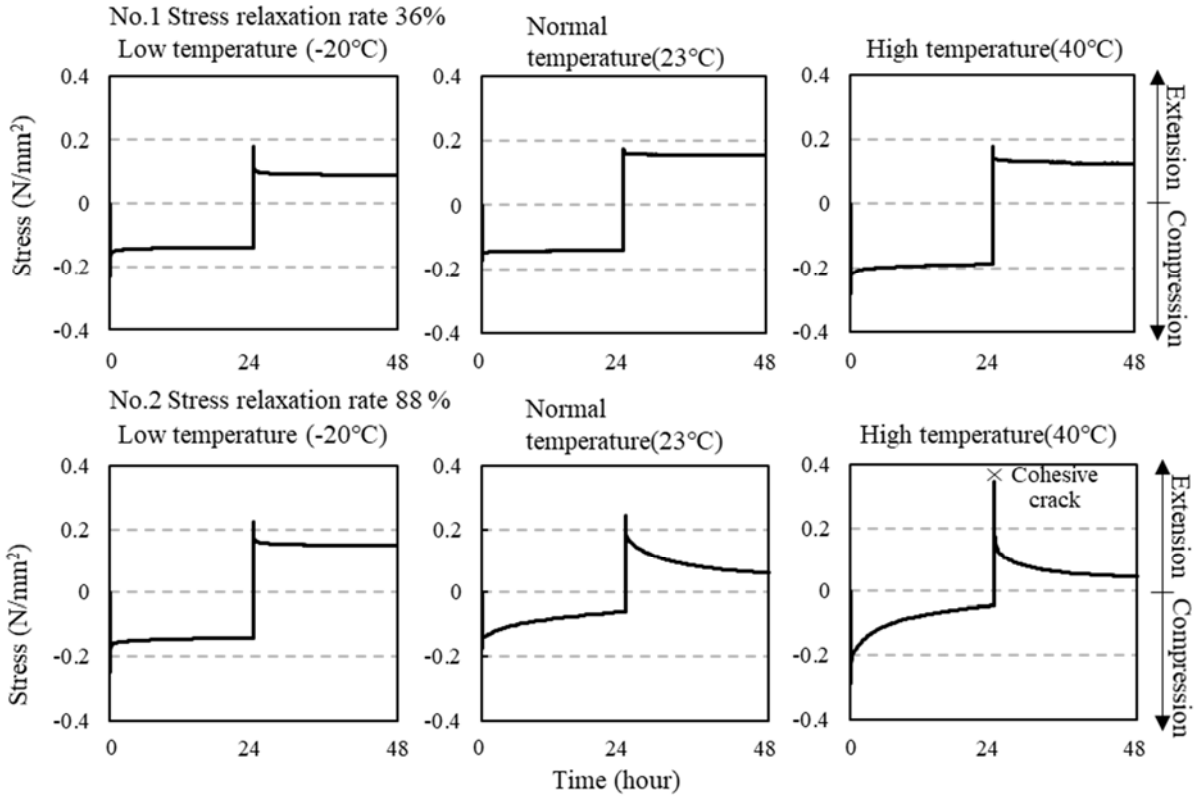

Figure 4. Temporal variation of stress.

Table 2. Stress relaxation rate measured by the load-measuring apparatus.

Specimen	Stress relaxation rate in extension as measured by the load-measuring apparatus [*1] (%)		
	Low temperature(-20℃)	Normal temperature(23℃)	High temperature(40℃)
Specimen1	50	11	30
Specimen2	61	72	92

3 Conclusion

The main contributions of the present study are as follows.

- We have developed an apparatus for measuring the load on a sealant during movement. Although an apparatus can handle any deformation rate, any temperature environment, any speed, and any movement period, it is difficult to perfectly match the movement speed each time because it is manually operated at present. Therefore, it is planned to

develop a load-measuring device for automatically generating a movement in the future.

- In order to verify the validity of the apparatus, we measured the load when 30% deformation was given at temperature (23 ° C), high temperature (40 ° C), and low temperature (-20 ° C) using two kinds of modified silicone sealants with different stress relaxation rates, it was found that the load gradually relaxed after compression and extension at normal temperature and high temperature but hardly relaxed at low temperature for prototype sealant with a stress relaxation rate of 88%. Meanwhile, the prototype sealant with a stress relaxation rate of 36% was hardly affected by temperature. The effect of temperature on the load can be measured using the load-measuring apparatus. It was shown that the effect of temperature on the load can be measured using the load-measuring apparatus.
- Although the purpose of this study was to develop of a load-measuring apparatus, our ultimate goal is to clarify the occurrence of sealant damage from the viewpoint of the load applied to the sealant. Therefore, in the future, it is planned to carry out repeated load measurement while applying other weathering such as ultraviolet rays by changing the type of sealant, stress relaxation rate, and deformation.

Financial Management of Construction Companies

Jiří Kusák[1] **and Eva Vítková**[2]

[1] Brno University of Technology, Faculty of Civil Engineering, Institute of Structural Economy and Management, Veveří 331/95, Brno, Czech Republic, jiri.kusak@vutbr.cz

[2] Brno University of Technology, Faculty of Civil Engineering, Institute of Structural Economy and Management, Veveří 331/95, Brno, Czech Republic, vitkova.e@fce.vutbr.cz

Abstract: *The objective of financial management of construction companies is to generate profit and provide financial stability. Financial stability is provided by managing the amount of both fixed and current assets, the amount of equity and external capital. Therefore, in order to reach the objective of financial management, it is necessary to comply with the basic financial rules. In the framework of nationwide analyses of economic indicators for different industries, there is data published on the website of the Ministry of Industry and Trade, which, however, apply to all construction companies. For this reason, the authors of the article focused on individual subcategories of construction companies (small, medium and large), which are defined by turnover, assets and number of employees. The research studied whether these subcategories fulfil all or part of the basic financial rules, including the following rules: golden rule of risk equalization: the ratio of own and external resources should be in the ratio of 1:1, golden balance rule: fixed assets should be covered by long-term resources; golden "pari" rule: fixed assets should be covered by equity. The research also monitored the structure of assets, i.e. the ratio between fixed and current assets and was based on elementary methods of financial analysis (vertical and horizontal methods). The outputs of the paper will be further used for the next step of the research, which will focus on tax optimization of individual categories of construction companies in relation to financial management of fixed assets.*

Keywords: *Financial Management, Construction Companies, Basic Financial Rules, Vertical and Horizontal Methods, Financial Analysis.*

1 Introduction

Financial management of companies, not exclusively construction companies, represent one component of important strategic management in terms of managing the entire economic development of the company. Financing is not only reflected in the indebtedness of the selected company and its liquidity, but also in providing cost-effectiveness, *i.e.* profitability. It is important to create a positive economic result for any viable company. This can be achieved by different financial resources. In general, the definition says that external sources of financing are always cheaper than own sources of financing (Srpová, Řehoř *et al.*, 2010). The Ministry of Industry and Trade publishes quarterly, semi-annual and annual statistics on financial indicators for individual sectors. Financial indicators relate not only to the percentage share of fixed assets on total assets, external resources of financing on total liabilities, and other indicators resulting from the vertical analysis of financial statements, but also ratios such as liquidity of all three levels, return on equity, indebtedness and others. In these statistical surveys, the above-mentioned indicators are kept by industrial sectors. This means that the closest sector to this research is construction industry, which is further divided in these statistics

into building construction, civil engineering and specialized construction activities. The total number of samples for the whole Czech Republic for these statistics was 85 companies. However, these statistics do not reflect the size of the company. The Accounting Act divides companies as accounting units into micro, small, medium and large according to their size, where the criteria for classification into a certain category are the amount of assets, the amount of turnover and the number of employees. For the above-mentioned reasons, the research was focused on the survey of selected financial indicators according to the categories corresponding to company sizes. The selected financial indicators for the research were mainly: the percentage share of fixed and current assets on total assets, percentage share of own and external capital (financial resources) on liabilities and other indicators that confirm basic financial rules for each size category of construction company doing business in the construction industry.

2 Present State References

Act No. 563/1991, on Accounting (1991) in Section 1b defines the categories of accounting unit sizes (companies) as micro, small, medium and large. This division is governed by the balance sheet data, at which the thresholds for the amount of assets, the total net annual turnover and the average annual number of employees are defined. EU Recommendation 2003/361/EC (2003) of 6 May 2003, published by the Ministry of Industry and Trade and the Office for the Protection of Competition, also defines the sizes of companies as micro, small and medium-sized companies. This definition, as well as the Accounting Act, deals with the amount of assets, the total net turnover and the average number of employees.

Srpová and Řehoř et al. (2010) in their book determine the basic rule of financing, which is related to time and states that fixed assets cannot be financed by short-term resources. From this definition it therefore applies that for proper financing, fixed assets should be covered by long-term resources.

Another financial rule is the risk equalization rule (Srpová, Řehoř et al. 2010), which states that the ratio of own and external resources should be 1:1, over time the ratio has changed to 1:2, and also to 1:3.

In her book, Kislinger (2007) defines the golden “pari” rule which states that fixed assets should be financed by company's own resource.

Biliavska, Mizunska and Yurii (2019) assessed the real financial status of both, identifying possible ways to improve the management of the existing assets of the two companies and the companies´ compliance with the golden rule of financing was analysed.

In the second paper, Biliavska, Mizunska and Kovalchuk (2019) assessed liquidity of two companies and the basic problems of the unstable financial condition of the companies determined with the help of calculated coefficients and the steps expedient for stabilization of the situation suggested.

Viszlai (2015) in his paper analysed structure of assets and capital structure in different forest companies and searched for differences between the model situation and real conditions. He used three basic financial rules for assessing and analysing assets and capital structure - golden rule of financing, current ratio and one to one rule.

Isik and Meric (2009) in their paper challenged the proposition that the golden rule of public sector borrowing its consistent with the principle of intertemporal allocative efficiency.

Groneck (2010) compared growth and welfare effects of various budget rules within an

endogenous growth model with productive public capital, utility enhancing public consumption and public debt. He found out that introducing a fixed deficit regime does not affect the long run growth rate compared to a balanced budget while establishing a golden rule results in higher growth.

Konečný (2013) in the paper studies whether the golden rules of financing are (or are not) respected depending on financial strategy in the sub-phases of the company life cycle.

3 Methodology

From a methodological point of view, the research was run on 17 samples for all categories of construction companies. The principle that at least 5 samples should fall within a given category has always been observed. In order to obtain input data from public sources, just the following categories were taken into account: small, medium and large. Financial statements from the website www.justice.cz, where financial statements for each accounting period are published, were used as input data. The period 2009–2017 was taken as the monitored period.

Individual categories of company sizes are defined by Act No. 563/1991 Coll., On Accounting, as follows:

- Small companies: total assets totalling at CZK 100,000,000, annual total net turnover of CZK 200,000,000, average number of employees 50; must not exceed at least 2 of the specified limits,
- Medium-sized companies: total assets totalling at CZK 500,000,000, annual total net turnover CZK 1,000,000,000, average number of employees 250; must not exceed at least 2 of the specified limits,
- Large companies: those that exceed at least 2 of the limits set out for medium-sized companies.

Financial indicators were processed using the basic method of financial analysis, namely vertical analysis. The principal of the vertical analysis is the ratio between the examined quantity and the basic quantity stated as a percentage.

$$Determination\ of\ percentage = \frac{researche\ quantity}{basic\ quantity} * 100 \quad (1)$$

The basic financial rules for efficient and sound company management are based on three pillars:

- 1st golden rule of risk equalization: the ratio of own and external resources should be 1:1,
- 2nd golden balance rule: fixed assets should be covered by long-term resources,
- 3rd golden "pari" rule: fixed assets should be covered by equity.

The Ministry of Industry and Trade (www.mpo.cz) in its statistical surveys and analytical materials lists only some indicators that can be used for the golden rules of financing. These are the indicators that assess the first golden rule of risk equalization and the third golden "pari" rule. It is necessary to note that the resulting values represent only the construction sector, the resulting values of the statistical survey do not reflect company size in any way. In the monitored years, according to analyses by the Ministry of Industry and Trade, the annual

percentages shares were as follows, see Tables 1 and 2.

Table 1. Ratio of own and external resources in the construction sector.

Year	2009	2010	2011	2012	2013	2014	2015	2016	2017	2018
Own resources (%)	35.20	37.31	38.56	40.96	40.68	40.53	40.12	45.30	45.49	44.23
External resources (%)	63.14	60.91	59.65	57.34	36.32	31.75	58.33	53.02	53.09	54.39

Table 2. Ratio of fixed and current assets in the construction sector.

Year	2009	2010	2011	2012	2013	2014	2015	2016	2017	2018
Fixed Assets (%)	27.93	30.44	32.17	29.93	33.04	33.61	34.37	33.78	33.71	32.78
Current assets (%)	71.21	68.93	67.09	69.12	66.17	65.80	65.08	65.74	65.71	66.75

The research therefore deals mainly with the differences in the individual golden rules of financing, which were researched according to the company size and, to a lesser extent, also the differences between the reported statistical surveys of the Ministry of Industry and Trade and values based on company sizes.

4 Results

Following financial indicators were monitored within the research using the vertical method, which is classified as an elementary method of financial analysis:

- own resources (equity)
- external resources
- fixed assets
- current assets
- long-term resources
- short-term resources

Within the individual golden rules, the research reached the following conclusions.

The first golden rule, which states that own resources of financing and external resources of financing should be in ratio of 1:1 and are evaluated by a nationwide statistical survey of the Ministry of Industry and Trade (see Table 1), was analysed according to the company size categories in the 2009-2017 period as follows, see Tables 3 and 4.

Table 3. Representation of own resources in individual categories of companies.

Year	2009	2010	2011	2012	2013	2014	2015	2016	2017	Average
Small	47.82	60.98	64.20	67.69	61.30	69.85	76.32	71.29	66.10	65.06
Medium	53.94	55.71	47.67	47.84	49.37	46.03	45.98	42.11	42.04	47.85
Large	28.33	29.15	29.84	29.79	29.08	29.18	29.24	26.25	30.28	29.02
Average	*43.36*	*48.61*	*47.24*	*48.44*	*46.58*	*48.35*	*50.51*	*46.55*	*46.14*	*47.31*

Table 4. Representation of external resources in individual categories of companies.

Year	2009	2010	2011	2012	2013	2014	2015	2016	2017	Average
Small	52.18	39.02	34.15	32.18	38.25	29.86	23.51	28.51	32.96	34.51
Medium	44.50	43.34	51.76	51.45	50.13	53.09	52.38	57.16	57.25	51.23
Large	69.71	68.82	68.74	68.78	69.87	69.49	69.58	72.54	68.37	69.54
Average	*55.41*	*50.40*	*51.55*	*50.80*	*52.75*	*50.81*	*48.49*	*52.74*	*52.86*	*51.76*

It is clear from the above-mentioned values that if we take into account the average values of own and external resources for all companies, they almost reach the ratio 1:1, which would confirm the first golden rule. However, if the average values of individual categories of company sizes were analysed, it was found out that the golden rule of financing was not exactly observed in any case. The analysis shows that small companies finance their activities more from their own resources, on average they were at 65%, and large companies, on the contrary, more from external resources, the average percentage share of external resources was about 70%. The medium-size companies were almost close to the 1:1 financing rule, where the difference was 2%, which is negligible. When comparing the resulting average values given in Table 3 and Table 4 with the average values calculated for the same period, i.e. 2009 - 2017 period by the Ministry of Industry and Trade listed in Table 1, it could be seen that within own resources the values differ by -7% and within external resources by +0.85%, which can be considered as insignificant deviations in both cases. These deviations can be caused by two factors, either a small sample for the research, or by several samples of one category of company size in the statistical survey of the Ministry of Industry and Trade, which affected the resulting values. It can be stated from the above analyses that the first golden rule of financing was almost observed for the medium-sized companies, however, not for small companies, where own resources are used more for financing and large companies, where external resources of financing are more used.

The second golden rule - the golden balance rule states that fixed assets should be covered by long-term resources (see Tables 5 and 7).

Table 5. Representation of fixed assets in individual categories of companies.

Year	2009	2010	2011	2012	2013	2014	2015	2016	2017	Average
Small	40.09	33.95	41.94	39.69	32.30	39.28	40.39	35.08	31.15	37.10

Large	15.98	16.96	16.43	16.41	15.72	15.78	14.52	16.55	18.40	16.31
Average	*29.00*	*28.23*	*29.26*	*28.64*	*27.95*	*30.02*	*29.46*	*27.65*	*26.81*	*28.56*

Table 6. Representation of current assets in individual categories of companies.

Year	2009	2010	2011	2012	2013	2014	2015	2016	2017	Average
Small	58.04	65.47	56.57	59.63	67.15	60.09	58.86	63.28	68.31	61.93
Medium	67.78	65.24	70.10	69.77	63.89	64.67	66.09	68.36	68.75	67.18
Large	84.26	84.90	86.19	86.51	87.14	86.35	86.53	86.67	84.63	85.91
Average	*70.03*	*71.87*	*70.95*	*71.97*	*72.72*	*70.37*	*70.49*	*72.77*	*73.90*	*71.67*

Table 7. Representation of long-term financial resources in individual categories of companies.

Year	2009	2010	2011	2012	2013	2014	2015	2016	2017	Average
Small	59.37	66.76	68.75	71.57	63.70	71.62	80.54	75.64	70.42	69.82
Medium	63.65	65.52	54.88	55.55	56.68	56.02	55.00	55.58	55.75	57.62
Large	39.22	41.98	41.79	42.38	40.80	41.67	43.99	46.11	46.69	42.74
Average	*54.08*	*58.09*	*55.14*	*56.50*	*53.73*	*56.44*	*59.85*	*59.11*	*57.62*	*56.73*

Table 8. Representation of short-term financial resources in individual categories of companies.

Year	2009	2010	2011	2012	2013	2014	2015	2016	2017	Average
Small	40.63	33.24	29.61	28.29	35.84	28.09	19.29	24.17	28.63	29.75
Medium	34.79	33.53	44.56	43.74	42.81	43.11	43.36	43.69	43.54	41.46
Large	58.83	55.99	56.78	56.18	58.15	57.01	54.82	52.68	51.96	55.82
Average	*44.75*	*40.92*	*43.65*	*42.73*	*45.60*	*42.73*	*39.16*	*40.18*	*41.38*	*42.34*

From the above-mentioned values (see Tables 5 and 7), it can be concluded that the second golden rule of financing was observed both in average values for all companies and for individual categories of company sizes.

In general, it can be stated that all companies had more current assets than long-term assets. A more significant difference in the share of fixed and current assets was in large companies, where it is clear that a larger financial volume is held in current assets, i.e. in inventories, receivables and cash, than in fixed assets. When comparing the resulting average values given in Table 5 and Table 6 with the average values calculated for the same period, i.e. 2009–2017 period by the Ministry of Industry and Trade from Table 2, it can be concluded that within fixed assets, the values differed by –3.55% and within current assets by +4.50%, which can be considered as insignificant deviations in both cases. These deviations can similarly be caused by two factors, either by a small sample used in the research, or by more samples of one category of company size in the statistical survey of the Ministry of Industry and Trade, which

would affect the resulting values.

Within the financial coverage of assets, long-term resources were used more in average values, which include share capital, profit or loss, funds, reserves, loans and liabilities with a maturity of more than 1 year. There was a more significant difference in small companies, where long-term resources were significantly more used, especially the positive economic result from previous years than short-term resources in the form of loans, credits or liabilities with a maturity of up to 1 year.

The third golden financing rule - golden "pari" rule states that fixed assets should be covered by equity (see Table 9).

Table 9. Average percentage share of fixed assets and equity for all analyzed companies.

Year	2009	2010	2011	2012	2013	2014	2015	2016	2017	Average
Fixed ass.	29.00	28.23	29.26	28.64	27.95	30.02	29.46	27.65	26.81	28.56
Own res.	43.36	48.61	47.24	48.44	46.58	48.35	50.51	46.55	46.14	47.31

It is clear from the values that the third golden rule of financing is fulfilled in all cases. This is mainly due to the low volume of fixed assets in individual categories of company sizes and, conversely, the greater share of own sources of financing. Items from the balance sheet such as share capital, funds, economic result were taken into account as own sources of financing.

5 Conclusions

The aim of the paper was to analyse the financial management of construction companies operating in the Czech Republic. Financial management of the companies was based on the confirmation or rejection of three basic financing rules, which include the share between own and external resources of financing, coverage of fixed assets by own and external long-term sources, and coverage of fixed assets only by own resources of financing. A financial analysis for individual industrial sectors published by the Ministry of Industry and Trade is published once a year within the framework of statistical surveys and analyses. The sector selected for the research corresponded to the basic activities of the companies analysed, namely construction industry. However, the size of company is neglected in these analyses. Therefore, the research was focused on examining financial management according to the company size. It was concluded from the overall research survey that the second and third financing rules were confirmed for all company sizes, unlike the first rule on company indebtedness was almost confirmed for medium-sized companies. The analysis of indebtedness showed that small companies use own resources more for financing their activities and, conversely, large companies use external resources more for financing their activities.

This article represents a basic input into the overall investigation into the financial management of companies according to their size. Further research will be based on the investigation into the financial management of only fixed assets of companies with an impact on the economic result and in the next step the impact on taxation. The size of the company will be reflected in the subsequent research as well.

Neural Model of Projecting Compressive Strength of Cement Concrete Intended for Airfield Pavements

Małgorzata Linek

Kielce University of Technology, Faculty of Civil Engineering and Architecture, Department of Transportation Engineering, Aleja Państwa Polskiego Street 7,25-314 Kielce, Poland, tel.+48 41 3424844, e-mail: linekm@tu.kielce.pl

Abstract. *This work present to the mathematical model in the form of ANN, intended for projecting concrete compressive strength. Input data was classified according to the type of component material and its content in concrete mix (cement contents, coarse aggregate, fine aggregate, water and admixtures). In order to determine mathematical model, a multilayer, one-way perceptron network was used, recursion network with sigmoidal neurons. The model assumes that neurons are gathered in some layers (one input layer, hidden layers and one output layer). The conducted cross-section of the influence of variables parameters values (learning constant - α and momentum values - η) on the accuracy of representation of compressive strength was analyses. Assessment criterion was assumed taking into consideration the lowest mistake level and 100% compliance. According to the obtained analysis results ANN was assumed the best representing network for constant value of momentum 0,3, learning constant of 0,05 and 6 neurons in a hidden layer. Very good coincidence of component models with experiment results was achieved. At testing stage, the coincidence was achieved at the level of 99.74%, in case of the assumed network structure. During model verification by means of experimental results, the average coincidence was 99.83%.*

Keywords: *Compressive Strength, Cement Concrete, Airfield Pavements, Neural Model, Artificial Neural Networks.*

1 Introduction

The knowledge of mathematical model defining concrete resistance depending on the type of components and contribution thereto is interesting in terms of science and practice. Using Artificial Neural Networks (ANN) for this purpose and the opportunity to apply thereof for communications engineering and its particular applications are of the main interests of researchers of this field and construction branch in its general aspects. Potential capacities of ANN were proved, among others, in the following works (Bayrak *et al*., 2009; Bishop, 1995; Ceylan *et al*., 2007; Kasperkiewicz, 2004; Kim *et al*., Manerowski *et al*., 2006; Waszczyszyn, 2001). This work is an attempt to use ANN in order to design concrete mixtures intended for airfield pavements, define properties of hardened concrete and project the strength thereof. ANN provide the opportunity of structural dimensioning of susceptible and rigid pavements (*e.g*. Bilgehan *et al*., 2010; Ceylan *et al*., 1684; Ioannides *et al*., Noorzaei *et al*., 2007; Pożarycki, 2012; Thanoon *et al*., 2007; Urbańska *et al*., 2002). Using own collected database containing strength, laboratory test results, the mathematical model in the form of ANN, intended for projecting concrete strength, was presented. The essence of ANN is the selection of network structure (the number of layers and the number of neurons in particular layers) and defining the parameters thereof (constant values and weights).

2 Materials and Methods

This research paper concerns the issue of projecting the compressive strength of concrete intended for airfield pavements as far as structure durability is concerned. As a result of own laboratory and field tests (*e.g*. Linek *et al*., 2016; Linek, 2017; Linek *et al*., 2018), the strength of concrete containing various components of diversified contents were determined.

Consequently, the significant database was collected which enabled to prepare mathematical model allowing to determine concrete strength. Application of ANN resulted from the necessity to identify the diversification of compressive strength, which was the effect of changes in case of aggregate composition of concrete mix. One of the basic parameters of hardened concrete, which has the direct influence on the durability thereof in case of airfield pavement, is compressive strength (Glinicki, 2011; Nita, 2005; Szydło, 2004). This property depends on the diversified factors, among which there are the cement type and content, amount of coarse and fine aggregate and agents added to the mix aimed at the improvement of its parameters, and consequently also the parameters of hardened concrete. In case of each out of 6500 mixes, coarse and fine aggregate.

The aggregate should be distinguished by high durability and frost resistance, abrasion and polishing resistance and low absorbability. The designed aggregate compositions each time complied with (PN-EN 206-1:2003) and (NO 17A 204:2015). Mix composition included clean-clinker Portland cement in various amounts CEM I 42,5 (which fulfilled the requirements of (PN-EN 197-1)) and water (complied with (PN-EN 1008:2004)), designing diversified water-content ratio with reference to cement amount (w/c). Water-cement ratio significantly influences concrete durability. Limit content of individual mix components have been presented in the table 1.

Table 1. Limit component contents of the analyzed concrete mixes (content in kg/m^3).

Elements content	Cement	Coarse aggregate	Fine aggregate	Water	Admixtures
Min / Max	335 / 380	1149 / 1401	358 / 604	120 / 150	0.0 / 6.4

On the 28th day since concreting, each sample, prepared and cured in accordance with the requirements of (PN-EN 12390-2:2009), was subject to destructive tests by means of hydraulic press in compliance with (PN-EN 12390-4:2009). Maximum force destructing the sample, obtained according to the measurements, taking into consideration the assumed constant loading speed of 0,5MPa/s, was the basis for defining compressive strength of individual samples. The subject of further analyses included the samples which proved proper nature of destruction, after destructive test, according to (PN-EN 12309-3:2009). In case of each sample the compressive strength - f_c was determined, according to $f_c = F/A_c$, where F refers to maximum load registered in the course of sample destruction, while A_C refers to cross-sectional area of the sample which is influenced by the compressive force. The strength values obtained in this way were the input base to assess compressive strength of cement concrete intended for airfield pavements using ANN. All obtained test results concerning individual research series corresponded to the assumptions of the designed concrete classes and they were statistically essential. Therefore, they were the reliable source of input data for ANN identification, reflecting concrete strength in case of various compositions thereof.

3 Data Preparation

Operation of neural network depends on the type of neuron which will be accepted. Among the most commonly used, there are linear neurons, MLP, RBF, GRNN and Kohonen (Ossowski, 2006; Tadeusiewicz, 1993). Neuron used in the course of network designing process consists of output signal being the total of constant and relevant input signals multiplied by weight. Output signal structure in case of the analyzed network has been presented as follows (1):

$$y_i = S_i + \overline{X_\iota}(i,i)\,\overline{w^T}\,(i,i) \tag{1}$$

In case of equation (2) input signals take the form of $\overline{X_\iota} = [\,x_{i1}, x_{i2} \ldots x_{in}]$, while the corresponding weights $\overline{w_\iota} = [\,w_{i1}, w_{i2} \ldots w_{in}]$. The essence of the prepared network is to determine individual weights and constants S_i. Due to the fact that neurons have learning opportunities, synaptic scales were used, which can provide variable values and which are the basis for network learning. The applied activation function was presented by means of the following: $F(y_i) = 1 / (1+\exp(-2y_i))$. The assessment of representation accuracy of values from the experiment and coefficients generated by neural network was defined on the basis of two parameters. The first one is the average of the sum of squares of differences between the values of outputs from the real structure ($y_{rz\,i}$) and model (N) for experimental data (i = 1, 2, ..., N). The sum of squares of differences was determined according to the relationship (2).

$$\Delta\, y_{sr} = \frac{\sum_{i=1}^{N}(y_{SSN\,i} - y_{rz\,i})^2}{N} \tag{2}$$

However, the other parameter is the number of positive occurrences. Positive occurrences are understood, as the figure among all measurements which comply with the: $(y_{SNN\,i} - y_{rz\,i})^2 \leq \varepsilon$. Where y_i reflects output values of real measurements, i_i reflects output values from the model, while ε refers to the determined value of 0.01. The significant factor which influences the accuracy of projection of concrete strength by ANN is creating representative input dataset to determine thereof. Input data was classified according to the type of component material and its content in concrete mix. The following material types were considered: 9 types of cement, 17 types of coarse aggregate, 2 types of fine aggregate, 5 types of additives and 6 types of mix consistency as technological parameter, influencing proper structure performance related process. There were 6500 of diversified mix compositions collected, out of which 70% was assumed as input database for ANN, 15% was intended for testing purposes of the educated network, and the remaining 15% for network verification.

The selection of network structure is determined by the opportunity of feedback occurrence. These issues, among others, have been discussed in detail in the following work (Haykin, 1994), and their essence is the occurrence or absence of return connection (from latter to previous neurons), according to recursion and one-way structure. For the research paper purposes it was assumed that the feedbacks will not occur. Figure 1 presents schematic normalization process of input signals X and output signals y performed using ANN of the subject research paper. The results obtained as part of the conducted actual laboratory experiments were considered as the data. In case of the data which was subject to normalization, neural network was determined and then dimensional values thereof were calculated. In order to determine mathematical model, a multilayer, one-way perceptron

network was used, recursion network with sigmoidal neurons using JETNET 2.0 program (Lónnblad et al., 1992). The software used for network learning includes algorithm of moment method of backward mistake propagation (Rutkowski, 2005). ANN structure was presented in Figure 2. The data collected in the course of experiments was referred to as input layer of the prepared model. Input layer included 5 elements corresponding to individual cement contents (C), coarse aggregate (Kg), fine aggregate (Kd), water (W) and admixtures (D). The model assumes that neurons are gathered in some layers, among which there is one input layer, hidden layers and one output layer. It was assumed that input signals will be subject to normalization and have numeric values from 0 to 1. Among the available methods (among others min-max, Z-score, zero-mean, decimal calibration) normalization was selected in accordance with linear initial data transformation in compliance with: $\overline{x_l} = (x_i - x_{min})/\Delta x$, where $\overline{x_i}$ refers to normalized data, x_i – particular real values, x_{min} – minimum value of real values, while Δx refers to the difference between maximum and minimum value, i = 1, 2, ..., 5. Analogously for the output data in compliance with: $\overline{y_l} = (y_i - y_{min})/\Delta x$.

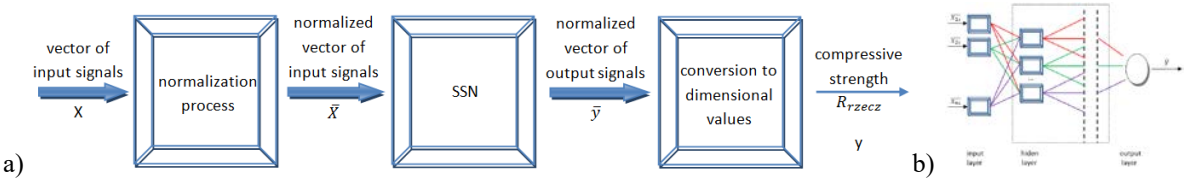

Figure 1. a) Diagram of using ANN in the model of compressive strength value estimation; b) graphic model of structure presenting the assumed multilayer artificial neural network.

4 Results

Analyses using artificial neural networks were conducted by means of NNair program creating regressive model, where it was expected to provide a specific numerical value being the solution to the problem. In case of the analyzed case this value was identified with the assumed compressive strength value. In order to conduct cross-section analysis of the influence of variables parameters values (α and η) on the accuracy of representation of compressive strength, analyses including matrix of 90x90 elements. According to the obtained results it was proved that the selection of α and η has significant influence on the extent of the obtained representation.

Table 2. Influence of learning constant value α on the accuracy of compressive strength representation (assuming constant value of momentum η = 0.3 and ε = 0.01).

No ANN	α	η	Number of inputs	Number of neurons	Number of outputs	Percentage of positive events	Δ y_{sr}
1-1	0.03	0.3	5	5	1	100	0.0034718
1-2	0.04	0.3	5	5	1	100	0.0031399
1-3	0.05	0.3	5	5	1	100	0.0028273
1-4	0.06	0.3	5	5	1	99.6	0.0025851
1-5	0.07	0.3	5	5	1	99.4	0.0024215

Table 3. Influence of momentum valueα (from 0.3 to 0.7) on the accuracy of compressive strength representation (assuming constant learning constant value of learning constant = 0.04 and ε = 0.01).

No ANN	α	η	Number of inputs	Number of neurons	Number of outputs	Percentage of positive events	Δ y_{sr}
2-1	0.04	0.30	5	4	1	99.6	0.0023666
2-2	0.04	0.40	5	4	1	99.4	0.0023475
2-3	0.04	0.50	5	4	1	99.4	0.0023339
2-4	0.04	0.60	5	4	1	98.2	0.0023255
2-5	0.04	0.70	5	4	1	97	0.0023281

Table 4. Influence of neurons number (5-10) in a hidden layer on the accuracy of representation of compressive strength at constant value of momentum 0.4, learning constant 0.03 and ε = 0.01.

percentage of positive events	the number of neurons in the hidden layer					
	5	6	7	8	9	10
	100	100	100	98,6	100	59,4
Δ y_{sr}	0.0028273	0.0022759	0.0031341	0.0022653	0.0027379	0.014378

Analyzing the data presented in table 2 and 3, the initial tolerance of learning constant was assumed at 0.05 and the initial tolerance of momentum was assumed at 0.3 for further analyses. In case of such assumed tolerance, the least value of the generated mistake, at the highest compliance of results was obtained.

Table 5. Influence of neurons number (1-5) in a hidden layer on the accuracy of representation of compressive strength at constant value of momentum 0.3, learning constant 0.05 and ε = 0.01.

No. ANN	α	η	number of inputs	Number of neurons in the hidden layer		number of outputs	percentage of positive events	Δ y_{sr}
				I	II			
3-1	0.05	0.30	5	6	1	1	87.0	0.004376
3-2	0.05	0.30	5	6	2	1	42.6	0.035561
3-3	0.05	0.30	5	6	3	1	46.2	0.029934
3-4	0.05	0.30	5	6	4	1	42.6	0.034757
3-5	0.05	0.30	5	6	5	1	46.2	0.028068
3-6	0.05	0.30	5	1	6	1	42.6	0.031157
3-7	0.05	0.30	5	2	6	1	46.2	0.028427
3-8	0.05	0.30	5	3	6	1	46.2	0.030317
3-9	0.05	0.30	5	4	6	1	87.0	0.004865
3-10	0.05	0.30	5	5	6	1	42.6	0.033186

According to the obtained analysis results ANN (tab. 4, 5) was assumed the best representing network for constant value of momentum 0.3, learning constant of 0.05, 6 neurons in a hidden layer and assumed ε = 0.01. In case of network of 5-6-1 structure, the first digit (5) refers to the number of inputs, next (6) the number of neurons in a hidden layer, and the last one (1) refers to one output identified with the assumed compressive strength value. This structure was assumed as a result of accuracy tests of representing real compressive strength values by the network. Assessment criterion was assumed taking into consideration the lowest mistake level and 100% compliance. Figure 3 presents the courses of learning in case of network of 6 neurons in a hidden layer. It can be observed that minimum values

$\Delta\, y_{sr}$ amount to 0.008, and maximum values amount to 0.520 in case of the assumed number of iterations. According to the obtained results of ANN analysis it was proved that the determined network can be recognized reliable for 38000 iterations.

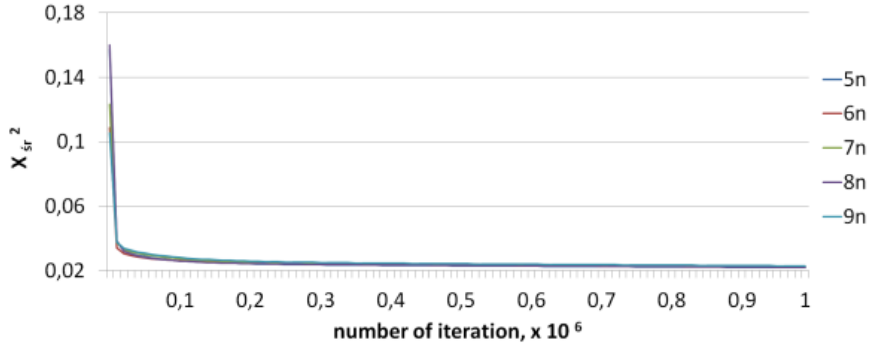

Figure 3. The course of learning process by ANN of diversified neurons number in a hidden layer.

Table 6 presents approximate contents of individual mix components intended for network testing. Figure 4(a) presents graphic summary of data determined at testing stage by the educated network. According to the obtained characteristics (Tab. 7 and Tab. 8) it was proved that the testing and verification of artificial neural network model reflects the values determined by the network. The obtained average value from 1300 events coincidence over 99% is very high. Average value of coincidence is 99.08 %. The obtained average value from 1300 events coincidence over 99% is very high. Average value of coincidence is 99.05 %.

Table 6. Limit component contents of the analyzed concrete mixes (content in kg/m^3).

8.	417	1318	743	166	2.4	33.0	33.0	100.00
9.	359	1207	591	143	2.7	37.9	37.8	99.77
10.	379	1402	692	151	2.8	36.2	36.2	100.00

5 Conclusions

It should be concluded that the assumptions concerning the construction of ANN model and the course of analysis can credibly anticipate parameters of composite material – concrete.

The results obtained as a result of the conducted analyses prove the purpose of application of the presented method in case of modeling the composition of concrete mix and projecting the strength obtained by concrete after 28 days of curing in standard conditions.

The analyzed structure 5-6-1 allows drawing the conclusions regarding material parameters even in case of limited number of elements. Based on the obtained results, the network structure has a large influence on the accuracy of mapping results from the experiment through the network. The network analyzing five neurons in an input layer, diversified in terms the selection of hidden neurons amount, complies with model assumptions. It was proved that 5-6-1 network, with learning constant of 0.05, momentum 0.3 and ε=0.01,is the most favorable structure for the assumed data. Very good coincidence of component models with experiment results was achieved. At testing stage, the coincidence was achieved at the level of 99.08%, in case of the assumed network structure. During model verification by means of experimental results, the average coincidence was 99.05%.

Platform Development for Drone Utilization in the Architectural Field

Hiroyuki Miyauchi

Department of Building Materials and Components, Building Research Institute, 1 Tachihara, Tsukuba-shi, Ibaraki, 305-0802, Japan, miyauchi@kenken.go.jp

Abstract. *The utilization of drones is expected to streamline the process of building inspection in Japan; however, no known drone utilization platform exists in the region's architectural sector. Therefore, in this study we pioneered the development of a drone platform based on an industry–government–academia collaboration within Japan's architectural field. We first investigated drone-related trends, such as a utilization roadmap, flight rules, the drone market, new technologies and issues relating to the architecture field. Subsequently, we worked on solutions for drone utilization in the building sector, including methods for building inspection, determination of drone-flight risk factors relative to building inspection and the creation of a drone safety operation manual. Through field tests, we validated the effectiveness of the drone platform in building inspection, i.e., the determination of a cost–time relation during inspection, the merits of applying a high-resolution camera for inspection, the possibility of utilizing an infrared camera for exfoliation detection in exterior wall tiles and the development and efficiency of a built-in automatic inspection system. Furthermore, trial tests were conducted for the application of a drone-inspection system in disaster areas and a micro-drone in small building spaces. The findings of this study confirmed that the new drone platform achieved inspection- and disaster-related objectives within the architectural sector.*

Keywords: *Drone, Industrial Advances, Building Inspection, Risk Assessment, Field Test.*

1 Introduction

In Japan, the total number of pre-1980 housing stocks exceeds 13.69 million and is increasing every year. To ensure longevity, the assessment of buildings and their required maintenance has become an urgent issue. As such, efficient regular inspections are required as an important component of building maintenance. For example, periodic inspection reports according to Article 12 of the Building Standards Law are required for building health diagnosis. For the exterior wall inspection of buildings, a manual hammering test is required, especially for buildings that are more 10 years old. However, this test requires the setting up of temporary scaffolding for areas that cannot be reached by the investigator, making it costly for the building owner. There is an urgent need to develop a rational inspection method. In meeting this requirement, the use of drones is expected to play a significant role. An inspection technology for the maintenance of such buildings, the various potential uses of drones are being explored.

In 2016, the authors began research on (i) building inspection technology using drones and (ii) the construction of drone platforms. In the academic field, the Architectural Institute of Japan (AIJ) established a committee relating to the use drones and held the Architectural Drone Symposium to establish the current state of the art in drone usage. In the industrial field, the Japan Architectural Drone Association (JADA) was established in 2017 to address human resource development, technical support and standardization relating to the safe use of

doi:10.23967/dbmc.2020.110

drones. JADA has organized workshops and committees covering the safe operation of drones. In general, the use of drones in industry, government, and academia is gradually increasing.

Based on the above background, we herein report on (i) drone-related trends and levels of technology in the architectural field, (ii) demonstration experiments related to drone inspections and (iii) future prospects for drone usage.

2 Trends in the Use of Drones in the Architectural Field

2.1 Drone Technology Trends in Japan

As seen for Japan during 2018 (Figure 1), the use of drone services in sectors such as agriculture, surveying, aerial photography, inspection, crime prevention and logistics is expanding. Furthermore, by 2024 the infrastructure inspection sector is expected to outpace the agricultural sector. Figure 2 shows the roadmap for the utilization of drones according to the flight levels reported by the Ministry of Economy, Trade and Industry (METI). Level 1 corresponds to surveys such as those of a detached roof. Level 2 corresponds to a large area roof inspection or wall inspection. Level 4 is expected to be used for (i) the inspection of skyscrapers that are assumed to be non-visual flight in the 2022, (ii) logistics and security in cities and (iii) disaster-related issues. Therefore, in the architectural field, it is necessary to create a social infrastructure that assumes the use of drones in population-intensive areas. Table 1 shows the uses of drones in the architectural field. From all the papers submitted up to 2018, the importance of drone use follows the order: inspection, disaster, city/region, construction, environmental measurement, transportation and cultural heritage.

In particular, the use of drones for inspection is increasing, particularly in relation to the inspection of the outer walls of high-rise buildings, which would otherwise require scaffolding. These building inspection surveys are generally classified into primary to tertiary surveys according to the level of inspection, as shown in Table 2. Currently, primary and secondary surveys of a non-contact type are used for building inspection.

2.2 Drone Technology Development and Dissemination Efforts in the Architectural Academic Field

In April 2016, “WG on Application Guide of UAV to Building Performance Survey”

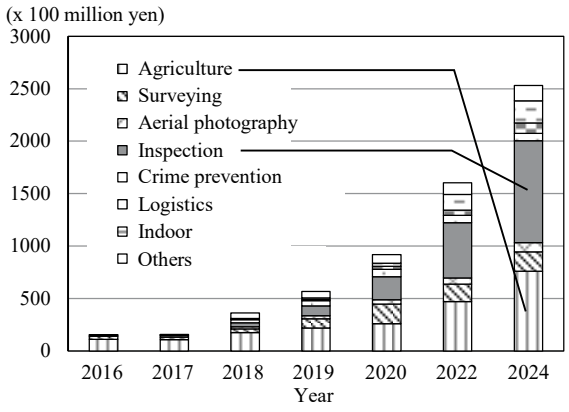

Figure 1. Drone service market in Japan.

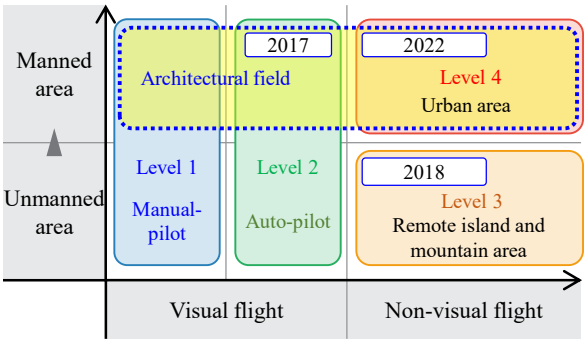

Figure 2. Utilization in architectural field at different flight levels.

(currently, Sub-committee for utilization of drone technology; Chairperson: H. Miyauchi) was established in the Durability and Maintenance Steering Committee, AIJ. The main foci of this WG were (i) the use of drones for the survey of building exterior walls, (ii) the collection of technical information, (iii) field trials and (iv) the examination of data collection and analysis methods. In May 2017, the first Architectural Drone Symposium was held with the aim of highlighting the advantages of drone technology across the entire architectural field. In 2019, a third symposium provided the latest information on the use of drones, covering regular use through to their use in disaster situations.

2.3 Challenges and Initiatives for the Utilization of Drones in the Construction Industry

The challenges facing the use of drones in the architectural field can be divided into (i) the damage caused by drone collisions and (ii) human issues. Regarding (i), Figure 3 shows the number of accidents caused by drones, based on information provided to Ministry of Land, Infrastructure, Transport and Tourism (MLIT). Compared with the 45 accidents for which no application for flight was required by the MLIT, 96 accidents (i.e., more than double) did require an application for flight. In particular, there are many population-intensive areas assumed during surveys of buildings and accidents when flying less than 30 m, and so sufficient safety measures are required when using drones in urban and architectural areas. Regarding (ii), there is a risk that video taken by drones may infringe privacy, as related to the

Table 1. Research topics with keyword "Drone and UAV" in AIJ annual paper.

Uses of drones in the architectural field	Year						Total
	2012		2015	2016	2017	2018

Personal Information Protection Law. There are also problems relating to noise during drone flight; therefore, it is necessary to give sufficient consideration to residents.

Against this background, JADA was established in September 2017 to develop human resources that can utilize drone technology across various applications in the architectural field. JADA also provides technical support and standardization. Activities were commenced with the aim of contributing to the realization of a safe, secure and sustainable society when conducting business. In particular, we are strengthening efforts relating to the safe operation of drones for building inspections. For example, as shown in Figure 4, the "Safety Manual for Drone Utilization in Buildings" was created, explaining basic knowledge relating to (i) drone utilization, (ii) drone technology and safe operation and (iii) construction management and inspection surveys for buildings. In addition, this manual is used in the "Building Drone Safety Education Workshop" to ensure thorough safety education.

3 Evaluation of Building Inspection using Drones

3.1 Effects of Cost and Time during Drone Inspection Surveys

Judgment criteria that show the superiority of drone usage over existing building inspections include (i) cost and time requirements from inspection to analysis and (ii) whether or not the level can be inspected under the same conditions as it can from the ground. From the above, using a six-story experimental wooden house at the Building Research Institute (BRI), the

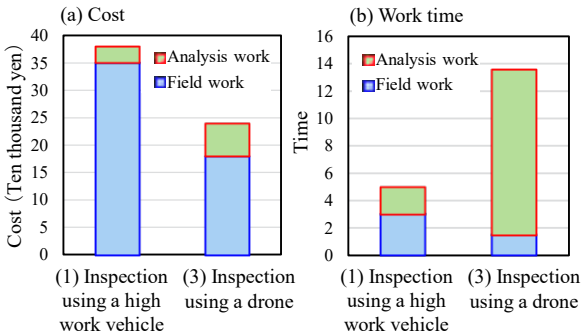

Figure 6. Comparison of cost and time requirements for high level manual inspection and drone photography inspection.

advantages of using a drone for building inspection were evaluated by comparison with a conventional inspection, as shown in Figure 5. Table 3 shows the results of comparing (2) ground photography and (3) drone photography. If a drone can secure a safe flight distance from a target object, it can photograph to the same accuracy as a visual inspection from the ground. For example, because the image size and image quality of the object can be kept constant during photographing by the drone, it is easy to subsequently analyze the image.

Figure 6 shows the results of comparing the cost and time requirements between (1) inspection using a high work vehicle and (3) inspection using a drone. Inspection by drone photography can be implemented at a lower price than that for a high work vehicle. On the other hand, the cost and time of image processing of drone images is higher; in particular, the analysis work is time consuming. These finding indicate the potential efficiency of on-site drone inspections but also suggest that image processing needs to be simplified and incorporate automated processing techniques.

3.2 Assessment of the Use of a High Resolution Camera

One of the important criteria that can be applied to building inspections is inspection accuracy in relation to specified requirements. Therefore, using a general-purpose 20-million pixel camera and a 100-million pixel camera (upper limit of resolution), we conducted a drone photographing experiment to evaluate the building inspection accuracy. Table 4 shows the performance values of the cameras used in the study. Figure 7 shows the visibility results of both cameras when a crack scale is attached to the outer wall and the drone flight shown in Figure 8 is taken. At a photographing distance of 5 m, it is difficult to see a 1.5-mm wide crack when using the 20-million pixel camera. However, at 100 million pixels, visual confirmation is possible down to a crack width of about 0.25 mm.

3.3 Assessment of the Applicability of using an Infrared Camera

When tiles are used for the exterior of a building, there is a risk of them peeling off due to a loss of adhesion between the base and the tiles. As an investigation method for this peeling, an expected inspection method is the use of a drone-mounted infrared ray camera. A demonstration experiment of this approach was conducted by MLIT in 2017–2018. At BRI,

Table 4. Specifications to satisfy 1-mm/pixel resolution

Performance	100-million pixel camera	20-million pixel camera
Distance	32.6 m	13.7 m
Photography area (H x W)	8.7 m x 11.6 m	5.3 m x 4.0 m
Viewing angle	15.2°	16.4°

Figure 7. Inspection test by drone.

Figure 8. Images from different resolution cameras.

the test specimens included defect part between substrate and tile with 1m wide x 1m high were made as parameters with defect area and peeling depth. As shown in Figure 9, these specimens were placed on the roof of the building and aerial photographs were taken using two types of infrared camera mounted on a drone. An example of the detection of the defective part of a tiled specimen, as shown in the infrared image, is shown in Figure 10. When environmental conditions, such as solar radiation and temperature, and the performance of the applied infrared camera were appropriate, the detection rate of tile peeling was high. However, it was found that it is important to define the application range when using a drone-mounted infrared camera because the peeling conditions and photographic environment may differ in an actual building.

3.4 Development of Automatic Inspection and a Building Inspection System

Although drones are generally controlled by GPS, it is difficult to capture GPS signals in areas where buildings are densely packed, increasing the risk of crashing and potentially decreasing building inspection accuracy. In this study, we used SLAM (Simultaneous Localization and Mapping), as shown in Figure 11, which estimates the position of the camera based on the image information of the camera (i.e., independent of GPS signal). Figure 12 shows the results of a demonstration experiment of automatic drone inspection using an

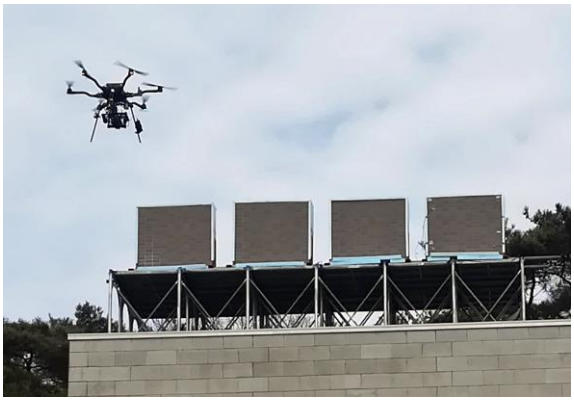

Figure 9. Inspection of tiled specimens using drone.

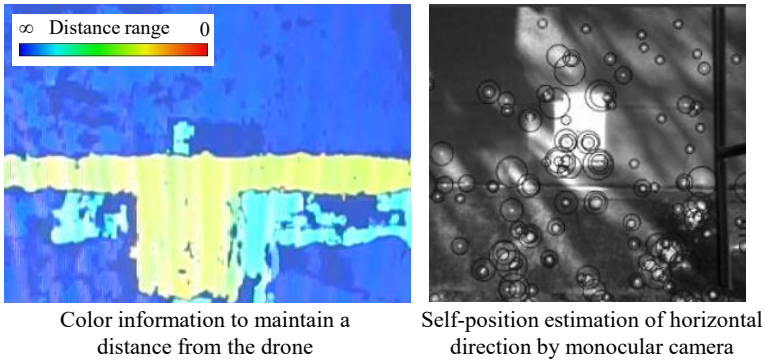

Figure 12. Test results for drone with Visual SLAM technology.

experimental building. The left of Figure 12 shows the use of a stereo camera to identify distance based on color information while maintaining a distance of 3 m from the drone. Furthermore, a downward camera was able to estimate self-position in the horizontal direction of the drone flight based on characteristic points on the asphalt pavement surface, as shown on the right of Figure 12.

3.5 Use for Data Recording and Analysis

It is important to record and measure building deterioration information on a regular basis. This information then needs to be stored and later used for building maintenance as required. Therefore, in Figure 13 we show an example of recording and storing deterioration information relating to a waterproof membrane sheet on the building roof. The resolution of the image was set to 1.2 mm/pixel and the altitude was set to 38 m from the roof. The entire roof surface was photographed during an automatic flight and a series of deterioration conditions for the roof were acquired. As shown in Figure 14 (m units), the flow of drainage on the waterproof sheet and the roof area could be measured. In cm units, the situation around the drain was able to confirm, in mm units, the crack and repair status of the waterproofing sheet. Therefore, it is possible to simultaneously record these states of degradation using a drone and archive them for use in future repairs.

3.6 New Methods for Building Inspection

Many natural disasters such as earthquakes, typhoons and floods occur in Japan and it is expected that drones will be used following such events to assess damage. A demonstration experiment using a drone was conducted on a three-story building damaged by the earthquake in Kumamoto Prefecture in 2016. The flow of the experiment is shown in Figure 15. Initially, the drone operator takes a picture of the building near the crack. The investigator wears VR goggles at a position away from the building and verifies whether the image information taken by the drone can be determined by extracting cracks that the investigator wants to confirm. Based on this assessment, it is considered possible to investigate damaged buildings via drone by remote control.

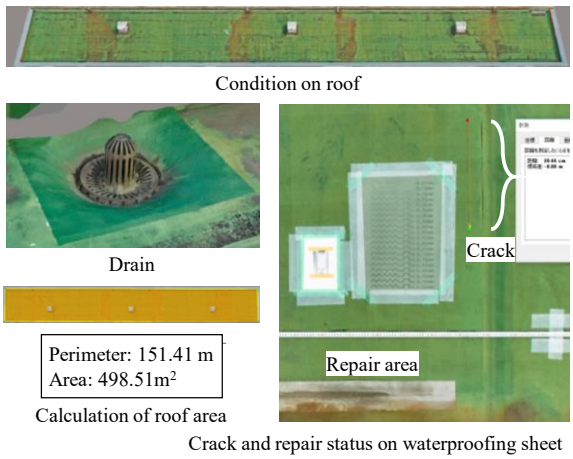

Figure 14. 3D model of degradation information (100-million pixels).

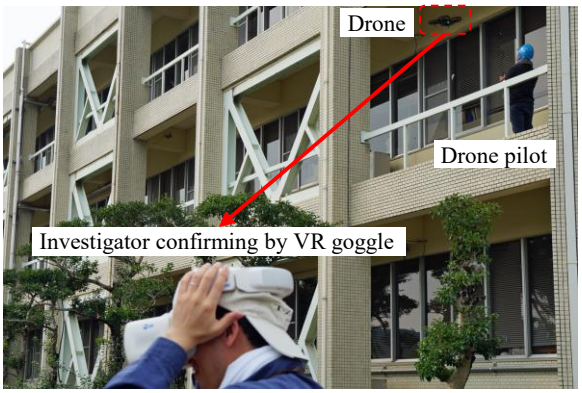

Figure 15. Remote investigation by drone in damaged building.

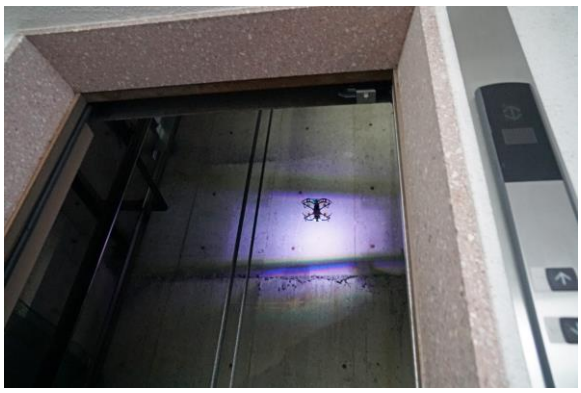

Figure 16. Drone inspection in confined space (elevator shaft).

Many external spaces related to buildings can be assessed using drones; however, drones are also highly usable in narrow spaces where human access is difficult, *e.g.*, behind ceilings and under floors. Therefore, in this study, we investigated the inner wall of an elevator shaft using a micro drone with a non-GPS control function that weighs less than 200 g, as shown in Figure 16. It was found that this approach can be used for inspection even in dark and confined spaces.

4 Conclusions

In this study, we investigated drone use trends in industry–government–academia for application to the architectural field. In addition, drone flight safety, cost reduction and labor-saving, inspection accuracy, application to archiving, and inspection automation were evaluated by field tests. Overall, the effectiveness of drone utilization was demonstrated. In addition to building inspection, drone technology is expected to be used across a wide range of fields, including disaster surveys, architectural education, information systems, facilities, design, urban planning, environmental engineering, architectural history, crime prevention and so on. It will be possible to create a new construction drone platform by strengthening the connected industries that link drones with various technologies (AI, AR, the cloud, etc.). For this purpose, it is very important to work with related parties so that the technology can effectively contribute to society.

Abstract. *Vertical Greenery Systems (VGS) applied on building has proven economic, environmental and social benefits which made it one of the widely accepted green building design strategies to support sustainable development. However, incorporating vertical greenery systems into innovative facades generates maintainability challenges. This paper highlights the best and good practices Design for Maintainability scoresheet, as well as the VGS defects and issues. The Design for Maintainability (DfM) assessment scoresheet will be beneficial in assessing and avoiding potential VGS defects leading to its maximum performance, longevity and sustainability. This research has established a list of best practice guidelines and measures with weighted scoring system for evaluating the maximum performance and efficient maintainability of VGS applications on facades while minimizing cost, risks, negative environmental impacts and consumption of matter/energy. The paper's contribution will be the improvement of the designers' decision making process, expanded library on vertical greenery systems defects as well as the importance of integrating maintainability of high-rise VGS facades in tropical conditions during its design inception.*

1 Introduction

Vertical Greenery Systems (VGS) applied on building has proven economic, environmental and social benefits (Chew and Conejos, 2016; Perini *et al.,* 2017) which made it one of the widely accepted green building design strategies to support sustainable development. However, incorporating vertical greenery systems into innovative facades generates maintainability challenges such as spoilt or falling leaves (Wong *et al.*, 2010), defective irrigation systems and inadequate installation methods which surges costs on operations and maintenance (Safikhani *et al.*, 2014), damaged surfaces due to plant roots infiltrating cracks (Manso and Castro-Gomes, 2015), lack/insufficient maintenance access (Behm and Poh, 2012; Köhler, 2008; Perini and Rosasco, 2013; Pérez *et al.,* 2014).

Chew and Conejos (2016) reports that less research has been undertaken concerning the maintainability of VGSs in tropical settings via design-based values, since this entails the vertical greenery system's sustainability (Emilsson, *et al.*, 2007). There is a need for the development of guidelines for VGS sustainability (Dvorak and Volder, 2010; Giordano *et al.,* 2017) which prompted the development of the Design for Maintainability guidelines for high rise vertical greenery systems in the tropics by Chew *et al.* (2019).

Chew and Conejos (2016) highlights various vertical greenery systems defects and issues in

Singapore and categorize them into technical and environmental defects based on previous research study and continually establishes more evidenced based issues and defects through qualitative approaches in this study in order to ascertain best practices as basis for a Design for Maintainability scoresheet in support for the design decision tool developed to assess the performance of vertical greenery systems.

2 Green Maintainability

The Green Maintainability concept (Chew, 2016; Conejos *et al.,* 2019) was established with the five green maintainability factors which incorporated facility management with sustainability right at the outset; such as: (1) maximizing performance – refers to the optimal competence of the building's function through design values, building science and engineering, efficient energy use and sustainability; (2) minimizing cost – pertains to the decrease in operations and maintenance costs and boosting savings throughout the entire building lifespan; (3) minimizing risk – denotes to the reduction of possible building defects occurrences and risks in the future; (4) minimizing negative environmental impact – concerns in the decrease of potential damaging effects caused by the discharge of a substance in the environment; and (5) minimizing consumption of matter and energy – indicates the conservation and management of the building's material, water and energy usage.

3 Research Methods

a) Qualitative Approach - The application of instrumental case study stipulates a comprehensive and in-depth interpretation of the cases, thereby in improving a theory (Stake, 1995), thus this approach was undertaken in the study to determine and establish evidence-based defects of high rise vertical greenery systems in the tropics. The selected instrumental case studies (Table 1) are physically accessible for field observation surveys and a wealth of recent data is on hand. The five green maintainability factors are used qualitatively in assessing the case studies' vertical greenery systems green maintainability potential via field observation survey and interview with expert and supported by stakeholders' via walkthrough interviews. b) Quantitative Approach – To provide an assessment scoresheet, a survey was conducted among practitioners and experts involved in designing and installing green facades. The Analytical Hierarchy Process (AHP) which is proven robust (Saaty, 1980) was used in analyzing the coded survey data in excel format.

Table 1. Instrumental Case Studies.

	Case Study (Year completed) and Awards Received	Vertical Greenery System (and Implementation)	Height
CS01	Commercial Bldg. (2014) BCA Green Mark Platinum Award	Support type system (Steel structure and high tensile steel cables)	5 storeys (M)

4 Discussion of Findings

The identified critical high rise vertical greenery systems defects are due to lack of coordination among professionals lack of/insufficient coordination among building professionals which sometimes led to design oversights or inconsistencies. The following critical defects are:

- Lack of maintenance considerations such as insufficient/lack of maintenance access and safety issues/risks during cleaning and repairs. In some case studies, workers have to get through private balconies, pump rooms and air-conditioning units; climb over pool, parapet or glass enclosure; pass through pillars and traverse into narrow corridors that inhibits bulky maintenance equipment.
- VGS installation at the pool deck or over it which required frequent cleaning to preserve water quality.
- Lack/improper drainage system due to flat gradient or no screeding or lacking drains which causes water stagnation/ponding that will lead to pest infestation, mosquito breeding and algae/mould growth. In some instances, the drainage gutter has chokage issues due to falling leaves leading to water stagnation and possible mosquito breeding that will affect the health of residents and the public.
- Issues concerning infrequent/improper maintenance regimes due to the evident fallen leaves and dirt accumulation caused by heavy rainfall and strong winds. In some cases, the vines on the steel cable have thickened putting additional load to the support as it was not pruned or well maintained.
- Withering plants due to the suitability of plant species where in some cases where non-

tropical plants were installed which led to the drying and dying of plant species. The wrong choice of plant species can be considered a design oversight.
- Poor/faulty irrigation and water dripping issues caused by chokage or faulty components will lead to irregular plant growth or plants dying, rust of structural components, and high water consumption costs.
- Insufficient sunlight exposure also prevents plant growth and lead to plant dying or premature plant replacement regardless of proper irrigation regimes.
- Issues on maintenance cost (i.e. LCC) which entails a high cost of expenses when maintaining defective VGS.
