Abstract. The magnetorheological (MR) performance of MR elastomers mainly depends on the types of matrix and magnetic particles. Whether the MR effect of MR elastomers can be enhanced by using flower-like particles as the active phase was left unknown. In this study, flower-like cobalt particles and sphere cobalt particles with similar particle size were synthesized and used as the active phase to prepare MR elastomers. The experimental results indicated the MREs with flower-like cobalt particles present higher crosslink density and enhanced interfacial bond strength, which leads to their higher storage modulus and higher loss modulus with respect to the MREs with sphere cobalt particles. More meaningfully, the field-induced storage modulus tunable range was also improved by using flower-like cobalt particles as the dispersing phase.

1 INTRODUCTION

Magnetorheological (MR) elastomers are smart materials whose dynamic viscoelasticity can be tuned and modified reversibly within a few milliseconds by applying an external magnetic field.^[1-4] The magnetic field dependent dynamic viscoelasticity is defined as MR effect. Such unique effect makes MR elastomers have a wide range of engineering applications, such as suspension bushings, seismic protection, engine mounts, adaptively tuned vibration absorbers, stiffness tunable isolators and so on.^[5-10] Typical MR elastomers are composed of magnetizable particles and non-magnetic polymer matrix. The MR performance of MR elastomers mainly depends on the types of matrix and magnetic particles. In the past decades, most studies focused on matrix, and various kinds of polymer, such as silicone rubber, natural rubber, polyurethane, and polybutadiene rubber have been used to prepare MR elastomers with different properties.^[11-15] In contrast to plenty choices of matrix, limit kinds of particles can be used as the active phase; besides carbonyl iron particles, which were widely used due to their excellent soft magnetic properties and low cost, only cobalt particles and nickel particles^[16-17] have the potential to

be used to prepare MR elastomers.

In terms of composition, MR elastomers can be considered as a kind of particles filled polymer-based composites (PFPCs). Therefore, it can be expected that the interaction between particles and polymer matrix also has non-negligible effect on their MR effect as well as mechanical properties. Gong et al. used silane coupling agents to improve the interaction between the carbonyl iron particles (CIPs) and silicone rubber, and obtained an enhanced MR performance.^[19] Yu et al studied the effect of PANI-modified CIPs on improving the interfacial interactions of MR elastomer based on PU/EP IPNs matrix, which indicated that the strong interfacial interactions of PANI-MRE improved the MR effect and reduced the loss factor.^[13]

Although the influence of matrix, particles composition, and particle/matrix interface on MR properties of MR elastomers have been fully investigated, to the best of our knowledge, few studies analysed the effect of particles morphologies; in previous studies, sphere CI particles were the most widely used active phase of MR elastomers.^[20-22] By contrast, the influence of particles morphology on properties of MR gels and MR fluids, which are another two branches of MR materials, have been reported recently. Yang et.al synthesized a magnetorheological gel based on the conventional CIPs and flower-like CIPs. The experimental results indicate that, with flower-like CIPs, the maximum dynamic yield stress and magneto-induced shear yield stress of MR gel were 1.39 and 1.37 times of the MR gel with conventional sphere CIPs.^[23] We prepared a magnetorheological fluid with flower-like cobalt particles. Compared with the MR fluid with sphere cobalt particles, the flower-like cobalt particles based MR fluids showed higher yield stress and better sedimentation stability.^[24] However, whether the MR effect of MR elastomers can be enhanced by using flower-like particles as the active phase was left unknown. In this study, we designed experiments to find the detail influence of particles' flower-like morphology on MR effect of MR elastomers.

2 EXPERIMENTAL

The flower-like cobalt particles (FCPs) and the sphere cobalt particles (SCPs), which used to prepare different MR elastomers were prepared by a typical solvothermal reaction according to our previous report.^[24] The main reagents used were cobalt chloride hexahydrate ($\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$), sodium hydroxide (NaOH), ethylene glycol, 1,3-propanediol. All reagents were of analytical grade and used without further purification. Silicon rubber RTV-2 and catalyst were obtained from Zhuhai COCA New Material Co., Ltd. Dimethyl silicon oil ($\eta=100 \text{ mPa}\cdot\text{s}$, 25°C) was bought from Beijing Hangping Silicon and Chemical Co., Ltd. To prepare MR elastomers, the silicon rubber and dimethyl silicon oil with equal weight were mixed at room temperature by using a stirrer bar. After 10 min, they were mixed with cobalt particles. All the ingredients were mixed at room temperature during 30 min by a stirrer bar. Subsequently, the homogeneous mixture was placed into a mold with a cylinder cavity of $\phi 20 \text{ mm} \times 1 \text{ mm}$. The curing process was performed in a 240 mT orientation magnetic field along the thickness of the sample for about 6 h.^[25] The orientation filed could make the particles align to form column-like structures, and obtain anisotropic MR elastomers. A number of studies have proved that anisotropic MR elastomers have more excellent MR response than isotropic composites with random distributed particles.^[26,27] The percentage of cobalt particles

were 10% in volume for all the samples. The samples with sphere cobalt particles and flower-like particles are named as SCP-MRE and FCP-MRE for short, respectively.

The brittle fraction sections of MR elastomers were cryogenically fractured in liquid nitrogen and the fracture surfaces of the MR elastomers after a swelling treatment were cut off by a knife. All the samples were coated with a thin layer of gold prior to SEM (ZEISS SUPRA 55) observation. Magnetic measurements were carried out using a vibrating sample magnetometer (JDM-13T).

The crosslink densities of the MREs were obtained from a swelling measurement. First, pre-weighted dry MRE samples were immersed in 80 mL of toluene at 30 °C for 72 h in a vacuum case. The toluene was replaced once at 36 h to make sure all the MREs achieved swelling equilibrium. The MRE samples were taken out after 72 h and the toluene on their surface was dried with filter paper. After recording the swollen mass of these MRE samples, they were transferred to a vacuum at 80 °C for 24 h, which was prepared for the SEM observation. For each type of MRE, three specimens were measured and the average values were calculated. According to the Flory–Rehner equations, the crosslink density of MREs can be estimated^[28, 29].

The dynamic viscoelasticity of MR elastomers under various conditions were measured by a Physica MCR301 rheometer (Anton Paar, Austria) fitted with a magneto-rheological module (MRD180), which can apply different magnetic fields on the parallel-plates system (PP20) by changing direct current. The test gap was 1 mm. The dynamic viscoelasticity of MR elastomers was tested by an oscillatory mode. In order to get the appropriate amplitude and frequency of shear strain, the changes of storage modulus and loss modulus with strain amplitude (0.001~100%) and frequency (0.1~50 Hz) under different magnetic flux density (0, 115, 234 and 456 mT) were tested. Thereafter, the influence of the magnetic flux density on dynamic viscoelasticity was measured by setting the measured appropriate constant strain amplitude and frequency. All measurements were performed at 25 °C.

3 RESULTS AND DISCUSSIONS

3.1 Characterization of cobalt particles

Figure 1 shows the crystal phase, magnetic properties and SEM images of the cobalt particles with different morphologies. It indicates that the two kinds of particles have similar crystal structures, similar magnetic properties, and similar diameters (2~5 μm).

3.2 Structures of MR elastomers

The section SEM microphotographs of the FCP-MRE and SCP-MRE samples used in the swelling measurements are shown in Figure 2. As shown in Figure 2a and Figure 2b, both sphere cobalt particles and flower-like cobalt particles form chain-like structures along the direction of the orientation magnetic field applied during the preparation process. As expected, the silicon oil in the matrix has not participated in the crosslinking reactions of the MR elastomers. The dissolving of silicon oil and the swelling of the silicon rubber proceeded in toluene, and the weak connections between the particles and the matrix was destroyed during this treatment. By contrast, as shown in Figure 2c and

Figure 2d, some bridging structures are observed between particles and rubber matrix, indicating strong connections between the particles and the rubber. Figure 3 shows the crosslink density of the MREs filled with the two kinds of cobalt particles. It indicates the crosslink density of the FCP-MRE is about 30% higher than that of the SCP-MRE.

Figure 3: Crosslink densities of SCP-MRE and FCP-MRE

3.3 Dynamic viscoelasticity of MR elastomers

Figure 4 shows the storage modulus and loss modulus of the MRE samples as a function of applied strain amplitude under constant frequency (5 Hz) and different magnetic flux densities (0, 115, 234 and 456 mT). In absence or present of a magnetic field, as shown in Figure 4a, their storage modulus keeps unchanged at low strain amplitude and then decreases with increasing strain amplitude when it reaches a critical value ($\sim 0.1\%$). Below the critical strain amplitude, the MR elastomers are considered in their linear viscoelastic (LVE) region. As particles filled rubber-based composites, the particles form a microscopic network structure. At low strain amplitude, the structure is stable, while over the critical value, the structure is destroyed, which is the Payne effect. In addition, the low magnitude of the Payne effect factor can reflect the strong interaction in particle-particle and particle-matrix.^[30] From Figure 4a, the Payne effect factor in absence of magnetic field was calculated^[31]. The Payne effect factors are 77% for SCP-MRE and 72% for FCP-MRE, respectively. It indicates the particle-particle and particle-matrix interaction in FCP-MRE is stronger than that in SCP-MRE. When the shear amplitude exceeds the critical value, the network structure formed by the particles become unstable, it consumes more energy than when no magnetic field is applied. This corresponds to the larger loss modulus value shown in Figure 4b when the strain amplitude exceeds $\sim 0.1\%$ in different magnetic field strengths. Furthermore, the storage modulus and the loss modulus of the two samples increase with increasing magnetic field strength, which can be attributed to the stronger network structure at higher magnetic field. It indicates both SCP-MRE and FCP-MRE present significant magnetorheological effect.

Figure 5 shows the dependence of the storage modulus and loss modulus of the MR elastomers on magnetic flux density at a constant strain amplitude of 0.01% and constant frequency of 5 Hz. As the magnetic flux density rises, the storage modulus of the two MRE samples increases. It means both SCP-MRE and FCP-MRE present typical MR effect, which can be attributed to the increasing magnetic attractive interaction between the adjacent particles along the field direction. Besides, the storage modulus of the FCP-MRE is much higher than that of the SCP-MRE in absence and present of magnetic field,. The initial enhancement of the storage by using flower-like particles with respect to

sphere particles can be attributed to the higher crosslink density due to the larger specific surface area. Under an applying magnetic field, the attractive interaction between the neighboring flower-particles is stronger than that between the neighboring sphere particles due to the improved interface transferring properties. As a result, the storage modulus of FCP-MRE is higher than that of SCP-MRE. For the same reason, the loss modulus of FCP-MRE is higher than that of SCP-MRE. Interestingly, the loss modulus curve in Figure 6b first increases and then decreases. This can be explained by Chen's research.^[32] Loss modulus reflects the dissipation of material energy during deformation. The magnetic interaction (F_m) between particle and matrix is accordingly increased with the increase of the magnetic field. The larger F_m will lead to more energy dissipated on the interface slipping of the MR elastomers. In these conditions, the loss modulus increases with the increase of the magnetic field. On the other hand, the slip displacement is not a constant but a function of the F_m . It is easy to understand that if large normal force is applied, the slipping will become difficult, and the displacement of interfacial slipping will be reduced. As the increase of the magnetic field and the magnetic force, the slip displacement is reduced. Accordingly, the loss modulus declines. For those reason, the loss modulus initially increases at low field levels but decreases at high field levels.

Figure 4: Storage modulus G' (a) and loss modulus G'' (b) of SCP-MRE and FCP-MRE under different magnetic flux densities as a function of strain amplitude

Figure 5: Storage modulus G' (a) and loss modulus G'' (b) of SCP-MRE and FCP-MRE at a constant strain amplitude and frequency as a function of magnetic flux density

The magnetic field-induced storage modulus $\Delta G'$ is an important indicator to evaluate the properties of MR elastomers, which is defined as the value of the storage modulus at each magnetic flux density G' minus zero-field storage modulus G_0' . Figure 6 shows the dependence of the magnetic field induced storage modulus of the two MR elastomers on magnetic flux density. As it is shown, the field-induced storage modulus tunable range was enlarged by using flower-like particles. In Figure 6, when the magnetic field exceeds 50 mT, both SCP-MRE and FCP-MRE present a sharply increasing $\Delta G'$ with rising magnetic field, hereafter, the increases in $\Delta G'$ of both samples tend to be gentle after the magnetic flux density reaches about 400 mT. Taking into account the similar magnetic properties of the two MRE samples, the difference between their $\Delta G'$ is mainly due to their different particle morphology. During the shear process, the particles in MREs tend to keep a linear structure along the magnetic field, while the rubber matrix easy to move along the shear direction. If the adhesion between rubber matrix and particles is weak, there will be gaps presenting at the interface between the particles and rubber matrix due to the debonding. This will cause the microstructure of MREs become unstable and reduce the storage modulus of MREs. Flower-like particles can increase cross-linking with the rubber matrix and the adhesion due to the undulating surface. This may be the reason that FCP-MRE shows higher magnetic field-induced storage modulus during the shear stress.

Figure 6: Magnetic field induced storage modulus of SCP-MRE and FCP-MRE as a function of magnetic flux density

4 CONCLUSIONS

Flower-like cobalt particles and sphere cobalt particles with similar particle size were used to prepare different MREs, whose dynamic viscoelasticity was tested and compared to verify the mechanism model. The experimental results indicated the flower-like cobalt particles based MREs presented enhanced storage modulus in absence and present of magnetic field with respect to sphere cobalt particles based ones. More meaningfully, the field-induced storage modulus tuneable range was also improved by using flower-like cobalt particles as the dispersing phase.

Key words: Nitinol, superelasticity, stent, fatigue, Smith-Watson-Topper model

Abstract. In this work, a fatigue/failure analysis of Nitinol stents such as those employed in endovascular aneurysm repair (EVAR) is presented. The study is conducted for one billion hemodynamic cycles, that is more than 15 years of service life. The strain-stress curves are obtained using the fluid-structure interaction (FSI) analysis in Abaqus/Simulia and the high-cycle loading fatigue analysis is done on Ansys.

The stent we use for the study is a honeycomb closed-cell structure. It our own design. The geometry of the aorta is a cylindrical shell with three concentric layers. The aorta is modelled with the Holzapfel-Gasser-Ogden (HGO) hyperelastic equations which account for the anisotropy of the aorta. We use Nitinol superelastic property to study the stent structural fatigue. This is done with the Smith-Watson-Topper (SWT) model which takes into account the mean stress on the structure. The fatigue behaviour is obtained from fatigue life, fatigue damage, fatigue safety factor and a biaxiality indication contour plots.

Results indicate that the stent can withstand 10 years of pulsatile hemodynamic load, as recommended by the US Federal Food & Drug Administration (FDA). The fatigue safety factor (FSF) decreases as the number of cycle increases. Increasing the load by 25% decreases the stent life by approximately half (down to $5.61e8$ cycles) and doubling the load results in the stent failing. Areas of the stent struts subjected to pure uniaxial load are shown to be most prone to failure.

This study can give insights into the optimal design of self-expanding stents in addition to new directions to improve their functionality.

1 INTRODUCTION

Aortic aneurysm (AA) is characterized by an enlargement of the aorta to at least 1.5 times its initial size. It causes the walls to weaken and possibly rupture, resulting in over 10,000 people in the United States to die each year. Among possible surgical treatments, endovascular aneurysm repair (EVAR) using stents or stent-grafts require only minor incision. The patient can return to daily activities faster than with open-heart surgeries so EVAR procedures have become increasingly popular during the last fifteen years. Typically, arteries pulse at 72 times a minute, that is some 40 million times per year. This

causes significant stresses and strains on the stent, which can lead to fatigue and ultimately device failure [1, 2]. Thus, it is important to keep this in mind when designing stent, particularly that the US Food & Drug Administration (FDA) recommends that stents be able to withstand between ten and fifteen years of pulsatile loading cycles during testing before failure, that is between 400 to 600 million loading cycles [3, 4, 5, 6]. It is true that in comparison to blocked stent due to the body endothelial cells growth on the device (in-stent restenosis), stent fracture may not be the most common type of device failure but even so, the potential for the stent to fracture does not seem to be widely recognised and is largely underestimated [7].

Among stent materials, stainless steel is common and cheap but wires are thick which can prevent designing stents with complex geometries. In addition, the material is not completely biocompatible with human tissues. On the other hand, Nitinol (NiTi) is an alloy of Nickel and Titanium belonging to the family of smart material alloy (SMA). The material is expensive but with an excellent biocompatibility and a good resistance to fatigue and corrosion, it is widely used in the manufacturing of self-expanding endovascular stents and other medical devices [8].

Nitinol possesses a superelastic and a shape memory effect (SME) property. Superelasticity refers to the ability of the material to stretch extraordinarily, up to 10 times the original length and return to its original length when the loads are removed. SME involves the material crystallographic structure reacting to a temperature change and causing the material to return to its original shape when unloaded. However, these very same properties are also responsible for causing a complex fatigue behaviour, in contrast to conventional metals [8].

Typically for an healthy adult, the hemodynamic load can be described as oscillating between 80 mmHg and 120 mmHg. Such loading pattern generates a mean stress (average of maximum and minimum stress) and an alternating stress (difference between max and min stress/2) which need to be accounted for. The stress cycle is also not completely reversed because of the different max and min values of stress. Another thing to consider is that for Nitinol and other SMAs, the failure criterion is strain-based in contrast to most metals, where a particular combination of stresses serve as a criterion for failure [9, 10]. In [11], the authors show that the alternating strain plays a major role in predicting the life of Nitinol as opposed to the mean strain.

Generally speaking, structural fatigue can occur as a result of high cycle loadings (HCF between 10^4 to 10^8 cycles) or low cycle loadings (LCF) which is the term used when failure occurs for less than 10^4 cycles. In high-cycle loading, material fatigue is stress-based and is characterized by a stress-cycle (S-N) curve. In low-cycle loading, accounting for the stress is not as relevant but instead, the strain can provide more accurate information. Strain-based fatigue life can also be used when dealing with HCF and be used in determining if crack initiates in the structure [12].

Finally, Nitinol has a structural and a functional fatigue component. The structural fatigue refers to the physical failure of Nitinol stents while the term functional fatigue is used to describe some loss of superelasticity and shape memory properties during cyclic loading [13].

In this paper, numerical simulations are used to understand the structural fatigue of Nitinol and to predict the life of the stent subjected to ten years of blood flow. We do not evaluate the life of the aorta. Two commercial finite element packages Abaqus/Simulia (Version 6.13 [14]) and Ansys (Version 18.2 [12]) are used. That is because Abaqus/Simulia possesses a low-cycle fatigue but not a high-cycle fatigue analysis scheme. On the other hand, Ansys does not have in it library of materials, the constitutive equations for anisotropic materials which are needed to accurately describe the aorta. Abaqus/Simulia does.

The methodology is thus two-fold: we first conduct a fluid-structure interaction (FSI) analysis of a stented-aorta structure subjected to blood flow using the built-in capability in Abaqus/Simulia. We

generate stress-strain curves for three cardiac cycles. The stress-strain curves are then exported to Ansys and we proceed to a strain-based fatigue analysis of the material using mean and alternating strains.

The fatigue analysis is based on the Smith-Watson-Topper (SWT). This model takes into account the mean stress on the structure and the amount of strain it generates. With that strain vs. number of cycle (E-N) curves can be manipulated to predict the number of cycles at which the structure will fail.

Details of the methodology are included in Section 2. We present the results of the analysis in Section 3 before ending with some conclusive comments in Section 4.

2 METHODOLOGY

The first part of the analysis deals with the interaction of the fluid (blood) on the structure (stented-aorta) and generates stress-strain curves.

2.1 FSI

We use the built-in fluid-structure interaction (FSI) analysis in Abaqus/Simulia. The FSI analysis assumes that the walls are deformable, not rigid as in the elementary theory. This is indeed the case since during a cardiac cycle, the aortic walls can deform between 10% -15% [15]. The basis for FSI is to insert a fluid domain into the solid domain of the same dimensions provided conditions at the interface are enforced. FSI combines a finite element (FEM) solution for the solid to a computational a fluid dynamic (CFD) analysis for the fluid.

	Material	Thickness t (mm)	Fiber orientation θ (deg)	μ (kPa)	k_1 (kPa)	k_2 (kPa)	Poisson's ratio
Human Aorta (3 layer, hy- perelastic, anisotropic)	Intima	0.33	18.8 ± 8.2	20.30	182.59	228.58	0.49
	Media	1.32	37.8 ± 20.6	2.31	8.45	12.84	0.49
	Adventitia	0.96	58.9 ± 14.8	6.16	32.89	167.31	0.49

The geometry of aorta is a cylindrical structure 6.2 cm long, 2.54 mm inner diameter and 2.61 mm thick with three layers representing the intima, media and adventitia aortic layers (Fig. 1). The aorta is meshed with 153849 modified quadratic tetrahedral hybrid elements (C3D10MH). The aorta is modeled with the Holzapfel-Gasser-Ogden (HGO) equations that were developed in year 2000 to describe human

tissues [18]. This is a powerful hyperelastic model which takes into account the anisotropic behaviour of the aorta due to the layers, each having its own stiffness.

The geometry of the stent is generated with the 2015 \times 64 Edition of Solidworks (Fig. 1). It is 6.2 cm long, 25 mm in inner diameter and 0.3 mm thick. The stent diameter is slightly below the diameter of the aorta. This in order to provide complete sealing upon expansion and prevent the stent from migrating. It is meshed with 38840 modified quadratic tetrahedral elements (C3D10M). We use the superelastic constitutive model developed by Auricchio and Taylor (1997) for Nitinol [19]. The material properties of the human aorta and Nitinol are shown in Table 1 and Table 2 respectively.

Table 2: Nitinol material's properties[14]

Properties	Symbol	Values
Density	ρ	6450 kg/m ³
Austenite elasticity	E_A	68 GPa
Austenite Poisson's	ν_A	0.33
Martensite elasticity	E_M	36 GPa
Martensite Poisson's	ν_M	0.33
Transformation strain	ε^L	0.041
$\delta\sigma/\delta T$ loading	$\left(\frac{\delta\sigma}{\delta T}\right)_L$	6.5
Start of transformation loading	σ_{tL}^S	520 MPa
End of transformation loading	σ_{tL}^E	635 MPa
Reference temperature	T_0	37°C
$\delta\sigma/\delta T$ unloading	$\left(\frac{\delta\sigma}{\delta T}\right)_U$	6.5
Start of transformation unloading	σ_{tU}^S	180 MPa
End of transformation unloading	σ_{tU}^E	26 MPa

Blood is assumed to be an incompressible, Newtonian and turbulent medium. These are chosen to represent physiological human conditions. In Abaqus/Simulia, the equations for such a flow can be solved with standard Navier-Stokes equations [20]. Blood flow has a time-dependent profile (Fig. 2). The blood dynamic viscosity is 0.003 Pa.s and its density is 1050 kg/m³. We use the Spalart-Allmaras (SA), one of the two turbulent models available in Abaqus/Simulia. This model is recommended when solving problems with pressure gradients. The blood is meshed with 29610 linear wedge elements of type FC3D6. There are three boundaries: inlet, outlet and a surface with outer normal in the positive Z direction (Fig. 3).

Figure 2: Blood physiological pressure profile

Figure 3: Blood model used in the numerical simulation

Contact is assumed between the aorta and the stent. It is implemented in Abaqus/Simulia via an algorithm that uses the inner wall of the aorta as the master surface and the stent outer diameter is the slave surface. A contact friction coefficient of 0.2 is also needed to guard against slipping between the surfaces and to prevent the stent from migrating. Displacement in the axial and the radial directions is allowed but it is constrained in the circumferential direction.

2.2 Fatigue analysis

With the stent being subjected to that many loading and unloading cycles, it is inevitable that material weakening will occur and alter the stent intended functions. In this work, the fatigue analysis is done on Ansys. It is based on a strain-life method as should be the case for Nitinol. In addition, cyclic loading fatigue tests often assume completely reversed loading with constant amplitude. This is not the case here. The cyclic hemodynamic load generates a mean stress on the stent, which is always tensile (positive difference in pressure). Smith-Watson-Topper (SWT) proposed an equation to account for the mean-stress in strain-life prediction. This model adequately predicts fatigue due to tensile stress.

SWT is expressed as,

$$\sigma_{max} \frac{\Delta \epsilon}{2} = \frac{(\sigma_f)^2}{E} (2N_f)^{2b} + \sigma_f \epsilon_f (2N_f)^{b+c} \quad (1)$$

where the various symbols are fatigue strength coefficient σ_f , number of reversals to failure $2N_f$, fatigue ductility coefficient ϵ_f , fatigue strength exponent b , fatigue ductility exponent c , modulus of elasticity E to measure the maximum stress σ_{max} and total strain amplitude $(\Delta \epsilon/2)$.

The strain-life fatigue properties of Nitinol are taken from reference [8] and have been generated experimentally. They are summarized in Table 3. It shows that the number of cycles to failure (N_f) of Nitinol is $1e9$.

Table 3: Strain-life fatigue properties of Nitinol[8]

Properties	Symbol	Values
Fatigue strength coefficient	σ_f	1335 MPa
Fatigue ductility coefficient	ϵ_f	2.11
Fatigue strength exponent	b	-0.085
Fatigue ductility exponent	c	-0.679
Fatigue strength factor	k_f	0.42
Loading ratio	R_e	$\epsilon_{min}/\epsilon_{max}$
Cycles		$1e9$
Ultimate stress	σ_u	1040 MPa

In Ansys, the fatigue analysis returns four contour plots: fatigue life, fatigue damage, fatigue safety

factor and biaxiality indication.

Fatigue life is an indicator of how long the structure will last before it fails. It is a measure of the number of loading cycles a structure can sustain before it fails. The material, structure, geometry and temperature are factors that influence the fatigue life of a component. The methodology for obtaining the fatigue life from SWT model can be summarised as follows: first, we input the coefficients from Table 3 in Eq. 1 and get the strain amplitude. The strain values obtained from the FSI simulations in Abaqus are exported to Ansys to serve as input to the fatigue analysis. We compare the strain values obtained from the fatigue analysis with the strain amplitude calculated from the SWT model (Eq. 1). If the numerical strain is less than the value calculated from Eq. 1, the stent will last 10e8 cycles (fatigue life).

Fatigue damage is expressed as the ratio of design-life to available life. Here the design-life of the stent is 10e8 cycles. The value of available life is obtained from the simulations. Damage is irreversible. A value greater than 1 indicates that the structure will fail before the design life is reached.

Fatigue safety factor (FSF) relates the maximum stress to the design stress (aka allowable stress or working stress). A FSF equal to 1 means the structure (stent) experiences the same amount of stress as the design stress. The structure cannot support any additional load. Any additional increase of the load on the structure will result in failure.

Biaxiality indication shows how accounting for a multi-state of stress, not just a uniaxial stress, affects the material fatigue. It is defined as the ratio of minimum principal stress to maximum principal stress. A 0 value of biaxiality indication corresponds to a uniaxial stress, a -1 value corresponds to pure shear, and a 1 value corresponds to a pure biaxial state of stress. Principal stresses close to zero are neglected.

3 RESULTS

3.1 FSI

We obtained the stress-strain response of the stented aorta for three cardiac cycles using the FSI analysis capability in Abaqus/Simulia. The blood pressure profile used in the simulations is shown in Fig. 2. One can recognise the 120 mmHg peak value and the 80 mmHg minimum value corresponding to the systole and diastole blood pressure. The principal stress contours on the stented aortic region obtained from the simulations are shown on Fig. 4 and the principal strain contours on Fig. 5. It shows that the maximum stress experienced by the stent is 145 MPa (red color) while it is approximately 0.7 MPa for the aorta (blue color). On the other hand, the stent undergoes about half the strains (0.6%) compared to the aorta (1.5%) (Fig. 5). Simulations have been conducted assuming a 37°C temperature for Nitinol was maintained.

Figure 4: Principal stresses on the aorta and the stent. (Recorded at systolic pressure, Units are Pascals)

Figure 5: Principal strains on the aorta and the stent. (Recorded at systolic pressure)

Figure 6 shows the strain experienced by the stent during three cardiac cycles. It is clearly oscillating. Relevant computed quantities shown on the figure are: maximum strain ($\epsilon_{max} = 0.6\%$) and minimum strain ($\epsilon_{min} = 0.48\%$), from which the other quantities, mean strain (ϵ_m), alternating strain (ϵ_a) and a strain range (ϵ_r) can be calculated using

$$\epsilon_m = \frac{\epsilon_{max} + \epsilon_{min}}{2} \quad (2)$$

$$\epsilon_a = \frac{\epsilon_{max} - \epsilon_{min}}{2} \quad (3)$$

$$\epsilon_r = \epsilon_{max} - \epsilon_{min} \quad (4)$$

Figure 6 shows that the maximum strain (ϵ_{max}) occurs during the systole stage and the minimum (ϵ_{min}) strain, during the diastole. Here ϵ_{max} and ϵ_{min} are both tensile. Using these values, one can compute ϵ_m , ϵ_r and ϵ_a as 0.53%, 0.143% & 0.072% respectively. These values are used in the fatigue analysis.

Figure 6: Principal strains experienced by the stent during three cardiac cycles

3.2 Fatigue

3.2.1 Fatigue life

Figure 7 shows the fatigue life contours on the stent obtained on Ansys. The red color indicates that the stent can withstand one billion (10^8) cycles without failure. There is no indication from the contours

obtained that some parts of the stent are more prone to failure than others. On the contrary, every part of the stent has the same life and it can sustain 400 million cycles, the equivalent amount of cycles for 10 year-operation.

Figure 7: Stent fatigue life contour

Figure 8 shows the loading cycles vs. the loading history as described in Ansys. On the figure, the range for the horizontal axis is 0.5 to 2.5. These represent the % of the current load. For instance, 0.5 means that the load is 50% of the current load, 2.5 means that the load is 250% of the current load and 1 refers to the current loading (100%). The curves shows that increasing the load by 25% (i.e. 1.25) will result in the stent-life decaying rapidly until the stent is subjected to approximately twice the load (i.e. 2), value at which the stent will fail (zero).

Figure 8: Stent available life vs. loading history

3.2.2 Fatigue Damage

Figure 9 shows the fatigue damage of the stent obtained for one billion ($10e8$) cycles, which is above the 400-600 million cycles threshold recommended by the FDA. The fatigue damage contour was generated using the design life ($10e8$ cycles) and the available life of the stent (also equal to $10e8$) obtained from Fig. 9. The blue contours on the stent are equal to one, which can be interpreted as meaning that the stent will not fail until the design life value is reached.

3.2.3 Fatigue Safety Factor

Figure 10 shows the fatigue safety factor (FSF) contours obtained from the FEM simulations. With sufficient zooming, one can see that the stent struts are orange, indicating a fatigue factor of safety above

Figure 9: Stent fatigue damage contour

to one, even though these regions can fail first due to the curvatures. The other regions are either blue or green, which correspond to a very high factor of safety (10-15) or 5-10, respectively. There is no red-color contours, where FSF is less than one. Red color contour would mean failure of the stent before the time it has been designed to operate is reached. Thus, our stent as designed, can safely operate for 10 years.

Figure 10: Stent fatigue safety factor contour

Figure 11 shows the FSF as a function of the loading history. The loads range from 0.5 to 2.5 which correspond to loading the sent at a 50% and 250% increase of the original load, respectively. The value 1 (i.e. 100%) represents the life of the stent at the current level of loading. The results indicate that when the original load is increased by 25% or more (i.e. 1.25 value), FSF drops below 1 and the stent cannot be deemed safe to operate.

Figure 11: Stent fatigue safety factor vs. loading history

3.2.4 Biaxiality Indication

Figure 12 shows the biaxiality indication on the stent due to the hemodynamic load. The color coding is such that red, orange, yellow are positive values less than one and the others are negative values between zero and one. Green coding has some positive and some negative values close to zero, which means that most regions of the stent are in pure uniaxial stress, although not completely. Again, with enough image zooming, one can see that the struts curvatures experience some pure shear (blue color) and that the end cells are in a pure biaxial state of stress (red color). Combined with the fatigue safety factor contours, we can say that the most vulnerable regions of the stent are those experiencing pure uniaxial stresses. This indicates that uniaxial stress is the primary mode of failure for the stent.

Figure 12: Stent biaxiality indication contour

4 CONCLUSIONS

In this work, we analysed the fatigue/failure behaviour of a Nitinol stent used in endovascular aneurysm repair (EVAR) procedures. The analysis assumed that the stent was subjected to one billion cycles (design life), representing more than twenty years of cycling hemodynamic loading.

The fluid-structure interaction (FSI) analysis in Abaqus/Simulia was first employed to generate the stress-strain curves of a stented aorta during three cardiac cycles. The aorta was modeled as an anisotropic material. The stress-strain curves were exported to Ansys for a strain-based high-cycle fatigue life analysis using the Smith-Watson-Topper (SWT). This model takes into account the mean stress on the structure.

Four contour plots were generated on Ansys: fatigue life, fatigue damage, fatigue safety factor and a biaxiality indication.

Results indicated that the stent was able to sustain $10e8$ cycles without failing. The fatigue factor of safety decreased exponentially as the number of cycles increased. Increasing the load by 25% decreased the stent life by approximately half ($5.61e8$ cycles) and doubling the load will result in the stent failing.

The biaxiality indication showed that the pulsatile hemodynamic load mostly caused the stent to experience a pure uniaxial state of stress. Area of the struts subjected to pure uniaxial loading were most prone to failure.

This fatigue analysis showed that our honeycomb stent design was capable of withstanding 10-15 years of pulsatile hemodynamic load, as recommended by the FDA.

This study can provide insights into optimal design of self-expanding stents as well as giving new directions to improve their functionality.

Abstract

This paper discusses new findings on fatigue crack growth in an NiTi shape memory alloy. Despite the importance of the topic, there are very few papers that systematically studied fatigue crack growth with investigation of measurements of effective stress intensity at crack tips. It has become clear that one must account for the crack tip wake closure forces in modeling of crack tip stress intensity as they could produce net forces that are substantial. The tractions in the crack wake can reduce the driving forces but the calculation is rather complicated. Instead, we present stress intensity determination based on experimental displacement measurements at crack tips. We utilize digital image correlation to establish vertical and horizontal displacements in NiTi. We then compare the stress intensity determination based on regression of displacement results, which is termed the effective stress intensity range, with that of the stress intensity range based on LEFM. We find that the effective stress intensity range is lower than that based on classical LEFM solution, the difference being more significant at longer crack lengths.

1 INTRODUCTION

Since their discovery in the early 1960s, the NiTi shape memory alloys (SMA) have captivated the attention of the materials science community with potential for a multitude of applications ranging from biomedical stents to advanced instruments in space exploration. Two characteristic properties of SMAs are often exploited in applications: the shape memory effect, where large levels of deformation are recovered upon heating, or the superelastic effect, where again large levels of deformation are spontaneously recovered upon unloading. Despite significant advances in SMA research, knowledge gaps still persist particularly under fatigue loading conditions, motivating further research [1].

Various shape memory material compositions have been developed over the years in addition to NiTi, such as NiTiCu, CuZnAl, CuNiAl, NiFeGa, CoNiAl, CoNiGa, NiTiHf, FeNiCoTi and FeMnSi among others [1]. However, NiTi continues to be the most important SMA, partly because of its biocompatibility. It also exhibits large transformation strains and better functionality compared to other alloys especially in polycrystalline form. It is important to note that large number of fundamental studies have been undertaken on single crystals; however, it is important to report on polycrystalline properties as they are relevant to applications.

The most comprehensive previous work on fatigue crack growth in NiTi has been undertaken by Ritchie et al.[2-4]. More recently there has been efforts to report on NiTi single crystals. One must note that the compositional effects, texture effects, grain sizes and heat treatments are all expected to affect the results so direct comparison of results is difficult. In a recent study, effective stress intensity calculations accounting for closure forces were compared to stress intensities measured via regression of displacements with excellent agreement [5]. This provides a justification for the present approach of determining the stress intensity from the measured displacements. Extracting the effective stress intensity by measuring the normal and horizontal displacement fields at the crack tip and fitting them to the elasticity theory solutions resulted in 10- 30% reduction in maximum stress intensity in NiFeGa [5, 6]. Therefore, our current paper builds upon these novel experimental techniques outlined previously and applied them to investigate the NiTi fatigue crack growth behavior in the temperature regime where superelastic conditions prevail. We note that only preliminary findings are presented in this paper.

2 EXPERIMENTAL TECHNIQUES

The current investigation considers polycrystalline NiTi samples, of composition with an at. Ni of 50.8%. The material is the same NiTi that is reported in our early studies with an aging treatment of 450°C for 1.5 hours[7, 8]. The transformation temperatures were $A_s = 21^\circ\text{C}$; $A_f = 38^\circ\text{C}$; $M_s = 0^\circ\text{C}$; and $M_f = -20^\circ\text{C}$. The specimens were of the dog-bone geometry with a gauge section of 10 mm in length, 1.5mm thickness and 3mm in width. Edge notches 0.5 mm in length are introduced using EDM. Prior to testing, all specimens were polished using SiC paper, after which a fine speckle pattern was applied for full-field strain and displacement measurements using Digital Image Correlation (DIC).

Fatigue crack growth experiments were conducted with an R ratio of 0.05 and a 3 Hz frequency. The tests were run at a temperature of 45°C, at which the behavior was confirmed to be superelastic by uniaxial tension experiments. A constant stress amplitude of 142 MPa was employed. Optical images were collected during each loading cycle allowing for extraction of displacement fields, from which the stress intensity factor was calculated via regression which will be further explained in the next section.

3 EXTRACTION OF STRESS INTENSITY FACTOR FROM DISPLACEMENTS USING ANISOTROPIC ELASTICITY VIA REGRESSION

The displacement fields determined with Digital Image Correlation (DIC) are fitted to the crack tip displacement fields. These solutions are available by Sih *et. al* [6]. It is then possible to extract the stress intensity by regression fit to the following equations:

$$\begin{aligned} u^1 = & K_1 \sqrt{2r} \operatorname{Re} \left[\frac{1}{\mu_1 - \mu_2} (\mu_1 p_2 \sqrt{\cos \theta + \mu_2 \sin \theta} - \mu_2 p_1 \sqrt{\cos \theta + \mu_2 \sin \theta}) \right] \\ & + K_2 \sqrt{2r} \operatorname{Re} \left[\frac{1}{\mu_1 - \mu_2} (p_2 \sqrt{\cos \theta + \mu_2 \sin \theta} - p_1 \sqrt{\cos \theta + \mu_2 \sin \theta}) \right] + \\ & a_{11} Tr \cos \theta + Ar \sin \theta + B_u \end{aligned} \quad (1)$$

$$\begin{aligned} v^1 = & K_1 \sqrt{2r} \operatorname{Re} \left[\frac{1}{\mu_1 - \mu_2} (\mu_1 q_2 \sqrt{\cos \theta + \mu_2 \sin \theta} - \mu_2 q_1 \sqrt{\cos \theta + \mu_2 \sin \theta}) \right] \\ & + K_2 \sqrt{2r} \operatorname{Re} \left[\frac{1}{\mu_1 - \mu_2} (q_2 \sqrt{\cos \theta + \mu_2 \sin \theta} - q_1 \sqrt{\cos \theta + \mu_2 \sin \theta}) \right] + \\ & a_{12} Tr \cos \theta + Ar \sin \theta + B_v \end{aligned} \quad (2)$$

$$a_{11} \mu^4 - 2a_{16} \mu^3 + (2a_{12} + a_{66}) \mu^2 - 2a_{26} \mu + a_{22} = 0 \quad (3)$$

Where Re represents the real part of a complex number, T is the T-stress, A is the rigid body rotation, B_u and B_v are the rigid body translations in u^1 and v^1 directions, respectively. The terms a_{11} , a_{12} , a_{16} , a_{22} , a_{26} and a_{66} are the compliance components in the coordinate system of the crack, r and θ are the polar coordinates with their origin at the crack tip. μ_1 and μ_2 are the roots of equation (3). The p_i and q_j in equations (1) and (2) are the anisotropic terms defined as:

$$\begin{aligned} p_i &= a_{11} \mu_i^2 + a_{12} - a_{16} \mu_i \\ q_i &= a_{12} \mu_j + \frac{a_{22}}{\mu_j} - a_{26} \end{aligned} \quad (4)$$

The formulation above is general but for purposes of simplicity the fitting was conducted for isotropic case. In the above formulation we allow for provision of Mode II stress intensity levels as well. The details of the methodology have been published earlier [5, 9-11].

4 EXPERIMENTAL RESULTS

The regression-extracted stress intensity is plotted against that acquired with a classical handbook calculation for a single edge notch case. The results are seen in Figure 1. The results in the Paris regime can be described with the following equation

$$\frac{da}{dN} = 3.10^{-9} (\Delta K_{\text{eff}})^{1.73} \text{ where } \frac{da}{dN} \text{ is measured in m/cycle and } \Delta K_{\text{eff}} \text{ is measured MPa}\sqrt{\text{m}}.$$

It is evident that the material's effective stress intensity levels (red) are substantially lower compared to that determined from LEFM solution (black). The LEFM solution is the product of stress range and square root of crack length and the correction for an edge crack for finite width effects. The effective threshold stress intensity is reduced by about $2 \text{ MPa}\sqrt{\text{m}}$ compared to the LEFM value using the entire stress range. The threshold stress intensity based on LEFM is $9 \text{ MPa}\sqrt{\text{m}}$ while it is $7 \text{ MPa}\sqrt{\text{m}}$ upon fitting the experimental displacement fields. This difference increases substantially as evident from Figure 1. Many factors play a role in the reduction of the crack tip stress intensity compared to the external loading based levels. The residual stress induced transformation zone is verified in the crack wake and ahead of the crack tip based on comparing the strains from digital image correlation at different stages of crack growth. Additional closure effects associated with plastic flow in the form of slip further contribute to the reduction of stress intensity levels.

The regression window is outlined on the left of Figure 2 with a dashed red box. It is approximately centered at the crack tip. The crack tip is marked with a large dot and the displacements are measured with respect to the crack tip. Because the crack front is normal to the applied loading direction the zero displacement contours are horizontal along the crack line. Experimentally measured and regression determined displacement fields are superimposed on the same plot on the right of Figure 2. It is evident that experiment (blue) and theory (red) are in very good agreement increasing the confidence in the measurement of effective stress intensity. The regression-based results represent a more accurate measure of the crack tip driving forces as all possible crack tip phenomena such as plasticity and stress induced transformation are reflected in the results. Further analysis of the results is needed to confirm the evolution of the residual displacements and strains that are responsible for shielding effects. This is a topic that is far from resolved in shape memory alloys.

Figure 1 – $\frac{da}{dN}$ vs ΔK plot. The red data points are acquired via regression (also termed the effective stress intensity range), while the black points represent the classical handbook solution for the single edge notch case calculated using the full range of applied stress. The reduction in stress intensity due to shielding effects is indicated with an arrow and increases (the difference between the two curves) with increasing crack length.

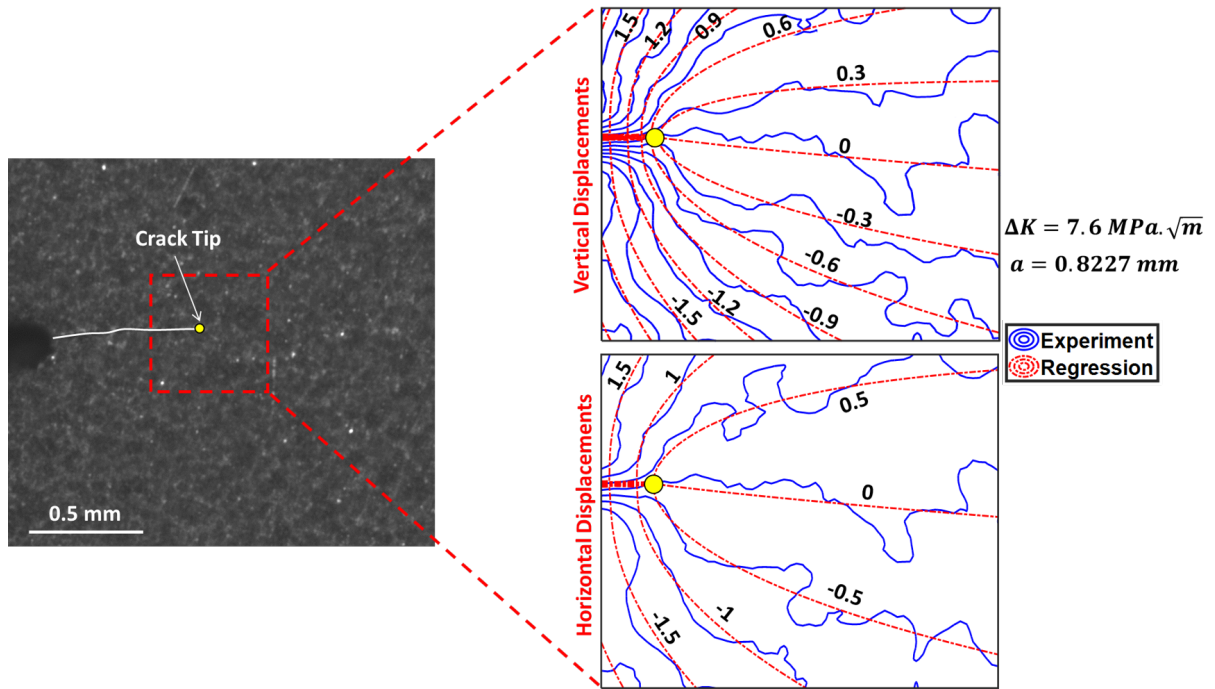

Figure 2 – Regression and experimental displacement contours overlay. The displacements are given in microns and the extracted stress intensity is $7.6 \text{ MPa}\sqrt{\text{m}}$ in this case.

5 CONCLUSIONS

The work supports the following conclusions:

- 1) The superelastic NiTi, undergoing reversible stress induced martensitic transformation, exhibits an effective threshold stress intensity level of $7 \text{ MPa}\sqrt{\text{m}}$ based on the present work. The experimentally determined effective stress intensity range is substantially lower than the stress intensity range calculated based on stress intensity handbook (LEFM) solutions particularly at longer crack lengths. Also, the experimental results produce a Paris exponent of 1.73, which is rather small and indicative of fatigue crack growth resistance. These results suggest potentially significant shielding effects, ie. reduction of crack tip stress intensity ranges.
- 2) The determination of effective stress intensity based on crack tip displacements encompasses the cumulative role of various shielding mechanisms that are rather complex. These effects include the role of transformation induced slip and residual transformation strains. In this study, an experimental determination of the effective stress intensity range based on regression of crack tip displacements during loading and unloading was undertaken which provides insight into the role of shielding effects on crack tip driving forces.

Key words: Shape memory alloys, porous NiTi, phenomenological modeling

Abstract. Porous NiTi's mechanical behaviour is similar to the human bone's and it shows good biocompatibility which make it an attractive material for biomedical applications. In this study, the aim is to develop a macro-scale phenomenological model to describe the mechanical behavior of porous NiTi SMAs within the framework of generalized standard materials with internal constraints including the porosity as an additional internal variable. The model includes the effect of hydrostatic pressure due to the presence of porosity. The constitutive equation obtained is used to simulate the pseudoelastic compressive response of a porous NiTi. In addition to stress-strain behaviour, evolution of phase transformation and porosity are also calculated. Numerical results show a qualitative agreement with the experimental results in the literature.

1 INTRODUCTION

Similar to the bulk NiTi SMA, porous form of NiTi which possesses the shape memory effect, pseudoelasticity and good biocompatibility is an attractive material in many applications including energy absorption or light-weight actuators, and most commonly the biomedical applications [1]. In addition, porous NiTi has some additional benefits superior to classical metallic foams (e.g., Ti or stainless steel), such as low density, high specific surface area and high permeability [2, 3], and it shows a mechanical behavior similar to the human bone as a result of its unique pseudoelastic characteristic near ambient temperature [4]. Especially with the low density and elastic modulus, achieved by controlling the porosity, porous NiTi is one of the most widely used materials for hard-tissue implantation [4].

In the literature, there are some experimental studies to observe the mechanical behaviour of porous NiTi produced by different powder metallurgy techniques [5–11]. Since porous NiTi is mainly exposed to compressive loadings under operation, researchers focus on the mechanical behaviour under compression. Zhao et al. [7] presented the stress-strain diagrams of 13% and 25% porous NiTi produced by spark plasma sintering, under uniaxial compression. It is observed that the stress plateau shifts down and the slope of the elastic portion decreases significantly with increasing porosity. They also stated that the

phase transformation has decreased with increasing porosity due to the weak interconnection between NiTi powders. Namet et al. [8] showed the superelastic loop of 12% porous NiTi and observed 1% residual strain after unloading of the specimen which was loaded upto 6% global strain. Bram et al. [9] and Guo et al. [10] performed studies on the compressive behaviour of high porosity NiTi SMAs and showed that the amount of superelastic strain is lower under high porosity. More recently, Saedi et al. [11] tested the NiTi under compression with different porosity and observed the effect of porosity. From the experimental results in the literature, the effects of porosity on pseudoelastic compressive behaviour of NiTi can be summarized as the decrease in critical stresses for phase transformation, elastic modulus and the amount of transformation.

Due to the unusual behavior of SMAs such as pseudoelasticity, modeling of porous SMAs is not a simple procedure. Some researchers used the micromechanical averaging techniques or unit cell finite element method as reviewed by Yuan et al. [2]. Although these techniques can give estimates of the stress-strain curves, they are not sufficient to observe the evolution of phase transformation or porosity. In the literature, there are only a few studies where the porosity is introduced as a parameter into the analytical model. Since porous materials are pressure sensitive, Olsen and Zhang [12] proposed the Gurson [13] type yield function, which includes the hydrostatic part of the stress tensor, to calculate the transformation strain of porous SMAs. Similarly, Ashrafi et al. [14] introduced the effect of hydrostatic pressure by using a yield function which was originally proposed by Deshpande and Fleck [15] based on their experimental studies on metallic foams. It is seen that there is a limited number of studies on analytical modeling of the mechanical behaviour of the porous SMAs, thus the subject is open to further contributions.

In this study, a macro-scale phenomenological modeling to describe the mechanical behavior of porous SMAs is presented. The original ZM (Zaki-Moumni) model [16] for dense SMAs within the framework of generalized standard materials with internal constraints [17] is modified to include the porosity as an additional internal variable. The constitutive equation obtained is then used to simulate the 1D compressive behaviour of porous NiTi SMA in Matlab. In addition to the stress-strain curve, the phase transformation and the evolution of porosity are also observed. Numerical results have shown that the present model is capable of qualitatively representing the effect of porosity on the pseudoelastic behaviour of porous NiTi under compression.

2 ANALYTICAL MODELING

In the following, the analytical modeling of the porous SMAs which is a generalization of the phenomenological ZM model for SMAs is presented. More details regarding the original ZM model can be found in [16].

2.1 State variables and free energy formulation

The phenomenological ZM model [16] for dense SMAs is modified including the effect of porosity. The representative elementary volume (REV) is a combination of the solid SMA matrix and the porosity as shown in Figure 1, which is called the skeleton. In this study, the porous region is assumed to be connected and the occluded porosity which is usually small compared to the amount of connected porosity is neglected.

Figure 1: Skeleton particle [18]

The free energy density, ψ , of the REV is formulated as a function of the following variables:

$$\psi = \psi(\boldsymbol{\epsilon}', \theta, T, \boldsymbol{\epsilon}'_A, \boldsymbol{\epsilon}'_M, \boldsymbol{\epsilon}_{ori}, z, \phi) \quad (1)$$

where $\boldsymbol{\epsilon}'$ and θ are the deviatoric and hydrostatic parts of the strain tensor of the skeleton ($\boldsymbol{\epsilon} = \boldsymbol{\epsilon}' + \frac{\theta}{3}\mathbf{I}$), T is the temperature, $\boldsymbol{\epsilon}'_i$ is the local deviatoric strain tensor of the corresponding phase (A for austenite, M for martensite), $\boldsymbol{\epsilon}_{ori}$ is the orientation strain tensor of martensite, z is the volume fraction of martensite and ϕ is the porosity which is defined as the porous volume divided by the total volume of the REV. In short, the porosity is introduced into the ZM model as an additional internal variable.

In classical ZM model for bulk SMAs, the free energy density of a REV is constructed as follows;

$$\psi = (1 - z)\psi_A + z\psi_M + I_z \quad (2)$$

where ψ_i is the free energy density of the corresponding phase and I_z is the interaction energy between the phases or martensite variants. For the porous SMA, the free energy density of the skeleton particle is formulated as follows:

$$\psi = (1 - \phi)[(1 - z)\psi_A + z\psi_M + I_z] + \frac{1}{2}H\theta^2 \quad (3)$$

where H is a material parameter related to hardening and θ is the inelastic volumetric strain due to the change in porosity. It is assumed that the volume change of the matrix is negligible compared to the one of the porosity ($\theta_A = \theta_M = 0$).

The energy terms in Equation 3 are written as follows:

$$\psi_A = \mu_A(\boldsymbol{\epsilon}'_A : \boldsymbol{\epsilon}'_A) \quad (4)$$

$$\psi_M = \mu_M[(\boldsymbol{\epsilon}'_M - \boldsymbol{\epsilon}_{ori}) : (\boldsymbol{\epsilon}'_M - \boldsymbol{\epsilon}_{ori})] + C(T) \quad (5)$$

$$I_z = G\frac{z^2}{2} + \frac{z}{2}[\alpha z + \beta(1 - z)]\left[\frac{2}{3}\boldsymbol{\epsilon}_{ori} : \boldsymbol{\epsilon}_{ori}\right] \quad (6)$$

where μ_i is the shear modulus, $C(T)$ is the latent heat density due to phase transformation and G , α and β are material parameters.

2.2 Constraint equations and Lagrange potential

The state variables must obey some physical rules as stated below:

$$(1 - z)\boldsymbol{\epsilon}'_A + z\boldsymbol{\epsilon}'_M - \boldsymbol{\epsilon}' = 0 \quad (7)$$

$$z \geq 0; \quad (1 - z) \geq 0 \quad (8)$$

$$\epsilon_0 - \sqrt{\frac{2}{3} \epsilon_{ori} : \epsilon_{ori}} \geq 0 \quad (9)$$

$$\phi - \phi_0 - \theta = 0 \quad (10)$$

$$\phi \geq 0; \quad (1 - \phi) \geq 0 \quad (11)$$

where ϵ_0 is the limit for transformation strain and ϕ_0 is the initial porosity. Using the constraint equations above, a Lagrange potential is constructed as follows,

$$\begin{aligned} \psi_l = -\lambda : [(1 - z)\epsilon'_A + z\epsilon'_M - \epsilon'] - v_1 z - v_2(1 - z) - \mu[\epsilon_0 - \sqrt{\frac{2}{3} \epsilon_{ori} : \epsilon_{ori}}] \\ - \lambda_1[\phi - \phi_0 - \theta] - v_3 \phi - v_4(1 - \phi) \end{aligned} \quad (12)$$

where λ , μ , μ_1 and v_i are Lagrange multipliers. ψ and ψ_l together construct the Lagrangian $L = \psi + \psi_l$, which is then used to obtain the state equations:

$$\begin{aligned} L = (1 - \phi) \left[(1 - z) \left(\mu_A(\epsilon'_A : \epsilon'_A) \right) + z \left(\mu_M[(\epsilon'_M - \epsilon_{ori}) : (\epsilon'_M - \epsilon_{ori})] + C(T) \right) \right] + G \frac{z^2}{2} \\ + \frac{z}{2} [\alpha z + \beta(1 - z)] \left[\frac{2}{3} \epsilon_{ori} : \epsilon_{ori} \right] + \frac{1}{2} H \theta^2 - \lambda : [(1 - z)\epsilon'_A + z\epsilon'_M - \epsilon'] - v_1 z - v_2(1 - z) \\ - \mu[\epsilon_0 - \sqrt{\frac{2}{3} \epsilon_{ori} : \epsilon_{ori}}] - \lambda_1[\phi - \phi_0 - \theta] - v_3 \phi - v_4(1 - \phi) \end{aligned} \quad (13)$$

2.3 State equations

State equations below are obtained based on the Clausius-Duhem inequality for a solid medium:

$$s = \frac{\partial L}{\partial \epsilon'} = \lambda \quad (14)$$

$$\frac{tr(\sigma)}{3} = \frac{\partial L}{\partial \theta} = \lambda_1 + H \theta \quad (15)$$

$$0 = \frac{\partial L}{\partial \epsilon'_A} = (1 - z) [2\mu_A \epsilon'_A (1 - \phi) - \lambda] \quad (16)$$

$$0 = \frac{\partial L}{\partial \epsilon'_M} = z [2\mu_M (\epsilon'_M - \epsilon_{ori}) (1 - \phi) - \lambda] \quad (17)$$

$$\begin{aligned} -A_\phi = \frac{\partial L}{\partial \phi} = - \left[(1 - z) \mu_A(\epsilon'_A : \epsilon'_A) + z \left(\mu_M(\epsilon'_M - \epsilon_{ori}) : (\epsilon'_M - \epsilon_{ori}) + C(T) \right) \right] + G \frac{z^2}{2} \\ + \frac{z}{2} [\alpha z + \beta(1 - z)] \left[\frac{2}{3} \epsilon_{ori} : \epsilon_{ori} \right] - \lambda_1 \end{aligned} \quad (18)$$

$$\begin{aligned} -A_z = \frac{\partial L}{\partial z} = (1 - \phi) \left[-\mu_A(\epsilon'_A : \epsilon'_A) + \left(\mu_M[(\epsilon'_M - \epsilon_{ori}) : (\epsilon'_M - \epsilon_{ori})] + C(T) \right) \right] + G z + \\ [\alpha z + \beta(\frac{1}{2} - z)] \left[\frac{2}{3} \epsilon_{ori} : \epsilon_{ori} \right] - \lambda(\epsilon'_M - \epsilon'_A) \end{aligned} \quad (19)$$

$$-A_{ori} = \frac{\partial L}{\partial \epsilon_{ori}} = (1 - \phi) z \left[2\mu_M(\epsilon_{ori} - \epsilon'_M) + \frac{2}{3} \epsilon_{ori}(\alpha z + \beta(1 - z)) \right] + \frac{2}{3} \mu \left[\frac{\epsilon_{ori}}{\sqrt{\frac{2}{3} \epsilon_{ori} : \epsilon_{ori}}} \right] \quad (20)$$

where A_z , A_ϕ and \mathbf{A}_{ori} are the thermodynamic forces associated with phase transformation, volume change and orientation of martensite, respectively.

The constitutive relation between deviatoric stress and strain is obtained from the state equations as shown below:

$$\mathbf{s} = 2(1 - \phi)\mu_{eq}[\boldsymbol{\varepsilon}' - z\boldsymbol{\varepsilon}_{ori}] \quad (21)$$

where

$$\mu_{eq} = \left(\frac{1-z}{\mu_A} + \frac{z}{\mu_M} \right)^{-1} \quad (22)$$

The thermodynamic forces can be rewritten as follows:

$$A_z = \frac{1}{3}\sigma_{VM}^2 \frac{(1+\nu)}{(1-\phi)} \left(\frac{1}{E_M} - \frac{1}{E_A} \right) + \mathbf{s} : \boldsymbol{\varepsilon}_{ori} + (1-\phi)(-C(T) - Gz - [\alpha z + \beta(\frac{1}{2} - z)][\frac{2}{3}\boldsymbol{\varepsilon}_{ori} : \boldsymbol{\varepsilon}_{ori}]) \quad (23)$$

$$A_\phi = \frac{1}{3}\sigma_{VM}^2 \frac{(1+\nu)}{E_{eq}} + zC(T) + Gz^2 + \frac{z}{2}[\alpha z + \beta(1-z)][\frac{2}{3}\boldsymbol{\varepsilon}_{ori} : \boldsymbol{\varepsilon}_{ori}] + \frac{tr\boldsymbol{\sigma}}{3} - H(\phi - \phi_0) \quad (24)$$

$$\mathbf{A}_{ori} = z\mathbf{s} - \frac{2}{3}z(1-\phi)(\alpha z + \beta(1-z))\boldsymbol{\varepsilon}_{ori} - \frac{2}{3}\mu \left[\frac{\boldsymbol{\varepsilon}_{ori}}{\sqrt{\frac{2}{3}\boldsymbol{\varepsilon}_{ori} : \boldsymbol{\varepsilon}_{ori}}} \right] \quad (25)$$

where

$$E_{eq} = \left(\frac{1-z}{E_A} + \frac{z}{E_M} \right)^{-1} \quad (26)$$

2.4 Dissipation pseudo-potential and evolution of internal variables

In the framework of generalized standard materials, evolution of internal variables is obtained from a dissipation pseudo-potential which is a function of the rates of dissipative variables, $D(\dot{z}, \dot{\boldsymbol{\varepsilon}}_{ori}, \dot{\phi})$.

Assume;

$$D = (1-\phi)[a(1-z) + bz]|\dot{z}| + z^2 Y \sqrt{\frac{2}{3}\dot{\boldsymbol{\varepsilon}}_{ori} : \dot{\boldsymbol{\varepsilon}}_{ori}} + P(1-\phi)|\dot{\phi}| \quad (27)$$

where a , b , Y and P are positive materials constants. The dissipation pseudo-potential is related to thermodynamic forces as follows:

$$A_z \in \partial_{\dot{z}} D; \quad A_{ori} \in \partial_{\dot{\boldsymbol{\varepsilon}}_{ori}} D; \quad A_\phi \in \partial_{\dot{\phi}} D \quad (28)$$

which give the set of yield functions:

$$F_z^1 \leq 0, \quad F_z^2 \leq 0, \quad F_{tr} \leq 0, \quad F_\phi^1 \leq 0, \quad F_\phi^2 \leq 0 \quad (29)$$

associated to the forward martensitic transformation, reverse martensitic transformation, martensite orientation, increase in porosity and decrease in porosity, respectively. The yield functions are given below:

$$F_z^1 = \frac{1}{3}\sigma_{VM}^2 \frac{El_{MA}}{(1-\phi)} + \mathbf{s} : \boldsymbol{\varepsilon}_{ori} + (1-\phi) \left(-C(T) - Gz - [\alpha z + \beta(\frac{1}{2} - z)][\frac{2}{3}\boldsymbol{\varepsilon}_{ori} : \boldsymbol{\varepsilon}_{ori}] - [a(1-z) + bz] \right) \quad (30)$$

$$F_z^2 = -\frac{1}{3}\sigma_{VM}^2 \frac{El_{MA}}{(1-\phi)} - \mathbf{s} : \boldsymbol{\varepsilon}_{ori} - (1-\phi) \left(-C(T) - Gz - [\alpha z + \beta(\frac{1}{2} - z)][\frac{2}{3}\boldsymbol{\varepsilon}_{ori} : \boldsymbol{\varepsilon}_{ori}] \right)$$

$$- [a(1-z) + bz] \quad (31)$$

$$F_{ori} = \frac{F_{tr}}{z} = \left\| \mathbf{s} - \frac{2}{3}(1-\phi)(\alpha z + \beta(1-z))\boldsymbol{\epsilon}_{ori} - \frac{2\mu}{3z} \left[\frac{\boldsymbol{\epsilon}_{ori}}{\sqrt{\frac{2}{3}\boldsymbol{\epsilon}_{ori} : \boldsymbol{\epsilon}_{ori}}} \right] \right\|_{VM} - zY \quad (32)$$

$$F_{\phi}^1 = \frac{1}{3}\sigma_{VM}^2 \frac{(1+\nu)}{E_{eqt}} + zC(T) + Gz^2 + \frac{z}{2}[\alpha z + \beta(1-z)] \left[\frac{2}{3}\boldsymbol{\epsilon}_{ori} : \boldsymbol{\epsilon}_{ori} \right] + \frac{tr\boldsymbol{\sigma}}{3} - H(\phi - \phi_0) - P(1-\phi) \quad (33)$$

$$F_{\phi}^2 = -\frac{1}{3}\sigma_{VM}^2 \frac{(1+\nu)}{E_{eqt}} - zC(T) - Gz^2 - \frac{z}{2}[\alpha z + \beta(1-z)] \left[\frac{2}{3}\boldsymbol{\epsilon}_{ori} : \boldsymbol{\epsilon}_{ori} \right] - \frac{tr\boldsymbol{\sigma}}{3} + H(\phi - \phi_0) - P(1-\phi) \quad (34)$$

During evolution of the internal variables, the yield functions must satisfy the following conditions:

$$F = 0, \quad \dot{F} = 0 \quad (35)$$

where F is the corresponding yield function; \dot{z} , $\dot{\epsilon}_{ori}$ and $\dot{\phi}$ are calculated using Equation 35.

2.5 Parameter identification

The material parameters listed in Table 1, except for P and H , can be calculated from orientation and pseudoelastic uniaxial experiments performed on a dense SMA as explained in [16]. For now, transformation temperatures are assumed to be constant under different porosity.

P and H are the additional material parameters to be determined for a porous material. For now, P is chosen to be 10 MPa and H is assumed to depend on porosity as $H = H_0(1 - \phi_0)^2$ to observe the evolution of porosity in the simulations.

Table 1: Material parameters used in the simulations [16]

Parameter	Value	Parameter	Value
E_A	39100 MPa	a	28.94 MPa
E_M	18000 MPa	b	27.46 MPa
ν	0.33	ϵ_0	0.102
Y	265 MPa	G	37.3 MPa
α	539 MPa	β	3137 MPa
ζ	0.4775 MPa °C ⁻¹	κ	13.9 MPa
A_f^0	40 °C	T_0	50 °C
P	10 MPa	H_0	10000 MPa

3 NUMERICAL STUDY ON COMPRESSION OF POROUS NiTi

Since the experimental studies in the literature are devoted to compressive behaviour of the porous NiTi, the present model is simplified to simulate uniaxial compression.

3.1 Simplification of the model to uniaxial compression (1D)

The equations above are simplified to their 1D version in order to observe the pseudoelastic behavior of the porous SMAs under uniaxial compression; the stress-strain relation can be written as follows:

$$\sigma = 3(1 - \phi)\mu_{eqv}\left[\varepsilon - \frac{(\phi - \phi_0)}{3} - z\varepsilon_{ori}\right] \quad (36)$$

For the ease of simplicity, it is assumed that the martensite is completely transformed if the temperature is well above austenite finish temperature A_f^0 , and under this condition $\varepsilon_{ori} = \varepsilon_0$. In addition, the volume change is assumed to be totally irreversible, therefore there is no increase in volume during unloading.

For uniaxial compression, the yield functions are obtained as follows:

$$F_z^1 = \frac{3}{4} \frac{El_{MA}}{(1 - \phi)} s^2 + \frac{3}{2} s \varepsilon_0^2 + (1 - \phi) \left(-C(T) - Gz - \varepsilon_0^2 [\alpha z + \beta(\frac{1}{2} - z)] \right) - [a(1 - z) + bz] \quad (37)$$

$$F_z^2 = -\frac{3}{4} \frac{El_{MA}}{(1 - \phi)} s^2 - \frac{3}{2} s \varepsilon_0^2 - (1 - \phi) \left(-C(T) - Gz - \varepsilon_0^2 [\alpha z + \beta(\frac{1}{2} - z)] \right) - [a(1 - z) + bz] \quad (38)$$

$$F_\phi = -\frac{3}{4} \frac{(1 + \nu)}{E_{eq}} s^2 - zC(T) - Gz^2 - \frac{z}{2} [\alpha z + \beta(1 - z)] \varepsilon_0^2 - \frac{s}{2} + H(\phi - \phi_0) - P(1 - \phi) \quad (39)$$

3.2 Algorithm and numerical results

The phenomenological model for 1D compression test is programmed in Matlab following the algorithm below. Here, exponent test indicates an estimate for the step $i + 1$ by using the values of z and ϕ at step i .

Input: model parameters, ε , T , z^0 , ϕ^0

Output: z , ϕ

While $i < n$

divide the loading path into n intervals: $\varepsilon^{i+1} \leftarrow \varepsilon^i + \Delta\varepsilon$

- compute $\sigma^{(i+1),test}$ using ε^{i+1} , z^i , ϕ^i
- compute $F_z^{1,(i+1),test}$, $F_z^{2,(i+1),test}$, $F_\phi^{(i+1),test}$
- **if** $F_z^{1,(i)} > 0$ **and** $F_z^{1,(i+1),test} > F_z^{1,(i)}$ **and** $1 - z > 0$
forward phase transformation
- **if** $F_z^{2,(i)} > 0$ **and** $F_z^{2,(i+1),test} > F_z^{2,(i)}$ **and** $z > 0$
reverse phase transformation
- **if** $F_\phi^{(i)} > 0$ **and** $F_\phi^{(i+1),test} > F_\phi^{(i)}$ **and** $\phi > 0$
porosity change
- **if** no active transformation and porosity change
 $\Delta z = 0$, $\Delta\phi = 0$
- **if** forward phase transformation only
 $\dot{F}_z^1 = 0$ gives Δz , $\Delta\phi = 0$

- **if** reverse phase transformation only
 $\dot{F}_z^2 = 0$ gives $\Delta z, \Delta \phi = 0$
 - **if** porosity change
 $\dot{F}_\phi = 0$ gives $\Delta \phi, \Delta z = 0$
 - **if** forward phase transformation and porosity change
 $\dot{F}_z^1 = 0$, and $\dot{F}_\phi = 0$ give $\Delta z, \Delta \phi$
 - **if** reverse phase transformation and porosity change
 $\dot{F}_z^2 = 0$, and $\dot{F}_\phi = 0$ give $\Delta z, \Delta \phi$
- $z^{(i+1)} \leftarrow z^{(i)} + \Delta z, \phi^{(i+1)} \leftarrow \phi^{(i)} + \Delta \phi$, compute $\sigma^{(i+1)}$ with $z^{(i+1)}$ and $\phi^{(i+1)}$
 $i \leftarrow i + 1$, compute $F_z^{1,(i)}$
End while

Fig. 2 shows the comparison of the stress-strain curves of dense and 25% porous NiTi under uniaxial compression. Numerical results demonstrate that the porous NiTi shows a similar hysteresis loop with some differences when compared to the one of the dense NiTi. As expected, elastic modulus, critical stresses for forward and reverse phase transformation and hysteresis area decrease under porosity. It is also observed that there is a residual strain at the end of unloading due to the irreversible volumetric strain resulting from the evolution of porosity.

Figure 2: Numerical results of the stress-strain behaviour of dense and 25% porous NiTi under compression

The effects of porosity explained in the previous paragraph are more pronounced in Figures 3, 4a and 4b where the results are compared for different porosity levels. Fig. 3 shows that the amount of residual strain is increasing with increasing the porosity as observed by Saedi et al. [11]. The same result can also be seen by looking at Fig. 4a where the evolution of porosity is presented. Fig. 4b shows the evolution of martensitic phase transformation by following the volume fraction of martensite. It is

observed that the phase transformation is recovered back, but the amount of martensite phase produced decreases by increasing the porosity which is also stated by Zhao et al. [7] according to their experimental results. This result can also be related to the decrease in the hysteresis area which is a sign of martensitic transformation.

Figure 3: Numerical results of the stress-strain behaviour of 25%, 50% and 75% porous NiTi under compression

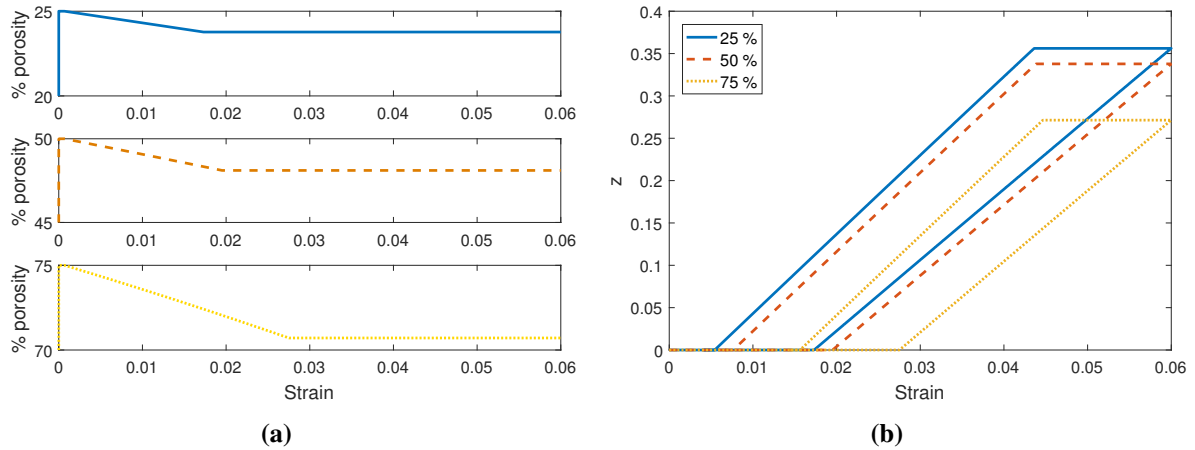

Figure 4: Numerical results of the evolution of (a) porosity and (b) martensitic volume fraction of 25%, 50% and 75% porous NiTi under compression

The numerical results show that the present phenomenological model is able to represent qualitatively the effect of porosity on the compression behaviour of NiTi SMA, and continuing research on the model holds a great promise. In order to achieve a quantitative agreement with experimental results, the material parameters in the model must be determined precisely. The dissipation potential will also be formulated more precisely after performing a few experiments on a porous NiTi.

4 SUMMARY

In this paper, a macro scale phenomenological model of porous SMAs is presented. The analytical model is a generalization of the ZM model which represents the mechanical behaviour of dense SMAs within the framework of generalized standard materials with internal constraints. The porosity is introduced into the ZM model as an additional internal variable and the effect of hydrostatic pressure is taken into account. The model is then simulated numerically using Matlab for uniaxial behaviour of a porous NiTi SMA under compression. The stress-strain behaviour of the NiTi SMA is presented and the evolution of martensitic phase transformation and porosity are calculated for different porosity levels. The numerical results have qualitative agreement with the experimental results available in the literature and it shows that the present model is able to represent the effect of porosity on the pseudoelastic uniaxial compression behaviour of a porous SMA. Experiments on porous NiTi are needed to characterize additional material parameters and to obtain a quantitative agreement between the analytical model and experiments.

Key words: Thermal signature, thermo-mechanical coupling, dissipation

Abstract. Several applications use superelastic shape memory alloys (SMA) parts in order to benefit from their large recoverable strain. These structures are generally subject to cyclic loadings, which can lead to fatigue rupture. Unfortunately, the fatigue of SMA has not been much studied and their fatigue is not taken into account in the dimensioning of SMA structures.

In this study, we begin to determine fatigue properties of the material by using a fast method based on self-heating measurements firstly proposed for steels.

A model describing the probabilistic apparition of superelastic inclusion in an elastic matrix is developed based on a macroscopic model of SMA behavior. It permits to reproduce self-heating results and then, by choosing an adapted fatigue criteria, is able to predict fatigue properties of the samples. These results have been validated using classic fatigue tests on the hourglass samples.

1 INTRODUCTION

The shape memory alloys (SMA) are materials able to recover a large elastic deformation under thermomechanical loading. These properties are due to a very particular aspect of the mechanical behavior: the superelasticity. When these materials are loaded at a temperature higher than the A_f temperature (Austenite Finish), an reversible strain occurred and can reach 6% to 10%. The strain mechanism at the origin of this phenomena is based on a solid-solid phase transformation [1]. The properties of these alloys make them interesting for innovative applications. For example they are used for biomedical applications or in transport. The thermomechanical behavior of these alloys has been studied since several years. Several models have been developed to describe the behavior. Unfortunately, the fatigue property of these alloys remains an unexplored area. Currently in the design phase of structures using SMA, fatigue is not considered. This is the reason for which we try to determine fatigue properties of nickel-titanium (NiTi) is studied in this study. However fatigue tests are time consuming, thus we proposed a fast method to determine fatigue properties of SMA. This study begins by conducting self-heating measurements on samples. They permit to empirically estimate the mean endurance limit of the material. Then a two-scale probabilistic model has been developed. It permits to simulate the temperature evolution in the material

during self-heating tests and to identify some fatigue related parameters of the material. Finally a fatigue criterion has been used in order to predict the fatigue curves associated to probability of failure. The results have been validated by comparison with classic fatigue tests on the same samples.

2 EXPERIMENTAL SELF-HEATING

In this section, the material and the geometry of specimens are presented. Then, the loading conditions of self-heating tests are explained and the resulting self-heating curves are shown and analyzed. Finally, an empirical analysis, allowing the prediction of the mean endurance limit corresponding to a failure probability of 50% at 2 million cycles, is applied.

2.1 Material and geometry of specimens

The shape memory alloy used in this study is an as-received medical graded NiTi (50.8 at.% – 49.2 at.%). The alloy is superelastic at room temperature.

The specimens are obtained from cold-drawn wires of 1 mm diameter. In order to avoid influence of limit conditions in the grips on fatigue life, to force localization of martensitic transformation in a specific spot and then to make the study of self-heating feasible, an hourglass shaped notch has been realized on the samples using same manufacturing process as the one used for the fabrication of endodontic files.

The mechanical behavior in traction of these samples have been determined using an extensometer with an initial length of 10 mm which covers more than the entire hourglass shape. The identified Young modulus, E , transformation yield stress, σ_0 , hysteresis size, δ , and slope of transformation plateau, C , are reported in table 1. The results on figure 1 show a classic NiTi shape memory alloy behavior with a transformation plateau. The transformation limit is high compared to the ones observed in other tests from literature which doesn't take precaution about localization of transformation in the jaws like we did by the use of the hourglass shape of the specimen.

Table 1: Behavior characteristics of the specimens.

E (GPa)	σ_0 (MPa)	δ (MPa)	C (MPa/%)
72	770	410	0.17

Figure 1: Stress-displacement behavior of NiTi hourglass specimens at 20 °C.

2.2 Loading and measurements conditions

Self-heating loadings consist of several steps with increasing maximum stress. During each step, a sinusoidal cyclic loading is applied between 10 MPa and given maximum stress for 100 seconds at 30 Hz, followed by a pause during another 100 seconds to let the specimen cool down to ambient temperature.

During a step, the temperature of each points of the central part of the specimen is registered using the infrared camera using a frequency of 100 Hz. The spatial mean temperature of the notched zone for each frame is calculated. To this temperature is subtracted the mean temperatures of the grips to obtained the mean temperature elevation. Then, a temporal mean temperature is determined from this one to give the mean cycle temperature elevation. Finally, the stabilized value of this temperature elevation during each cyclic loading step is extract to give the stabilized mean cycle temperature elevation, $\bar{\theta}_{cycle}^{0D}$.

The result of self-heating tests is the self-heating curve that represent for each step the stabilized mean cycle temperature elevation, $\bar{\theta}_{cycle}^{0D}$, versus the corresponding maximum stress (figure 2).

2.3 Empirical identification of the mean endurance limit

As it is proceeded for metallic materials like in [2], we performed an empirical identification of the mean endurance limit using the self-heating results, $\bar{\Sigma}_{\infty}^{sh}$. It consists of a linear regression on last points of the self-heating curve. Then the mean endurance limit correspond to the intersection of this line with the x-axis (see figure 2). The results are shown in table 2.

Figure 2: Temperature elevation versus maximum stress, with empirical determination of mean endurance limit.

If self-heating is related to fatigue behavior, then this value should correspond to the mean endurance limit determined by classic fatigue tests, $\bar{\Sigma}_{\infty}^{fat}$.

2.4 Experimental fatigue

In order to validate the self-heating results, classic fatigue tests have been realized using the same type of specimens, set-up and experimental conditions that were used for self-heating tests.

2.4.1 Whöler curves

The tests were carried up to two millions cycles if not rupture occurs. The obtained Whöler curves are shown on figure 3. The dashed green line represent the least squares power law fitting, and the dashed

red line, the corresponding mean endurance limit.

Figure 3: Maximum stress versus number of cycles to rupture.

We observe a large dispersion of the fatigue results, which is normal for high cycle fatigue tests.

2.4.2 Mean endurance limit comparison

The comparison of the mean endurance limit between classic fatigue tests and self-heating tests has been realized in table 2. It shows a good agreement between the mean endurance limits determined by the two methods.

Table 2: Comparison of mean endurance limits determined with classic fatigue tests and empirical determination using self-heating.

$\bar{\Sigma}_{\infty}^{fat}$ (MPa)	$\bar{\Sigma}_{\infty}^{sh}$ (MPa)	Δ (%)
501	574	14.5

This results show that the self-heating of SMA is probably related to the fatigue behavior. This first empiric approach permits to determine the mean endurance limit of an SMA from self-heating curve, but it only use a small part of the informations that self-heating curves contain. To extract this informations we need to develop a model permitting to simulate the self-heating during cyclic tests.

3 TWO-SCALE PROBABILISTIC MODEL

In order to simulate self-heating curves of SMA we need a two-scale probabilistic model. Indeed, firstly, the self-heating curves are realized in elastic part of the behavior of SMA as maximum stress is lower than transformation yield stress. So we assume that some phase transformation occurs at a lower scale and generate heat. Secondly, the shape of the self-heating curve suggest a probabilistic behavior since a deterministic one should leads to a two-slope curve of self-heating instead of a curved curve [3].

Then we consider a Representative Elementary Volume (REV) constitute of an elastic matrix containing inclusions presenting phase transformation at a lower stress than the apparent transformation yield stress of material (see figure 4). The probabilistic behavior is taken into account into the distribution of the transformation yield stress of inclusions.

Figure 4: Representation of an inclusion in the matrix.

3.1 Behavior of an inclusion

In this part we present the behavior of an inclusion by describing the thermodynamic framework and calculate the induced dissipation.

As self heating tests consist of stress driven cyclic uniaxial loadings, we can write the evolution of the stress tensor in the matrix as

$$\boldsymbol{\sigma} = \tilde{f}(t)\mathbf{N} \quad (1)$$

with $\tilde{f}(t)$ a time periodic function that must observe $\tilde{f}(0) = 0$, and $\mathbf{N} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}$.

3.1.1 Thermodynamic framework

An inclusion is considered to have a low transformation yield stress and then present phase transformation at studied stress amplitudes. We propose to take the following specific free energy for an inclusion

$$\rho\psi^i(\boldsymbol{\epsilon}, T, \boldsymbol{\epsilon}^{tr}, H) = \rho W_{\text{elast}}^i + \rho z W_{\text{chem}}^i + \rho W_{\text{int}}^i \quad (2)$$

with W_{elast}^i the elastic work in the inclusion

$$\rho W_{\text{elast}}^i = \frac{1}{2} \boldsymbol{\epsilon}^e : \underline{\underline{\mathbf{C}}} : \boldsymbol{\epsilon}^e + \rho C_\alpha \left(T - T_0 - T \ln \frac{T}{T_0} \right) \quad (3)$$

W_{chem}^i the chemical work in the inclusion due to transformation

$$\rho W_{\text{chem}}^i = \mu_0 (T - T_*) \boldsymbol{\epsilon}^{tr} : \mathbf{N}' \quad (4)$$

W_{int}^i the work induced by interactions between martensite variants

$$\rho W_{\text{int}}^i = \gamma H \quad (5)$$

$\boldsymbol{\epsilon}$ the total strain tensor in the inclusion, $\boldsymbol{\epsilon}^{tr}$ the transformation strain tensor, H an internal variable, z the martensite volume fraction, $\boldsymbol{\epsilon}^e$ the elastic strain tensor in the inclusion, μ_0 the slope of the evolution of forward transformation (austenite to martensite) yield stress versus temperature, T_* the reference temperature for forward transformation, \mathbf{N}' the deviatoric part of \mathbf{N} and γ the maximum transformation strain.

In the inclusion, we assume the strain decomposition into elastic strain, transformation strain and thermal strain

$$\boldsymbol{\epsilon} = \boldsymbol{\epsilon}^e + \boldsymbol{\epsilon}^{tr} + \lambda \theta \mathbf{I} \quad (6)$$

Thermodynamics forces are the stress tensor in inclusion, σ , associated to the total strain tensor in inclusion

$$\sigma = \rho \frac{\partial \Psi^i}{\partial \varepsilon} = \underline{\underline{C}} : (\varepsilon - \varepsilon^{tr} - \lambda \theta \mathbf{I}) \quad (7)$$

the entropy in inclusion, s , associated to temperature

$$s = -\frac{\partial \Psi^i}{\partial T} = \frac{E\lambda}{\rho(1-2\nu)} \text{tr}(\varepsilon - \varepsilon^{tr}) + C_\alpha \ln \frac{T}{T_0} - \frac{\mu_0}{\rho} \varepsilon^{tr} : \mathbf{N}' \quad (8)$$

a thermodynamic force tensor, π , associated to the transformation strain tensor

$$\pi = -\rho \frac{\partial \Psi^i}{\partial \varepsilon^{tr}} = \underline{\underline{C}} : (\varepsilon - \varepsilon^{tr} - \lambda \theta \mathbf{I}) - \mu_0 (T - T_*) \mathbf{N}' = \sigma - \mu_0 (T - T_*) \mathbf{N}' \quad (9)$$

and a thermodynamic force, P , associated to the internal variable H

$$P = -\rho \frac{\partial \Psi^i}{\partial H} = -\gamma \quad (10)$$

The thermoelastic coupling term is then

$$\rho T \frac{\partial^2 \Psi^i}{\partial T \partial \varepsilon} : \dot{\varepsilon} = -\frac{E\lambda T}{1-2\nu} \text{tr}(\dot{\varepsilon}) = -\lambda T \dot{f}(t) - \frac{3E\lambda^2 T}{1-2\nu} \dot{\theta} \quad (11)$$

The thermo-mechanical transformation coupling term is

$$\rho T \frac{\partial^2 \Psi^i}{\partial T \partial \varepsilon^{tr}} : \dot{\varepsilon}^{tr} = T \left(\frac{E\lambda}{1-2\nu} \mathbf{I} + \mu_0 \mathbf{N}' \right) : \dot{\varepsilon}^{tr} \quad (12)$$

As martensitic transformation in SMA is almost isochoric [4, 5], it is often assumed that transformation strain is deviatoric. Furthermore, normality rule implies that the direction of transformation strain is identical to elastic strain direction (in the deviatoric plan) for uniaxial loadings. And finally transformation strain is proportional to martensic volume fraction. The transformation strain can then be express as

$$\varepsilon^{tr} = \frac{3}{2} \gamma_z \mathbf{N}' \quad (13)$$

So

$$\rho T \frac{\partial^2 \Psi^i}{\partial T \partial \varepsilon^{tr}} : \dot{\varepsilon}^{tr} = \mu_0 T \gamma \dot{z} \quad (14)$$

The thermo-mechanical interaction coupling term is

$$\rho T \frac{\partial^2 \Psi^i}{\partial T \partial H} : \dot{H} = 0 \quad (15)$$

The transformation dissipation term is

$$\rho \frac{\partial \Psi^i}{\partial \varepsilon^{tr}} : \dot{\varepsilon}^{tr} = -\pi : \dot{\varepsilon}^{tr} = -(\tilde{f}(t) - \mu_0 (T - T^*)) \gamma \dot{z} \quad (16)$$

And the interaction dissipation term is

$$\rho \frac{\partial \Psi^i}{\partial H} : \dot{H} = \gamma \dot{H} \quad (17)$$

In order to include this terms in the heat equation and resolve it, we need to express \dot{z} and \dot{H} in terms of θ , $\dot{\theta}$ and t .

In order to express \dot{z} , we use a simplified version of the thermo-mechanical model developed in [6], which give

$$\dot{z} = \frac{\dot{f}(t) - \mu_0 \dot{\theta}}{\gamma C} \quad (18)$$

Using the assumption that the intrinsic dissipation is the same during loading and during unloading we then obtain

$$H(z) = \frac{\gamma C z - \delta}{2} z \quad (19)$$

and then

$$\dot{H}(z) = \left(\gamma C z - \frac{\delta}{2} \right) \dot{z} \quad (20)$$

3.1.2 Dissipation during cyclic loading

The purpose of this modeling is to determine the stabilized mean cycle temperature elevation, $\bar{\theta}_{cycle}^{0D}$ during cycling loading. We have then to calculate the mean dissipation of an inclusion during a stabilized cycle as a function of the transformation yield stress of the inclusion. The dissipation in an inclusion is defined as

$$\Delta_i = \sigma : \dot{\epsilon} - \rho (\dot{\psi}^i + s \dot{T}) \quad (21)$$

Then

$$\Delta_i = -\rho \frac{\partial \psi^i}{\partial \epsilon^{tr}} : \dot{\epsilon}^{tr} - \rho \frac{\partial \psi^i}{\partial H} \dot{H} = (\sigma - \mu_0(T - T_*)) : \dot{\epsilon}^{tr} - \gamma \left(\gamma C z - \frac{\delta}{2} \right) \dot{z} \quad (22)$$

Self-heating curves correspond to the stabilized temperature during a cyclic loading. We can then integrate the dissipation during a thermodynamical cycle to obtain the cyclic dissipated energy

$$D_i(\sigma_0) = \oint \Delta_i dt = \oint \sigma : \dot{\epsilon}^{tr} dt + \oint \mu_0(T - T_*) : \dot{\epsilon}^{tr} dt - \oint \left(\gamma C z - \frac{\delta}{2} \right) dz \quad (23)$$

Since we integrate on a thermodynamic cycle, the last two integrals are equal to zero

$$\oint \mu_0(T - T_*) : \dot{\epsilon}^{tr} dt = \oint \left(\gamma C z - \frac{\delta}{2} \right) dz = 0 \quad (24)$$

The expression of the first one and then of the cyclic dissipated energy depends on the value of the transformation yield stress, σ_0 , in the inclusion

$$D_i(\sigma_0) = \frac{\delta}{C} (\sigma_{max} - \sigma_0) \quad (25)$$

3.2 Activation and dissipation of inclusions

As said previously, the probabilistic behavior is taken into account into the distribution of the transformation yield stress of inclusions. For this, a Point Poisson Process (PPP) is used [7, 8]

$$N(\sigma_{max}) = \lambda V \quad (26)$$

with N the quantity of active inclusions (i.e., with a transformation yield stress σ_0 lower or equal to the maximum stress, σ_{max}) in the considered domain of volume V , and λ the mean density of active inclusions. The evolution of this mean density with maximum stress is assumed to be a power law

$$\lambda(\sigma_{max}) = \frac{1}{V_0} \left(\frac{\sigma_{max}}{S_0} \right)^m \quad (27)$$

with m and $V_0 S_0^m$ two material parameter or set of parameters.

Then, the quantity of inclusions with a transformation yield stress of σ_0 can be expressed as the derivation of the quantity of active inclusions for a maximum stress σ_{max} equal to the transformation yield stress

$$N'(\sigma_0) = \left. \frac{dN}{d\sigma_{max}} \right|_{\sigma_{max}=\sigma_0} \quad (28)$$

The density of inclusions with a transformation yield stress of σ_0 is then

$$\lambda'(\sigma_0) = \left. \frac{d\lambda}{d\sigma_{max}} \right|_{\sigma_{max}=\sigma_0} \quad (29)$$

In order to obtain the total dissipated energy, we have to integrate the dissipated energy of the total population of inclusions versus their transformation yield stress. The total dissipated energy for inclusions with a transformation yield stress of σ_0 is the dissipated energy for one inclusion with this transformation yield stress, $D_i(\sigma_0)$ (expressed in equation 25) multiplied by the quantity of inclusion with this transformation yield stress, $N'(\sigma_0)$

$$D = \int_{\sigma_0=0}^{\infty} D_i(\sigma_0) N'(\sigma_0) d\sigma_0 = \int_{\sigma_0=0}^{\infty} D_i(\sigma_0) \lambda'(\sigma_0) V d\sigma_0 \quad (30)$$

Using equation 25, we obtain

$$D = \frac{\delta V}{CV_0 S_0^m (m+1)} \left((\delta + \sigma_{min} - \gamma C)^{m+1} - (\delta + \sigma_{min})^{m+1} - (\sigma_{max} - \gamma C)^{m+1} + \sigma_{max}^{m+1} \right) \quad (31)$$

As γC (stress increase during the plateau) is very low for NiTi, this equation can be simplified using a Taylor decomposition as

$$D = \frac{\delta V \gamma}{V_0 S_0^m} (\sigma_{max}^m - (\delta + \sigma_{min})^m) \quad (32)$$

3.3 Description of self-heating curves

The heat conduction equation on a specimen is given by

$$\begin{aligned} \rho C_\alpha \left(\dot{\theta} + \frac{\theta}{\tau_{eq}} \right) = & -f_v \rho \frac{\partial \psi^i}{\partial \epsilon^{tr}} : \dot{\epsilon}^{tr} - f_v \rho \frac{\partial \psi^i}{\partial H} \dot{H} + f_v \rho T \frac{\partial^2 \psi^i}{\partial T \partial \epsilon^{tr}} : \dot{\epsilon}^{tr} \\ & + f_v \rho T \frac{\partial^2 \psi^i}{\partial T \partial H} \dot{H} + f_v \rho T \frac{\partial^2 \psi^i}{\partial T \partial \epsilon} : \dot{\epsilon} + (1 - f_v) \rho T \frac{\partial^2 \psi^m}{\partial T \partial E} : \dot{E} \end{aligned} \quad (33)$$

with τ_{eq} the characteristic time of the specimen and f_v the volume fraction of inclusions.

If we integrate this equation on a thermodynamic cycle, the temperature elevation, θ , becomes the mean cycle temperature elevation, θ_{cycle}^{0D} , the coupling terms become zero, and the dissipation terms become the cyclic dissipated energy D multiplied by the loading frequency, f_r

$$\rho C_\alpha \left(\dot{\theta}_{cycle}^{0D} + \frac{\theta_{cycle}^{0D}}{\tau_{eq}} \right) = f_v f_r D \quad (34)$$

And since self-heating tests represent the stabilized mean cycle temperature elevation, we can just consider the stabilized solution of this equation

$$\frac{\rho C_\alpha}{\tau_{eq}} \bar{\theta}_{cycle}^{0D} = f_v f_r D \quad (35)$$

And, using equation 32, as a function of the maximum stress, σ_{max}

$$\bar{\theta}_{cycle}^{0D} = \frac{f_v f_r \tau_{eq} \delta V \gamma}{\rho C_\alpha V_0 S_0^m} (\sigma_{max}^m - (\delta + \sigma_{min})^m) \quad (36)$$

Since δ has already been identified on macroscopic behavior curves (see table 1), and σ_{min} is constant, there is only two parameter or set of parameters to identify: m and $\frac{f_v f_r \tau_{eq} \delta V \gamma}{\rho C_\alpha V_0 S_0^m}$. Their values are presented in table 3.

Table 3: Identified parameters of the self-heating model.

$\frac{f_v f_r \tau_{eq} \delta V \gamma}{\rho C_\alpha V_0 S_0^m} (\text{K} \cdot \text{MPa}^{-m})$	$m (-)$
6.23×10^{-19}	6.31

The self-heating curve is compared to the experimental one on figure 5 with, in orange, the simulated self-heating curves plus or minus the precision error of the thermal measurements with the infrared camera (± 25 mK).

Figure 5: Temperature elevation versus maximum stress, with parameters identification.

3.4 Prediction of fatigue properties

Assuming that the inclusion activation governs the physical process of fatigue initiation, the developed self-heating model can then be used to predict the fatigue properties of the material.

In order to determine the fatigue life of the material from the model, a fatigue criterion is also needed. For our material, it is assumed that failure initiation occurs when a given critical energy, E_c is dissipated in an inclusion. As dissipated energy is constant between each stabilized cycles, the critical energy can be expressed in function of the number of cycles to failure, N , and the dissipation in the inclusion, D_i

$$E_c = N(\sigma_{max}, P_F) D_i(\Sigma_\infty(P_F)) f_v V \quad (37)$$

where the dissipation can be expressed as

$$D_i(\Sigma_\infty(P_F)) = \frac{\delta}{C} (\sigma_{max} - \Sigma_\infty(P_F)) \quad (38)$$

with $\Sigma_\infty(P_F)$ the fatigue limit for a given probability of failure

$$\frac{\ln(1 - P_F)}{\ln(1 - 1/2)} = \left(\frac{\Sigma_\infty(P_F)}{\Sigma_\infty(1/2)} \right)^m \quad (39)$$

and $\Sigma_\infty(1/2) = \bar{\Sigma}_\infty \frac{\ln(2)^{\frac{1}{m}}}{\Gamma(1 + \frac{1}{m})} \approx \bar{\Sigma}_\infty = \bar{\Sigma}_\infty^{sh}$.

The number of cycles to failure is then

$$N(\sigma_{max}, P_F) = \frac{E_c C}{f_v V \delta (\sigma_{max} - \Sigma_\infty(P_F))} \quad (40)$$

with parameter $\frac{E_c C}{f_v V \delta}$ identified using number of cycles to failure of highest maximum stress loading.

The corresponding curves are plot and compared to experiment results on figure 6. We can observe a very good agreement between classic fatigue tests results and probability curves determined with self-heating tests and modeling.

Figure 6: Expected maximum stress versus number of cycles to rupture curves with several probability of failure.

4 CONCLUSION

In this paper we describe a method that permits to determine the fatigue properties of NiTi shape memory alloys (mean endurance limit and SNP curves). The benefits of this method are that it only need one sample and results can be obtained in a few hours of tests and post-processing of data, when classic fatigue method would require at least a month of continuous testing. The method is based on a self-heating test and a dedicated modeling of self-heating that permits to identify material parameter m and to relate the number of cycles to failure to the loading maximum stress, the probability of failure and the critical energy.

A validation of the method has been realized by comparing its results from two types of NiTi SMA samples with results of classic fatigue tests.

Abstract. We have developed a method to integrate sensor functionality into metal castings during the casting process. The method allows for cost efficient total integration into the foundry production process, for both iron and aluminium castings. The sensors are added to the casting mould before the molten metal is poured into the mould. Several sensor functionality tests have been performed on the resulting cast metal component. Tests verify that the signals from the integrated sensor have a clear relationship to static or dynamic forces applied to the castings. Tests also indicate that the integrated sensors do not have significant effects on the mechanical properties of the castings, though this need to be tested for each new application. It is expected that specific guidelines for integrated sensor may need to be developed. Our method has advantages compared to both after mounted sensors and more advanced sensors, particularly with regards to cost and robustness, but particularly since they allow for integration in high scale serial production. Hereby these integrated sensors enable any piece of cast metal to be equipped with sensors, which in practice establishes sensor equipped cast metal as an innovation platform for digital business innovation on and for metal components.

The development has been achieved as a spearhead innovation and development project (Smart castings, Dnr 2017-01973) between the RISE - Rise Research Institutes of Sweden, Husqvarna and SKF, with financial support from Vinnova - Sweden's innovation agency.

1 INTRODUCTION

This paper presents the verification of a uniquely new method to integrate sensor functionality into metal castings during the casting process. The verification and method is based on our previous reported work [1-3]. The method allows for cost efficient total integration of sensors into the casting during the foundry casting process while the metal is liquid, in both iron and aluminium castings.

The goal has been to achieve effective and robust digitally active cast metal components, that are low weight and cost efficient. The technology has many potentials, including effective contributions to several of the UN sustainability goals, as well as allows for a revolution of metal-based industry, and for entirely new and widespread applications for embedded robust and cost-efficient sensor systems in machinery, equipment and constructions.

The advantages of adding sensors during the casting, compared to both after mounted sensors and more advanced sensors, regards not only cost and robustness, but particularly because the technology allows for integration in high scale serial production. Hereby these integrated sensors enable any piece of cast metal to be equipped with sensors. In practice this establishes sensor equipped cast metal as an innovation platform for digital business innovation on and for metal components, and not only an innovation in itself.

Technically a full sensor system consists of several subsystem including both the sensor itself as well as signal amplification, filtering and signal analysis in order to obtain the total output signal (see figure 1). The sensor element (sensor material) reacts on an external stimulus (e.g. force) that can be measured using an appropriate sensor method. In order to obtain the total output signal the raw sensor signal generally needs to be amplified and filtered, as well as be processed by some signal analysis (e.g. calibration).

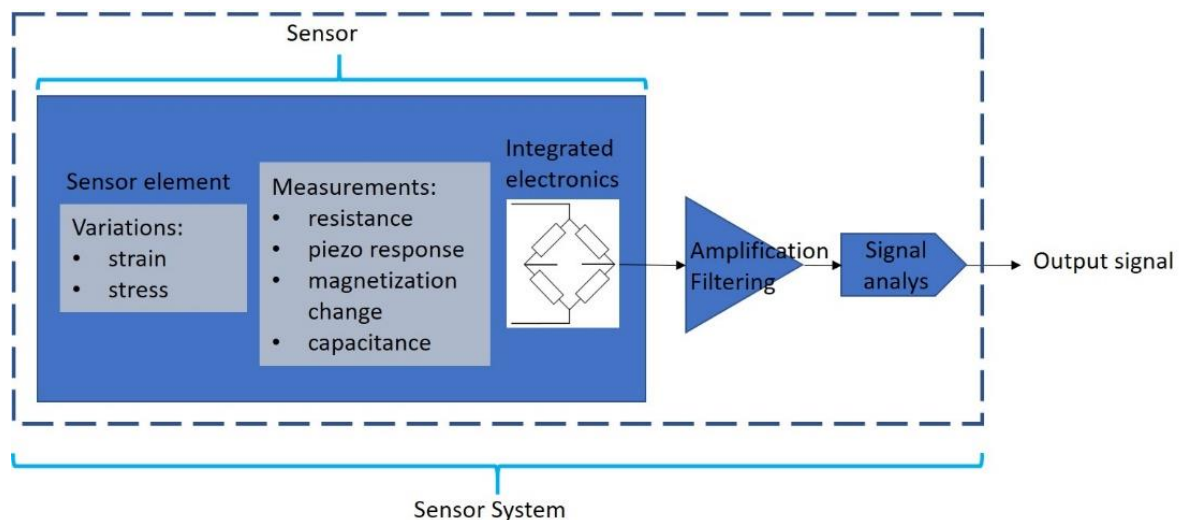

Figure 1: Schematic picture of full sensor system showing the sensor element (including the sensor element and integrated electronics in case of active sensors) and amplification, filtering and signal analysis in order to obtain the total sensor output signal.

In order to measure mechanical properties such as force and strain in metal systems several sensor methods can be used, such as strain gauges, fiber-optics, magnetoelastic and piezoelectric sensors.

Commercial products and previous studies have shown integrated sensors in metal parts after production of the metal parts, for instance of measuring tension in bolts using commercial strain gauge sensors [4] and using piezo-sensors in rock-bolts [5]. Some sensors have been implemented in production processes in ultrasonic 3D printing of the metal parts and, in this case, using fiber-optics [6] for monitoring force and strain. Of course there are sensor methods to monitor the mechanical state by measuring from outside the metal to inside of the metal using no integrated metal parts in the cast metal, i.e. non-destructive evaluation methods (NDE), for instance using eddy-currents [7], or acoustic resonance spectroscopy (ARS) [8] or acoustic emission (AE) [9], but in these cases it is hard to exactly know from where the signal originates from the metal part, as compared to integrated sensor elements at a specific positions and orientations.

To succeed with actually integrating a sensor system in a casting metal during the high temperature casting process (ca 650 C° for aluminium and ca 1500 C° for iron) it is only the sensor element (i.e. sensor material) that can be integrated in the casting metal. The electronics and signal analysis are instead placed outside the cast metal, after the casting and its post-processing is completed. This is the key to this innovative technology. In this paper we present how we have verified that this innovative technology also works in practice, by summarizing how we have developed and verified it.

The work has been achieved as a spearhead innovation and development project between the RISE - Rise Research Institutes of Sweden, and the companies Husqvarna and SKF, with financial support from Vinnova - Sweden's innovation agency.

2 PRINCIPLE

Figure 2 presents a schematic picture of the prototype system together with the integrated thread and its dimensions.

Figure 2: Schematic picture of the integrated metal thread in the aluminium or iron cast metal. The dimensions of the circular part of the prototype and the metal thread are also shown in the figure. The prototypes were

mounted in a tensile testing system that creates a force (F) on the prototype. In the end and start of the above shown cylindrical part of the prototype, mounting parts to the tensile testing system was also constructed (part in the casting process). The signal S is actuated into the metal thread and the resulting force dependent signal $S'(F)$ is measured.

The general approach is to create internal solidified structures for both sensing and traversing sensor signals. Such structures may be introduced as threads of gradually deviating material integrated during the casting process, or as identifiable boundaries between differently solidified areas that are either induced or that naturally arise during the casting process within the cast metal structure. The signal S is any physically induced signal appropriate for the combination of choices of cast metal and thread material and of the application. It is not necessary that S and $S'(F)$ are at opposite ends of the thread. $S'(F)$ may as well be the reflected signal. In this paper we show how we have verified that this simple approach has a technologically large potential. This will enable cast metal components to provide data about e.g. the component's elongation, shear, temperature and vibrations, with purpose to monitor and control systems based on one or several of these components.

3 METHODS

3.1 Metal casting and sensor integration

The sensors are added to the casting mould before the molten metal is poured into the mould. Metallurgical and mechanical tests indicate that the integrated sensors do not have significant effects on the properties of the castings, though this need to be tested for each new application. It is expected that specific guidelines for integrated sensor may need to be developed.

Metal threads are integrated in the casting prototypes during the casting process. The choice of integrated metals was chosen from the melting temperature of the casting material relative to the metal threads. Further, the metal threads were placed in the centre of the prototype and the thread was sticking out a few cm from the cast metal on each side of the integrated thread to be used for actuation and oscillation detection of the threads. Figure 3 shows a set of 12 aluminium prototypes while still in the 3D-printed sand mould, all equipped with different threads of different materials and different casting/thread properties to be tested.

Figure 3: Photo of a set 12 prototype castings with different integrated threads, not yet taken out of the 3D-printed sand mould and rinsed from excessive material.

3.2 Actuation and measurement system

From one side of the integrated metal thread (S in Figure 2) the thread was actuated with mechanical sinusoidal oscillations within a specific frequency range that creates elastic oscillations in the mechanically coupled cast and metal thread system. On the other outer part of the thread from the cast metal (S'(F) in Figure 2) we detected the amplitude of oscillations by a dedicated detection unit that was specially developed in the project. The signals from the detection unit was measured with a lock-in amplifier (LIA) that used the actuating oscillation frequency as a reference signal (see figure 4). The prototypes were mounted in a tensile testing system, so it was possible to subject the casting metal/integrated metal thread system with different forces (F). At sequentially applied force steps the amplitude distribution over a frequency spectrum around the actuation frequency were detected by the Detection unit and the frequency at the peak amplitude was logged.

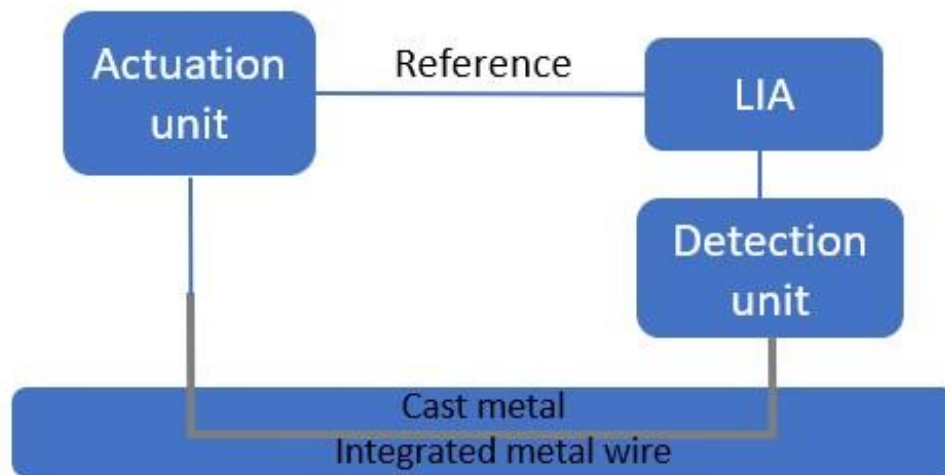

Figure 4: The different parts in the measurement unit to actuate and sense the oscillations of the cast metal and integrated metal thread. The actuation unit and the lock-in-amplifier (LIA) are all controlled by a computer (Labview program).

Furthermore, the developed measurement system was correlated with a laser doppler vibrometer (LDV) system and we found similar result when comparing with the measurement system.

4 RESULT AND DISCUSSION

In Figure 5 oscillation amplitude versus frequency of the aluminium and iron cast metal can be seen at different applied forces to the cast metal system.

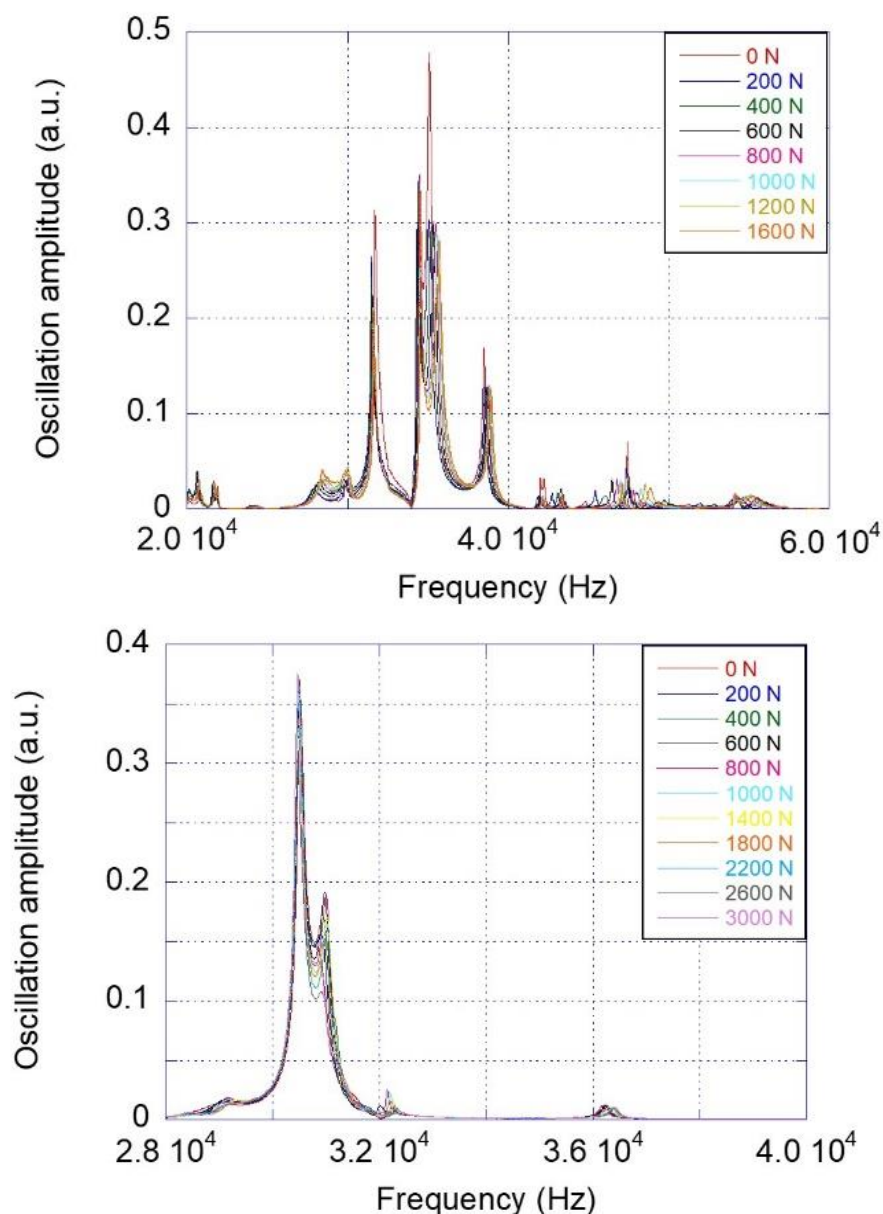

Figure 5: Oscillation amplitude versus excitation frequency for aluminium casting (top) and the iron cast metal (below) at different applied forces to the prototypes (as listed in the legends). The figure shows the spectra were all of the resonance peaks are located in the frequency plane. At lower and higher frequencies compared to the frequencies shown in the figures, no resonance peaks could be found for both aluminium and iron cast metal.

As can be seen in figure 5 at specific frequencies there is an increase in the oscillation amplitudes that is due to mechanical resonances and also that the coupled system cast metal and integrated metal thread, shows a very complex shaped mechanical resonance spectrum. The obtained resonance frequencies at zero applied force correspond somewhat to the frequencies of standing waves in the prototype, using the sound velocities of the cast metal (longitudinal and transversal sound velocities) and wavelengths that corresponds to multiples of the length of the prototype. However, as seen in Figure 3 the resonance frequencies are not evenly spread

in the frequency plane that have been expected if it was an ordinary standing wave phenomenon in the prototype systems.

We noted the similarities between these resonance frequency spectrums and the resonance frequency spectrums of Acoustic Resonance Spectrums (ARS) [8]. We therefore performed experimental tests with discontinual threads (i.e. the thread is cut off inside of the casting, disconnecting the two ends of the integrated thread from each other by a gap that contains only the cast metal) not traversing complete through the cast metal. These results showed that the resonance spectrums were damped in oscillation amplitude as well as constituted by a very different resonance spectrum indicating that the integrated metal thread enhance the resonances and probably that the induced elastic waves is somewhat concentrated to the integrated metal thread. These verifications are not presented in this paper.

When we zoom in on the resonance spectra around 38.4 kHz for the aluminium cast metal and around 36.2 kHz for the iron metal casting the result is shown in Figure 6 and Figure 7.

Figure 6: Oscillation amplitude versus excitation frequency for the aluminium casting (top) around frequencies of 38.4 kHz and the difference in resonance frequencies relative to the resonance frequency at zero force (below) at different applied forces (listed in the legend). The resonance frequency is defined as the frequency where the oscillation amplitude peaks.

Figure 7: Oscillation amplitude versus excitation frequency for the iron casting (top) around frequencies of 36.2 kHz and the difference in resonance frequencies (relative to the resonance frequency at zero force) (below) at different applied forces (listed in the legend). The resonance frequency is defined as the frequency where the oscillation amplitude peaks.

As can be seen in Figure 6 and Figure 7 the resonance frequency increases with applied force for both aluminium and iron cast metal, in a linear behaviour at low forces and a slight non-linear behaviour at higher forces. The resonance frequency change for a specific force change in the linear range is larger for aluminium than compared to iron casting (0.34 kHz/kN for aluminium and 0.1 kHz/kN for iron), which scales almost to the inverse of the elastic modulus for respective cast material (60 GPa for aluminium and 200 GPa for iron). Further, the onset of the non-linearities occurs at lower forces for aluminium than compared to the iron cast metal. In fact, the non-linearities starts at lower forces when comparing to the onset of the non-linearities in the stress-strain curves for respective prototype system. The large amount of increase in resonance frequency when the force is increased cannot be explained by just studying the relative length change of the prototype (i.e. the obtained strain from the applied stress divided with the elastic modulus) and also that the resonance frequency increases for increasing applied forces. From modelling of the prototype (force applied to a cylinder performing transversal oscillations) and Finite-Element (FE) analysis of the prototype we have obtained a linear increase in resonance frequency when increasing the applied force but the change in resonance frequency per applied force is much lower than compared to the experimental obtained values. This can probably be explained by that the change in resonance frequency when the force is applied, is enhanced by the integrated metal thread and that several resonance modes take part in the total resonance process.

At the moment of writing this we are working with decreasing the measurement time using optimal pulsed actuation, continuing the FE analysis in order to understand the resonance

phenomena in more detail and also how to develop the sensing system in more complex casting structures. In this spirit we have implemented the sensing system in an aluminium prototype cast component of a Husqvarna AB product, see Figure 8. Measurements on this cast metal component is in progress.

Figure 8: Implementation of the sensing system where the actuation and detection unit are integrated in the chassis that is connected to the cast metal product.

5 CONCLUSIONS

We have shown that it is possible to integrate metal threads during the cast metal process that together with the host cast metal can be used in a sensing system for measuring mechanical forces in cast metal systems. From the experimentally obtained resonance spectra we have seen that in some parts of the spectrum the change in resonance frequency correlates well with the applied force and can be used to monitor the force in the prototype. Analyzing all measurements presented in figures 5 to 7, the theoretical modelling and the measurements made with a discontinual thread, we believe that we have verified that the large shift in resonance frequency to the applied force shown in figures 5 to 7 is likely to result from the integrated metal thread.

Key words: Iron based Shape Memory Alloys (Fe-SMA), Pseudoelasticity, Dynamic Mechanical Analyzer (DMA), Heat Treatment.

Abstract. Since their discovery, Iron based Shape Memory Alloys (Fe-SMA) have attracted much attention of researchers and industrials thanks to their low cost and excellent workability combined to smart properties such as SME (Shape Memory Effect) and damping capacity [13] due to pseudoelasticity [7]. In this paper, the damping capacity of the Fe-30Mn-6Si-5Cr is investigated through pseudoelasticity characterization by cyclic tensile tests using a tensile machine and a Dynamic Mechanical Analyzer (DMA). Specimens underwent a specific heat treatment in order to improve their properties. At ambient temperature, the studied alloy can be found at different microstructures. In order to define the best alloy initial conditions guaranteeing maximum damping capacity, different types of the alloy microstructures were investigated: purely austenitic state and biphased states (austenite + stress induced and/or thermal martensite). Specimens were studied under different parameters such as vibration frequencies (0.1 Hz, 0.5 Hz, 1 Hz and 5 Hz), pre strain amount (4%, 8% and 14%) and stress amplitudes at different temperatures.

1 INTRODUCTION

High performance and low cost Fe-Mn-Si based alloys are known to be a prospective candidate in civil applications. When deformed, iron based Shape Memory Alloys (SMA) can recover their initial shape by simple heating until a strain amount of 2-4%. This behaviour, called the Shape Memory Effect (SME) [1] or the one way SME, is due to a martensitic transformation stress induced from parent phase austenite FCC (Face Centred Cubic) to

martensite HCP (Hexagonal Close Packed) that can be reversed by heating. In addition, this class of materials has been found to exhibit internal friction and thus have a noticeable damping capacity. These excellent properties combined to good mechanical properties, low cost and excellent workability [2] and weldability[3] made of iron based SMA a good alternative in civil applications.

Authors, with slight differences, have agreed that damping capacity in iron based SMA, arising from internal friction, is associated to $\varepsilon \rightarrow \gamma$ reverse transformation [4] and precisely to the reversible motion of ε/γ interfaces attributed to ε martensite and stacking faults in common [5] which is accomplished by the reversible movement of Shockley partial movement at the tip of the martensite variant[6]. It was also found that pseudoelasticity also called partial super-elasticity is attributed to the reversibility of the γ/ε transformations [7] by the reversible motion of Shockley partial dislocation [8-9]. Besides, some authors attributed it to the existence and formation of stacking faults and the reversible movement of their associated partial dislocations [10]. Thus, damping capacity for iron based SMA can be linked and resulting from pseudoelastic behavior of the material.

The present work aims to assess the damping behaviour arising from the alloy pseudoelasticity. Tensile sinusoidal loading unloading cycles were realised using an electro dynamic testing machine. Hysteretic loops area resulting were measured to characterize the damping behaviour of the studied alloy under different conditions.

The contribution targeted in this study is an optimization establishment of the Fe-30Mn-6Si-5Cr damping behaviour for civil purposes. In this context, and in order to define conditions guaranteeing good damping capacity at service conditions, test were realised under several parameters: Temperature (from ambient to 70 °C), frequency (0.2 Hz to 5 Hz), static pre-strain (4%, 8% and 12%) and stress amplitude.

In this paper, the material, experimental equipment and tests conditions will be described first. Then results and interpretation will be detailed.

2 MATERIAL AND METHODS

The studied alloy is the Fe-30Mn-6Si-5Cr an iron based shape memory alloy obtained from Awaji Company¹. Its precise chemical composition given in table 1 has been determined by an EDS (Energy Dispersive spectroscopy) analysis whose spectrum is illustrated in figure 1.

In order to guaranty a homogeneous austenite structure, the conventional heat treatment that iron based shape memory alloys are subjected to is a 1 hour annealing for 1 hour at 600°C followed by water quenching. When applied to the as received alloy, shape memory effect was not so good. Besides, its martensite start transformation temperature point is a bit low. In order to ameliorate these deficiencies, the alloy has been subjected to a 1 hour annealing at 1050°C followed by water quenching then a second annealing at 600°C for 30 min followed by an air quenching.

¹ AWAJI MATERIA CO., LTD.: a Japanese company with a capital of 80 million yen and specialized in shape memory alloys products manufacturing

Figure 1.EDS spectrum of the alloy studied

Table 1. Chemical composition of the studied SMA iron based in weight percent

Element	Fe	Mn	Si	Cr
Wt (%)	59	29.7	5.9	5.4

Specimens of 1 mm thickness were cut by wire EDM (Electrical Discharge Machining). Their dimensions are as schematised in figure 2. They were subsequently heated for 30min at 600°C to eliminate any possible microstructure modification due to machining.

Figure 2.Test specimen geometry

Tests were realised using a Zwick/Roell LTM1 (1kN) electro dynamic testing machine equipped with a heating cell. As illustrated in figure 3, first phase is a tension loading until a strain percentage of 4, 8 or 12 at a strain rate of $10^{-4}.s^{-1}$. The second consists in 3 sets of 20 sinusoidal cycles of loading unloading between σ_{max} and 0MPa at a given frequency (0.2 Hz, 0.5Hz, 1Hz and 5Hz). In each set, σ_{max} is 100 MPa less than previous one. For example, for a tension loading rate of 4%: $\sigma_{max1} = 350MPa$, $\sigma_{max2}=250 MPa$ and $\sigma_{max3}=150 MPa$.In order to study the damping behaviour at service conditions, tests were done in a variety of temperature from ambient to 60 °C (20, 30, 40, 50 and 70°C).

Figure 3. Test phases diagram

3 ANALYSIS CONCEPT

Among several metric characterization methods of damping capacity in literature, in this paper, the energy loss during loading unloading cycles [11] that is in our case revealed by hysteretic loops areas has been adopted. Therefore, we used this method in order to characterize the damping capacity of the studied alloy at different parameters. The loops area resulted during loading unloading cycles have been measured at each cycle in all tests. In fact, it represents the energy dissipated during loading unloading due to the alloy pseudoelasticity.

4 RESULTS AND DISCUSSION

4.1. EFFECT OF FREQUENCY

As illustrated in figures (4, 5 and 6), loops area decrease while cycling progressing up to a stable average of 75% of first loop area (frequency 0.2Hz and 0.5Hz in figure 4).

Figure 4. Loops area measures during 19 sinusoidal tension loading unloading (400 MPa) cycles at ambient temperature for 0.2 Hz and 0.5 Hz test frequency on 4% pre strained specimen

Cycling tests of tension loading unloading ($\sigma_{\max}=320$ MPa) performed on a 4% tensile pre strained specimen at ambient temperature with different frequencies: 0.2 Hz and 0.5 Hz showed respectively stabilised loops area values of 14.6 (MPa.%) and 9 (MPa.%). Hence, the frequency affects noticeably the damping behaviour of the alloy. It decreases with frequency increase.

4.2. EFFECT OF STRESS AMPLITUDE

Tests performed at 4% tensile pre strained specimen at ambient temperature and 0.5 Hz cycling frequency showed that loops area increase with stress amplitude increase. Tests with different stress amplitudes (350 MPa, 250 MPa, and 150 MPa) realised on the same specimen revealed that the loops area stabilised value is respectively 19, 4.3, and 0.5 (MPa.%) (see figure 5). Likewise, tests done separately with same frequency, pre strain and temperatures values with different stress amplitude showed that loops area value increases with stress amplitude: 19 and 21.5 (MPa.%) for respectively 400 MPa and 350 MPa (see figure 6).

In fact, when stress is above a critical value, the damping capacity of iron based shape memory alloys is coming from the breaking away of Shockley partial dislocations. Therefore, with the stress increasing, the amount of Shockley partial dislocations that possibly can break away from pinning points increases quickly, thus the alloy internal friction increases sharply [12]. Consequently, the damping behaviour is enhanced by stress amplitude increase as shown in figure 5 and 6.

Figure 5. Loops area measures during 19 sinusoidal tension loading unloading cycles at ambient temperature for 0.5 Hz test frequency on 4% pre strained specimen with 3 stress amplitudes: 350 MPa, 250 MPa and 150 MPa during the same test (internal loops).

Figure 6. Loops area measures during 19 sinusoidal tension loading unloading cycles at ambient temperature for 0.2 Hz test frequency on separate specimens 4% pre strained at 2 stress amplitudes: 400 MPa and 350 MPa.

5 CONCLUDING REMARKS:

From this preliminary study, it was found that the pseudoelastic damping behaviour of the Fe-30Mn-6Si-5Cr assessed from loops area tensile cycles during dynamic test decreases until stabilizing at 75% of its first cycle value.

Furthermore, it increases considerably with cycles stress amplitude increase.

Moreover, it was clearly observed that frequency has a determinate impact on the damping behaviour of the studied alloy, it decrease obviously with frequency increase.

This preliminary study is been actually continuing experimentally with more details: frequencies higher, various microstructures and temperature influence and will be joined very soon. This study will allow setting an optimization of the pseudoelastic damping behaviour of the studied alloy.

Key words: Vibration damping, Electromagnetic and piezoelectric shunt damping, Smart Structures

Abstract. Electromagnetic (series) RC and piezoelectric (parallel) RL shunt damping can both be represented by an equivalent mechanical vibration absorber with a spring, dashpot and inerter in series. A common calibration procedure for these electromechanical shunt dampers is therefore obtained from this mechanical equivalence. It includes the influence from residual vibration modes of the flexible structure via an augmented modal representation of the absorber motion with two additional correction terms that are explicitly calibrated from the natural frequencies associated with fully locked absorber dashpots. Furthermore, the mechanical equivalence between the two shunt dampers implies that the electromagnetic shunt can be directly calibrated from principles derived for a piezoelectric shunt, and vice versa. The theory is expanded to multiple vibration absorbers targeting a single resonant vibration mode and the numerical examples demonstrate that accurate absorber calibration is obtained.

1 INTRODUCTION

Electromechanical transducers may be installed in vibrating structures to mitigate excessive dynamic response due to for example resonant loading by dissipation in supplemental shunts. For piezoelectric transducers, the concept of *RL* shunt damping was propelled by [1] and [2], analyzing and calibrating series and parallel *RL* shunts, respectively. Various calibration strategies for both series and parallel *RL* shunts have been derived based on different optimization criteria [3, 4, 5]. The electromechanical coupling effect is also available in electromagnetic transducers, for which calibration of a series *RC* shunt has been a recent research problem [6, 7, 8].

In several cases the calibration of electromagnetic series *RC* shunts has been based on the calibration principles by [1] for piezoelectric series *RL* shunts. However, as demonstrated in the present paper, a mechanical analogy instead exists between the electromagnetic series *RC* and the parallel *RL* shunt for piezoelectric transducers. And therefore a common calibration procedure for these two electromechanical systems is provided. Initially, the governing equations for electromagnetic and piezoelectric shunt damping are summarized and a common vibration absorber is proposed, with a spring, dashpot and inerter placed in series. Both electromechanical shunt dampers can therefore be consistently calibrated based on the tuning principles for the equivalent mechanical vibration absorber. The influence from the residual vibration modes of the flexible structure is represented by an augmented modal representation adopted from [9, 10], where the correction terms can be adjusted using the natural frequencies of the structure for infinite absorber damping. These limiting frequencies can be determined numerically or

even experimentally, and as demonstrated the correction procedure is accurate for multiple vibration absorbers acting on a flexible structure.

2 ELECTROMECHANICAL SYSTEMS

The mechanical properties of electromechanical transducers are in the following described with respect to a physical displacement (elongation) x across the apparent transducer terminals. For an electromagnetic transducer the displacement x directly represents the relative motion of the coil, with a force $f = K_m I$ proportional to the current I in the wire by the electromechanical coupling coefficient (motor constant) K_m . For a piezoelectric transducer, x represents the apparent deformation obtained by the integration of the corresponding strain over the effective transducer length and the force $f = K_p V$ is instead proportional to the voltage with K_p representing the effective coupling coefficient. In the following harmonic motion is assumed, with a temporal dependence represented by the factor $\exp(i\omega t)$, where i is the imaginary unit, ω is the angular frequency and t is time.

2.1 Electromechanical shunt damping

The aim of the shunt damping concept is to formulate a common resonant absorber format for electromagnetic and piezoelectric transducers. The transducer models contain intrinsic damping, represented by an equivalent resistor, whereby the resulting absorber damping is comprised of intrinsic and shunt contributions. The equivalent mechanical absorber model is shown in Fig. 1(a), with a spring k , viscous dashpot c and inerter m placed in series, whereby its mechanical flexibility relation can be written as

$$x = \left(\frac{1}{k} + \frac{1}{i\omega c} - \frac{1}{\omega^2 m} \right) f \quad (1)$$

As demonstrated in the following, the stiffness k and damping c are composed of contributions from both the transducer and the supplemental shunt, while the absorber inertance $m = m_s$ is entirely realized by the shunt. It is demonstrated that resonant shunts can be formulated for both electromagnetic and piezoelectric transducers that in theory retain the series absorber model in Fig. 1(a).

2.1.1 Electromagnetic transducer

The electrical load applied by the moving coil inside an electromagnetic transducer is represented by an alternating voltage source $V_m = i\omega K_m x$, proportional the velocity amplitude $i\omega x$ of the transducer

Figure 1: (a) Desired mechanical absorber, (b) electromagnetic shunt absorber and (c) effective modal absorber.

Figure 2: Electric network for (a) electromagnetic and (b) piezoelectric transducer with shunt $Z(\omega)$.

deformation. When the transducer terminals are shorted, the current I in the coil is governed entirely by its inherent electrical impedance, which can be represented by an inductance L_m and a resistance R_m , as illustrated in Fig. 2(a). The desired damping is introduced by a supplemental shunt with impedance $Z_m(\omega)$, defined by $V = Z_m(\omega)I$, where V is the voltage across the terminals. The amplitude of the voltage source V_m can now expressed both in terms of the structural motion and the electrical network,

$$V_m = i\omega K_m x = (R_m + i\omega L_m + Z_m(\omega))I \quad (2)$$

The latter relation then determines an apparent mechanical flexibility relation

$$x = \left(\frac{L_m}{K_m^2} + \frac{R_m}{i\omega K_m^2} + \frac{Z_m(\omega)}{i\omega K_m^2} \right) f = \left(\frac{1}{k_m} + \frac{1}{i\omega c_m} + \frac{1}{i\omega h_m(\omega)} \right) f \quad (3)$$

defining an apparent spring stiffness, viscous coefficient and frequency dependent damping coefficient,

$$k_m = \frac{K_m^2}{L_m}, \quad c_m = \frac{K_m^2}{R_m}, \quad h_m(\omega) = \frac{K_m^2}{Z_m(\omega)} \quad (4)$$

as shown in Fig. 1(b). Thus, the impedance $Z(\omega)$ must be constructed so that the frequency dependent viscous parameter $h_m(\omega)$ provides the necessary inertance m to recover the series absorber in Fig. 1(a).

2.1.2 Piezoelectric transducer

For the piezoelectric transducer the induced electrical loading from local straining velocity amplitude $i\omega x$ is described by the current source $I_p = i\omega K_p x$, as shown in Fig. 2(b). The piezoelectric material is dielectric and when covered by electrodes it exhibits a substantial capacitance C_p placed in parallel with the current source I_p . Furthermore, an intrinsic loss of energy from hysteresis may be represented by an equivalent resistance R_p , whereby the resulting transducer model is governed by the network in Fig. 2(b). The current I is now expressed by the impedance relation $V = Z_p(\omega)I$ for the shunt in Fig. 2(b) with impedance function $Z_p(\omega)$. The current source I_p can be expressed in terms of either the mechanical straining or the transducer network model in Fig. 2(b), whereby

$$I_p = i\omega K_p x = \left(i\omega C_p + \frac{1}{R_p} + \frac{1}{Z_p(\omega)} \right) V \quad (5)$$

As for the electromagnetic transducer, the latter equality determines an equivalent mechanical model

$$x = \left(\frac{1}{K_p^2 C_p^{-1}} + \frac{1}{i\omega K_p^2 R_p} + \frac{1}{i\omega K_p^2 Z_p(\omega)} \right) f = \left(\frac{1}{k_p} + \frac{1}{i\omega c_p} + \frac{1}{i\omega h_p(\omega)} \right) f \quad (6)$$

defining the stiffness, viscous damping and shunt damping function as

$$k_p = K_p^2 C_p^{-1}, \quad c_p = K_p^2 R_p, \quad h_p(\omega) = K_p^2 Z_p(\omega) \quad (7)$$

This model corresponds to that in Fig. 1(b) for the electromagnetic transducer, when replacing subscript m by p .

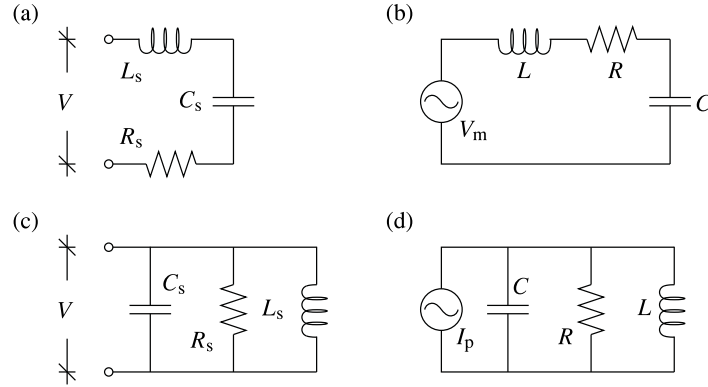

Figure 3: Shunts (a,c) and resulting circuits (c,d) for electromagnetic (a,c) and piezoelectric (b,d) transducers.

2.2 Resonant vibration absorber

The viscous transfer functions $h_m(\omega)$ and $h_p(\omega)$ are constructed to recover the desired series absorber in Fig. 1(a). For both transducers, the supplemental shunt must therefore provide the supplemental inertance m , while the introduction of additive stiffness and damping elements yields a more flexible absorber design, as for example negative shunt components have become more recognized [11].

2.2.1 Electromagnetic shunt

An equivalence between the series shunt absorbers in Fig. 1(a) and (b) is obtained by the shunt in Fig. 3(a), with shunt inductance L_s , resistance R_s and capacitance C_s connected in series. When introducing this shunt impedance $Z_m(\omega)$ into the network in Fig. 2(a), the resulting circuit for the shunt electromagnetic transducer is shown in Fig. 2(b), with resulting components

$$L = L_m + L_s, \quad R = R_m + R_s, \quad C^{-1} = C_s^{-1} \quad (8)$$

The equivalent mechanical components k , c and m of the series vibration absorber in Fig. 1(a) are subsequently obtained as summarized in Table 1.

Table 1: Mechanical vibration absorber parameters.

Absorber	Electromagnetic	Piezoelectric
k	$\frac{K_m^2}{L_m + L_s}$	$K_p^2 \frac{C_p^{-1} C_s^{-1}}{C_p^{-1} + C_s^{-1}}$
c	$\frac{K_m^2}{R_m + R_s}$	$K_p^2 \frac{R_p R_s}{R_p + R_s}$
m	$\frac{K_m^2}{C_s^{-1}}$	$K_p^2 L_s$

2.2.2 Piezoelectric shunt

For piezoelectric shunt damping the desired equivalence with the mechanical vibration absorber is obtained by the shunt in Fig. 3(c), with shunt components L_s , R_s and C_s placed in parallel. The resulting circuit model for the shunted piezoelectric transducer is therefore as shown in Fig. 2(d), with

$$\frac{1}{C^{-1}} = \frac{1}{C_p^{-1}} + \frac{1}{C_s^{-1}} \quad , \quad \frac{1}{R} = \frac{1}{R_p} + \frac{1}{R_s} \quad , \quad L = L_s \quad (9)$$

and equivalent mechanical components given in the last column of Table 1. It is found that increasing values of C_s^{-1} , R_s and L_s result in increasing mechanical parameters k , c and m , respectively. For piezoelectric transducers the inverse of the inherent capacitance C_p^{-1} is notoriously small for low-frequency vibrations and the required shunt inductance L_s must therefore be realized synthetically.

3 STRUCTURAL DYNAMICS

A mechanical vibration absorber may be calibrated based on a suitable compromise between maximum damping in the targeted vibration mode and minimum response amplitude when the structure is excited near the corresponding resonance frequency [1, 12]. However, for absorbers placed locally on a flexible structure, the interaction with non-resonant or residual vibration modes may be taken into account [9]. In the following, an augmented modal representation of the absorber displacement contains additional terms that represent the additional contributions from the residual modes.

3.1 Dynamic equations

In a frequency domain formulation, the equations of motion for a flexible structure can be written as

$$(-\omega^2 \mathbf{M} + \mathbf{K})\mathbf{u} + \mathbf{W}\mathbf{f} = \mathbf{f}_e \quad (10)$$

where \mathbf{u} contains the complex response amplitude, \mathbf{f}_e represent the external loading, whereas \mathbf{M} and \mathbf{K} are mass and stiffness matrices, respectively (omitting structural damping). The vector \mathbf{f} represents the transducer forces, at individual locations on the structure determined by the columns in the participation array \mathbf{W} . Figure 4 shows a classic 10-storey shear frame with absorbers in storeys 1, 2 and 6, whereby the participation array \mathbf{W} contains three columns, as further demonstrated in the numerical example.

It is assumed that all (three) absorbers are governed by the flexibility relation (1) associated with the same mechanical model in Fig. 1(a). The deformation across the series vibration absorbers is contained

Figure 4: Shear frame structure with three vibration absorbers at storeys 1, 2 and 6, respectively.

in the vector $\mathbf{x} = \mathbf{W}^T \mathbf{u}$, whereby the mechanical relation for multiple absorbers can be written as

$$\mathbf{x} = \mathbf{W}^T \mathbf{u} = \left(\frac{1}{k} + \frac{1}{i\omega c} - \frac{1}{\omega^2 m} \right) \mathbf{f} \quad (11)$$

Hereby all transducers simultaneously target the same structural resonance. The closed-loop equations (10) to (11) can now be written in block matrix format as

$$\left(-\omega^2 \begin{bmatrix} \mathbf{M} & \mathbf{0} \\ -m\mathbf{W}^T & m\mathbf{I} \end{bmatrix} + i\omega \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0}^T & \frac{km}{c}\mathbf{I} \end{bmatrix} + \begin{bmatrix} \mathbf{K} & k\mathbf{W} \\ \mathbf{0}^T & k\mathbf{I} \end{bmatrix} \right) \begin{bmatrix} \mathbf{u} \\ \mathbf{f}/k \end{bmatrix} = \begin{bmatrix} \mathbf{f}_e \\ \mathbf{0} \end{bmatrix} \quad (12)$$

The homogeneous form is used in the subsequent numerical example to obtain complex root trajectories.

3.2 Modal properties

The modal characteristics of the flexible structure are determined from the homogeneous form of (10) without absorbers ($\mathbf{f} = \mathbf{0}$),

$$(-\omega_j^2 \mathbf{M} + \mathbf{K}) \mathbf{u}_j = \mathbf{0} \quad (13)$$

governing the real-valued natural frequency ω_j and mode shape vector \mathbf{u}_j . This eigenvalue problem therefore corresponds to the open-circuit limit ($I = 0$) for the electromagnetic transducer, while for the piezoelectric transducer it oppositely corresponds to shorted electrodes ($V = 0$). The vibration amplitude is represented by an expansion in the mode shape vectors,

$$\mathbf{u} = \sum_j \frac{\mathbf{u}_j}{v_j} u_j \quad , \quad v_j^2 = \mathbf{u}_j^T \mathbf{W} \mathbf{W}^T \mathbf{u}_j \quad (14)$$

where the individual vibration modes are conveniently normalized by the square root of the corresponding modal strain energy factor v_j^2 .

In the following the vibration absorbers are calibrated with respect to a single resonant vibration mode $j = r$, with modal equation obtained by substitution of (14) into (10) followed by pre-multiplication with \mathbf{u}_r^T / v_r ,

$$(-\omega^2 m_r + k_r) u_r + f_r = f_r^e \quad (15)$$

The modal mass, stiffness, load and modal absorber force are given as

$$m_r = \frac{1}{v_r^2} \mathbf{u}_r^T \mathbf{M} \mathbf{u}_r \quad , \quad k_r = \frac{1}{v_r^2} \mathbf{u}_r^T \mathbf{K} \mathbf{u}_r \quad , \quad f_r^e = \frac{1}{v_r} \mathbf{u}_r^T \mathbf{f}_e \quad , \quad f_r = \frac{1}{v_r} \mathbf{u}_r^T \mathbf{W} \mathbf{f} \quad (16)$$

where f_r comprises modal contributions from each individual absorber targeting mode $j = r$.

3.3 Augmented modal representation

As demonstrated in [9] the interaction with residual modes can be accurately represented by the augmented representation of the modal displacement

$$\mathbf{x}_r = v_r^{-1} \mathbf{W}^T \mathbf{u}_r u_r = \mathbf{x} + \left(\frac{1}{\kappa_r' k_r} - \frac{1}{\mu_r' m_r \omega^2} \right) \mathbf{f} \quad (17)$$

where $\mathbf{x}_r = v_r^{-1} \mathbf{W}^T \mathbf{u}_r u_r$ is the absorber deformation from the resonant mode $j = r$. The terms in the parenthesis represent modal flexibility and inertia from non-resonant residual modes, constituting the

discrepancy between \mathbf{x} and \mathbf{x}_r . First the absorber displacement \mathbf{x} is eliminated by (11), while the equation is subsequently pre-multiplied by $\mathbf{v}_r^{-1} \mathbf{u}_r^T \mathbf{W}$. Hereby, the last equality in (17) can be written as

$$u_r = \left(\frac{1}{\kappa_r k_r} + \frac{1}{i\omega \beta_r \sqrt{k_r m_r}} - \frac{1}{\mu_r m_r \omega^2} \right) f_r \quad (18)$$

introducing the modal stiffness ratio κ_r , mass ratio μ_r and damper ratio as

$$\frac{1}{\kappa_r} = \frac{k_r}{k} + \frac{1}{\kappa'_r}, \quad \frac{1}{\mu_r} = \frac{m_r}{m} + \frac{1}{\mu'_r}, \quad \beta_r = \frac{c}{\sqrt{k_r m_r}} \quad (19)$$

Thus, the correction parameters κ'_r and μ'_r represent changes to the actual single mode stiffness and mass ratios, respectively. The mechanical model associated with the modal deflection u_r is shown in Fig. 1, while the corresponding scalar equations (15) and (18) now govern the vibrations of mode $j = r$.

4 Residual mode parameters and design procedure

The modal correction coefficients κ'_r and μ'_r are determined to secure the correct modal properties of the full flexible structure with rigid absorber dashpots associated with $c \rightarrow \infty$ for all absorbers. The coupled equations (12) are in this limit reduced to

$$\left(\begin{bmatrix} \mathbf{K} & \tilde{k}\mathbf{W} \\ \mathbf{0}^T & \tilde{k}\mathbf{I} \end{bmatrix} - \omega^2 \begin{bmatrix} \mathbf{M} & \mathbf{0} \\ -\tilde{m}\mathbf{W}^T & \tilde{m}\mathbf{I} \end{bmatrix} \right) \begin{bmatrix} \mathbf{u} \\ \mathbf{f}/\tilde{k} \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \end{bmatrix} \quad (20)$$

where $(\tilde{\cdot})$ refers to representative estimates of the absorber parameters.

Assume that N_a absorbers are placed on the flexible structure and initially calibrated independently with respect to the targeted vibration mode $j = r$. When the $(\tilde{\cdot})$ -parameters are chosen sufficiently accurate, it is possible from the above eigenvalue problem (20) to identify $N_a + 1$ natural frequencies associated with the targeted mode $j = r$. The present procedure relies on the fact that two of these frequencies are associated with coupled absorber-structure vibrations, while the remaining $N_a - 1$ frequencies represent redundant absorber modes with significant damping. For the 10-storey shear frame building in Fig. 4, with three absorbers attached, the root locus diagram is shown in Fig. 5, where the two trajectories from ω_A and ω_B govern the dynamics of the flexible structure, while the remaining two poles approach the imaginary axis along a central backbone locus from ω_C . The residual mode parameters κ'_r and μ'_r may thus be calibrated to recover ω_A and ω_B in the limit $c \rightarrow \infty$ (for all absorbers).

The free vibration characteristics of the targeted vibration mode are governed by the roots of the characteristic equation, represented by the denominator of the modal frequency response function $u_r k_r / f_r^e$ obtained by eliminating f_r between (15) and (18). For vanishing damping by $\beta_r \rightarrow \infty$, the characteristic equation reduces to

$$\tilde{\mu}_r \left(\frac{\omega}{\omega_r} \right)^4 - \left[(1 + \tilde{\kappa}_r) \tilde{\mu}_r + \tilde{\kappa}_r \right] \left(\frac{\omega}{\omega_r} \right)^2 + \tilde{\kappa}_r = 0 \quad (21)$$

The two roots $\omega^2 = \omega_A^2$ and ω_B^2 to this quadratic equation are obtained from the eigenvalue problem (20) with absorber stiffness $k = \tilde{k}$ and inertance $m = \tilde{m}$. The stiffness ratio $\tilde{\kappa}_r$ and mass ratio $\tilde{\mu}_r$ can therefore be determined from (21). The sum and product of the two roots can be written as

$$\left(\frac{\omega}{\omega_r} \right)_A^2 + \left(\frac{\omega}{\omega_r} \right)_B^2 = 1 + \tilde{\kappa}_r + \frac{\tilde{\kappa}_r}{\tilde{\mu}_r}, \quad \left(\frac{\omega}{\omega_r} \right)_A^2 \left(\frac{\omega}{\omega_r} \right)_B^2 = \frac{\tilde{\kappa}_r}{\tilde{\mu}_r} \quad (22)$$

Figure 5: Trajectories for resonant mode $r = 1$ of shear frame in Fig. 4 with three identical absorbers.

Elimination of the ratio $\tilde{\kappa}_r/\tilde{\mu}_r$ determines the apparent stiffness ratio $\tilde{\kappa}_r$, while the mass ratio is then obtained from the latter equation. The two parameter ratios are obtained as

$$\tilde{\kappa}_r = \left[1 - \left(\frac{\omega}{\omega_r} \right)_A^2 \right] \left[\left(\frac{\omega}{\omega_r} \right)_B^2 - 1 \right] \quad , \quad \tilde{\mu}_r = \left[1 - \left(\frac{\omega_r}{\omega} \right)_B^2 \right] \left[\left(\frac{\omega_r}{\omega} \right)_A^2 - 1 \right] \quad (23)$$

The correction coefficients κ'_r and μ'_r can finally be determined from the definitions in (19) as

$$\frac{1}{\kappa'_r} = \frac{1}{\tilde{\kappa}_r} - \frac{k_r}{\tilde{k}} \quad , \quad \frac{1}{\mu'_r} = \frac{1}{\tilde{\mu}_r} - \frac{m_r}{\tilde{m}} \quad (24)$$

The parameters \tilde{m} and \tilde{k} are conveniently obtained by simply applying the classic tuning without residual mode correction.

Some of the most common calibration formulae are summarized in Table 2, whereby the estimates $m = \tilde{m}$ and $k = \tilde{k}$ follow directly from (19) when $\kappa'_r = 0$ and $\mu'_r = 0$. In the present case, the bottom expressions with a ‘balanced calibration’ and equal modal damping is applied, whereby a desired supplemental damping ratio ζ_{des} is a suitable design parameter [13]. It follows from [5] that the corresponding modal stiffness ratio is $\kappa_r = 8\zeta_{\text{des}}^2$, whereby the mass and damper ratio are subsequently obtained by

$$\mu_r = \kappa_r \quad , \quad \beta_r = \sqrt{\frac{1}{2}\kappa_r} \quad (25)$$

Table 2: Calibration formulae for vibration absorber.

Principle	μ_r	β_r
Minimum amplitude [2]	$\frac{\kappa_r}{1 - \frac{1}{2}\kappa_r}$	$\sqrt{\frac{1}{2}\kappa_r}$
Fixed point [4]	$\frac{\kappa_r}{1 - \frac{1}{2}\kappa_r}$	$\sqrt{\frac{2}{3}\kappa_r}$
Maximum damping [3]	κ_r	$\sqrt{\frac{1}{4}\kappa_r}$
Balanced calibration [5]	κ_r	$\sqrt{\frac{1}{2}\kappa_r}$

Table 3: Design procedure for shunt damping.

1)	Determine κ_r
2)	Determine μ_r and β_r from Table 2
3)	Determined \tilde{k} and \tilde{m} from (26)
4)	Determine $(\omega/\omega_r)_{A,B}$ by solving (20)
5)	Determine $\tilde{\kappa}$ and $\tilde{\mu}$ from (23)
6)	Determine κ'_r and μ'_r from (24)
7)	Determine k , m and c from (19)
8)	Determine L_s , R_s and C_s from Table 1

Next the preliminary absorber parameters are determined as

$$\tilde{k} = \kappa_r k_r, \quad \tilde{m} = \mu_r m_r \quad (26)$$

without influence from the, yet to be determined, correction ratios κ'_r and μ'_r . Now the frequency ratios $(\omega/\omega_r)_A$ and $(\omega/\omega_r)_B$ are determined from (20) or from measurements on the actual structure, whereby $\tilde{\kappa}_r$ and $\tilde{\mu}_r$ are obtained by (23). Thus, the residual mode coefficients μ'_r and κ'_r can finally be obtained by the expressions in (24). The design procedure is summarized in Table 3.

5 Damping of shear frame

The shear frame structure in Fig. 4 is used to demonstrated the design procedure. Figure 6 shows the first three vibration modes of the shear frame with absorber locations represented by the red inter-storey crosses. At each storey the figure provides the local modal mass ratio m_s/m_j^* , where m_s is the total translational mass of the structure, while m_j^* represents the modal mass determined by (16a) for a single absorber placed within the specific storey. Absorbers are optimally placed where this mass ratio is large, resulting in the absorber locations inside storeys 1, 2 and 6, as indicated in the figure. For identical sizing

Figure 6: Modes $j = 1$ to 3 with mass ratio m_s/m_j^* obtained for a single absorber placed at the particular storey.

Table 4: Absorber parameters for shear frame modes $r = 1$ to 3, with $\mu_r = \kappa_r = 0.02$ and $c/\sqrt{k_r m_r} = 0.10$.

r	κ'_r	μ'_r	k/k_r	m/m_r
1	0.7792	19.616	0.0205	0.0200
2	0.5632	3.3588	0.0207	0.0201
3	3.0608	16.171	0.0201	0.0200

of the absorbers, the participation array becomes

$$\mathbf{W}^T = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 \end{bmatrix}$$

The modal mass ratio m_s/m_r , with m_r in (16a) obtained for this participation array, is determined for the first three vibration modes as $m_s/m_1 = 0.1024$, $m_s/m_2 = 0.8198$ and $m_s/m_3 = 1.3954$, which corresponds to the sum of the individual mass ratios in Fig. 6.

Three calibration cases are considered, in which the three vibration absorbers are jointly calibrated with respect to target modes $r = 1, 2$ and 3 , respectively. In all three cases the desired damping ratio is $\zeta_{\text{des}} = 0.05$, whereby the modal stiffness ratio $\kappa_r = 8\zeta_{\text{des}}^2 = 0.02$, whereas $\mu_r = \kappa_r = 0.02$ follows from the bottom row of in Table 2. The residual mode parameters for the three cases are given in Table 4, from which it is seen that the residual mode flexibility κ'_r has the greater impact on the absorber calibration. It is seen that the residual mode correction implies a 3.5% increase of k for damping of mode $r = 2$.

Table 5 presents the six damping ratios associated with the first three vibration forms of the shear frame when the targeted mode is $r = 1, 2$ and 3 , respectively. The first three columns represent the damping ratios obtained with the proposed calibration procedure, while the last three columns are obtained without residual mode correction ($\kappa'_r = 0$ and $\mu'_r = 0$). Because $N_a = 3$, four of the six modes in each column of the table are associated with the resonant vibration form $j = r$, while the remaining two damping ratios represent the damping introduced to the two other (non-targeted) vibration forms ($j \neq r$). The damping ratios are ordered with respect to ascending frequency and the values for the targeted mode are highlighted in boldface. The first and last damping ratios for the specific target mode are associated with structural vibrations, while the two intermediate damping ratios represent the redundant absorber modes. For the calibration with residual mode correction (first three columns), the damping ratios of the two structural modes are almost exactly equal to the desired value $\zeta_{\text{des}} = 0.05$, while the pure absorber modes are highly damped with damping ratios that are approximately twice the desired value. The two non-targeted modes are virtually unaffected by the presence of the absorbers. Without residual mode correction (last three columns), the two structural modes are not equally damped and for the three cases

Table 5: Damping ratios for first three modes, with and without residual mode correction.

Figure 7: Complex root trajectories for resonant mode $r = 1$ of shear frame structure with three identical vibration absorbers. Balanced calibration with residual mode correction.

the reduction in damping ratio is 13.2%, 16.0% and 3.4%, respectively.

Figure 7 shows the complex trajectories of the four modes associated with the first vibration form ($r = 1$). The (red) markers indicate the real-valued frequencies ω_A (○), ω_B (□) and ω_C (×) introduced in connection with Fig. 5, which are all slightly lower than the corresponding frequencies in Fig. 7 for the optimally calibrated set of vibration absorbers. Furthermore, the two outer trajectories in Fig. 7 meet at the bifurcation point, indicating that an optimal balance is found between the two modes [5]. The asterisks (*) represent the complex poles associated with the optimal damper calibration $\beta_r = 0.1$, based on $\mu_r = \kappa_r = 0.02$. For the outer trajectories associated with structural vibrations, the two complex roots (*) are located with sufficient separation from the bifurcation point, to avoid undesirable vibration amplification at resonance, while the two (almost coinciding) redundant poles on the backbone curve appear well above the bifurcation point.

6 CONCLUSION

The mechanical equivalence between parallel RL shunt damping with piezoelectric transducers and series RC shunt damping by electromagnetic transducers is used to formulate a common vibration absorber format that contains a spring, dashpot and inerter placed in series. Thus, optimal calibration is obtained simultaneously for both transducer types when determining the desired properties of this representative vibration absorber. Furthermore, the equivalence implies that tuning results derived for piezoelectric (parallel) RL shunt damping can be directly used for electromagnetic (series) RC shunt damping. The theory is subsequently extended to multiple vibration absorbers acting on a flexible structure with multiple vibration modes, although only targeting a single dominant vibration form. For transducers acting locally on the flexible structure, the absorber calibration is often distorted by the interaction with residual vibration modes not targeted by the set of shunt dampers. A simple correction principle is however devised, in which the natural frequencies of the structure with fully locked absorber dashpots are used to determine two correction coefficients, which represent the interaction with the residual modes. For piezoelectric shunt damping these limiting frequencies are associated with infinite (shunt) resistance, while in the case of electromagnetic shunt damping they are determined for vanishing resistance. The frequencies are readily obtained numerically from a mathematical model of the structure, while in experimental analysis the presence of intrinsic damping (represented by R_m or R_p) might slightly deteriorate the determination of the correction coefficients. The accuracy and robustness of the shunt calibration procedure is verified by a numerical example.

Abstract. Several solutions for multimodal vibration damping of thin mechanical structures based on piezoelectric coupling have been developed over the years. Among them, piezoelectric network damping consists in using piezoelectric transducers to couple a structure to an electrical network, where the transferred electrical energy can be dissipated. In particular, the effectiveness of coupling rods, beams and plates to networks which are their electrical analogues has been proven. This work is the first step going towards more complex structures. After defining and experimentally validating a new electrical analogue of a simply-supported plate, the study is extended to the damping of a non-periodic plate. Experiments show that in this case, a broadband damping is achieved once the piezoelectric transducers are coupled to an adequate analogous network. A finite element model of the structure coupled to its analogous network is concurrently developed and validated.

1 INTRODUCTION

Single mode damping of mechanical vibrations using the piezoelectric coupling goes back to the 1990s, when the resonant shunt was described by Hagood and Von Flotow [1]. The concept of piezoelectric damping has then been extended to multimodal damping. Some passive solutions consider connecting a multi-branch shunt to a piezoelectric transducer [2, 3]. While adding only one piezoelectric transducer to the structure is barely intrusive, its position and dimensions cannot simultaneously maximize the electromechanical coupling for all modes [4]. For these reasons, the damping performance might be limited. Other solutions include several independent piezoelectric transducers, each one being shunted in order to damp one mode of the structure. However, the resulting electromechanical coupling coefficients are inferior to the ones that would be induced by interconnecting all piezoelectric transducers.

In the early 2000s, the idea of interconnecting piezoelectric transducers with electrical components emerged. The concept of achieving broadband damping by coupling a structure to an electrical network was first proposed by Vidoli and dell'Isola [5]. Meanwhile, the electrical analogues of mechanical structures, as defined by MacNeal and Bescoter [6, 7] in the early 1950s, have been revived for multimodal vibration attenuation purposes [8]. As a consequence, piezoelectric network damping of plates has been studied [9, 10], and implemented recently [11, 12]. The next objective is to study the multimodal damping of complex structures coupled to their electrical analogues. To study the case of a non-periodic plate is considered as the first step towards this goal.

Moreover, a predictive model of the dynamics of the coupled system would be helpful to investigate the limits of the analogy between the structure and its electrical analogue. It could also be used to find the resistive components to add to the network to get an optimized damping performance. To develop such a model, the work of Thomas et al. [13] concerning a structure covered by thin piezoelectric patches is taken as the starting point.

Section 2 explains how to define a plate electrical analogue. It is applied to a practical setup of a simply-supported plate, and validated by comparing mechanical and electrical measurements. In section 3, we develop a finite element model of the plate coupled to its electrical analogue. The model is validated by comparing simulated and experimental results. Finally, the case of a non-periodic plate is addressed in section 4. A mass is added on the plate to break its symmetry. The designed electrical analogue is experimentally validated and passive broadband damping is still achieved.

2 PLATE ELECTRICAL ANALOGUE

In this first section, the direct electromechanical analogy is applied to a finite difference model of a square plate. The resulting set of equations can be represented by an electrical circuit with lumped elements. The electrical analogue of a square plate is then assembled to produce a plate electrical analogue, which is implemented and validated. The validation is conducted by comparing the operational shapes of the plate and of its electrical analogue.

2.1 Finite difference model of a square plate

The motion of a plate of thickness h , mass density ρ and bending stiffness D is described by the Kirchhoff-Love plate theory, so that

$$-D \left(\frac{\partial^4 w}{\partial x^4} + 2 \frac{\partial^4 w}{\partial x^2 \partial y^2} + \frac{\partial^4 w}{\partial y^4} \right) = \rho h \ddot{w}. \quad (1)$$

In harmonic motion at angular frequency Ω , Eq. (1) is equivalent to

$$\begin{cases} \frac{\partial Q_x}{\partial x} + \frac{\partial Q_y}{\partial y} = -\frac{m}{a} \Omega^2 w \\ M = aD \left(\frac{\partial \theta_x}{\partial x} + \frac{\partial \theta_y}{\partial y} \right) \end{cases} \quad \text{where} \quad Q_x = -\frac{\partial M}{\partial x}, \quad Q_y = -\frac{\partial M}{\partial y}, \quad \theta_x = \frac{\partial w}{\partial x}, \quad \theta_y = \frac{\partial w}{\partial y}. \quad (2)$$

With these notations, w is the displacement in the direction normal to the plate, a is the side of the square plate, $m = \rho h a^2$ is its mass, Q_x and Q_y are the shear forces in the plate, θ_x and θ_y are the angles along the principal directions, and M is a linear combination of the bending moments along the x and y directions defined by Timoshenko in [14]. A finite difference pattern, as represented in Figure 1, is then applied to the plate model. The resulting system of equations obtained from Eqs. (2) is expressed by

$$\begin{cases} Q_T - Q_B + Q_R - Q_L = -m\Omega^2 w_I \\ M_I = D(\theta_T - \theta_B + \theta_R - \theta_L) \end{cases}, \quad \frac{a}{2} \begin{pmatrix} -Q_B \\ -Q_L \\ Q_R \\ Q_T \end{pmatrix} = \begin{pmatrix} M_I - M_B \\ M_I - M_L \\ M_I - M_R \\ M_I - M_T \end{pmatrix}, \quad \frac{a}{2} \begin{pmatrix} \theta_B \\ \theta_L \\ -\theta_R \\ -\theta_T \end{pmatrix} = \begin{pmatrix} w_I - w_B \\ w_I - w_L \\ w_I - w_R \\ w_I - w_T \end{pmatrix} \quad (3)$$

2.2 Design of the plate electrical analogue

The direct electromechanical analogy, such as presented by Bloch in [15], allows the representation of mechanical structures with passive electrical components. In the case here studied, this means that the electrical analogue of a square plate is defined by replacing mechanical quantities in Eqs. (3) by electrical quantities, according to the analogy in Table 1. The first two equations in the system of Eqs. (3) can

be understood as constitutive equations of an ideal inductor of inductance m and an ideal capacitor of capacitance $1/D$. The remaining equations can be interpreted as constitutive equations of transformers of ratio $a/2$. Hence, the Figure 2 represents the unit cell of the plate electrical analogue. The electrical analogue of a rectangle plate can then be defined by assembling this unit cell along the x and y directions.

Moreover, the boundary conditions of the plate should be reproduced in the electrical network. In particular, the simply-supported and clamped edges have direct equivalent electrical connections. Indeed, if for example the left edge of the unit cell is a boundary, then the simply-supported condition is equivalent to command that $V_{\theta L} = 0$ and $\dot{q}_{wL} = 0$, while the clamped condition is equivalent to command $\dot{q}_{\theta L} = 0$ and $\dot{q}_{wL} = 0$ [12].

Finally, the electrical components should be tuned so that the natural frequencies of the network are equal to the natural frequencies of the plate [11]. This ensures identical bending wave propagation properties in the two media. In this case, the modal coupling condition is

$$\frac{1}{a^2} \frac{D}{m} = \frac{1}{\hat{a}^2} \frac{1}{LC}. \quad (4)$$

Figure 3: Measurement of five operational deflection shapes of the plate

Figure 4: Measurement of five operational electrical current shapes in the network

2.3 Validation of the plate electrical analogue

The considered setup is a simply-supported aluminium plate of dimensions $420 \times 360 \times 3 \text{ mm}^3$. It is periodically covered with 42 square piezoelectric patches of dimensions $50 \times 50 \times 0.5 \text{ mm}^3$. The objective is to develop the electrical analogue of this structure. Hence, a network made of 42 identical unit cells has been assembled. The structure and its analogous network are shown in Figure 7, while one unit cell is shown in Figure 2. A way to validate the plate electrical analogue is to compare its operational electrical current shapes to the deflection shapes of the plate.

Since the network should be tested alone for validation, the piezoelectric patches are replaced by ceramic capacitors which have a nominal capacitance of 145 nF. Then, following the method described in [16], the inductors are made by winding conductive wire around a RM10 core of N48 ferrite material from Epcos TDK. The nominal inductance and series resistance of the produced inductors are $L = 244 \text{ mH}$ and $R_{sL} = 13.7 \Omega$. Finally, the ratio of the transformers is $\hat{a} = 4$, and their nominal series resistance is 16.8Ω when used with a 1:1 ratio. An inductor and several transformers are pictured in Figure 2.

By analogy with an exciting external force, an external voltage is applied between two unit cells of the network. The voltage V_{ex} is applied through an isolation transformer of ratio k , such as represented in Figure 5. At the same time, the voltage drop V_L across each inductor of the network is measured. Dividing V_L by the impedance $R_{sL} + jL\Omega$ leads to the electrical current \dot{q}_{wI} flowing through each inductor. As a consequence, plotting the shapes of $\dot{q}_{wI}/kV_{\text{ex}}$ is equivalent to plotting the operational deflection shapes of a plate excited by a point load. Several operational deflection shapes of the plate have been measured using a laser vibrometer and are represented in Figure 3. These can be compared to the operational current shapes in Figure 4. Plotted shapes look alike, even though some shapes are slightly different, such as in Figure 3c and Figure 4c. This can be explained by the heavy damping due to resistive components in the electrical network. Hence, operational electrical current shapes may spill over onto each other. It is the case in Figure 4c, where the measured current distribution looks like a combination of modes (1,2) and (2,1). For this reason, further investigations could include the experimental modal analysis to separate the contributions of modes. Anyway, comparing operational shapes offers a first validation of the plate electrical analogue.

Figure 5: Schematic representation of the excitation setup for the measurement of network modes

Figure 6: Experimental and simulated FRFs, with V_L measured across the inductor of the unit cell highlighted in blue in Figure 5

Furthermore, we developed a lumped model of the entire network. The unit cells, as schematised in Figure 2, are put together following an assembly process. The boundary conditions are then set such as described in section 2.2. The numerical Frequency Response Functions (FRFs) V_L/kV_{ex} can thus be compared to measurements. As an example, a comparison is plotted in Figure 6 for V_L measured in the unit cell highlighted in blue in Figure 5. The simulated FRFs fit with the the measured ones. The remaining differences can be reduced by taking other parasitic elements of the transformers into account, such as the magnetizing branch and the winding capacitance. These kinds of refined models are not presented for the sake of conciseness, and because the correlation between the proposed model and experiments is considered good enough to validate the concept of the plate electrical analogue.

3 FINITE ELEMENT MODEL OF A STRUCTURE COUPLED TO ITS ELECTRICAL ANALOGUE

The main steps to model the dynamics of a mechanical structure covered by piezoelectric patches are recalled. Then, the effect of the interconnections between patches via an electrical network is accounted for. The simulated results are finally compared to experiments in order to validate the approach.

3.1 Finite element formulation

To model the vibrations of a continuous medium covered with piezoelectric patches, we follow the method described by Thomas et al. in [13]. Though all equations are not detailed in this paper, the main steps to develop a finite element model of the structure are recalled.

The electric field is denoted \mathbf{E} . The electric displacement is denoted \mathbf{D} . Using the Voigt notation, the linearized stress and strain vectors are respectively denoted $\boldsymbol{\sigma}$ and $\boldsymbol{\varepsilon}$. The electro-mechanical constitutive equations linking these quantities are

$$\begin{aligned}\boldsymbol{\sigma} &= \mathbf{C}^E \boldsymbol{\varepsilon} - \mathbf{e}^T \mathbf{E}, \\ \mathbf{D} &= \mathbf{e} \boldsymbol{\varepsilon} + \boldsymbol{\epsilon}^E \mathbf{E},\end{aligned}\tag{5}$$

where \mathbf{C}^E is the matrix of elastic coefficients at constant electric field, \mathbf{e} is the matrix of piezoelectric coefficients, and $\boldsymbol{\epsilon}^E$ is the matrix of dielectric permittivities at constant strain. The structure is modelled as an isotropic homogeneous linear elastic medium in which $\mathbf{e} = \mathbf{0}$. Furthermore, the piezoelectric transducers exhibit transverse isotropic properties and are polarized in their transverse directions $\mathbf{n}^{(i)}$. The

patches thickness's, denoted $h^{(j)}$, are considered small when compared to their longitudinal dimensions. Hence, the electrical field $\mathbf{E}^{(j)}$ in the j -th piezoelectric patch is supposed uniform and normal to the electrodes. It can be expressed as a function of the potential difference $V^{(j)}$ between electrodes of each patch:

$$\mathbf{E}^{(j)} = -\frac{V^{(j)}}{h^{(j)}} \mathbf{n}^{(j)}. \quad (6)$$

To derive the mechanical equation of the variational formulation, the elastodynamic equation, in which prescribed body forces are neglected, is considered. To derive the electrical equation, it is Gauss's law involving no free charges which is considered. These equations are then multiplied by test functions and integrated over the entire volume of the structure. The prescribed surface forces and free charge densities are taken into account as boundary conditions. Then, the constitutive equations of the medium are applied to get the variational formulation in terms of displacement \mathbf{u} and electric potential $V^{(j)}$.

The equations of the variational formulation are then discretized. Following an assembly process, we obtain a finite element formulation of the coupled problem:

$$\begin{pmatrix} \mathbf{M}_m & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \ddot{\mathbf{U}} \\ \ddot{\mathbf{V}} \end{pmatrix} + \begin{pmatrix} \mathbf{K}_m & \mathbf{K}_c \\ -\mathbf{K}_c^T & \mathbf{K}_e^{-1} \end{pmatrix} \begin{pmatrix} \mathbf{U} \\ \mathbf{V} \end{pmatrix} = \begin{pmatrix} \mathbf{F} \\ \mathbf{Q} \end{pmatrix}, \quad (7)$$

where \mathbf{U} contains the nodal values of the displacement field \mathbf{u} and \mathbf{V} contains the voltage values $(V^{(1)}, \dots, V^{(P)})$ on the upper electrodes of the piezoelectric patches. \mathbf{F} represents the external mechanical forces applied to the structure, while \mathbf{Q} are the electrical charges on the upper electrodes of the piezoelectric patches. \mathbf{K}_c is the coupling matrix, and \mathbf{M}_m and \mathbf{K}_m are the mass and mechanical stiffness matrices. \mathbf{K}_e is a diagonal matrix in which the j -th term is the inverse of the blocked piezoelectric capacitance $C^{(j)}$ of the j -th patch, which is

$$C^{(j)} = \frac{\epsilon_{33}^{\mathcal{E}} S^{(j)}}{h^{(j)}}, \quad (8)$$

where $S^{(j)}$ is the j -th patch surface and $\epsilon_{33}^{\mathcal{E}}$ is the transverse permittivity of a piezoelectric medium with no strain. In the case of plate bending, this quantity can be estimated with materials constants. More details are available in [11].

3.2 Coupling of a structure to its electrical analogue

The piezoelectric patches bound to the structure are interconnected via the plate electrical analogue. Hence, using the notations in Figure 2, \mathbf{V} contains in fact the voltage values $(V_{\theta I}^{(1)}, \dots, V_{\theta I}^{(P)})$, while the j -th element of \mathbf{Q} is equal to the charge $q_{\theta B}^{(j)} - q_{\theta T}^{(j)} + q_{\theta L}^{(j)} - q_{\theta R}^{(j)}$ flowing through the capacitance $C^{(j)}$. As a consequence, the network is a passive electrical controller that commands a relationship between \mathbf{V} and \mathbf{Q} . We choose to express these vectors in terms of the 42 electrical charges q_{wI} flowing through the inductors of the network, whose values are contained in the vector \mathbf{Q}_w . Using a symbolic solver, we obtained these relations:

$$\begin{aligned} \mathbf{V} &= -(\mathbf{M}_e \ddot{\mathbf{Q}}_w + \mathbf{D}_e \dot{\mathbf{Q}}_w), \\ \mathbf{Q} &= \mathbf{P} \mathbf{Q}_w, \end{aligned} \quad (9)$$

which leads to the finite element formulation of the mechanical structure coupled to its electrical analogue:

$$\begin{pmatrix} \mathbf{M}_m & \mathbf{0} \\ \mathbf{0} & \mathbf{M}_e \end{pmatrix} \begin{pmatrix} \ddot{\mathbf{U}} \\ \ddot{\mathbf{Q}}_w \end{pmatrix} + \begin{pmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{D}_e \end{pmatrix} \begin{pmatrix} \dot{\mathbf{U}} \\ \dot{\mathbf{Q}}_w \end{pmatrix} + \begin{pmatrix} \mathbf{K}_m + \mathbf{K}_c \mathbf{K}_e \mathbf{K}_c^T & \mathbf{K}_c \mathbf{K}_e \mathbf{P} \\ \mathbf{K}_e \mathbf{K}_c^T & \mathbf{K}_e \mathbf{P} \end{pmatrix} \begin{pmatrix} \mathbf{U} \\ \mathbf{Q}_w \end{pmatrix} = \begin{pmatrix} \mathbf{F} \\ \mathbf{0} \end{pmatrix}. \quad (10)$$

Figure 7: Setup including the plate covered with piezoelectric transducers, a shaker, a laser vibrometer and the plate electrical analogue

Figure 8: Meshing of the mechanical structure and location (in red) of both the excitation and the velocity measurement

The expressions of the electrical "mass" matrix \mathbf{M}_e , the electrical damping matrix \mathbf{D}_e , and the transfer matrix \mathbf{P} are not detailed in this work for the sake of conciseness. We just precise these three matrices depend on the transformer ratio \hat{a} . Moreover, \mathbf{M}_e is a function of the inductance value L , while \mathbf{D}_e is a function of the series resistance of the inductors R_{sL} and the series resistance of the transformers.

3.3 Validation of the finite element model

Numerical simulations are compared to practical measurements to validate the finite element model developed in the previous sections. The experimental setup is presented in Figure 7. The simply-supported plate periodically covered with piezoelectric patches is suspended. A shaker applies a point load and a force transducer measures it. A laser vibrometer measures the velocity on the other side of the plate. The red marker in Figure 8 represents the location of both the excitation and the velocity measurement. Moreover, the upper electrodes of the patches are either connected to the ground or to the network thanks to switches, which can be spotted in Figure 2.

The structure is modelled with 20-node hexahedral elements. Both the plate and the piezoelectric patches are meshed with one element in depth. In the other directions, the piezoelectric patches as well as the plate beneath them are meshed with $n_x \times n_y$ elements. Taking $n_x = n_y = 3$ leads to converged values for natural frequencies of the undamped structure up to 1 kHz. As a consequence, the Figure 8 represents the mesh used to obtain all the following numerical results.

The plate is made of duralumin. Its Poisson's ratio and density are respectively set at 0.346 and 2800 kg/m³. Its Young's modulus is set at 68.8 GPa to adjust the eleventh natural frequency of the plate calculated with short-circuited piezoelectric patches to the corresponding resonances in the experimental measurement. This corresponds to the last peak before 900 Hz as plotted in Figure 9. The piezoelectric patches are made of the PIC 153 PZT material. The coefficients of matrices in Eq. (5) are either taken from manufacturer's data when available, or extrapolated from datasheets of other PZT materials.

The case of short-circuited patches is simulated by imposing all voltage values in \mathbf{V} to ground potential in Eq. (7). The plotted results in Figure 9 show that the numerical simulation forecasts the dynamics of the structure up to 900 Hz rather well. Moreover, the remaining differences between numerical and experimental results could be reduced. First of all, the plate is linked to a rigid frame via thin supports.

Figure 9: Experimental and simulated FRFs with short-circuited piezoelectric patches

Figure 10: Experimental and simulated FRFs when the plate is coupled to its electrical analogue

The plate is the only part of the assembly that is modelled. Since the peak at 687 Hz is a frame mode, it can not be predicted. Furthermore, the gaps between the first simulated and measured peaks can be attributed to the non-ideal experimental boundary conditions. This has been explained by Robin et al., who designed a first version of the setup in [17]. Finally, the structural damping has been neglected, which explains the amplitude differences at resonances.

The case of the structure being coupled to its passive electrical analogue is then considered. As seen in Figure 10, a broadband vibration damping is achieved. Meanwhile, the frame mode at 687 Hz is barely affected by the connection to the network, which was expected. Besides, the model in Eq. (10) is able to predict the dynamics of the structure coupled to its electrical analogue. The modelling limits highlighted in Figure 9 remain true in this case. Hence, this model could be used to find the optimal resistive components to be added to the network in order to optimize the damping performance.

Figure 11: Experimental and simulated FRFs with short-circuited piezoelectric patches and an added mass

4 BROADBAND VIBRATION DAMPING OF A NON-PERIODIC PLATE

In this section, the broadband damping achieved by coupling a structure to its electrical analogue is extended to the case of a non-periodic plate. A mass is locally added on the plate, and its influence on the dynamics of the system is modelled. We then define the non-periodic plate electrical analogue and verify that the first few modes of the structure are significantly damped.

4.1 Non-periodic plate electrical analogue and validation

Designing the electrical analogue of a non-periodic plate is the first step towards more complex structures. As a consequence, we decided to add a mass which is a 22 mm thick, 40 mm diameter cylindrical rod of 207 g. This mass is added on the side of the plate which is not covered by piezoelectric patches, on the hatched position in Figure 8.

The mass is added in the finite element model as well, in the form of a 22 mm thick patch covering the same surface as a piezoelectric patch. Its Young modulus is set at 325 MPa. This way, the seventh simulated natural frequency of the plate with short-circuited patches is adjusted to the seventh peak on the measured FRF. The correlation between numerical and experimental results in this case is shown in Figure 11. When compared to the results in Figure 9, one can notice that the natural frequencies of the plate have been lowered, that the contact with the added mass induces damping in the measured FRF, and that a frame mode at 203 Hz is now excited. Since the structural damping and the frame are not taken into account, their effects are not foreseen by our model. The simulated FRF fits quite well with the measured one nonetheless.

The non-periodic plate here considered is obtained by locally adding some mass and some stiffness to the structure. To get its electrical analogue, the first natural frequency of the electrical network should be adjusted to the first natural frequency of the non-periodic plate. The first simulated resonance in Figure 11 is used as a reference value for the structure. In other words, Eq. (4) should remain true, while a and \hat{a} have set values and D and m are locally modified. Thus, one should modify the product of the capacitance C by the inductance L of the corresponding unit cell of the network. Not to deteriorate the electromechanical coupling [18], only L is modified to adjust the first natural frequency of the electrical network. The calculations, which are not detailed here, show in this case that the initial inductance of

Figure 12: Measurement of five operational deflection shapes of the plate when a 207 g mass (in black) is added

Figure 13: Measurement of five operational electrical current shapes in the network when a 1.34 H inductance (in black) replaces a 244 mH inductance of the network

244 mH should be replaced by an inductance of 1.34 H.

As previously explained in section 2.3, one way to validate the non-periodic plate electrical analogue is to compare the mechanical and electrical operational shapes. The measurements are still made with the setups presented in Figures 7 and 5. The results are shown in Figures 12 and 13. Since the plotted shapes look alike, we consider that the non-periodic network is the electrical analogue of the modified structure.

4.2 Multimodal vibration damping

The non-periodic plate is now coupled to its passive electrical analogue. The FRF measurement is made with the same setup as described in section 3.3. As seen in Figure 10, broadband damping is achieved in this case as well. This result validates the approach of coupling a non-periodic structure to its fully passive electrical analogue for multimodal damping purposes.

Moreover, the simulated results fit rather well with the measured ones. The remaining differences are due to the differences already spotted in Figure 11, and hence could be reduced by modelling the structural damping. As it is, it seems that the finite element model developed in this work can be used to predict the dynamics of a complex structure coupled to its electrical analogue. It could also be used to forecast where resistive components could be added in the network to improve the damping performance.

5 CONCLUSION

The first objective of this work is to develop a finite element model of a structure coupled to an electrical network interconnecting piezoelectric transducers. A structure covered with thin piezoelectric patches is considered. The electrical network is viewed as a passive controller that commands a relationship between the voltages and the charges on the upper electrodes of the piezoelectric transducers. The numerical results show a good agreement with measurements, even though the model could be improved. In the case here studied, the possible improvements include taking into account the structural damping

Figure 14: Experimental and simulated FRFs when the non-periodic plate is coupled to its electrical analogue

of the plate and the non-ideal boundary conditions of the setup. Anyway, the actual model can predict the dynamics of the coupled system. It could also be used to validate the analogy between a mechanical structure and its electrical analogue.

The other objective of this work is to extend to non-periodic structures the concept of coupling to an electrical analogue for passive multimodal damping purposes. To do that, the electrical analogue of a simply-supported plate is designed and its dynamics is experimentally validated. Finally, we measure the damping performance that is attainable by connecting the plate electrical analogue to the structure. These steps are repeated in the case of a plate on which a mass has been added in order to make it non-periodic. The final measurements highlight the achievable damping performance with a fully passive electrical network connected to the non-periodic structure. It is a first step towards trying to couple a complex structure to its electrical analogue for multimodal damping purposes.

Keywords: Vibration control, Electromagnetic Shunt Damper, Electromechanical Coupling Factor, Tuning and Optimization

Summary: *In this study, we address the topic of the reduction of structural vibrations by means of an electromagnetic shunt damper (EMSD) made up of a voice coil actuator (VCA) with an electronic circuit. The classical resistive and resonant shunt solutions are studied. The main goal of this paper is to estimate the damping performance of shunts combined with a tuned mass damper (TMD), in the case of forced vibrations, for an arbitrary resonant elastic host structure. Two architectures, that differs with the placement of the EMSD with respect to the TMD, are tested. It is shown that the EMSD enhances the vibration control for a specific combination of TMD and EMSD. If the TMD parameters cannot be changed, the performance of vibration reduction is affected by one free parameter: the Electromechanical Coupling Factor (EMCF). This factor conditions the optimal mitigation of a mechanical vibration mode. Experiments are proposed and a good agreement with the theoretical model is obtained, validating it. For these experiments, a digital signal processor (DSP) generates the EMSD (the tuning parameters depend on the VCA and the DSP itself as well). A cantilever beam with a mass clamped at its free end serves as the TMD, whose tuning parameters include the bending stiffness and the clamped mass.*

1 INTRODUCTION

The conception and the optimisation of an electromagnetic shunt damper (EMSD) are studied. The EMSD is used to obtain a dissipation of mechanical energy by converting mechanical

vibrations into electrical energy through a magnetic interaction realised by a voice coil actuator (VCA). This transducer is composed of a coil, connected to the shunt circuit, which oscillates in a magnetic field created by a permanent magnet. Like piezoelectric materials, VCA has a fundamental electromechanical reversibility. So, the EMSD can be compared to a mechanical damper [1], e.g. the traditional Frahm damper, also called the tuned mass damper (TMD) [2], or the traditional piezoelectric shunt [3, 4]. Optimum tuning parameters have been defined for classic passive dampers by Den Hartog [5] on the one hand and for equivalent shunt systems [3, 6] on the other hand.

In comparison to a piezoelectric transducer, the VCA can be advantageously oversized in order to increase the Electromechanical Coupling Factor (EMCF). Actually, the effective EMCF, as a function of the actuator mass for both electromagnetic transducers and piezoelectric transducers, has allowed to show that, for an equivalent actuator mass, piezoelectric transducers depend only on the material properties and do not depend on transducer size in first approximation, while the coupling factor of the VCA increases with its mass [7]. Some studies have used the combination of piezoelectric shunt damper and the EMSD in order to reduce the vibrations and/or to harvest it in electrical energy [8, 9, 10, 11, 12].

The objective of this paper is to apply an EMSD in order to enhance the vibration control of a TMD in the case of forced vibrations, for an arbitrary resonant elastic host structure. Two architectures, that differ with the placement of the EMSD with respect to the TMD [13, 14], are tested in the conservative case. In the first section of this paper, we present the global system made up of a combination of the primary system, the TMD and the EMSD for the two kinds of combinations only for conservative system. In the following section, we discuss and comment the experiments and their results. Finally, the last section leads to the conclusion that experiments give a good agreement with the theory.

2 MODELS

We consider a primary system like a single degree of freedom (SDOF) coupled with a TMD and with an EMSD with two architectures possible seen in Figure 1. m_1 , c_1 , k_1 are the mass, the viscous damping coefficient and the stiffness coefficient of the primary system, respectively. An external force F sets in motion this system, which its displacement is x_1 . The natural frequency of the primary system is $\omega_1 = \sqrt{\frac{k_1}{m_1}}$ and the damping ratio is $\xi_1 = \frac{c_1}{2\sqrt{k_1 m_1}}$. The TMD [2] is designed by a mass m_2 , a viscous damping coefficient c_2 and a stiffness coefficient k_2 . The displacement of m_2 is x_2 . However, we prefer to use x_d , the relative displacement x_2 in relation to x_1 ($x_d = x_2 - x_1$). The natural frequency of the TMD is $\omega_2 = \sqrt{\frac{k_2}{m_2}}$ and the damping ratio is $\xi_2 = \frac{c_2}{2\sqrt{k_2 m_2}}$. The mass ratio between the TMD and the primary system $\mu = \frac{m_2}{m_1}$ is the coupling factor of both systems. We consider the EMSD also like a resonant conservative system composed by an electrical circuit with the inductance of the VCA L and an impedance in serial connection made up by a capacitance C and a resistance R . This system is named the RC-shunt [4]. An electric charge Q flowed through the shunt. The natural frequency of the RC-shunt is

$\omega_e = \frac{1}{\sqrt{LC}}$ and the damping ratio is $\xi_e = \frac{R}{2} \sqrt{\frac{C}{L}}$. The EMSD is coupled with the primary system by the means of the VCA that induced a Lorentz force $\Phi \dot{Q}$ on the primary system and an electromotive force $\Phi \dot{x}_1$ on the shunt circuit, such as Φ is the force factor of the VCA [15] and $(\dot{})$ the derivate with respect to time. The force factor is the coupling factor between the primary system and the EMSD. It depends on the coil displacement, the coil geometry and the magnetic flux density generated through the air gap of the VCA, but it could be considered as a constant [16].

The dampers can be designed as conservative ($\xi_e = \xi_2 = 0$) or dissipative. The optimum criteria from these two systems are different. For the conservative resonant dampers, we want to design an antiresonance at the resonance of the primary system and also take away the two news resonances from the antiresonance designed. These two optimisation criteria are gathered by the knowledge of the frequency distance $\Delta\omega$. It corresponds to the difference between the resonant frequency of the primary system alone with the new resonant frequency generated by the coupling of both systems: the primary system and the damper. This optimisation is suited to mono-frequency excitation. For the dissipative system, we want to reduce the spectrum magnitude of the primary system. This method is called H_∞ optimisation [1]. We loose the antiresonance with this method but we benet from a weak resonant magnitude. This optimisation is suited to a large frequency range.

Den Hartog has dened the resonance frequencies in the case of two Degrees Of Freedom (2DOF) conservative mechanical system composed by a primary system and a TMD [5] as :

$$\omega_{r1} = \omega_2 \sqrt{1 + \frac{\mu}{2} - \sqrt{\mu + \frac{\mu^2}{4}}}, \quad \omega_{r2} = \omega_2 \sqrt{1 + \frac{\mu}{2} + \sqrt{\mu + \frac{\mu^2}{4}}}, \quad (1)$$

If ω_2 is tuned on ω_1 , we obtain an antiresonance frequency at ω_1 and the frequency distance is, in the case of a TMD, for $\mu \ll 1$:

$$\forall \mu \ll 1, \quad \Delta\omega_{TMD} \simeq \omega_1 \frac{\sqrt{\mu}}{2}. \quad (2)$$

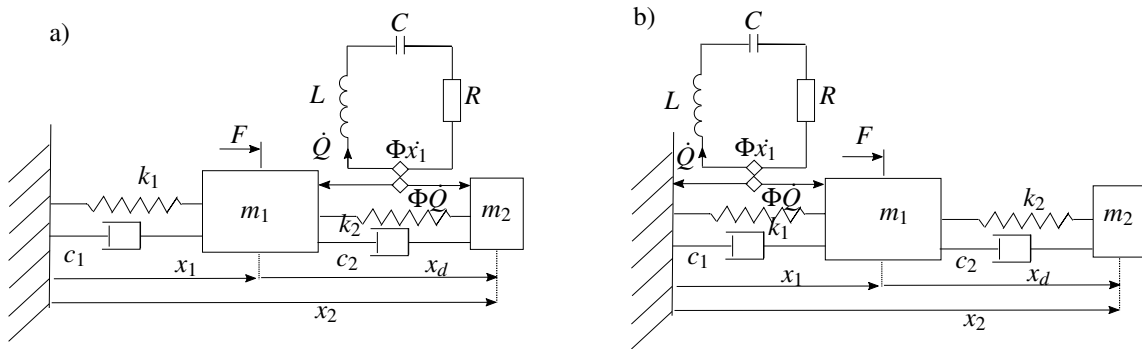

Figure 1: Schematic of primary system coupled with a TMD and an EMSD : a) Architecture I : EMSD placed between the primary system and the TMD (on the left), b) Architecture II : EMSD placed between the primary system and its building (on the right).

In regards to equation (2), we see the mass ratio μ is the parameter which defines the frequency distance.

2.1 EMSD between the primary system and the TMD

The governing equations of this first architecture (Arch. I) shown in Figure 1.a is made up of the mechanical equation of motion and the Kirchhoff's voltage law :

$$(1 + \mu)\ddot{x}_1 + \mu\ddot{x}_d + 2\xi_1\omega_1\dot{x}_1 + \omega_1^2x_1 = \frac{F_1}{m_1}, \quad (3)$$

$$\ddot{x}_d + \ddot{x}_1 + 2\xi_2\omega_2\dot{x}_d + \omega_2^2x_d + \kappa_2\omega_2\dot{\bar{Q}} = 0, \quad (4)$$

$$\ddot{\bar{Q}} + 2\xi_e\omega_e\dot{\bar{Q}} + \omega_e^2\bar{Q} - \kappa_2\omega_2\dot{x}_d = 0, \quad (5)$$

with \bar{Q} the equivalent electrical charge and κ_2 the EMCF of Arch. I :

$$\bar{Q} = \sqrt{\frac{L}{m_2}}Q, \quad \kappa_2 = \frac{\Phi}{\omega_2\sqrt{m_2L}}. \quad (6)$$

The Frequency Response Functions (FRFs) associated to equations (3) (4) (5) for conservative systems ($\xi_1 = \xi_2 = \xi_e = 0$) are :

$$\hat{x}_1 = \frac{F_1}{m_1} \frac{(-\Omega^2 + \omega_e^2)(-\Omega^2 + \omega_2^2) - \kappa_2\omega_2^2\Omega^2}{D_2(\Omega)}, \quad (7)$$

$$\hat{x}_d = \frac{F_1}{m_1} \frac{-\Omega^2(-\Omega^2 + \omega_e^2)}{D_2(\Omega)}, \quad (8)$$

$$\hat{\bar{Q}} = \frac{F_1}{m_1} \frac{j\kappa_2\omega_2\Omega^3}{D_2(\Omega)}, \quad (9)$$

with :

$$D_2(\Omega) = -\Omega^6 + [\omega_1^2 + (1 + \mu)(1 + \kappa_2^2)\omega_2^2 + \omega_e^2]\Omega^4 - [(1 + \kappa_2^2)\omega_1^2\omega_2^2 + \omega_1^2\omega_e^2 + (1 + \mu)\omega_2^2\omega_e^2]\Omega^2 + \omega_1^2\omega_2^2\omega_e^2, \quad (10)$$

with \hat{x}_1 , \hat{x}_d , $\hat{\bar{Q}}$ the complex amplitude of x_1 , x_d , \bar{Q} respectively defined by $x_1(t) = \Re(\hat{x}_1 e^{j\Omega t})$ and in the same way for x_d , \bar{Q} , and Ω the frequency of external force. The complex amplitude of the electrical current \hat{I} that flows through the shunt circuit is thus $\hat{I} = j\Omega\hat{\bar{Q}}$. In the case of conservative systems, we want to generate an antiresonance instead of the resonance frequency of the primary system ω_1 . Therefore, we need to determinate the antiresonance frequencies of \hat{x}_1 from equation (7), as follows :

$$\omega_{ar,I-} = \frac{1}{\sqrt{2}} \left[(1 + \kappa_2^2)\omega_2^2 + \omega_e^2 - \sqrt{[(1 + \kappa_2^2)\omega_2^2 + \omega_e^2]^2 - 4\omega_2^2\omega_e^2} \right]^{\frac{1}{2}}, \quad (11)$$

$$\omega_{ar,I+} = \frac{1}{\sqrt{2}} \left[(1 + \kappa_2^2)\omega_2^2 + \omega_e^2 + \sqrt{[(1 + \kappa_2^2)\omega_2^2 + \omega_e^2]^2 - 4\omega_2^2\omega_e^2} \right]^{\frac{1}{2}}. \quad (12)$$

So, we impose $\omega_{ar,I-}$ and $\omega_{ar,I+}$ equal to ω_1 . It allowed for the determining of the tuning terms of ω_e , and the following solutions are obtained :

$$\omega_e = \sqrt{\frac{\omega_1^4 - (1 + \kappa_2^2)\omega_1^2\omega_2^2}{\omega_1^2 - \omega_2^2}}, \quad (13)$$

$$\text{if } \omega_2 < \omega_1, \text{ for } \kappa_2 \leq \sqrt{\frac{\omega_1^2 - \omega_2^2}{\omega_2^2}}, \quad (14)$$

$$\text{else-if } \omega_2 > \omega_1, \forall \kappa_2. \quad (15)$$

However, the tuning frequency in equation (13) prevents the tuning of the TMD with the primary system $\omega_2 = \omega_1$, because it requires in practice the de-tuning of the TMD.

To check the efficiency of Arch. I, we use the FRFs corresponding to the primary system coupled with the TMD like references in relation with several FRFs related to these architecture. When looking at Figure 2, the criteria described in equations (13), (14) and (15) enable

Figure 2: Frequency response functions of the architecture I (Arch. I) for some values of both natural frequencies of the TMD ω_2 and the EMSD ω_e , and the EMCF κ_2 . The mass ratio is $\mu = 0.05$.

to generate an antiresonance at ω_1 . However, the nearest resonance of this antiresonance is systematically observed in return compared to the reference case with the coupled system of both primary system and the TMD, the reference case seen in Figure 2. The dynamics of this architecture is governed by three resonances and it is difficult to take them away from the antiresonance frequency. In the conservative case, Arch. I seems unsuitable to reduce largely the

vibration of the primary system owing to the EMSD placement, which is between the primary system and the TMD. This is a wrong option when considering to enhance the performance of a TMD in conservative case. However, this kind of architecture is seen in the study of energy harvesting systems because of it can improves the harvesting power can be improved when used in relation to a traditional SDOF energy harvester (i.e. shunt damper) [13, 17].

2.2 EMSD between the primary system and its support

The governing equations of this second architecture (Arch. II) shown in Figure 1.b is made up of the mechanical equation of motion and the Kirchhoff's voltage law :

$$(1 + \mu)\ddot{x}_1 + \mu\ddot{x}_d + 2\xi_1\omega_1\dot{x}_1 + \omega_1^2x_1 + \kappa_1\omega_1\dot{\bar{Q}} = \frac{F_1}{m_1}, \quad (16)$$

$$\ddot{x}_d + \ddot{x}_1 + 2\xi_2\omega_2\dot{x}_d + \omega_2^2x_d = 0, \quad (17)$$

$$\ddot{\bar{Q}} + 2\xi_e\omega_e\dot{\bar{Q}} + \omega_e^2\bar{Q} - \kappa_1\omega_1\dot{x}_1 = 0, \quad (18)$$

with \bar{Q} the equivalent electrical charge and κ_1 the EMCF of Arch. II :

$$\bar{Q} = \sqrt{\frac{L}{m_1}}Q, \quad \kappa_1 = \frac{\Phi}{\omega_1\sqrt{m_1L}}. \quad (19)$$

So, the FRFs of the equations (16)-(17)-(18) for conservative systems ($\xi_1 = \xi_2 = \xi_e = 0$) are :

$$\hat{x}_1 = \frac{F_1}{m_1} \frac{(-\Omega^2 + \omega_e^2)(-\Omega^2 + \omega_2^2)}{D_1(\Omega)}, \quad (20)$$

$$\hat{x}_d = \frac{F_1}{m_1} \frac{\Omega^2(-\Omega^2 + \omega_e^2)}{D_1(\Omega)}, \quad (21)$$

$$\hat{\bar{Q}} = \frac{F_1}{m_1} \frac{j\kappa_1\omega_1\Omega(-\Omega^2 + \omega_2^2)}{D_1(\Omega)}, \quad (22)$$

with :

$$D_1(\Omega) = -\omega^6 + [(1 + \kappa_1^2)\omega_1^2 + (1 + \mu)\omega_2^2 + \omega_e^2] \Omega^4 - [(1 + \kappa_1^2)\omega_1^2\omega_2^2 + \omega_1^2\omega_e^2 + (1 + \mu)\omega_2^2\omega_e^2] \Omega^2 + \omega_1^2\omega_2^2\omega_e^2. \quad (23)$$

In order to generate an antiresonance at ω_1 , we need to determine the antiresonance frequencies of \hat{x}_1 from equation (20), as follows :

$$\omega_{ar,II-} = \omega_2, \quad \omega_{ar,II+} = \omega_e, \quad (24)$$

When looking at the equation (7), the condition to generate an antiresonance at ω_1 is possible by the tuning of $\omega_e = \omega_1$ and $\omega_2 = \omega_1$, and creates a double antiresonance. In regards to the

application of this double antiresonance tuning, the expression of the resonance frequencies, obtainable by equation (23), is in ascending order :

$$\omega_{p-} = \omega_1 \sqrt{\frac{2 + \mu + \kappa_1^2 - \sqrt{(2 + \mu + \kappa_1^2)^2 - 4}}{2}}, \quad (25)$$

$$\omega_{p0} = \omega_1, \quad (26)$$

$$\omega_{p+} = \omega_1 \sqrt{\frac{2 + \mu + \kappa_1^2 + \sqrt{(2 + \mu + \kappa_1^2)^2 - 4}}{2}}, \quad (27)$$

In this case, we note ω_1 is at the same time an antiresonance frequency and an eigenfrequency, implying that the associated eigenmode has a motionless primary system. To check the efficiency of Arch. II, we use the FRF corresponding to the primary system coupled with the TMD like references in relation with several FRFs related to these architecture. In Figure 3, we notice

Figure 3: Frequency response function of the architecture II (Arch. II) for some values of both natural frequencies of the TMD ω_2 and the EMSD ω_e , and the EMCF κ_1 . The mass ratio is $\mu = 0.05$.

that the EMSD adds efficiency to the TMD. For Arch. II, we see that the increase of the EMCF κ_1 upgrades the frequency distance of this architecture II. Besides the mathematical expression of

the resonance frequencies (25) (27) in comparison to the resonance frequencies with a conservative TMD see in [5], in tuning the dampers on ω_1 , the role of μ and κ_1^2 are similar, so that we can define a coupling factor as the sum of both factors for this system. In regards to equations (25) and (27), the frequency distance following for $\mu, \kappa_1 \ll 1$ is :

$$\forall \mu, \kappa_1 \ll 1, \quad \Delta_{\omega, II} \simeq \omega_1 \frac{\sqrt{\mu + \kappa_1^2}}{2}. \quad (28)$$

Therefore, tuning $\omega_{ar, II-}$ and $\omega_{ar, II+}$ on ω_1 produces a larger frequency distance compared to the frequency distance for the primary system plus TMD tunes on ω_1 in equation (2). Moreover the graphic of \hat{x}_d shows more the EMCF increases more \hat{x}_d at the vicinity of ω_1 decreases. The dynamics of this architecture is ruled by three resonances, including one that can be avoided.

Another possible option with this architecture is to create an antiresonance at any frequency Ω by the tuning of the EMSD eigenfrequency at this Ω . Indeed if the antiresonance frequency $\omega_{ar, II-} = \omega_1$, then $\omega_{ar, II+}$ could be equal to any other frequency. That is possible because the EMSD tuning is uncoupled with the TMD tuning in this architecture. However, a third resonance will appear because there is no more degenerated eigenmode.

In the following section, the experimental setup of Arch. II is described then the results with this architecture are commented.

3 EXPERIMENTS

3.1 Experimental setup

We design a host structure made up of two equals aluminium plates sustained by four equals aluminium beams. Through geometric and mechanical properties, the two first eigenmodes of this structure are configured as the two first bending eigenmodes B_{x1} and B_{x2} in the direction called \vec{e}_x . Figure 4 shows the studied model and its equivalent model considered with m the

Figure 4: Schematic of the studied model equivalent at a Two Degrees Of Freedom (2DOF).

mass of a plate and k the bending stiffness of four parallel cantilever beams in the direction \vec{e}_x .

We obtain the eigenfrequencies :

$$\omega_{B_{x1}} = \sqrt{\frac{k}{m} \left(\frac{3 - \sqrt{5}}{2} \right)}, \quad \omega_{B_{x2}} = \sqrt{\frac{k}{m} \left(\frac{3 + \sqrt{5}}{2} \right)}. \quad (29)$$

The dimension of the host structure is chosen thanks to the equations (29), and a Finite Element Method (FEM) through a CAD software (Catia, Dassault Systèmes, France) in order to determine the two first torsional mode of this structure T_1 and T_2 . The established setup for the host structure are plates of 240mm long, 200mm wide, 12mm thick, and beams of 200mm long, 40mm wide and 5mm thick.

A laser Doppler vibrometer (PSV-400, Polytec, Germany) with its acquisition computer or an accelerometer (352C65, PCB Piezotronics, USA) with acquisition cards (NI 9234, National Instruments, USA) are used for measuring the FRFs. A function generator, from the vibrometer equipment, is used in order to emit an excitation chirp signal amplified by a power amplifier (Amplifier type 2719, Brüel and Kjaer, Denmark) and transmitted to a magnetic exciter. This exciter made up of a coil and a neodymium cylindrical magnet, small enough to ignore its mass, put in movement the host structure. The exciter magnet is set on the larger face of one upper beam, near to the upper plate. The exciter coil is radially centring near to the magnet, and the half of the magnet is set at the interior of the coil. The signal emitted to the coil is controlled in current and the interaction between the magnetic ux density of the magnet and this current generate a stress on the host structure. As the magnetic exciter is placed in order to create a force excitation in the direction of the bending modes B_{x1} and B_{x2} (\vec{e}_x), the bending modes corresponding to the two others direction are not excited. Only the bending mode like B_{x1} , B_{x2} , and the torsional modes like T_1 , T_2 , are sensed (shown in Figure 5). The FRF in Figure (5) is obtained with the laser Doppler vibrometer. The eigenfrequencies and the damping ratio associated to one eigenmode are the B_{x1} mode with a frequency of 34.9Hz and a damping ratio of 0.0096, the B_{x2} mode with a frequency of 85.0Hz and a damping ratio of 0.0014, the T_1 mode with a frequency of 118.8Hz and a damping ratio of 0.0029 and the T_2 mode with a frequency of 460.3Hz and a damping ratio of 0.0011. These eigenmodes are weakly damped (less 1%). So we can used a TMD made by aluminium in order to design an experimental TMD with a weak damping ratio. This TMD is a cantilever beam with a mass clamped at its free end as seen in Figure 6. This TMD is tuned thanks to the beam length L_a in using the eigenmode reliant on the mass clamped m_a and the bending beam deflection v_a in the case of a concentrated load at the free end F_a which defined the stiffness coefficient associated k_a . The tunable resonance frequency is :

$$\omega_a = \sqrt{\frac{3Eb_a h_a^3}{12m_a L_a^3}}, \quad (30)$$

with E the Young's modulus, L_a the beam length, b_a the beam width and h_a the beam thickness. The tuning is mainly done with the beam length adjustment.

The EMSD consists of a VCA (AE30-01-01, Pack' Aero, France) without guidance made up of

a magnetic field assembly attached to an aluminium hollow structural section clamped to the host structure frame and a coil placed at the bottom of the upper plate of the host structure. Naturally, this VCA is placed in order to work in the direction \vec{e}_x such the coil go through the air gap of the magnetic field assembly. We determine the force factor at $2.98N/A$, which is an important constant for the vibration reduction, the coil inductance of $664\mu H$ and the coil internal resistance of 3.4Ω . In order to produce a conservative EMSD, we need a total resistance circuit of 0Ω . However, in this case we get a short circuit that we cannot generate. So we need to reduce this resistance as closely as possible to zero. Then, this shunt is resonant in adding a capacitor to the circuit. The tuning of ω_e (24) on bending eigenmodes of the primary structure requires a capacitance of :

$$C = \frac{1}{L\omega_1^2}, \quad (31)$$

such as ω_1 is one bending eigenfrequency. As we consider the B_{x1} mode, its eigenfrequency is $34.9Hz$ and the determined capacitance is $31.3mF$. This capacitance value is high for a standard capacitor. It is why a digital signal processor (MicroLabBox DS1202, dSPACE, Germany) is used so as to synthesize the RC-shunt. The DSP works on a sampling frequency of $30kHz$ that is enough for the measuring and the application in the range frequency $[0 - 400]Hz$. An interface circuit connect the VCA to the DSP, made of two operational amplifiers (Op-Amp). The first (OPA 445, Texas Instruments, USA) is used for measuring the current I by an inverting amplifier

Figure 5: Frequency response function of the host structure on a top left measurement point.

with a gain $G_{inv} = -1$ and a measuring resistance $R_m = 28.4\Omega$. So the current measured is $I_m = \frac{1}{R_m} \left(\frac{1}{G_{inv}} V_{in} \right)$ with V_{ADC} the ADC input voltage. The second (OPA 547T, Texas Instruments, Etats-Unis) is used for a voltage follower with a gain $G_{fol} = 1$. The two Op-Amp are supplied by a DC power supply (FI 1333, Française d'Instrumentation, France). The DSP is designed to be equivalent to an impedance Z_{sh} in order to generate a resonant shunt :

$$Z_{sh}(\Omega) = R_{sh} + \frac{1}{j\Omega C_{sh}}, \quad (32)$$

with the shunt resistance and capacitance, R_{sh} and C_{sh} respectively. The shunt resistance is in fact chosen negative to cancel the internal coil resistance r_L , in order to obtain a fully conservative resonant shunt and an antiresonance as perfect as possible.

3.2 Host structure coupled with a tuned mass damper and a digital resonant shunt

Now the TMD and the EMSD are used and tuned on the B_{x1} eigenmode of the host structure alternately then simultaneously like seen in Figure 6. The accelerometer measures the FRFs

Figure 6: Photograph of the host structure, the TMD (on the top). For the EMSD : the VCA (on the top), the interface circuit (on the left bottom) and the DSP (on the right bottom).

of the host structure dynamics. For the purpose of tuning the TMD, we use a beam of 300mm long, 20mm wide and 3mm thick with a mass clamped of 0.15kg and we tuned $L_a = 160mm$,

which is considered as the distance between the clamped mass m_a and the TMD support. The tuning of the RC-shunt is realised by the application of the numerical values $R_{sh} = -3.35\Omega$ et $C_{sh} = 31.3mF$. We note the EMCF of the B_{x1} mode $\kappa_{B_{x1}}$. By the correlation between models and experimentals measured, we can determine the mass ratio μ and the the EMCF $\kappa_{B_{x1}}$ for the combination of the host structure with the TMD and the EMSD respectively. Then the model for the host structure coupled with the TMD and the RC-shunt is used with the previous values determined of μ and $\kappa_{B_{x1}}$. Finally, Figure 7 shows the FRFs of experimental measurements and numerical modelling for the host structure alone, coupled with the TMD, coupled with the EMSD and coupled with the both damping systems. In Figure 7, experiments gives $\xi_{B_{x1}} =$

Figure 7: Magnitude of the frequency responses functions in the vicinity of the B_{x1} eigenmode

0.00728, $\mu = 0.05$ and $\kappa_{B_{x1}} = 0.24$. The theoretical models are computed ((th) in Figure 7) and present a good agreement with the experiments ((exp) in Figure 7). The superposition effect of the EMSD on the TMD are clearly made an enhancement on the vibration reduction of the host structure, even if these systems are weakly damped. In fact, the frequency distance is approximately gone from $3Hz$ to $5Hz$. So, these experimental results validate the theory on the enhancement of the vibration reduction in the conservative case. However, limitations on these experiments are the fact we need EMSD and TMD weakly damped in order to apply efficiency this method. This is why using a DSP as a digital shunt enables the reducing of the resistance in the RC-shunt, especially the coil resistance.

4 CONCLUSION

In this paper, an elastic host structure, a TMD and a shunt circuit which composed two kinds of architectures, Arch. I and Arch. II, are studied. The goal was to enhance the vibration reduction induced by the TMD in using the EMSD. We determined optimum parameters of the TMD and the EMSD systems in these architectures for a SDOF system, which corresponds to an eigenmode of the elastic host structure. It demonstrated Arch. II is more pertinent in comparison of host structure and TMD combination for conservatives dampers.

The vibration reduction is obtained by means of the TMD and/or the EMSD and conclusions attest of the correlation between theoretical models and experimental tests. For conservative systems, we observe that the application of these two damping systems is optimum when we apply the both same tuning parameters for the TMD and for the EMSD, when each is coupled with the host structure.

We have made a RC-shunt using a DSP in order to make a synthetic shunt. On the contrary of an analog shunt, the digital shunt has an advantage of tuning the RC-shunt by numerical inputs. The DSP generate a negative resistance aiming at reducing the total resistance induced by resistors and the VCA coil, and generate a capacitance aiming at create a resonant EMSD.

Abstract. The use of resonant piezoelectric shunts is a well-established solution to mitigate vibrations in flexible mechanical structures. However, very large inductance values are required in the shunt. These values are difficult to obtain for passive inductors and therefore, inductance values are often synthesized with operational amplifiers (OpAmp). The downside is that standard OpAmps can only handle up to 30V peak-to-peak and the state of the art amplifiers up to 100Vpp. Piezoelectric materials typically generate high voltages even for low vibration levels. With the increasing push towards lighter and more slender mechanical structures, the increased vibration levels result in even higher voltage levels such that even the most advanced OpAmps fall short. In this research, a synthetic inductor is proposed and built by combining the bridge amplifier configuration and the output voltage boost configuration, effectively quadrupling the range of the synthetic inductor to 400Vpp. The synthetic inductor is then employed to shunt a piezoelectric patch bonded on a cantilever beam.

1 INTRODUCTION

Excessive vibrations in mechanical structures are typically reduced by adding another mechanical oscillator on the structure, called a tuned mass damper (TMD) [1]. With addition of a well-designed TMD, the vibrations are relocated from the original structure to this oscillator where they are dissipated, significantly decreasing vibrations in the mechanical structure. Piezoelectric (PE) materials can convert mechanical into electrical energy and vice versa. Therefore, bonding PE material to a vibrating structure and shunting it with a resonant electrical circuit will have the same effect as a TMD [2]. However, very large inductance values are required in the shunt such that resonance in the electrical shunt matches one of the mechanical vibration frequencies. It is impractical to design a wirewound inductor coil with such a very large inductance and a low resistance at the same time. Therefore, this large inductance is often realized as a synthetic inductor, i.e., an active electronic circuit which mimics the electrical impedance of an inductor. A synthetic inductor consists of one or more operational amplifiers (OpAmps) and a number of passive resistors and capacitors. Another advantage of this approach is that the inductance can easily be made modified.

A well-known feature of piezoelectric material is its typically high-voltage and low-current operation. As OpAmps are limited in the voltage which they receive on their inputs, researchers have employed

“high voltage” OpAmps. The state-of-the-art high voltage OpAmps are the OPA445 (90V peak-to-peak) [3], used in many shunts which synthesize an inductor [4, 5], or more advanced, a negative capacitance [6] and more recently digital impedance [7]. The OPA454 (100Vpp) is another high-voltage OpAmp with better specifications and an exposed metal pad for cooling the chip [8].

As mechanical structures nowadays tend to be more light and slender, the magnitude of vibration during resonance can reach levels that induce much higher voltages than 100Vpp in a PE patch. Similar concerns were raised in [9], where it was claimed a shunt was built which could handle 350 Vpp. However, the design of the circuit was not disclosed.

In the field of analogue electronics, several techniques are known to boost the output voltage range of an amplifier. The most straightforward technique is the “bridge amplifier configuration”, where two similar amplifiers are driven anti-phase. The load is connected between the two amplifier outputs, effectively doubling the output voltage range.

Another, less common technique is the “output voltage boost configuration”, where the positive and negative power supply voltages of the main amplifier are delivered by supply boost amplifiers. By selecting the proper boost amplifier supplies and gain factors it is possible to create a set of power supply voltages for the main amplifier, of which the average tracks the desired output signal, effectively doubling the output voltage range in an alternative way.

Employing a combination of both techniques, it is possible to quadruple the output voltage range. A new circuit has been designed and built, employing 6 high-voltage operational amplifiers, successfully synthesizing an inductor for a voltage range up to 400V. The circuit is tested experimentally as a shunt to mitigate the vibrations of a small flexible cantilever beam. The measured deflection of the beam under resonance with and without shunt confirms the expected mitigation even when the shunt is subjected to higher voltage levels than 100Vpp.

2 HIGH VOLTAGE SYNTHETIC INDUCTOR

2.1 High-voltage gyrator

The high-voltage synthetic inductor is built around a high-voltage gyrator of which the circuit diagram is shown in Fig. 1. This gyrator employs an OPA454 OpAmp, produced by Texas Instruments, which is to our knowledge the OpAmp with the highest voltage of operation commercially available. The OPA454 is specified at 100V (or +50V and -50V) supply voltage, with an absolute maximum rating of 120V.

The simulated input impedance is given by Ohm’s law as

$$Z_{in} = \frac{V_{in}}{I_{in}}$$

The OpAmp is configured as a voltage buffer, delivering an output voltage

$$V_{out} = V_{in} \cdot \frac{R}{R + \frac{1}{j\omega C}} = V_{in} \cdot \frac{j\omega RC}{1 + j\omega RC}$$

Hence the voltage drop across R_L is equal to the difference between the input voltage and the OpAmp’s output voltage. Therefore the current through R_L can be found from Ohm’s law. As the components are chosen in order to make $R_L \ll R$, the input current is approximately equal to the current through R_L :

$$I_{in} \approx \frac{V_{in} - V_{out}}{R_L} = \frac{V_{in} - V_{in} \cdot \frac{j\omega RC}{1 + j\omega RC}}{R_L} = \frac{V_{in}}{R_L (1 + j\omega RC)}$$

Figure 1: High-voltage gyrator with OPA454 OpAmp

The resulting simulated impedance is

$$Z_{in} = \frac{V_{in}}{I_{in}} \approx j\omega RC \cdot R_L + R_L$$

This means the gyrator simulates an inductor with a value of $C \cdot R \cdot R_L$ Henry, in series with a small resistor R_L .

If the gyrator circuit is employed as a shunt to attenuating mechanical vibrations with piezo transducers, a series resistor larger than R_L often required so the presence of R_L does not compromise the performance of the vibration damping. Therefore it is not necessary to employ gyrator circuits without series resistance but with a higher OpAmp component cost, such as the standard Antoniou circuit, used in many resonant shunts [4, 5, 10].

2.2 Power supply boost configuration

It is possible to extend the voltage range of an amplifier by dynamically modifying the power supply voltages depending on the desired output voltage. The power supplies V_{pos} and V_{neg} of the central amplifier, used for the gyrator circuit, are now delivered by two similar OPA454 OpAmps, one supplied with a positive voltage and one with a negative voltage, referred to ground. By means of an equal-resistor voltage divider between the OpAmp's output and the positive or negative power supply voltage, followed by a voltage buffer, the supply boost OpAmps deliver

$$V_{pos} = \frac{V_{out} + 100V}{2}$$

$$V_{neg} = \frac{V_{out} - 100V}{2}$$

The principle is schematically drawn on Figure 2, where both left and right a gyrator is supplied this way.

Therefore the central amplifier's output voltage range is now extended to $200V_{pp}$ as the power supply voltages track the output voltage when referring to ground level, whereas the total supply voltage across the central OpAmp always remains equal to

$$V_{supply} = V_{pos} - V_{neg} = 100V$$

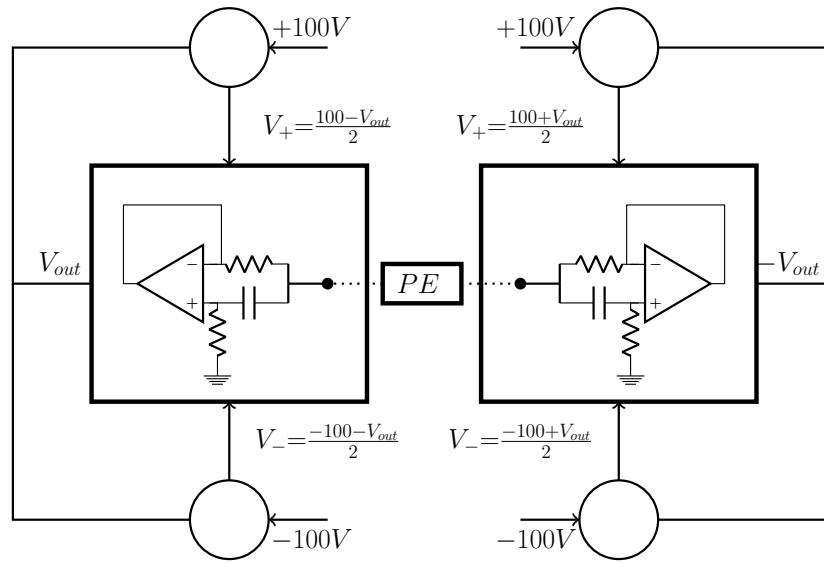

Figure 2: Extending the voltage range of a synthetic inductor with Power Supply Boost and Bridge configuration. Voltages determined based on antisymmetric excitation by the central piezo element PE.

The principle of operation is illustrated by means of the waveforms in Fig. 3. In this graph the power supply boosted gyrator is driven to its full output voltage range on a $\pm 100\text{V}$ symmetric power supply.

Figure 3: Power supply boost operation

2.3 Bridge configuration

The Bridge Tied Load (BTL) configuration is well-known in the field of amplifier design to be able to deliver an output amplitude which is twice the voltage range of an individual amplifier. To achieve this range extension, two amplifiers are driven antiphase and the load is connected between the two outputs. On Figure 2, the left and right gyrators are indeed driven antiphase, with the piezo element PE functioning as a source in between the two outputs, sourcing current in one terminal and sinking the same current from the other terminal.

This approach is used to provide a second doubling of the voltage range of the gyrator. Basically two simulated inductors with voltage boost configuration are employed in series, effectively quadrupling the output voltage range to $400V_{pp}$. Because the piezo transducer is connected between two gyrator outputs, the gyrators appear in series with respect to the piezo transducer, doubling also the simulated impedance. Using similar component values in both gyrator circuits, the resulting impedance is equal to

$$Z = 2j\omega C \cdot R \cdot R_L + 2R_L$$

Practical component values are $C = 1\mu F$, $R = 1M\Omega$ and $R_L = 100\Omega$, resulting in an inductance of 200H in series with a 200 Ω resistor. In the implementation R is determined by a 1M Ω potentiometer, allowing the inductor to be adjusted from 0 to 200H. On Figure 5a and Figure 5b show the experimentally constructed circuit.

3 ELECTROMECHANICAL SYSTEM

3.1 Theoretical model and tuning

The vibrating mechanical structure of the experiment is a cantilever beam, bonded with 2 PE patches near its fixed end, as shown on Figure 4. The first PE patch will be used to excite the beam, while the other patch on the opposite side will be shunted by the RL shunt, synthesized by the circuit presented in the previous section.

Figure 4: The considered dynamical system, a cantilever beam with PE1 used as an actuator and PE2 shunted with a RL shunt

By decomposing the dynamic deflection of the beam in a mode shape and a modal time coordinate $u(x,t) = \phi(x)r(t)$, the dynamical equation of the full system can be written as [11]

$$\begin{cases} \ddot{r} + 2\zeta\omega_n\dot{r} + \omega_n^2 r - \theta_2 V_2 = \theta_1 V_{in} \\ C_{p,2} V_2 + \theta_2 r = q \end{cases} \quad (1)$$

with ω_n the short circuit natural frequency, ζ the modal damping, θ_1 and θ_2 the modal coupling coefficient of each PE patch and C_p the capacitance of the second PE patch. The equation (1) can be seen as a mechanical oscillator excited by the first piezo and an electrical interaction with the second piezo, depending on shunt circuit. When shunted by an RL shunt, $V_2 = -R\dot{q} - L\ddot{q}$, the R and L can be optimized in such a way that the vibrations at the resonance conditions of the mechanical oscillator are minimized, while also avoiding to create other significant resonances. In this research, the optimizing

procedure is based on how mechanical TMD's are optimized [1], applied to resonant shunts [10]. The optimal electrical parameters are :

$$\omega_e = \omega_n \sqrt{1 + k^2} \quad \zeta_e = \sqrt{\frac{3}{8}} k$$

with $\omega_e = \frac{1}{\sqrt{LC_{p,2}}}$ the electrical natural frequency, $\zeta_e = \frac{RC_{p,2}\omega_e}{2}$ the electrical damping and $k = \sqrt{\frac{\omega_n^2 - \omega_{n,CC}^2}{\omega_{n,CC}^2}}$ the effective coupling coefficient with $\omega_{n,SC}^2$ the resonance frequency of the mechanical oscillator when $V_2 = 0$, meaning when the second patch is shorted over its terminals.

3.2 Experiment

The optimization described above is very practical as only the open and closed-circuit resonances are needed, two parameters which are easily found experimentally.

A 166 mm long, 35 mm wide and 0.2 mm thick aluminum beam was fitted with two PIC255 piezoelectric patches which are 30 mm wide, 50 mm long and 0.2 mm thick and have a C_p of 103 nF. Further material constants are found on [12]. To identify the closed and open circuit resonances, a sine sweep with amplitude 100 V was applied to the actuating PE-patch with the other patch first in closed circuit, then open circuit, and finally with the optimized circuit. The deflection of the beam at the free end is measured with a laser vibrometer and both the applied voltage and measured deflection are used to construct an experimental frequency response function as shown on Figure 6a. The experimental open-circuit resonance frequency is 67.68 Hz and the closed 67.33 Hz. The generalized coupling coefficient is $k = 0.1021$ resulting in an optimal $R = 2.9k\Omega$ and $L = 54$ H. As expected, the FRF when using the shunting PE patch, seen on Figure 6a, shows a significant, almost 10-fold decrease of the vibrations near the resonance of the mechanical oscillator.

To verify the high voltage over the RL shunt during vibration damping, the open circuit resonance frequency is applied to PE1 as a 200Vpp sine wave, while the voltage over PE is measured, once in open circuit and once when the RL shunt is applied, Figure 6b. The synthetic inductor can easily handle the measured voltage over the shunt (178Vpp), which would not be possible with conventional OpAmps, or with a single high-voltage OpAmp. Note that the applied voltage, 100V, corresponds to only 7 mm amplitude at the tip of the beam, Figure 6a when PE2 is in open or closed circuit.

4 CONCLUSIONS

This research presented a high-voltage synthetic inductor consisting of 6 operational amplifiers, with an increased range from 100Vpp up to 400Vpp. This way, resonant shunts used to mitigate vibration of mechanical structures are able to deal with the increasingly high vibration levels which induce high voltages in these shunts. By supplying a single gyrator circuit by output voltage boost configuration, where the supply of operational amplifiers depend on their output, the voltage range of the gyrator was doubled. Another doubling was achieved by then supplying two of these gyrators in an anti-phase manner. The circuit was designed and used as a shunt for a piezoelectric patch bonded to a cantilever beam. The vibration in the beam induced voltages up to 178Vpp in the shunt, a voltage level where previous implementations of synthetic inductors are not able to deal with.

Abstract. Resonant shunt circuit applied on a transducer such as a piezoelectric element or a voice coil is widely used as a passive control technique to damp a specific vibration mode. While very simple and robust, the damping capability is proportional to the electromechanical coupling of the transducer. On the other hand, one of the major difficulties that arises in practical implementation of purely active vibration control is the power consumption required for conditioners and control units. The idea of using a hybrid control system is proposed in this study to combine the passive shunt device with an active control in order to improve the performance with low power consumption. Both active voltage source and active current source are proposed and compared. The method of maximum damping, i.e. maximizing the exponential time-decay rate of the response subjected to the external impulse forcing function, is used to optimize the parameters of the passive and hybrid control systems. The advantage of using an hybrid control configuration in comparison with purely active control system is also investigated in terms of power consumption.

1 INTRODUCTION

Recently, the electromagnetic shunt damper has been proposed as a very simple and effective passive control technique. The key idea of this technique is to connect a capacitor of capacitance C and a resistor of resistance R to the electromagnetic transducer of inductance (L) to form a resonant R-L-C circuit. The absorber dissipates the vibrational energy by the resistor when the resonance of the circuit is tuned close to the resonance of the primary system thanks to the tuned capacitor [1]. Many optimization methods have been proposed to optimize the parameters R and C . de Marneffe [2] optimized the parameters through the root-locus analysis and H_∞ minimization when the system is under base excitation. He has also compared the resonant R-L-C shunt with a resistive shunt. Inoue et al. [3] derived the optimal parameters by using the fixed point theory for the mechanical vibration absorber proposed by Den Hartog [4]. In [5], the optimal parameters have been obtained analytically using both the H_2 and H_∞ optimization methods which consist in minimizing the root-mean-square (RMS) vibration under random excitation and the peak amplitude in the frequency domain, respectively. Moreover, Zhu et al.

[6] studied the analogy between the electromagnetic shunt damper and a tuned mass damper (TMD). Then, the optimal parameters of an electromagnetic shunt have been adapted from the optimal parameters of the TMD (obtained by Ormondroyd and Den Hartog [7]) by using an equivalent mass, stiffness and damping coefficient for the electromagnetic shunt damper. The main shortcoming of this method is that the optimal parameters can be used only when the equivalent mass ratio is small enough because a full dynamic analogy does not exist.

The hybrid control system may be an effective control configuration by combining the advantages of both active and passive control systems [8]. In other words, the active part of a hybrid system requires much less power than a similar purely active system, while providing better vibration suppression than the passive system alone. Despite this interest, no one to the best of our knowledge has studied the hybridization of the passive electromagnetic shunt damper with an active control system for the purpose of vibration damping improvement.

In the literature, there are a number of studies on active-passive hybrid piezoelectric network (APPN). In 1994, Agnes [9] proposed the concept of APPN and Tsai et al [10] presented more insight and fundamental understandings to the APPN configuration. Basically, the APPN integrates piezoelectric shunt damping with an active voltage or charge source to improve the control performance of the structure [11]. Morgan et al. [12] used active coupling feedback to enhance the electromechanical coupling of the transducer. In most studies about the APPN, a collocated piezoelectric sensor has been used to generate the feedback signal. However, MingMing et al. [13] employed a velocity feedback control for the application of the APPN by using a displacement sensor. The optimal values of the resistance and inductance could be quite different from those of the purely passive system in the case of APPN. Therefore, Tsai et al. [14] proposed a methodology to determine the optimal values of the resistor and inductor simultaneously with the control law.

In the present study, the active-passive hybrid electromagnetic shunt damper is proposed. This paper is organized as follows. First, a purely passive electromagnetic shunt damper is studied and the parameters of the R and C are optimized according to the method of maximum damping in Section 2. Then in Section 3, the hybrid configuration is modeled by combining either active voltage source in series and current source in parallel with the designed RC circuit. The power which flows between the structure and the transducer thanks to the application of an active control system with an hybrid configuration is discussed in Section 4. The conclusions are drawn in Section 5.

2 PASSIVE CONTROL SYSTEM

Figure 1 shows the system under consideration. It is an undamped single-degree-of-freedom (SDOF) oscillator with a mass m , spring k and an electromagnetic device connected to a resistor of resistance R and a capacitor of capacitance C . The system is excited by a disturbance force f_d ; in particular, and the impulse response of the SDOF system is of interest. The electromagnetic device which is made of a permanent magnet and a coil has the following parameters: coupling constant T , coil inductance L and coil resistance R_{coil} . It can generate a force f_a which is proportional to the current i flowing inside the coil. In addition, the voltage across the transducer V is proportional to the velocity of the mass. The governing equations of motion are written as:

$$m\ddot{x} + kx = f_d + f_a \quad (1a)$$

$$f_a = -Ti = -T\dot{q} \quad (1b)$$

$$V = L\ddot{q} + R\dot{q} + \frac{1}{C}q = T\dot{x} \quad (1c)$$

where q is the charge flowing inside the coil. For the sake of simplicity, R is considered as the total resistance of the circuit (Figure 1b). The above equations are normalized with respect to the dimensionless time $\tau = \omega_0 t$ where $\omega_0 = \sqrt{k/m}$ as below:

$$x_1'' + x_1 = f - \beta_1 \omega_0 x_2' \quad (2a)$$

$$x_2'' + 2\xi \alpha x_2' + \alpha^2 x_2 = \beta_2 / \omega_0 x_1' \quad (2b)$$

where the normalized parameters are:

$$\begin{aligned} \tau = \omega_0 t, \quad x_1(\tau) = x(t), \quad x_2(\tau) = q(t), \quad \Omega = \omega / \omega_0, \quad f = \frac{1}{k} f_d, \quad \beta_1 = \frac{T}{k} \\ \beta_2 = \frac{T}{L}, \quad \beta = \beta_1 \beta_2, \quad \omega_f = \frac{1}{\sqrt{LC}}, \quad \alpha = \frac{\omega_f}{\omega_0}, \quad \xi = \frac{R}{2} \sqrt{\frac{C}{L}} \end{aligned} \quad (3)$$

The transfer function of the system from the normalized external force f to the normalized displacement of the mass x_1 is then given by:

$$\frac{x_1}{f} = \frac{s^2 + 2\xi \alpha s + \alpha^2}{(s^2 + 1)(s^2 + 2\xi \alpha s + \alpha^2) + \beta s^2} \quad (4)$$

where $s = j\Omega$ is the Laplace variable. According to Eq. (4), the passive control system adds another DOF to the system which makes the closed-loop response having two complex poles. In order to obtain the optimal parameters, the method of maximum damping, i.e. minimizing the settling time of the transient response of the system to the impulse disturbance, is used. This can be achieved by realizing equal damping ratio and tuning the frequency of both poles of the closed-loop response. In other words, two

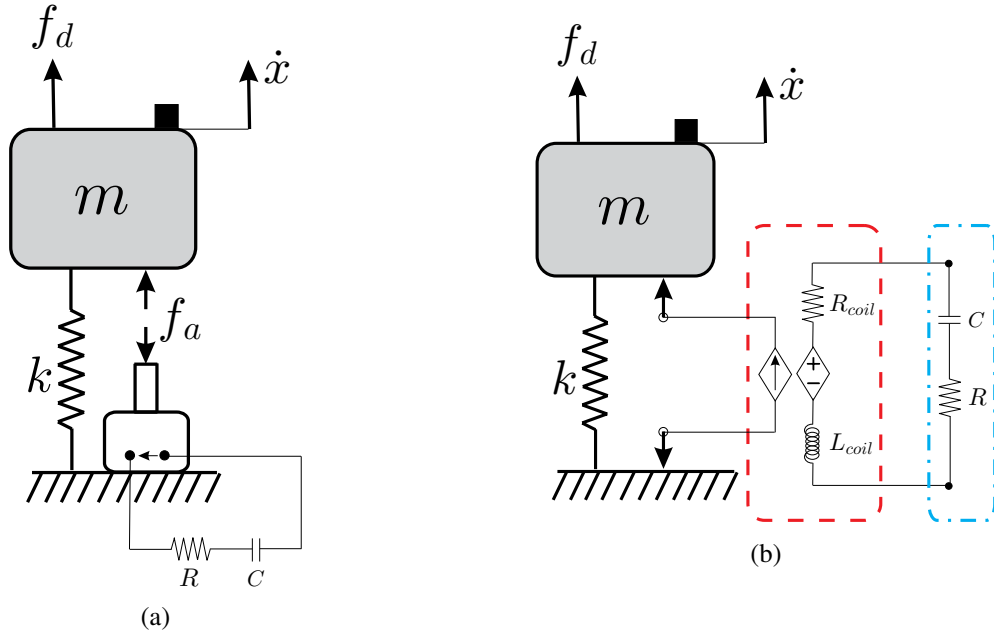

Figure 1: Single-degree-of-freedom (SDOF) oscillator combined with the electromagnetic shunt damper. (a) Mechanical model and (b) Electrical equivalent model of the transducer

poles are merged together. In this case, the normalized transfer function can be simplified as:

$$\frac{x_1}{f} = \frac{s^2 + 2\xi\alpha s + \alpha^2}{(s^2 + 2\eta\gamma s + \gamma^2)^2} \quad (5)$$

where η is the damping ratio, ω_c , and $\gamma = \omega_c/\omega_0$ are the resonance frequency and the normalized resonance frequency of the closed-loop response function, respectively. By matching the polynomial coefficients of the denominators of Eq. 4 and Eq. 5, the set of equations can be obtained as below:

$$4\eta\gamma = 2\xi\alpha \quad (6a)$$

$$4\eta^2\gamma^2 + 2\gamma^2 = \alpha^2 + \beta + 1 \quad (6b)$$

$$4\eta\gamma^3 = 2\xi\alpha \quad (6c)$$

$$\gamma^4 = \alpha^2 \quad (6d)$$

(a)

(b)

(c)

Figure 2: For the attached passive RC circuit, (a) root-locus of the system for a specific value of the resistance R and capacitance C , (b) frequency response as well as (c) the impulse response for different values of R

From Eqs. (6a), (6c) and (6d), it can be concluded that

$$\gamma_{opt} = \alpha_{opt} = 1 \quad (7)$$

which means that the optimal frequency of the circuit and the closed-loop resonance frequency of the system are equal to the resonance frequency of the primary system. Considering the above equation and Eq. (6b) yields:

$$\xi_{opt} = \sqrt{\beta} \quad (8)$$

As a consequence, the optimal parameters of resistance and capacitance can be obtained as:

$$C_{opt} = \frac{1}{L\omega_0^2} \quad (9a)$$

$$R_{opt} = \frac{2T}{\sqrt{kC_{opt}}} \quad (9b)$$

In the remaining of the paper, the following numerical values are used: $m=1\text{kg}$, $k=10^4\text{N/m}$, $T=1\text{N/Amp}$, $L=L_{coil}=10^{-3}\text{H}$, and $R_{coil}=0\Omega$ (the resistance of the coil is included in R). The root-locus of the system with an attached passive RC shunt circuit is shown in Figure 2a. The locus consists of two loops (red and blue) starting from the pole of the primary system (red pole) and the pole of the resonant shunt (blue pole), respectively. One of the loop goes to the origin and the other one goes to infinity. Both loops are intersecting at one point when using the optimal values of resistance R_{opt} and capacitance C_{opt} . Figure 2b shows the frequency response for five different values of the resistance R . All the curves are intersecting at two points which are called fixed-points. For $R < R_{opt}$, two resonances with equal peaks appear in the vicinity of the resonance frequency of the primary system. The controller is no longer effective in the terms of amplitude reduction when $R \rightarrow 0$. In addition, the performance degradation can also be observed when $R > R_{opt}$. Especially when $R \rightarrow \infty$, the controlled system acts like a primary system with no additional damping. The impulse response in the time domain is also shown in Figure 2c for three different values of R . As it can be seen, the minimum settling time can be achieved by considering the designed optimal value of R obtained in Eq. (9b)

3 HYBRID CONTROL SYSTEM

From Eqs. (6)-(8) and (3), it can be concluded that the optimal closed-loop damping is $\eta_{opt} = T/(2\sqrt{kL})$. This shows that the stiffness of the structure as well as the coupling constant and the inductance of the transducer limit the maximum achievable damping obtained by the passive control system. The potential of using active control to improve the control performance of the system in terms of magnitude of the response is investigated.

In the present study, two different configurations for the hybridization of the passive resonant shunt with an active control are considered (Figure 3). In the first configuration shown in Figure 3a, the electromagnetic transducer is connected in series with RC elements and an active voltage source. The active voltage source is proportional to the velocity of the structure. The total voltage across the transducer (V) is then obtained by the summation of the active input voltage (V_{in}) and the voltage across the RC shunt circuit (V_{shunt}). Furthermore in the second configuration shown in Figure 3b, the electromagnetic transducer is connected in series with the RC circuit, and the active current source is in parallel with the shunting elements. Considering this configuration, the total current flowing in the transducer (i) is given by the summation of the input active current (i_{in}) and the current flowing inside the RC shunt circuit ($i_{shunt} = \dot{q}_{shunt}$).

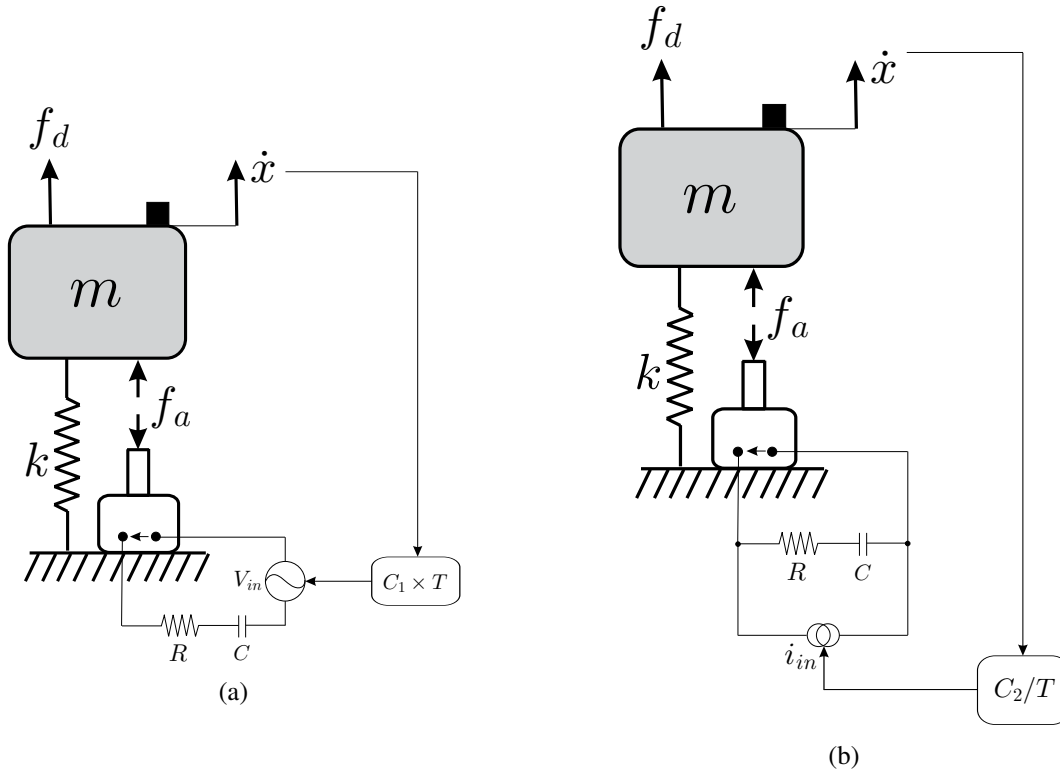

Figure 3: Schematic of a SDOF oscillator attached to an hybrid control system consisting of an electromagnetic transducer connected to the passive RC shunt (a) in series with an active voltage source and (b) in parallel with an active current source

3.1 Hybridization with an active voltage source

Considering the active voltage source, the equations of motion are modified as:

$$m\ddot{x} + x = f_d + f_a \quad (10a)$$

$$f_a = -T^* \dot{q} \quad (10b)$$

$$L\ddot{q} + R\dot{q} + \frac{1}{C}q + V_{in} = T\dot{x} \quad (10c)$$

$$V_{in} = -C_1 T \dot{x} \quad (10d)$$

By substituting Eq. (10d) into Eq. (10c), it can be seen that the active voltage source directly affects the effective coupling constant of the transducer. It is assumed that the transducer is ideal and there is a perfect balance between the electrical energy and the mechanical energy which means that there is no energy to be stored in the transducer [15]. According to the concept of energy conservation principle [16], the variation of the stored energy is the sum of the external power input and the internal power generation. This concept can be written for the electromagnetic transducer in the presence of the active voltage source when there is no shunt as:

$$dW = V dq + f_a dx = T(1 + C_1) \frac{dx}{dt} idt + T^* idx \quad (11)$$

where d and W are the derivative operator and the stored energy, respectively. By equating the above equation to zero, T^* can be obtained as:

$$T^* = T(1 + C_1) \quad (12)$$

Figure 4a shows the root locus of the system, shunted with a RC circuit and the active voltage source in series, for the variation of feedback gain C_1 . One sees that the system is stable because the poles are always placed in the left half plane of the locus for all values of the feedback gain C_1 . The locus has two complex poles and two zeros at the origin. By increasing the value of the feedback gain C_1 , one pole goes toward the origin and the other one goes to infinity. It makes the system having two different resonances in the vicinity of the primary ones with the lower values of the damping than the damping of the passive control system. According to the Eq. (9b), the optimal values of the resistance R is proportional to the coupling constant of the transducer. Considering the new constant of the transducer (Eq. (12)), the optimal value of the resistance can be modified as:

$$R_{opt}^* = \frac{2T}{\sqrt{kc}}(1 + C_1) \quad (13)$$

Figure 5a compares the frequency response of the system with the passive control system combined with the active voltage source for two different values of the feedback gain C_1 . For each value of C_1 , the result is shown with and without correction of the resistance R according to Eq. (13) and Eq. (9b), respectively. By updating the value of the resistance in this case, more energy can be dissipated in the resistor which leads to increase the damping of the system. A larger value of resistance is required by the application of the active voltage source than the purely passive system. In order to have a fail-safe and optimum design, the value of resistance should be changed to the lower one when the active control is turned off. For a specific value of the feedback gain C_1 , the impulse response is shown in Figure 5b when the value of the resistance R is modified based on Eq. (13). It can be seen that the exponential time-decay rate is maximized by updating the value of the resistance.

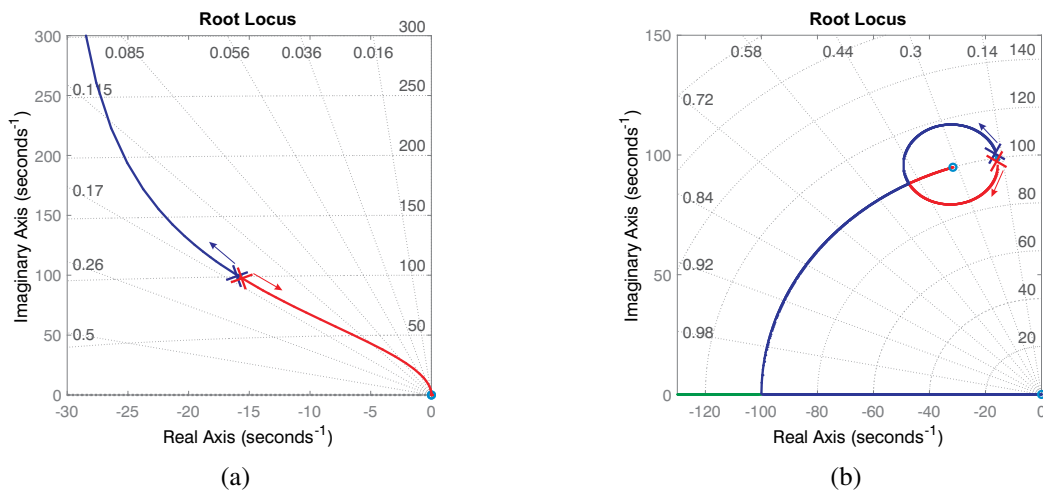

Figure 4: Root-locus of the system shunted with RC circuit combined with (a) active voltage source under and (b) active current source

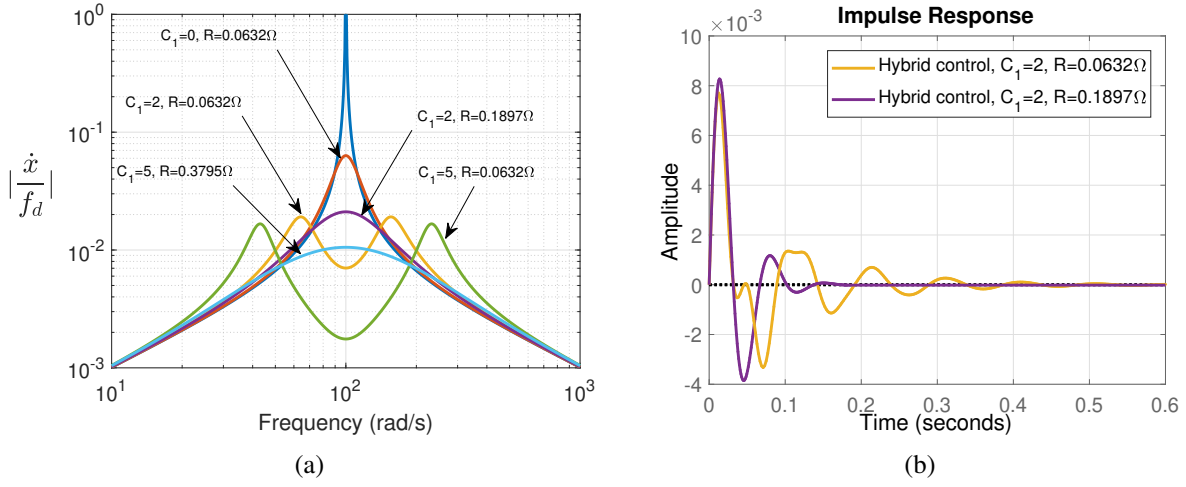

Figure 5: With the application of the passive control system combined with the active voltage source, (a) the frequency response of the system for different values of the feedback gain C_1 as well as the resistance R and (b) the impulse response with and without the correction of the resistance R

3.2 Hybridization with an active current source

The equations of motion with the application of the active current source read:

$$m\ddot{x} + kx = f_d + f_a \quad (14a)$$

$$f_a = -T(\dot{q} + i_{in}) \quad (14b)$$

$$i_{in} = \frac{C_2}{T}\dot{x} \quad (14c)$$

$$L\ddot{q} + R\dot{q} + \frac{1}{C}q = T\dot{x} \quad (14d)$$

The corresponding root locus of the system is shown in Figure 4b for the variation of feedback gain C_2 . The system is always stable by the application of the active current source because the closed-loop poles are always in the left half plane. Two poles are moving on the blue and red branches. The optimal feedback gain C_2 can be obtained when the two loops are intersecting at one point. Considering $\lambda = C_2\omega_0/k$ and Eqs. (3), (7), as well as (8), the normalized equations of motion are written as:

$$x_1'' + x_1 = f - \beta_1\omega_0x_2' - \lambda x_1' \quad (15a)$$

$$x_2'' + 2\sqrt{\beta}x_2' + x_2 = \beta_2/\omega_0x_1' \quad (15b)$$

The closed-loop transfer function from the normalized disturbance force f to the normalized displacement x_1 is obtained as:

$$\frac{x_1}{f} = \frac{s^2 + 2\sqrt{\beta}s + 1}{(s^2 + \lambda s + 1)(s^2 + 2\sqrt{\beta}s + 1) + \beta s^2} \quad (16)$$

When the two poles of the system have the same damping μ and normalized resonance frequency δ , the closed-loop transfer function can be re-written as:

$$\frac{x_1}{f} = \frac{s^2 + 2\sqrt{\beta}s + 1}{(s^2 + 2\mu\delta s + \delta^2)^2} \quad (17)$$

The following equations are obtained by equating the polynomial coefficients of the denominator of the fraction on the right hand side of Eqs. (16) and (17):

$$4\mu\delta = 2\sqrt{\beta} + \lambda \quad (18a)$$

$$4\mu^2\delta^2 + 2\delta^2 = 2\sqrt{\beta}\lambda + \beta + 2 \quad (18b)$$

$$4\mu\delta^3 = 2\sqrt{\beta} + \lambda \quad (18c)$$

$$\delta^4 = 1 \quad (18d)$$

The optimal value of the normalized tuning frequency δ is obtained from Eq. (18d) as:

$$\delta_{opt} = 1 \quad (19)$$

which shows that the closed-loop system has the same resonance frequency as the resonance frequency of the primary one. The optimal value of the normalized feedback gain can be realized by substituting the damping ratio μ obtained from Eq. (18a) and Eq. (19) into Eq. (18b):

$$\lambda_{opt} = 4\sqrt{\beta} \quad (20)$$

which yields:

$$C_2^{opt} = 4 \frac{T}{\omega_0} \sqrt{\frac{k}{L}} \quad (21)$$

It should be mentioned that the parameters of the passive RC circuit do not change. Figure 6a compares the frequency response of the passive control system combined with the active current source for two different values of the feedback gain C_2 . The optimal value is first used for the feedback gain $C_2 = 126.49$ and then it is increased to $C_2 = 200$ when a closed-loop pole touches the real axis and the other one merges with the zero. In this case, the zero cancels one of the poles and the other one adds damping to the system. This gain ($C_2 = 200$) can be defined as the second optimal value due to the fact that it

Figure 6: With the application of the passive control system combined with the active current source, (a) the frequency response and (b) the impulse response of the system for two different values of the feedback gain C_2

has almost the same settling time (Figure 6b) as the one corresponding to the first optimal value. For more than this value of the gain, the settling time is no longer minimized although it might realize lower magnitude of response than the magnitude of response obtained with the optimal values of the feedback gain. It should be mentioned that by the application of the active current source, the hybrid control system is fail-safe because it will continue to behave as the passive electromagnetic shunt damper described in Section 2 when the controller is turned off. The controller behaves like a direct-velocity-feedback (DVF) which is able to damp several modes as well. This topic is proposed for future studies

4 POWERFLOW ANALYSIS

In the previous section, it was shown that the hybrid control system can improve the control performance of the system in terms of the amplitude of response at the resonance frequency. A question may arise here is what is the main advantage of using a hybrid control system compared to a purely active control system. To answer this question, it is proposed to analyze the powerflow between the device and the primary structure due to the fact that an active control system requires an external power source for its operation. The less external power required, the better. The power which flows at the interface of the structure and the actuator device can be written as:

$$P(s) = F_{aa}(s) \times \dot{x}^*(s) \quad (22)$$

where P , F_{aa} and \dot{x} are the power, the control force applied by the active control system, and the velocity of the mass, respectively. The superscripts "*" represents the complex conjugate transpose. Considering $s = j\omega$, the real part of P is called the active power which corresponds to the dissipative behavior and the imaginary part is named the reactive power which corresponds to the energy exchanging between the device and the structure [17]. The average active power P_{ac} and the reactive power P_{re} can be written as:

$$P_{ac} = 1/2\Re(P(s)) = \frac{f_d^2}{2}\Re(G_f(s) \times G_{CL}(s) \times G_{CL}^*(s)) \quad (23a)$$

$$P_{re} = 1/2\Im(P(s)) = \frac{f_d^2}{2}\Im(G_f(s) \times G_{CL}(s) \times G_{CL}^*(s)) \quad (23b)$$

where $G_f(s)$ and $G_{CL}(s)$ are the transfer function from the velocity of the structure to the control force and the transfer function from the input force disturbance to the velocity.

For a unit forcing amplitude, Figure 7a compares the active and reactive power at a specific value of the closed-loop damping for purely active control system and the hybrid control system using active voltage source and current source, separately. DVF is used for the purely active control system. One can observe that the active power for all configurations is always positive through the entire frequency range. This means that the device does not deliver energy in the system and it is *hyperstable*. The reactive power for the hybrid control system when active voltage source is applied is positive before the resonance frequency and negative after that. This shows the amount of energy exchanged between the structure and the transducer. The total positive and negative reactive power is almost zero.

Figure 7b compares the H_2 norm of the active power as a function of the closed-loop damping ratio. One sees that the active power is zero for 16% damping ratio and below. This is because the passive control system is doing the job. While there is no external power required to realize 16% damping ratio by the passive control system, a similar purely active control system requires a large amount of external power. In addition, the active power for the hybrid control systems is always less than purely active control system. However, for high values of the closed-loop damping, the active power for the hybrid configurations is close to the active power for the purely active control system. This is because most of the work is done by the active portion of the hybrid systems.

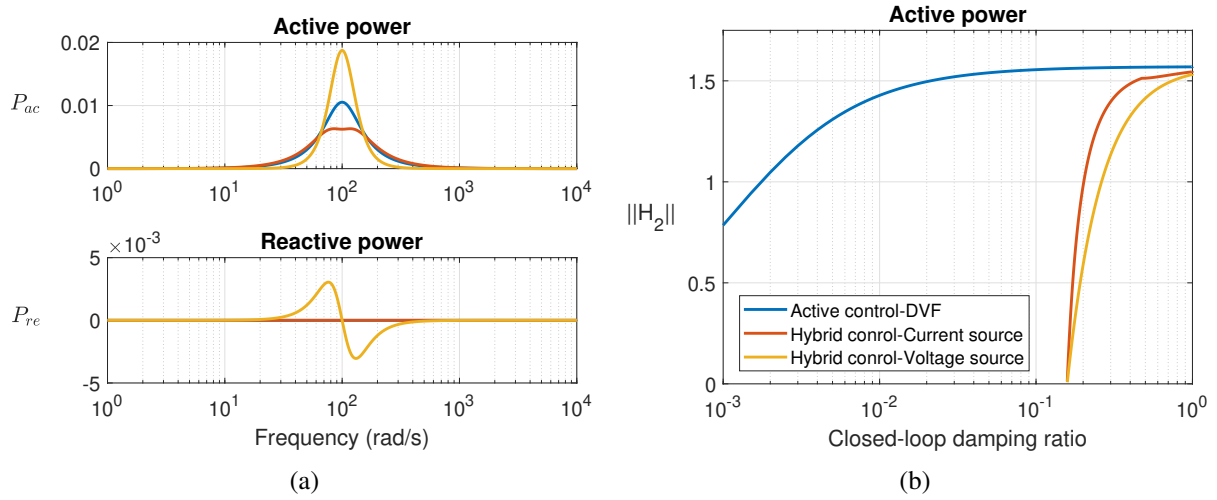

Figure 7: Comparison between the purely active control system (DVF) and Hybrid control systems using active voltage source and current source separately. (a) active and reactive power for a specific closed-loop damping ratio, (b) the H_2 norm of the active power

5 CONCLUSIONS

The hybridization of the passive electromagnetic shunt damper with the active control systems has been proposed and analyzed in details. The RC shunt has been used in series with an electromagnetic transducer as the passive control system and its parameters have been optimized based on the method of maximum damping. Both the active voltage source in series with RC elements and the active current source in parallel with it have been proposed for the hybrid configurations. It was shown that the system "electromagnetic device + active voltage source" can be seen as an equivalent transducer with an enhanced coupling constant T ; equivalence formulae have been presented. In this case, it was shown that the optimal value of the resistance R is modified to a larger value as a function of the feedback gain C_1 in order to improve the damping of the system. In addition, it was shown that the active current source behaves like a DVF. In this case, the feedback gain C_2 has been optimized based on the method of maximum damping while there is no need to change the parameters of the passive RC circuit. The fact that R does not need to be changed in this configuration is a major advantage compared to the implementation of the active voltage source, as it is much easier to implement a fail-safe system. Moreover, the power consumption was highlighted to compare the hybrid control systems and purely active control system (using DVF). As a consequence, it has been demonstrated that both hybrid control systems can improve the control performance of the purely passive system while it has less power consumption in comparison with the purely active control system.

Abstract. In previous work we have described the use of piezoelectric elements as means to obtain variable connectivity between the elements of a phononic crystal by exploiting the frequency dependent stiffness of resonantly shunted piezoelectric elements. There, piezoelectric disks were intercalated between an aluminum plate and aluminum stubs and were used to effectively disconnect the stubs creating a phononic structure from the substrate. Given the function of the investigated object, no special structural requirements were set to the piezoelectric disks. Here, we present work related to the structural integration of piezoelectric elements in a load bearing structure. The goal of the integration is to exploit frequency dependent stiffness properties of resonantly shunted piezos to modify the stiffness matrix of a simple truss structure. In order to demonstrate the proposed approach, a ring-shaped piezo-stack is axially mounted into the diagonal strut of a square frame. In order to guarantee the function of the piezoelectric element under the expected load conditions, axial pre-compression needs to be applied. This contribution describes the design, implementation and initial investigation of the dynamic response of a variable connectivity truss structure.

1 INTRODUCTION

The use of shunted piezoelectric elements for vibration damping purposes has now been demonstrated [1] for four decades, further developed and divulged in innumerable contributions [2, 3, 4, 5] and represents in some ways the golden standard in integrated multi-field vibration mitigation treatments. However, the implementation of this type of treatments implies the ability to correctly tailor the position and frequency response of the piezoelectric device and is subject to detuning or incorrect placement of the shunted piezoelectric element due to varying operational conditions, deterioration of the integrity of the structure or environmental effects. As such, in spite of their undoubted efficacy, their practical application is still limited to very specific cases. Recent research indicates that under certain conditions, the implementation of distributed elements for the mitigation of mechanical vibrations can offer substantial advantages in terms of robustness of the system. In this sense, with the understanding that structural vibrations are nothing else than the expression of the interaction of low frequency waves propagating through a structure and interacting with its boundaries and the imposed conditions, the focus of research is shifted to avenues for the manipulation of the propagation of mechanical waves. Here, the

groundbreaking work of Liu [6] has successfully demonstrated the wavenumber-independent attenuation of mechanical waves at a specific frequency using sub-wavelength features, employing local mechanical resonators and providing for robustness against the misplacement of the energy absorbers within the structure. Inspired by these findings, elegant implementations of local resonators based on electromechanical systems were devised, such as the ones presented by Spadoni [7], and Casadei [8], among others. This approach to wave propagation control offers the undoubted advantages of wavenumber independent attenuation of waves and orthogonality to structural properties [9] originating from the local nature of the resonators, however at the cost of a very narrow band effect. Wu [10] has demonstrated the realization of complete Bragg bandgaps in macroscopic systems, echoing the seminal work of Brillouin [11] on the propagation of waves in periodic media. Here it has been shown that in periodic arrangements of mass and spring elements the propagation of waves in certain ranges is suppressed by scattering phenomena. This effect can cover wide frequency ranges [12, 13, 14]. As long as the modulus, density, unit cell size of the phononic crystal allow for it, the position of the bandgaps can be positioned at arbitrarily low frequencies. However, it should be noticed that there are limits to what can be achieved in these terms [15]. In previous work we have shown a possible use of electromechanical resonators as variable stiffness elements to modify the connectivity in phononic crystals [16]. There, we introduced resonantly shunted piezoelectric disks between the stubs and the plate of a stubbed plate as described in [10]. If the resonance frequency of the piezoelectric element was positioned within the Bragg type bandgap created by the lattice created by the periodically arranged stubs, we could observe the appearance of a passband. We interpreted this observation as due to the effective modification of the connectivity of the stubs and the plate, due to the frequency dependence of the effective modulus of the piezoelectric disk around the electric resonance of the LC shunt. In this contribution we explore the implementation of frequency dependent stiffness elements (embodied by resonantly shunted piezoelectric elements) in lattice-type phononic crystals, as a way to adaptively modify the connectivity of the lattice, with the expectation that some useful property would emerge from this. The baseline expectation is that, the adaptive connectivity of the lattice can be used to strongly affect its response to dynamic loads. Here we present a numerical investigation of dynamic properties of a lattice structure with adaptive connectivity trusses and of the unit cell it is made of. Finally, we show the state of advancement of our effort to experimentally verify the behavior predicted by our models.

2 STRUCTURES WITH FREQUENCY-DEPENDENT STIFFNESS ELEMENTS

The implementation of active elements in truss structures has been presented in [17], where the effectiveness of discrete piezoelectric elements in an active vibration suppression scheme is outstandingly demonstrated. Here, we will discuss a passive approach, in which piezoelectric elements are implemented as frequency dependent stiffness elements. First, we will investigate the frequency response of the base element of the two-dimensional structure, that we will consider as the unit cell of a periodic structure and assess the frequency dependent stiffness of the unit cell (see fig. 1). Then we will show the effect of distributed frequency dependent elements in a periodic structure (see fig. 2) on its frequency response. The frequency dependent stiffness elements are represented by bulk piezoelectric elements in the numerical models presented in the following sections, for the sake of simplicity. Accordingly, the inductance values selected to obtain the electrical resonance of shunts at the frequencies of interest are very high. In the practical implementation, briefly discussed at the end of this work, piezostacks are chosen, over piezoelectric patches as a more effective way to exploit the electromechanical coupling in a load carrying structure. The simplification made in the numerical models does not affect the validity of the general findings they provide.

Figure 1: Base unit of the truss structure with frequency dependent stiffness elements, consisting of a diagonal brace, in which a piezoelectric element shunted over an inductor L is integrated, horizontal beams, and vertical beams to close the frame. In the model, the unit cell is fixed along its left edge.

2.1 Unit Cell

In two dimensions, a square frame with a diagonal shear stiffening element represents a very simple component from which a larger structure can be created by simple symmetry operations such as translation, rotation, and mirroring. The properties of such a structure are known to carry the imprint of its constituting components [18]. So, we are interested in understanding the effect of the electrical resonance in the shunted piezo on the dynamic properties of the unit cell. Assuming that the shunted piezoelectric element provides the frequency dependent stiffness postulated in [16], we can expect the shear stiffness of the truss to strongly vary as a function of frequency, around the resonant frequency of the piezoelectric resonator. The host structure is modeled in COMSOL Multiphysics as a two-dimensional object, assuming plain strain conditions, with an assigned thickness (z -direction) of 3.3mm. The host structure (grey) is modeled as an aluminum alloy, the piezoelectric element representing a piezoelectric stack is taken to have the properties of PZT-5H. The dimensions and the mechanical boundary conditions are shown in figure 1. A point force in $-y$ direction is applied to top right corner of the unit cell.

2.2 Structure

The structure we consider is inspired by the unit cell discussed above. The diagonal braces with the integrated piezoelectric element are identical with the one implemented in the unit cell. The horizontal

Figure 2: Structure that includes diagonal braces as discussed in the previous section. Additionally some horizontal beams are added to maintain the free length of the braces. The width of the outer frame is the same as in figure 1. The figure shows only one electric shunt (inductor $L=210.5H$), implying that each piezoelectric element is shunted individually over identical circuits. The numbers in blue color, next to the piezos, indicate the numbering scheme for the piezoelectric elements.

trusses have the same width as the quadratic frame of the unit cell, while the frame of the structure is slightly wider. In order to be able to include periodic arrays of braces with the same length as in figure 1, horizontal elements were included. The resulting structure is presented in figure 2. As in the model presented in the previous section, the left edge of the structure is fixed both in x - and in y -direction. The materials considered in the 2-dimensional model of the structure are the same as for the unit cell. The model also assumes plain strain conditions and has an assigned thickness of 3.3mm. A point force in y -direction is applied to top right corner of the unit cell.

The frequency response of the two structures described in the sections above, represented as the displacement amplitude for a unit force applied to the structure and the time average of the electric energy density within the piezoelectric elements will give us information about the effect of the the integrated variable stiffness elements on the dynamic response of the two structures.

3 RESULTS and DISCUSSION

In the following we report the displacement-amplitude recorded at the position where the point force is applied as a function of frequency for three different electrical boundary conditions applied to the piezoelectric elements: open circuit, where no current can flow in the shunt, short circuit, where the potential between the electrodes is zero and where the impedance of the shunt is determined by an ideal inductor with $L = 210.5H$. The reported quantity represents the compliance of the structure, with the units [mm/N]. For the same boundary conditions, we report also the time averaged electrical energy density in the piezoelectric elements, as a measure of the energy exchanged by the structure with the

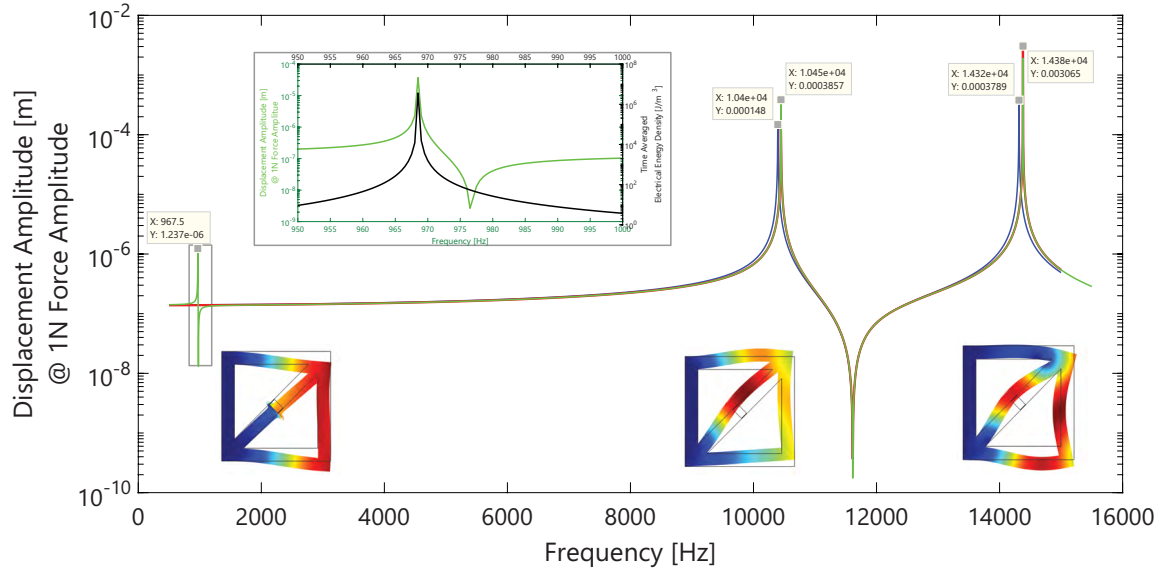

Figure 3: Overview of the frequency response (green, displacement amplitude) of the unit cell under open circuit, short circuit and inductively shunted ($L = 210.5H$) conditions, the color figures show the modal shapes for the corresponding eigenfrequencies, the insert shows a detail of displacement and electrical energy density (black) in proximity of the eigenfrequency of the LC resonator (shunted piezo).

shunted piezos.

3.1 Unit Cell

The frequency response of the unit cell, expressed as its compliance, well agrees in its essence with the results reported in [16]: The stiffness of the piezoelectric element is known to drop at frequencies immediately below the resonance frequency of the LC shunt and to increase again as the frequency exceeds it, accordingly the compliance of the structure increases and decreases again to values similar to the ones far away from resonance. Also the comparison between open and short-circuit boundary conditions confirms what we know: It is reasonable to state that -unsurprisingly- also in the configuration presented in this work, piezoelectric elements can be regarded as elements that can change their effective stiffness as a consequence of the electric boundary conditions.

3.2 Structure

The integration of shunted piezoelectric elements in a larger, periodically arranged structure is expected to carry in itself to a large extent the footprint of its constitutive elements. If in the piezoelectric elements a variation of the stiffness of the components occurs at a specific frequency, the effect of this variation can be expected to affect also the behavior of the larger structure. Now, since under the ideal conditions offered by a numerical model, we were able to tune all LC circuits composed of the piezoelectric element and the inductor to the same frequency (approximately $484Hz$ for the given piezos and an inductance value of $L = 842H$), the expectation would be to see an increase in compliance, i.e. of displacement amplitude in correspondence to the electric resonance, similar to what we see for the unit cell comprised of one piezoelectric element. This corresponds also to the observation made for local

Figure 4: Frequency response (displacement amplitude, black, and time-averaged electric energy density in the piezoelectric elements, colors) of the unit cell under inductively shunted ($L = 842H$) conditions at frequencies below the first global, structural eigenfrequency ($968.5Hz$).

piezoelectric resonators, as discussed in [8, 7], where a dip in the transmissibility of waves through the structure. Here, however, we observe phenomena that qualitatively and quantitatively deviate from the response of a single or of an array of *local* resonators: instead of a single peak and subsequent dip in compliance, the frequency response of the structure at hand shows a much richer behavior, spanning over a fairly wide range of frequencies, and characterized by a series of local displacement amplitude peaks and valleys. Interestingly, the electric energy density in the piezoelectric elements shows a rich frequency dependent behavior around the electric resonance, whereas, farther below and above it, this quantity only slightly differs among different piezos, and has a smooth behavior, as a function of frequency.

The plots of figures 5 and 6 show how the structure behaves, when the nominal resonance frequency of the shunted piezoelectric resonators is tuned to a structural eigenfrequency. Also here, if the array of tuned piezoelectric resonators were to act as local resonators, or if there were only one piezoelectric element coupled to the structure, the expected response would be the one of a two degrees of freedom (2DOF) system with two resonance peaks and one antiresonance, as shown in [1, 2]. However, the complexity that we have seen emerge from the presence of multiple resonators, tuned at the same nominal frequency, is visible also here. Globally, two resonance peaks at the edge of the frequency range in which the multi-resonator behavior is observed, are given (fig 5).

4 CONCLUSIONS and OUTLOOK

The numerical investigations of a structure comprised of multiple, tuned, piezoelectric resonators presented in this work, point to the emergence of phenomena originating from the interaction between mechanically coupled piezoelectric resonators: It appears that in spite of all being electrically identical, the shunted piezoelectric elements display inhomogeneous frequency responses among them, as clearly indicated by plots of the electrical energy density for the individual elements. An interpretation for this

Figure 5: Overview of the frequency response (displacement amplitude) of the truss structure under open circuit (red), short circuit (blue) and inductively shunted (green, $L = 210.5H$) conditions, around its first mechanical resonance.

Figure 6: Frequency response (time-averaged electrical energy density in the piezo. for each piezo) of the truss structure under open circuit (red), short circuit (blue) and inductively shunted (green, $L = 210.5H$) conditions, around its first mechanical resonance. The shade of the respective color indicates the piezo number the line refers to: black \rightarrow 1, color \rightarrow , see figure 2 for the piezo numbering scheme

observation can be found in the fact that not only do the mechanical properties of piezoelectric materials depend on the electric boundary conditions, but also the dielectric properties of the material depend on the mechanical boundary conditions. Out of this coupling arise complex interactions between the piezoelectric elements, mediated by the structure that lead to the rich response of the array of mechanically coupled resonators. Thanks to these emergent phenomena, distributed, coupled variable stiffness elements realized via shunted piezos, appear to qualitatively distinguish themselves from discrete piezoelectric treatments. The mechanisms that lead to the interesting dynamic behavior of the described structure will need further investigation.

4.1 Experimental verification and challenges

The next challenge of this work will be the experimental verification of these findings. For this purpose a way to properly integrate piezoelectric elements has to be devised. Unlike in the numerical model, the integration in a real setting presents a few practical challenges:

- Piezoelectric elements come in discrete sizes and designs, the structure needs to be designed around the best suitable candidate for the purpose
- To guarantee proper function, thick piezoelectric transducers need to be pre-compressed
- First investigations based on the numerical model appear to indicate that the system is sensitive to material damping and that the described phenomena are most easily observed in a weakly damped system. For this reason the use of conventional polymer based adhesives does not seem to be ideal.

The challenges listed above have lead us to design a 'dry mounted' system in which load transfer relies on clamping a ring stack actuator within the diagonal brace. This should allow to meet the requirements we have recognized as relevant so far. However, the realization of a clamped, pre-stressed structure, as the one shown in figure 7, requires high precision components and careful assembly. First experimental results to confirm the findings of the numerical model of the unit cell are expected soon. The preparation of a multi-resonator structure will be tackled once the technique for the preparation of the unit cell will have been refined.

Key words: Flow-induced vibrations, Resonant piezoelectric shunt, Passive vibration damping.

Abstract. Marine lifting surfaces undergo flow-induced vibrations leading to shorter life cycles due to structural fatigue and reduced acoustic performances. As such, accurate understanding of the fluid-structure response of marine structures, as well as vibrations control and damping, are critical to many maritime applications. In particular, this work investigates the potential of the electromechanical coupling inherent to piezoelectric materials for passive vibration damping of hydrofoils under hydrodynamic flows. An aluminium flat plate equipped with piezoelectric patches connected to a resonant shunt is considered. The structure is first tested under hydrodynamic flows for various Reynolds numbers to investigate its flow-induced vibrations. This allows to determine the natural frequency of interest to test the control solution. Second, an experimental modal analysis is carried out to determine the open and short circuit natural frequencies in order to compute the piezoelectric coupling factor. Indeed, the latter is related to the expected performance of the passive vibration damping strategy. Third, the values for the resistive and inductive components of the RL-shunt are inferred from the coupling factor and the natural frequencies. Last, the control solution is tested in still air and water in open and short circuits configurations. Comparisons of these two configurations are realised and the resonant shunt performance for vibration reduction of hydrofoils is estimated.

1 INTRODUCTION

Applications for high-speed ships fitted with hydrofoils, such as fast passenger-ferries and racing sailing boats, are progressively expanding and gaining economic importance. This leads to a renewed interest in the physical understanding of flow-induced vibrations of light flexible structures subjected to strong fluid-structure interactions. There is also a growing demand for

vibration control and damping solutions. Indeed, flow-induced vibrations may trigger a sharp increase in the vibration amplitude when there is a coincidence between a natural frequency of the structure and a hydrodynamic excitation frequency. The consequences of such high-amplitude vibrations are reduced acoustic performances (*e.g.* hydrofoil singing), and shorter life cycles [1,2]. As such, it is of prime importance to develop methods for vibration damping.

Several researches have been completed on the high potential of piezoelectricity for vibration control and damping. In particular, Lossouarn et al. [3] and Thomas et al. in 2012 [4] in 2017 successfully demonstrated the ability of passive piezoelectric shunts to reduce the amplitude of the vibrations of structures in air. Academic research is now turning to the application of this solution to the maritime domain [5]. The purpose of this work is to provide a first experimental prototype for the application of vibration damping using a resonant piezoelectric shunt in water. The methodology used to assess the performance of the solution and design the electrical components of the resonant shunt (inductance and resonance) from the natural frequencies in open circuit and closed circuit is first described. We then present a case of application on a flat aluminium plate.

2 VIBRATION DAMPING USING A RESONANT PIEZOELECTRIC SHUNT

Vibration damping using piezoelectricity consists in converting part of the vibratory mechanical energy into electrical energy, which is then dissipated through a resistor R . Moreover, it is possible to create an electric resonance with the addition of an inductance L to the electrical circuit. When this electric resonance matches one of the natural frequencies of the structure the energy transfer is increased. As a consequence, a passive resonant piezoelectric shunt behaves similarly to a tuned mass-damper [3]. Figure 1 represents a model for a mass-spring system (mass m and stiffness K) coupled to a resonant piezoelectric shunt and subjected to a force F . U represents the displacement of the mass, q represents the electric charge displacement, C the capacitance of the piezoelectric patch, and e is the piezoelectric constant, R and L respectively being the resistance and the inductor of the shunt.

Figure 1: Purely mechanical model of a structure coupled to a resonant piezoelectric shunt

Important electrical conditions and their corresponding natural frequencies are the “short circuit” and “open circuit” conditions. The former corresponds to zero voltage across the piezoelectric patch and a natural frequency ω_{sc} , while the latter corresponds to zero electric charge displacement ($q = 0$) and to a natural frequency ω_{oc} . The performances of the vibration damping solution are only dependant on the coupling factor k_c defined by the short circuit and open circuit natural frequencies:

$$k_c = \sqrt{\frac{\omega_{oc}^2 - \omega_{sc}^2}{\omega_{sc}^2}} \quad (1)$$

Once the coupling factor is known, the electrical inductor and resistor of the resonant shunt have to be designed according to:

$$L = \frac{I}{C\omega_{oc}^2} \quad (2)$$

$$R = \sqrt{\frac{3}{2}} \frac{1}{C\omega_{oc}^2} \quad (3)$$

These conditions correspond to the optimal values of L and R in order to set the electrical resonance on the mechanical resonance of interest [5]. Passive inductors are then produced according to these specifications using copper wire and appropriate magnetic circuits.

3 EXPERIMENTAL SETUP AND TECHNIQUES

3.1 Experimental Facility and Sensors

Experiments were carried out in the hydrodynamic tunnel at the Institut de Recherche de l'Ecole Navale (IRENav) in Brest, France, illustrated on Figure 2. The tunnel test section is 1 m long with a 192 mm square section. Available operational velocities in the test section range from 0 m/s to 12 m/s and available pressures range from 0.1 bar to 3 bar. Both are set up using a regulation system. Moreover, a honeycomb grid upstream of the test section allows for a 2% free stream turbulent intensity at the mid-section. Vibration measurements are realised using a scanning Doppler laser vibrometer located above the structure and a single point Doppler laser vibrometer located below the structure. For more information about the hydrodynamic tunnel and the experimental techniques, the interested reader may refer to [1,6].

Figure 2: Hydrodynamic tunnel at IRENav, [6]

3.2 Geometry and Materials

The structure considered in this work is a flat plate made of aluminium 5083 and equipped with four piezoelectric patches (two patches on each side of the plate). Base dimensions of the plate are 191 mm x 100 mm x 6 mm, with a 80 mm x 31 mm x 10 mm extension at its base, as

illustrated on Figure 3. This extension is used to clamp the structure to the tunnel wall. Furthermore, the piezoelectric patches are embedded in the structure *via* two pockets machined on both sides of the plate (Figure 3 and Figure 4). Indeed, embedding the patches in the structure avoids creating local roughness, which may cause added turbulence or flow detachment if the roughness size is in the order of the boundary layer thickness. The piezoelectric patches are vacuum-glued in the pockets using epoxy, then a layer of paraffin is added to fill the residual depth of the pocket. Pathways are also machined in the plate and the extension to allow the passage of cables from the electrodes (two on each patch) to the components of the electrical control circuit.

Figure 5 presents the geometry and dimensions of the piezoelectric transducers, in which a PIC 255 piezoelectric ceramic (black rectangle) is encapsulated. The dimensions of the patch are 61 mm long, 35 mm wide and 0.8 mm thick, for a piezoelectric part 50 mm long, 30 mm wide and 0.5 mm thick.

4 RESULTS

4.1 Test Cases Under Hydrodynamic Flows

Experiments are first carried out with the plate placed in water at an incidence of 0° , and incident flow velocities ranging from 1 m/s to 10.5 m/s, *i.e.* moderate Reynolds numbers from 10^5 to 1.05×10^6 . The objective is to investigate the flow-induced vibrations of the structure in order to determine the natural frequency of interest to test the control solution. Indeed, as detailed in Section 2, one has to know the value of the frequency to be controlled to guide the design choices of the electrical circuit (inductor and resistor). Therefore, piezoelectric patches are inactive in this first series of tests. Figure 6 shows the vibration spectra of the plate for the range of incident velocities considered. The first three natural frequencies are visible for respective values of 26.4 Hz, 174.1 Hz and 265.6 Hz. The spectra also exhibit additional components with a strong dependence to the Reynolds number: the local maximum close to 50 Hz for a Reynolds number of 1.5×10^5 is progressively shifted towards the high frequencies when increasing the Reynolds number. This phenomenon is characteristic of a vortex shedding process associated to Von Kármán alleyways [1,2,7,8]: The boundary layer is developing on both sides of the plate but meets with a singularity at the trailing edge. The boundary layer then starts to shed alternatively from both sides of the plate, leading to the formation of a vortex street in the turbulent wake. This alternate shedding causes a periodic fluctuation of the hydrodynamic loads applied on the plate and is thus a source of excitation associated to a shedding frequency f_{shed} . In the present case, we can observe a strong fluid-structure interaction between the second mode of the structure (corresponding to the first torsion mode) and the shedding frequencies when their respective values coincide (around 174 Hz). This strong fluid-structure interaction is characterised by a sharp increase of the vibration amplitude.

Figure 6: Vibration spectra under hydrodynamic flow for different incident velocities

Figure 7a presents the corresponding Reynolds-frequency diagram, which clearly highlights the linear evolution of the hydrodynamic excitation frequency with the Reynolds number, and therefore the velocity of the incident flow. This linear evolution is given by (4), with a constant Strouhal number close to 0.2 when vortex shedding occurs (d is the thickness of the plate and

U_0 the incident velocity) [7,8].

$$Sh = \frac{f_{shed} d}{U_0} \quad (4)$$

The linear evolution of the shedding frequencies with the Reynolds number according to Strouhal's law is also highlighted on Figure 7b, where the experimental data points correspond to the local maxima of the spectra presented on Figure 6. One can see that in the present case the Strouhal number is constant to 0.194, confirming the existence of vortex shedding. However, for some Reynolds numbers between 4×10^5 and 6×10^5 the shedding frequencies no longer follow Strouhal's law, but instead keep a constant value of 174 Hz, despite the increase in the number of Reynolds. This is the phenomenon of frequency lock-in around the first mode of torsion: Von Kármán's turbulent wake no longer evolves with its own dynamics (4) but is organized around the natural frequency of the structure [8,9]. As a consequence, the strong fluid-structure interaction previously mentioned corresponds to this lock-in phenomenon.

(a)

(b)

Figure 7: (a) Reynolds-frequency diagram and (b) shedding frequency vs Reynolds number and lock-in

4.2 Test Cases in Still Air and Water

The first series of tests highlighted the existence of a strong fluid-structure interaction between the first torsion mode and the hydrodynamic excitation frequencies due to Von Kármán vortex shedding, resulting in a large increase in the vibration amplitude. As a consequence, this structure is an interesting test case for the application of the vibration damping solution (described in Section 2) to the first torsion mode. The objective is to reduce the amplitude of the vibrations thanks to a passive resonant piezoelectric shunt adjusted on the natural frequency of the structure where the strong fluid-structure interaction occurs. As a first attempt for vibration damping in water using a piezoelectric shunt, this solution is indeed easier to setup than a Reynolds-dependent shunt that would follow the frequency shift of the hydrodynamic excitation.

For this purpose, a second series of tests is carried out both in air and then in still water in order to determine the open and short circuit natural frequencies and evaluate the performances of the control solution in a simplified case. Since the flow no longer provides the excitation of the structure, an alternative source of excitation is used: an electrical voltage is imposed on one of the patches (using a function generator) which then generates a vibratory excitation on the structure through the inverse piezoelectric effect. The other three patches are for the moment kept inactive. The main advantage of this method lies in its ability to provide the frequency responses functions (FRF) of the structure as both the input (voltage imposed on the patch) and output (velocity measured by the vibrometer) are known. On the contrary, when the excitation is generated by the hydrodynamic flow, the input is unknown. Here, a sinus excitation swept across the entire frequency band between 1 Hz and 100 Hz is applied on one of the patches. The temporal signal of this excitation is shown on Figure 8a and the corresponding temporal signal of the in-air and in-water responses are shown on Figure 8b.

Figure 8: Temporal signals associated to (a) the excitation by sweep and (b) the in-air and in-water vibrations of the structure

The frequency responses derived from the temporal signals are presented on Figure 9, where the first two modes of the structure are visible in air and the first three modes are visible in

water. Corresponding values are reported in Table 1: the comparison of the natural frequencies in air and in water shows significant added mass effects, with a reduction of the in-air natural frequencies up to 58.8%.

Figure 9: In-air and in-water frequency responses (without flow)

Table 1: Comparison of the in-air and in-water natural frequencies and added mass effects

	f_1	f_2	f_3
f_{air} [Hz]	63.3	295.9	-
f_{water} [Hz]	26.4	174.1	265.6
$\% f_{air}$	58.3	41.2	-

Last, a third series of tests was performed to evaluate the performances of the coupling solution with one of the patches providing the excitation, and the other patches activated for vibration damping. However, the coupling factors obtained (of the order of 3% for the first torsion mode) did not allow to observe a significant reduction of the amplitude of vibration. Such low coupling factors may be explained, on the one hand, by a problem of water sealing on the cables, and on the other hand by a poor placement of the patches to control the first torsion mode. To tackle this issue, two solutions may be considered. First, smaller patches could be used. This way, the location of the patches would be better suited for the control of the first torsion mode. Another solution is to control the first bending mode instead of the first torsion mode, as the coupling factors are more favourable for the bending. However, in order to get an electrical signal that is strong enough for clear measurements, it is preferable to increase the frequency of the first bending mode, for instance by decreasing the length of the plate from 191 mm to 100 mm. This second solution is currently under investigation.

5 CONCLUSIONS

This work presents the testing in water of an aluminium flat plate equipped with four piezoelectric patches. It constitutes a first experimental assessment of vibration damping in water using a resonant piezoelectric shunt. The dynamic response of the structure under hydrodynamic flow was first studied for various incident velocities, then the performances of the control solution were estimated. Prior characterization of the dynamic response of the

structure is indeed needed to determine the short and open circuit natural frequencies in order to compute the coupling factors and the optimal values for the inductance and resistance components of the piezoelectric shunt.

Results showed a strong fluid-structure interaction phenomenon between the natural frequencies of the structure and the hydrodynamic excitation frequencies due to Von Kármán vortex shedding in the turbulent wake. In particular, the hydrodynamic excitation frequencies present a linear dependence to the Reynolds number, with a constant Strouhal of 0.194, with the exception of a frequency lock-in around the first torsion mode (around 174 Hz). An original method for obtaining the frequency responses of the structure (FRF) in still water has also been implemented using one of the patches to provide the excitation of the structure, which allow non-contact excitation and measurement. However, the coupling factors obtained during these first tests to control the first torsion mode were too low to observe a significant reduction of the vibration amplitude, in particular due to a non-optimal placement of the piezoelectric patches. New tests are currently underway with a modified structure to ensure a better placement of the piezoelectric patches. A numerical analysis is also being carried out in order to numerically estimate the coupling factors before testing in water.

Abstract. A tuning procedure for resonant piezoelectric shunt damping based on measurable experimental data is proposed. The procedure is derived from a proposed resonant shunt tuning method designed for the implementation in commercial finite element (FE) software, including the contribution from non-resonant vibration modes. It has been found that this procedure is robust and effective for vibration mitigation in both beam and plate structures. In the present procedure a pseudo-random excitation signal is imposed on a structure with attached piezoceramic patches, while the piezoelectric electrodes are respectively in short- or open circuit. In both cases a time record of respectively the electric current and voltage is measured with a high quality multimeter. A Fast-Fourier-Transform is then used on these time records in order to determine the electric current and voltage frequency response functions. Finally, the optimum resonant shunt inductances and resistances are determined from the corresponding modal properties, which are extracted from the two frequency response functions. The method is demonstrated for a free beam with two pairs of piezoceramic patches, one pair used for the vibration excitation and the other for vibration mitigation. The experimental results are found to be in good agreement with the results from a corresponding numerical model build up in the commercial FE-software ANSYS®.

1 INTRODUCTION

The concepts of resonant piezoelectric shunt damping origin from the work by Forward [1], in which the mechanical equivalence to an electric capacitance, resistance and inductance are presented. It is then suggested that the shunt inductance (L) is tuned in order to neutralize the inherent capacitance of the piezoelectric material, whereby the damping introduced by the shunt resistance (R) is maximized. A concrete procedure for the optimum tuning of the resonant LR -shunt circuit was subsequently proposed by Hagood and von Flotow [2]. The method assumes the structural response around a target resonant frequency to be sufficiently represented by the corresponding modal properties. The tuning formulas are thus derived from a representative two degrees of freedom coupled electromechanical system. In [2] the series shunt circuit is considered, while the parallel shunt circuit was suggested later by Wu [3]. Alternative methods for the precise series and parallel shunt tuning have been suggested subsequently [4, 5], all based on the modal approximation. In recent years several authors have discussed the influence from the non-resonant vibration modes on the structural response, which alternate the optimum piezoelectric shunt tuning [6, 7, 8]. In [9] the influence from the non-resonant modes was described by a flexibility and

an inertia correction terms and the influence on the optimum tuning of tuned mass and inerter-based absorbers was demonstrated. In [8] the equivalence to resonant piezoelectric shunt damping was presented and in [10] an alternative formulation suitable for implementation in commercial software was suggested. In the present work, it is the aim to demonstrate the latter method through experiments carried out on a free beam employed with two pairs of piezoceramic patches.

The experimental design with a free beam is chosen in order to achieve high correlation between the experimental and numerical results. Disparancies between numerical and experimental results have been encountered in numerous contributions [2, 3, 4], where one of the common uncertainties is associated with an inaccurate numerical or theoretical approximation of the actual boundary conditions of the experimental setup. This can be dealt with by updating the finite element (FE) model according to the experimental results as proposed in [11]. However, such a procedure can be rather cumbersome, hence the free beam is chosen in the present case.

2 NUMERICAL SHUNT TUNING

In the present section the optimum shunt tuning procedure presented in [10] is summarized and an alternative way of determining the effective electromechanical coupling coefficient (EMCC) presented, where the latter becomes useful when reformulating the tuning formulas for subsequent experimental implementation. Optimum tuning of one shunt circuit is considered, which however may be connected to a network of several piezoceramic patches glued on to a mechanical structure. The coupled vibration problem of a mechanical structure with interconnected and shunted piezoceramic patches may be written according to [10], as

$$\left(\begin{bmatrix} K^E & k_{me}^E \\ (k_{me}^E)^t & -\tilde{C}_p^{\epsilon^S} \end{bmatrix} - \omega^2 \begin{bmatrix} M & 0 \\ 0 & 0 \end{bmatrix} \right) \begin{Bmatrix} U \\ V \end{Bmatrix} = \begin{Bmatrix} 0 \\ -Q \end{Bmatrix} \quad (1)$$

where $[K^E]$ is the elastic stiffness matrix of the structure with short circuit (SC) piezoceramic patch(es), $[M]$ is the mass matrix, $\{k_{me}^E\}$ the electromechanical coupling vector and $\tilde{C}_p^{\epsilon^S}$ the resulting modified capacitance of the piezoceramic patch(es).

The vibration problem Eq. (1) is limited by two eigenvalue problems associated with, respectively, SC and open circuit (OC) piezoceramic patch electrodes. When having SC electrodes the voltage vanishes $V = 0$ and the associated eigenvalue problem can be written as

$$([K^E] - \omega_j^2[M]) \{U\}_j = \{0\} \quad (2)$$

for a particular vibration mode j with circular frequency ω_j . The second equation in Eq. (1) further provides the (sensed) modal charge

$$\tilde{Q}_j = -\{k_{me}^E\}^t \{U\}_j \quad (3)$$

When no current can flow between the interface electrodes, the piezoceramic patch(es) is(are) said to be in OC. Vanishing current implies that the charge is zero, whereby the corresponding eigenvalue problem follows from Eq. (1), with $Q = 0$, as

$$\left([K^E] + \frac{1}{\tilde{C}_p^{\epsilon^S}} \{k_{me}^E\} \{k_{me}^E\}^t - \omega_j^2[M] \right) \{\hat{U}\}_j = \{0\} \quad (4)$$

while the second equation of Eq. (1) provides an OC modal voltage given as

$$\tilde{V}_j = \frac{1}{\tilde{C}_p^{\epsilon^S}} \{k_{me}^E\}^t \{\hat{U}\}_j \quad (5)$$

Table 1: Numerical parallel and series shunt tuning to target vibration mode r .

Parallel (p)	Series (s)
$L_p = \frac{\kappa_r^2}{Q_r^2} \quad , \quad R_p = \frac{\kappa_r^2 \omega_r}{Q_r^2} \sqrt{\frac{1}{2\kappa_r^2}}$	$L_s = \frac{\kappa_r^2}{Q_r^2(1 + \kappa_r^2)^2} \quad , \quad R_s = \frac{\kappa_r^2 \omega_r}{Q_r^2} \sqrt{\frac{2\kappa_r^2}{(1 + \kappa_r^2)^3}}$

The authority of the piezoceramic patch(es) on a given vibration mode of the electromechanical structure is associated with the relative difference between the SC and OC modal strain energies and defined by the effective EMCC. The effective EMCC is for resonant vibration mode $j = r$, given as

$$\kappa_r^2 = \frac{\hat{\omega}_r^2 - \omega_r^2}{\omega_r^2} \quad (6)$$

Pre-multiplying Eq. (2) with $\{\hat{U}\}_r^t$ and Eq. (4) with $\{U\}_r^t$, the terms involving $[K^E]$ may be eliminated such that the effective EMCC alternatively can be expressed as

$$\kappa_r^2 = \frac{\{U\}_r^t \{k_{me}^E\} \{k_{me}^E\}^t \{\hat{U}\}_r}{\omega_r^2 \bar{C}_p^{\epsilon^S} \{U\}_r^t [M] \{\hat{U}\}_r} \quad (7)$$

Introducing the SC modal charge Eq. (3) and OC voltage Eq. (5), the effective EMCC Eq. (7) can be written as

$$\kappa_r^2 = \frac{\tilde{Q}_r \tilde{V}_r}{\omega_r^2 \{U\}_r^t [M] \{\hat{U}\}_r} = \frac{Q_r V_r}{\omega_r^2} \quad (8)$$

The latter expression in Eq. (8) follows by normalizing the modal charge and voltage from Eqs. (3) and (5) by the intermediate modal mass $\tilde{m}_r = \{U\}_r^t [M] \{\hat{U}\}_r$ in the denominator of Eq. (8) as

$$Q_r = \frac{\tilde{Q}_r}{\sqrt{\tilde{m}_r}} \quad , \quad V_r = \frac{\tilde{V}_r}{\sqrt{\tilde{m}_r}} \quad (9)$$

In regard to experiments, the intermediate modal mass \tilde{m}_r may beneficially be determined from Eq. (8),

$$\tilde{m}_r = \frac{\tilde{Q}_r \tilde{V}_r}{\omega_r^2 \kappa_r^2} \quad (10)$$

In reality the intermediate modal mass \tilde{m}_r would be close to both the modal mass of the SC or OC electromechanical structure, since the corresponding mode shapes are almost identical and the mass distribution remains virtually unchanged.

In [10], a reduced order model was introduced in order to determine the optimum parallel and series resonant RL shunt tuning. The tuning formulas are provided in Table 1 for clarity, while the reader is referred to [10] for the extensive derivations. It is noted that the inertia effect from the non-resonant vibration modes on the shunt tuning is neglected according to [10].

The tuning formulas provided in Table 1 are favorable in terms of FE-analysis since the mode shapes and modal charge can be normalized in order to obtain unit modal masses as described in [10]. In terms of tuning based on experimental data it become beneficial to reformulate these tuning formulas as demonstrated subsequently in section 3.

3 EXPERIMENTAL SHUNT TUNING

In this section the resonant shunt tuning procedure in section 2 is reformulated to be dependent on measurable experimental data. The experimental procedure is very simple and consists of two steps. First, the electromechanical structure is excited by a pseudo-random excitation signal with a given frequency bandwidth and intensity, while the piezoceramic patch(es) are in SC condition. The SC condition is realized by connecting the interface electrodes of the piezoceramic patch(es) to a multimeter measuring the time record of the corresponding electric current $I(t)$. In the second step, a random excitation signal with the same frequency bandwidth and intensity is applied to the electromechanical structure with the piezoceramic patches in OC condition. The OC condition is realized by adjusting the multimeter to measure electric voltage $V(t)$, whereby an infinitely large resistance is imposed between the interface electrodes. From the measured current and voltage time records two frequency response functions (FRF) can be determined using a fast Fourier transform (FFT), from which the SC and OC frequencies and modal current and voltage amplitudes are read for each vibration mode in the analyzed frequency band.

The modal voltage is found directly as the resonant peaks $\tilde{V}_j = \tilde{V}(\hat{\omega}_j)$ in the generated frequency response, while the measured electric current time response $I(t)$ is used to determine the corresponding charge $\tilde{Q}(t)$. The electric current is given as the time derivative ($\dot{(\cdot)} = d/dt$) of the electric charge

$$I(t) = \dot{Q}(t) \quad (11)$$

Assuming harmonic solutions, the electric current and charge time functions may be expressed as

$$I(t) = \tilde{I}e^{i\omega t}, \quad Q(t) = \tilde{Q}e^{i\omega t} \quad (12)$$

with the complex amplitudes \tilde{I} and \tilde{Q} . Inserting (12) into (11) the relationship between the complex amplitudes of the current and charge may be written as

$$\tilde{I} = i\omega\tilde{Q} \quad (13)$$

Finally the modal charge are found as the resonant peaks $\tilde{Q}_j = \tilde{Q}(\omega_j)$ of the corresponding FRF.

The shunt tuning then follows by determining the effective EMCC Eq. (6) and the intermediate modal mass from Eq. (10), while the shunt tuning formulas in Table 1 can be reformulated by inserting κ_r^2 from Eq. (8) in the tuning formulas. For the parallel inductance tuning this gives

$$L_p = \frac{|V_r|}{|Q_r|\omega_r^2} = \frac{|\tilde{V}_r|}{|\tilde{Q}_r|\omega_r^2} \quad (14)$$

which is seen to be independent of any normalization of the modal charge and voltage and also does not require determination of the OC frequency and effective EMCC. The series inductance tuning and tuning of the optimum resistances follow similarly from inserting the effective EMCC κ_r^2 (Eq. (8)) into the tuning formulas provided in Table 1. The reformulated tuning formulas for the experimental RL shunt design are provided in Table 2 for both the parallel and series shunt circuits.

4 SYNTHETIC INDUCTOR

In the subsequent experimental verification of the tuning procedure presented in section 3, a so-called synthetic inductor is used to emulate the required shunt inductance. It consists of an Antoniou circuit [12] with the modification proposed in [13]. The circuit diagram of the modified Antoniou circuit and the prototype of the synthetic inductor used in the experiment can be seen in Figure 1.

Table 2: Experimental parallel and series shunt tuning to target vibration mode r .

Parallel (p)	Series (s)
$L_p = \frac{ \tilde{V}_r }{ \tilde{Q}_r \omega_r^2}$, $R_p = \frac{ \tilde{V}_r }{ \tilde{Q}_r \omega_r} \sqrt{\frac{1}{2\kappa_r^2}}$	$L_s = \frac{ \tilde{V}_r }{ \tilde{Q}_r \hat{\omega}_r^2 \hat{\omega}_r^2}$, $R_s = \frac{ \tilde{V}_r }{ \tilde{Q}_r \hat{\omega}_r} \frac{\omega_r^2}{\hat{\omega}_r^2} \sqrt{2\kappa_r^2}$

Figure 1: Synthetic inductor, circuit diagram (a) and prototype (b).

Details about the original Antoniou circuit can be found in [14], while the modification is given by the addition of the variable resistance R_R , see Figure 1(a). The latter permits the addition of negative resistance to the circuit impedance, added in order to compensate for eventual parasitic losses. The original Antoniou circuit was designed in order to emulate the effect of an inductance by keeping a constant current to voltage relationship at the circuit terminal defined as

$$V(t) = L\dot{I}(t) \quad (15)$$

Assuming harmonic solutions, the electric current may be expressed as in Eq. (12a) with a similar representation for the voltage,

$$V(t) = \tilde{V}e^{i\omega t} \quad (16)$$

Inserting Eqs. (12a) and (16) into Eq. (15) the emulated inductance can be defined as

$$L = \frac{|\tilde{V}|}{\omega|\tilde{I}|} \quad (17)$$

Analyzing the circuit diagram Figure 1(a), it may thus be found that the emulated inductance is given as

$$L = \frac{C_1 R_1 R_3}{R_2} R_L \quad (18)$$

The full effective impedance of the modified Anoniou circuit can further be determined as

$$Z = i\omega \frac{C_1 R_1 R_3}{R_2} R_L - \frac{R_1}{R_2} R_R \quad (19)$$

which is seen to correspond to the impedance of an inductance connected in series with a negative resistance. The properties of the constant electronic components are given by $R_1 = 2\text{k}\Omega$, $R_2 = 1\text{k}\Omega$,

Figure 2: Verification of synthetic inductor (a) FRF for the current and voltage and (b) the corresponding emulated inductance value, for $R_L = 25\Omega$ (—), 50Ω (---), 100Ω (-.-.), 200Ω (.....).

$R_3 = 1\text{k}\Omega$ and $C_1 = 10\mu\text{F}$, whereby the inductance and negative resistance can be determined by constant factors multiplied by respectively the variable resistances R_L and R_R ($0 - 1\text{k}\Omega$), as

$$L = (0.02\text{H}/\Omega)R_L \quad , \quad R = -2R_R \quad (20)$$

In order to verify the analytic expression Eq. (20a) for the emulated inductance, the terminal of the synthetic inductor is excited by a pseudo-random voltage signal for different R_L values, while the resistance R_R is kept constant to zero. The corresponding electric current time record is then measured with a high quality multimeter connected in series with the synthetic inductor. Finally, an FFT is used on the voltage and current time records in order to obtain the corresponding FRFs. In Figure 2(a) the FRFs corresponding to R_L values of 25Ω , 50Ω , 100Ω and 200Ω are provided, while the corresponding emulated inductance values determined from Eq. (17) are shown in Figure 2(b). It is seen that the input voltage signal is increased for the tests with larger R_L -values, in order to minimize the effect of the electric hums that are clearly visible in the FRF of the electric current. Disregarding these electric hums, it is seen from Figure 2(b) that the emulated inductance values agree well with the values predicted from Eq. (20a) and are almost constant in the analyzed frequency band.

The synthetic inductor is further tested at higher R_L values of 400Ω , 800Ω , 1600Ω and 3200Ω for which the FRFs of the current and voltage and corresponding emulated inductance can be seen in Figure 3. Again, the electric hums are clearly apparent in the FRF of the current and corresponding emulated inductance. Again, disregarding this noise, constant emulated inductance values predicted by Eq. (20a) are observed in the considered frequency band, except for the case of $R_L = 3200\Omega$ where a slight decrease in the emulated inductance is noted at higher frequencies. This may indicate that the emulated inductance becomes slightly non-linear for large R_L values at high frequencies. However, larger R_L and corresponding inductance is only relevant for piezoelectric shunt tuning to low frequent vibrations, since the optimum inductance tuning is inversely proportional to the target resonant frequency, see Table 2. It is thus verified that Eq. (20a) precisely predicts the emulated inductance of the synthetic inductor.

5 EXPERIMENTAL VERIFICATION

In this section, the optimum piezoelectric shunt tuning to a free beam with two pairs of piezoceramic patches is determined according to the tuning procedure presented in section 3. The free beam and the position of the two piezoceramic patch pairs can be seen in Figure 4, while the exact dimensions and

material properties of the beam and piezoceramic patches are provided in Table 3. It is noted that the piezoceramic patches of each patch pair are oppositely poled and connected in series. As indicated in Figure 4 the left piezoceramic patch pair is used for vibration excitation, while the right patch pair mitigates vibrations by connecting it to an optimally tuned resonant shunt.

The experimental setup can also be seen in Figure 4, where the left piezoceramic patch pair is connected to a power amplifier, while the right patch pair is connected to a multimeter. Both power amplifier and multimeter are connected to a PC used for data acquisition. A Laser Doppler Vibrometer is used to measure the dynamic response of the free beam.

Following the steps presented in section 3 a pseudo-random voltage excitation signal is imposed between the interface electrodes of the left piezoceramic patch pair, while the right patch pair is connected to a multimeter set to measure respectively current, whereby the right patch pair is in its SC condition, and voltage corresponding to the OC condition. The bandwidth of the pseudo-random excitation signal is set to 2kHz and the sample rate of the multimeter to 250 μ s. The tip velocity is further measured by the

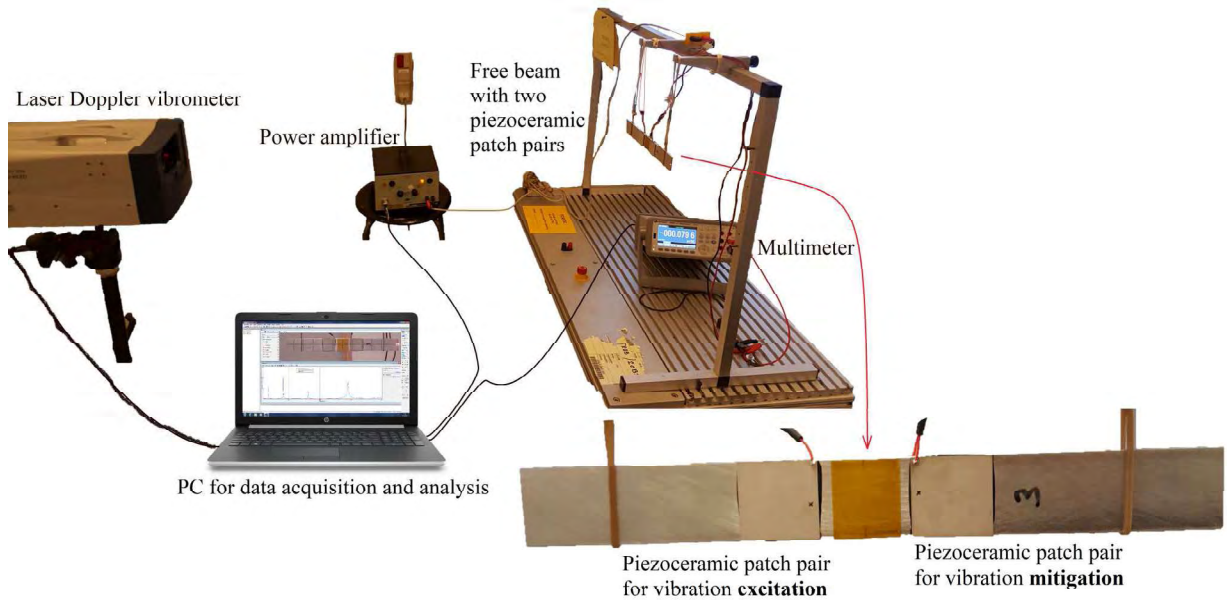

Figure 4: Free beam with two pairs of piezoceramic patches, experimental setup.

Laser Doppler Vibrometer in order to compare the mechanical response of the free beam and the electric response of the right piezoceramic patch pair. An FFT is performed on both mechanical and electrical time records, whereby the FRFs for, respectively, the tip displacements (determined from the tip velocity) in SC and OC condition and the electric current and voltage are obtained and shown in Figure 5.

It can be seen from Figure 5 that the mechanical and electrical responses correspond very well and that four resonant vibration modes appear in the investigated frequency band. In order to determine the optimum piezoelectric shunt tuning, only the FRFs for the electric charge and voltage in Figure 5(b) are considered, from which the SC and OC natural frequencies and modal charge and voltage are determined and provided in Table 4. The optimum shunt tuning then follows by the tuning formulas provided in Table 2 giving the optimum parallel and series shunt tuning listed in Table 4. For comparison, the free beam with the two piezoceramic patch pairs has been modeled in ANSYS®, where the SC and OC eigenvalue problems have been evaluated in order to determine the SC and OC frequencies and modal charge and voltage, which are also provided in Table 4. The FE-model used in ANSYS® consist of $225 \times 8 \times 4$ SOLID186 3D elements discretizing the beam and $100 \times 8 \times 2$ SOLID226 3D electromechanical elements discretizing each of the four piezoceramic patches. Finally, the equipotential condition is enforced for each piezoelectric electrode by applying a coupling constraint to the concerned electrical dofs, while the opposite polarization is obtained by using opposite signs for the stress piezoelectric coefficients in each piezoceramic patch pair.

It can be seen from Table 4 that there is a good correlation between the experimental and numerical SC and OC frequencies, except for the fourth torsional vibration mode predicted by the ANSYS® model, which can not be excited by the driving force from the left piezoceramic patch pair. The use of the left piezoceramic patch pair as the driving force for the vibrations means that only the flexural vibration modes are easily activated. Furthermore, the position of the patch pairs also influences how well each vibration mode may be sounded and damped. The mode shapes corresponding to the four flexural resonant frequencies in Table 4 and based on the measurement with the Laser Doppler Vibrometer can be

seen in Figure 6. The location of the piezoceramic patches are here indicated by the red arrows, and it can thus be seen that the third vibration mode is both hardly excited and damped since the two patch pairs are located close to a nodal point of the corresponding mode shape in Figure 6(c). This is also apparent by the corresponding effective EMCC in Table 4, which is close to zero. Oppositely, the largest effective EMCC is obtained for the fourth flexural vibration mode, for which it can be seen that the piezoceramic patches are located near a position of maximum curvature (Figure 6(d)) and therefore have good authority on the corresponding vibrations. The position of the piezoceramic patches with respect to the first and second vibration modes in Figure 6(a,b) are seen to be moderately good, also indicated

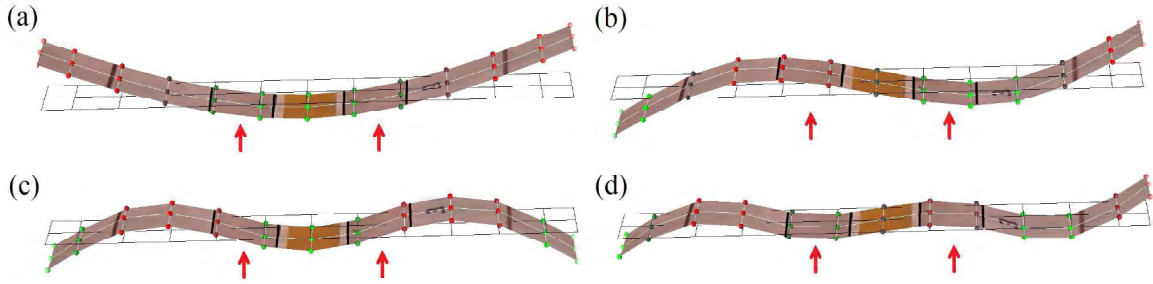

Figure 6: First four flexural mode shapes (a)-(d) of the free beam with two piezoceramic patch pairs located as indicated by the red arrows.

by the effective EMCCs in Table 4. Common for all the effective EMCCs is that there is a significant relative deviation between the numerical and experimental results. This may be explained by several uncertainties associated with the experimental setup, for instance the gluing of the piezoceramic patches to the beam, the actual electromechanical properties and eventual hysteretic behavior of the piezoceramic material, which is not considered in the tuning and numerical FE-model. Finally, it can be seen from Table 4 that there is good correlation between the numerical and experimental modal charge and voltage and the corresponding optimum parallel and series shunt tuning. The normalized modal charge and voltage are for the experiment determined from the measured modal charge and voltage amplitudes with Eq. (9), in which the intermediate modal mass is equated with Eq. (10).

It is now analyzed how well the optimum piezoelectric shunt tuning performs, when each individual shunt circuit for the four flexural vibration modes are wired in series to the right piezoceramic patch pair. The optimum inductance is emulated by the synthetic inductor described in section 4, which is further connected in series with a variable resistor. It is found that the optimum inductance values must be slightly altered in order to obtain the most optimum damping properties. The optimum inductance values are $L_1 = 128\text{H}$, $L_2 = 24.2\text{H}$, $L_3 = 6.6\text{H}$ and $L_5 = 2.0\text{H}$. The deviation between these values and the series tuning provided in Table 4 may be due to the neglect of structural damping in the tuning formulas and the fact that the forcing from the left piezoceramic patch pair does not act as an ideal modal load. However, the deviations are relatively small, in particular for the fourth flexural vibration mode with the largest effective EMCC. Regarding the resistance tuning to the first three flexural vibration modes, it is found that the parasitic loss in the synthetic inductor seems to exceed the optimum resistance tuning, even when negative resistance is added to the system through R_R . For the shunt circuit tuned to the fourth flexural vibration mode, the variable resistance is set to $R_4 = 2.4\text{k}\Omega$, approximately equal to the optimum series tuning in Table 4. With the respective implementation of these four shunt circuits the corresponding FRFs for both the tip displacements and electric voltages are determined using the FFT on the corresponding time records to a pseudo-random vibration excitation with the same frequency bandwidth and intensity as used previously. The FRFs can be seen in Figure 7.

It can be seen from Figure 7(a)-(d) that considerable amplitude reduction is obtained around each of the four flexural resonant frequencies when implementing the respective resonant shunt circuits. In particular, flexural vibration mode 4 in Figure 7(d) is seen to be highly damped and an almost flat plateau around the corresponding resonant frequency is obtained. The lowest vibration reduction is found for mode 3 in Figure 7(c), as expected due to the corresponding insignificant electromechanical coupling. Looking at the voltage responses in Figure 7(e)-(h), it can be seen that the damper response is increased around the resonant frequencies when implementing the resonant shunt circuits. This may be interpreted

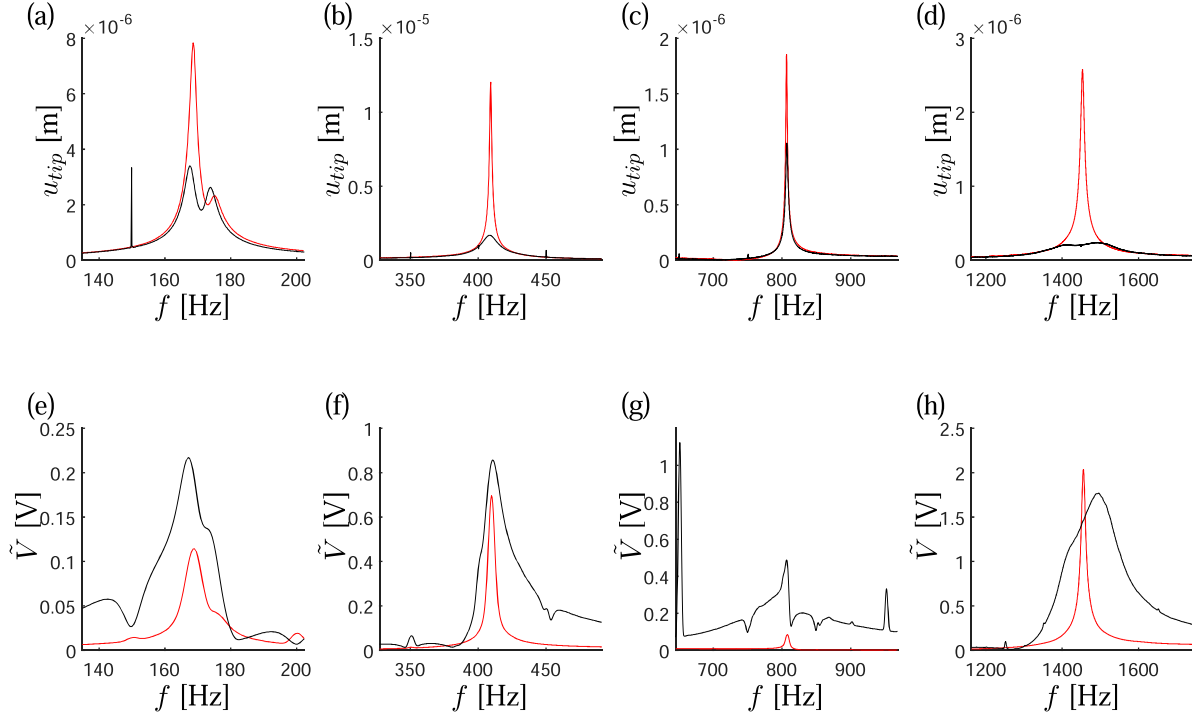

Figure 7: FRF for (a)-(d) the tip displacements and (e)-(f) shunt voltage, for OC (—) and optimally shunted to respectively flexural mode 1-4 (—) piezoceramic patches.

as an increase in the amount of energy dissipated by the shunt resistance. For the fourth flexural vibration mode in Figure 7(h) an almost flat plateau around the resonant frequency for the voltage is obtained, which agrees well with the theoretical damper response of the tuned piezoelectric shunt damper [10].

Although small deviations between the optimum and implemented shunt tuning has been encountered, the experimental shunt tuning method presented in section 3 has proven to be accurate and easy to implement, as the optimum shunt tuning to any resonant vibration mode in a given frequency band may be determined from only current and voltage responses to a pseudo-random vibration excitation.

6 CONCLUSIONS

A piezoelectric shunt tuning method based on measurable experimental data has been proposed. The procedure consists in imposing pseudo-random vibrations to a mechanical structure while the electric current and voltage responses are measured between the electrodes of an attached piezoelectric domain. A FFT is then used on the electric time records to obtain the FRF for the corresponding charge and voltage. The SC and OC natural frequencies and modal charge and voltage may finally be determined for each vibration mode in the analyzed frequency band, and the corresponding shunt circuit components optimally tuned. The method is verified by the analysis of a free beam with two pairs of piezoceramic patches, one pair used to excite the structure, while the second pair is connected to a shunt circuit optimally tuned to a target resonant vibration mode. The FRF for the electric charge and voltage have

been determined and the optimum shunt tuning evaluated for the first four flexural vibration modes of the free beam. Finally, it is found that the obtained optimum shunt tuning values are very close to the shunt tuning, which delivers the most substantial damping to the structure around the target resonant frequencies. The proposed method is beneficial as the necessary tuning parameters are determined from two FRF obtained by imposing pseudo-random vibrations to the investigated structure. Furthermore, the inductance tuning is independent of the relative difference between the SC and OC frequencies, which may be hard to determine. Instead, it relies on the ratio between the modal voltage and charge.

Abstract. The analytical framework of a semi active tuned mass damper (SATMD) is developed for the reduction of low-frequency aerodynamic vibrations in aeronautics structures. The SATMD entails a shunted piezoelectric connected in series to an RL electric circuit. Initially, the theoretical model of the SATMD is presented, including the equivalent electrical RL circuit, applied on a simplified system consisting of two structural modes. Subsequently, the SATMD concept is evaluated experimentally on a scaled-down simplified aircraft prototype constructed for this purpose. Finally, the simulated model is correlated with experimental measurements. In summary, both experimental and numerical results, illustrate that by choosing an appropriate auxiliary mass for the SATMD a specific mode can be targeted and can be substantially damped using a properly tuned shunt resistor. Subsequently the inductance can retune the system to another mode of interest. The obtained results indicate capabilities to reduce the structural acceleration of the main structure up to 20dB.

1 INTRODUCTION

Excessive vibrations may lead to material fatigue and structural failure. In addition, regarding their repercussions on aeronautic structures may cause discomfort both to the passengers and the pilots. A well-established method of passive vibration absorption is the inclusion of a device to reduce vibration levels of the main structure [1],[2]. Such devices are called dynamic vibrations absorbers (DVA) or tuned mass dampers (TMD). The classic TMD consists of a mass-spring-damper system tuned on a specific frequency of interest in the manner that the kinetic energy of the main mass is transferred to the auxiliary mass of the TMD and subsequently dissipated through the dashpot. However, a passive TMD is hindered by a phenomenon called ‘detuning’ caused by deterioration of the mechanical properties of the structure for example mass change due to fuel consumption. In such cases a passive TMD ceases to be effective until it is retuned. Another method to enhance the damping of the structure [3] has been proposed by Hagood and Von Flotow in 1991 [4], where a piezoelectric patch is attached on a beam connected with a resistive and inductive shunts [5]-[7]. Part of the

mechanical energy due to the piezoelectric effect is transformed to electric energy which causes charge to flow through the electric circuit and is dissipated by the resistor. This circuit is equivalent to adding a spring-mass-damper, with the inductor adding virtual mass, the resistor being the damper and the material capacitance being the spring. Optimal tuning of the RL values can be obtained using the Den Hartog method [9].

Taking into consideration the aforementioned crucial drawback of a passive TMD, a semi active tuned mass damper [10],[11] (consisted of an auxiliary mass and a piezoelectric stack connected in series with an RL electric circuit) is proposed. The SATMD offers tuning flexibility while retaining the robustness of the passive system. That is to say, the baseline vibration reduction of the SATMD at a single frequency is provided by the tuned auxiliary mass, while the introduction of electromechanical inertia by the inductor provides additional vibration reduction by dissipation of the electric energy through a resistor.

The rest of the paper is organized as follows: Initially, in Section 2 the equations of motion for the baseline structure modeled by two structural modes whose modal characteristics are predicted by modal analysis of a detailed Abaqus FEA model. Then the theoretical framework of the coupled electromechanical system (the structure with the SATMD attached and the RL network) is presented. Subsequently on Section 3 the SAMTD concept is evaluated on a scaled-down simplified aircraft prototype manufactured for this purpose. Furthermore, the experimental validation with the numerical predictions are presented in Section 4. Finally, in Section 5 are entailed the concluding remarks of the proposed work along with suggestions for future work.

2 FORMULATION

2.1 Baseline structure model

Considering the fact that the simplified structure is modelled by two structural modes, as shown in Figure 1, the modal displacements can be derived by the following second order differential equation,

$$\begin{aligned} [\Phi]^T \cdot [m] \cdot [\Phi] \cdot \ddot{\underline{q}}(t) + [\Phi]^T \cdot [c] \cdot [\Phi] \cdot \dot{\underline{q}}(t) + [\Phi]^T \cdot [k] \cdot [\Phi] \cdot \underline{q}(t) &= \underline{\Phi}^T \cdot \underline{F}(t) \\ [M] \cdot \ddot{\underline{q}}(t) + [C] \cdot \dot{\underline{q}}(t) + [K] \cdot \underline{q}(t) &= \underline{P}(t) \end{aligned} \quad (1)$$

where $\underline{q}(t) = \{q_1(t), q_2(t)\}^T$ is the vector of modal displacements, $[\Phi]$ is the 2×2 modal matrix of the eigenvectors, $[m]$, $[c]$ and $[k]$ are the mass, damping and stiffness matrices respectively, while $\underline{F}(t)$ is the applied force., $[M]$, $[C]$ and $[K]$ are the 2×2 modal mass, modal damping and modal stiffness matrices respectively and $\underline{P}(t)$ is the modal force vector. Finally, the transformation back to physical coordinates can be performed as follows

$$\underline{x}(t) = [\Phi] \cdot \underline{q}(t) \quad (2)$$

Figure 1: Baseline Structure Modal Representation

The baseline model parameters $[M], [\omega^n], [\zeta]$ are shown in Table 1, which were extracted from a detailed Abaqus FEA model of the Lab scale prototype presented in Section 3.

Table 1: Modal Data

	$i = 1$	$i = 2$	
M^i	4.09	4.38	$[kg]$
ω_i^n	48.8	65.3	$[Hz]$
ζ^i	0.1	0.1	$[\%]$

2.2 Structure with SATMD attached model

Assuming that the auxiliary mass and the piezostack stiffness are too small to change the mode shapes of the baseline structure, the new system (as shown on Figure 2) equations can be formulated.

Figure 2: Structure with SATMD attached Representation

Therefore, one more degree of freedom is added as the displacement of the auxiliary mass, as well as one more degree of freedom for the electrical charge that flows from the external network. Hence, the electromechanical system can be described by the following second order differential equation:

$$\begin{bmatrix} M & 0 & -e \cdot L \cdot \varphi_n^T \\ 0 & m_a & e \cdot L \\ 0 & 0 & L \end{bmatrix} \begin{Bmatrix} \ddot{q} \\ \ddot{x}_a \\ \ddot{Q}_2 \end{Bmatrix} + \begin{bmatrix} C + c_a \cdot \varphi_n^T \cdot \varphi_n & c_a \cdot \varphi_n^T & -e \cdot R \cdot \varphi_n^T \\ c_a \cdot \varphi_n & c_a & e \cdot R \\ 0 & 0 & R \end{bmatrix} \begin{Bmatrix} \dot{q} \\ \dot{x}_a \\ \dot{Q}_2 \end{Bmatrix} + \begin{bmatrix} K + k_a \cdot \varphi_n^T \cdot \varphi_n & k_a \cdot \varphi_n^T & 0 \\ k_a \cdot \varphi_n & k_a & 0 \\ e/C_p \cdot \varphi_n & -e/C_p & 1/C_p \end{bmatrix} \begin{Bmatrix} q \\ x_a \\ Q_2 \end{Bmatrix} = \begin{Bmatrix} P \\ 0 \\ 0 \end{Bmatrix} \quad (3)$$

Where x_a is the physical displacement of the auxiliary mass, m_a, c_a and k_a is the auxiliary mass, actuator damping and stiffness respectively, e is the piezoelectric coefficient and C_p is the stack capacitance.

Table 2: SATMD Properties

k_a	87	$[kN / m]$
m_a	574	$[g]$
ζ_a	1.4	$[\%]$
e	0.73	$[N / V]$
C_p	40	$[\mu F]$

The SATMD properties shown in Table 2 were experimentally identified by a series of tests on the device solely.

3 EXPERIMENTS

3.1 Experimental Setup

The manufactured scaled-down simplified aircraft weights approximately 112 kg and consists of the following components:

- a 3m steel tubular beam representing the fuselage of the aircraft
- two aluminum plate-strips for the wings and the horizontal tail and
- Three plastic connectors made of ACETAL, for the mounting of the wings, the horizontal tail and the SATMD of the horizontal tube. All the aforementioned components are illustrated in Figure 3.

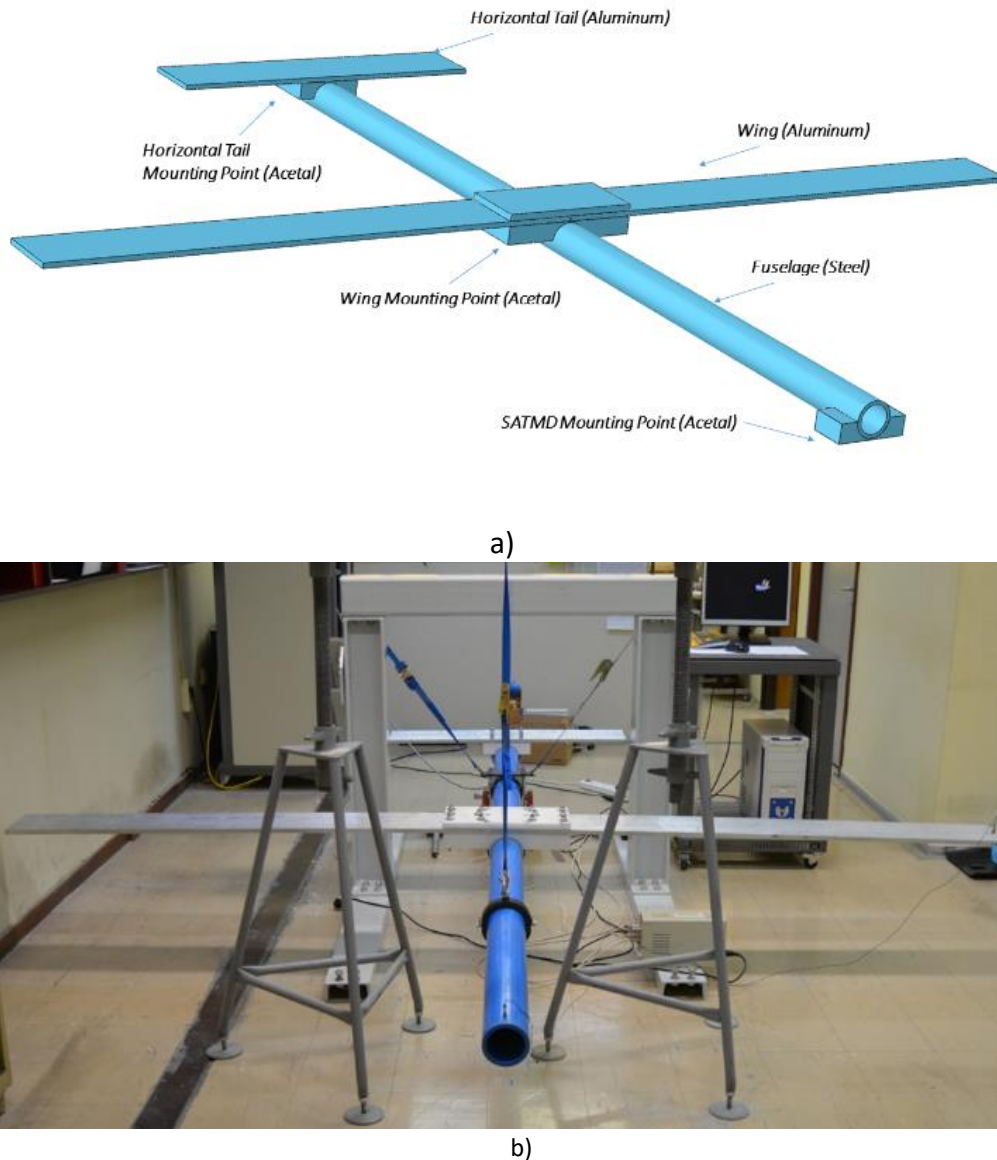

Figure 3: Design of Lab scale Aircraft Prototype; a) FEM model; b) Actual prototype

3.2 Experimental procedure

In order to simulate realistic testing flight conditions, the model was suspended with elastic belts from the modal points of the first bending modal frequency ($L/4$ and $3L/4$). The SATMD anti-vibration setup is placed on the Lab Prototype tip with the mechanism facing downwards. An electromechanical shaker was mounted at the middle of the rear horizontal tail, under the fuselage to excite the structure. The shaker was equipped with a load cell to measure the applied force on the prototype. A pair of accelerometers were used to measure the response located. One on the tip on the top of the tubular beam, while the second was located at the tip and the middle of the horizontal aluminium beam simulating the aircraft wing. The applied actuation

signal was a swept sine within the range of 1 to 200 Hz. The generated acceleration at the measuring locations as well as the applied force were collected via a National Instruments DAQ board, digitized and the corresponding frequency response functions were prepared.

This procedure was repeated with and without the SATMD attached to compare the system performance. Figure 4 presents the critical modal frequencies for the performed experimental analysis of the baseline, which are the 1st bending wing mode at 36Hz, the 1st bending modal frequency across the length of the fuselage at 48Hz and the 2nd bending modal frequency across the length of the fuselage at 65Hz.

Figure 4: Baseline Prototype Acceleration Response

4 EXPERIMENTAL RESULTS

4.1 Mass Tuning at the 1st Bending Frequency (48 Hz)

Initially, an auxiliary mass of 1027 g was used to tune the SATMD at the first bending frequency of the structure (48Hz), in order to study its performance for various resistance levels connected to the SATMD terminals. Initially, the response of the structure was measured without the presence of the SATMD as baseline, then the resistance was gradually increased and finally the case of the open circuit was examined (passive operation). Figure 5 shows the experimental results while in Figure 6 the formulated model is presented which appears to be in good agreement with the experimental measurements. In both cases the optimal resistance was found to be at 50Ω . Increasing the resistance beyond that value the response of the structure starts to increase again.

Figure 5: Measured Response for Variable Resistance levels Tuned at 48Hz

Figure 6: Simulated Response for Variable Resistance levels Tuned at 48Hz

Figure 7, presents a more complete picture of the reduction in dB of the acceleration compared to the baseline system achieved by various resistance levels in the neighbour of 40 to 50 Hz.

Both the experiment and the simulation present the same trends with the optimal value being at 50Ω . However the analytical model predicts a reduction of 28dB in comparison to the measured reduction of 26dB from the baseline at the experiment. This difference is negligible considering that in both cases the remaining oscillation is

Figure 7: Effect of Resistance at the neighbour of 48 Hz

4.2 Mass Tuning at the 2nd Bending Frequency (65 Hz)

For the case of the 2nd bending mode, the SATMD was tuned by using a mass 574 g. Consequently, a shunt resistor was connected on the SATMD terminals while multiple resistance levels were examined up to the case of an open circuit (passive operation). A maximum reduction of 23 dB was achieved at the optimum resistance level of 91Ω as shown on Figure 8. Simultaneously, a 9 dB reduction on the first mode was observed. In Figure 9, the predictions of the analytical model are presented, whose results are in line with the experimental measurements.

Figure 8: Measured Response for Variable Resistance levels Tuned at 65Hz

Figure 9: Simulated Response for Variable Resistance levels Tuned at 65Hz

Figure 10 presents the reduction of acceleration in dB compared to the baseline system in the neighbour of 60 to 75 Hz for various resistance levels.

Both the experiment and the simulation illustrate the same trends with the optimal value being at. However there is a discrepancy since the simulation predicts a reduction of 30dB in comparison to the measured reduction of 24dB from the baseline at the experiment.

Figure 10: Effect of Resistance at the neighbour of 65 Hz

4.2.1 Operation under variable inductive loads.

Furthermore, the effect of inductance to the system performance was examined, aiming to retune the SATMD from the 1st bending frequency to the 2nd. Thus, we mounted on the tip of the fuselage the SATMD with 574 gr auxiliary mass providing tuning of the mechanism at 65Hz. The performance of the lab prototype was measured with various inductance-resistance levels connected on the terminals of the SATMD. The mentioned resistance was the one measured at the terminals of the actuator when the inductor was connected. Figure 11 presents the measured FRFs at the neighbour of the tuning frequency (65Hz), while Figure 12 illustrates the FRFs of the response at the neighbour of the 1st bending modal frequency at 48Hz. Significant reduction is achieved simultaneously at both modal frequencies as the inductive load increases.

Figure 11: Measured Response for Variable Inductance levels in the neighbour of 65Hz

Figure 12: Measured Response for Variable Inductance levels in the neighbour of 48Hz

The overall performance of the anti-vibration setup with various inductive loads is illustrated in Figure 13. The achieved reduction on the 1st modal frequency as the inductance increases, while the mechanism is mechanically tuned at the 2nd modal frequency at 65Hz. The measured performance illustrates a reduction up to the level of 16dB for inductance values of 150mH

Figure 13: Effect of Inductance at the neighbour of 48 Hz

5 CONCLUSIONS

The scope of the present work was to develop an antivibration setup capable to tune at different frequencies. The proposed solution, the Semi-Active Tuned Mass Damper (SATMD) based on the support of the auxiliary TMD mass on a piezoceramic stack actuator, while a resistance and an inductor are connected parallel to the actuator. The presence of the resistance on the system adds damping via dissipation of the oscillation energy as the form of heat to the resistance terminals. Additionally, the dynamic characteristics of the inductor add virtual inertia on the oscillated mechanical system providing the flexibility to the SATMD to be tuned at various modal frequencies. Multiple tuning cases were examined and compared to the performance of the baseline system. Initially, the performance of a system while having solely adaptive resistance and concluding with the application of a R-L external network.

The manufactured lab-test prototype confirmed the analytical assumptions and the predicted dynamic characteristics were measured and validated. Two critical modal frequencies were identified, the 1st bending frequency at 48Hz and the 2nd bending at 65Hz.

Consequently, the assembled SATMD was attached on the prototype and tested under external mechanical excitation. The system was tested under various resistances, elucidating an optimal resistance of maximum performance of 91Ω with $23dB$ reduction at the tuned frequency, while at the same time the other resonance peak introduced a reduction of $9dB$.

Furthermore, by keeping the resistance constant, various values of inductance were applied. The outcome of this specific test was, that while changing the inductance the performance of the system could be tuned to a different frequency, resulting at an optimum value of $150mH$ with $16dB$ maximum reduction.

Finally, analytical simulations using the developed reduced-order mode superposition model were performed and correlated to the experimental measurements in order to validate the model. The correlations indicate that the analytical model is able to replicate very well the measured results concerning the effect of resistance. Regarding the effect of inductance discrepancies were observed, this specific issue seems to be quite complex and requires further investigation possibly due to nonlinearities of the piezoelectric stack thus requiring further investigation.

To sum up, the measured semi-active vibration reductions on the tested prototype has successfully demonstrated the feasibility of the proposed concept. The developed modelling tools produced reasonably good predictions of the measured prototype response.

Abstract. This work analyzes the nonlinear dynamics of a coupled system with dry-friction. The system has a mechanical part and an electromagnetic part. It is composed of a cart, whose motion is excited by a DC motor. The coupling between the motor and the cart is made by a mechanism called scotch yoke, so that the motor rotational motion is transformed in horizontal cart motion in a rail. It is considered the existence of dry-friction between the cart and the rail. The friction is modeled as Coulomb friction. The resulting motion of the motor can be characterized by two qualitatively different and alternate modes, the stick- and slip-modes, with a non-smooth transition between them. The focus of the work is to find the stick- and slip-mode parts of the trajectory for different values of the system parameters. This analysis could help in the development of control techniques to mitigate the occurrence of stick when this mode is not desirable in the system response.

1 INTRODUCTION

The analysis of electromechanical systems is not a new subject. The interest of analyzing their dynamic behavior is reflected by the increasing amount of research in this area. Electromechanical systems present an interesting behavior characterized by the mutual influence between the electrical and mechanical parts of the system, that is, the dynamics of the motor is heavily influenced by the mechanical system and the dynamics of the mechanical system depends on the dynamics of the motor [1, 2, 3, 4] Each part of the system affects the behavior of the other, i.e., they interact. The coupling varies with the coupling conditions, it is not a functional relation and depends on the initial conditions [5, 6] The dynamics of the coupled system is given by an initial value problem comprising a set of coupled differential equations [7, 8], in which the coupling torque appears as a parametric excitation, i.e., a time variation of the system parameters. The problem becomes even more interesting if it is considered the existence of dry-friction between bodies in the mechanical part of the system. The dry-friction can induce stick-slip oscillations [9, 10, 11]. The response of the mechanical part has a non-smooth behavior with two qualitatively different modes, the stick- and slip-modes. We call stick when the relative velocity between the bodies in contact is null in a time-interval and we call slip if the relative velocity is non-zero, or zero in isolated points. As these two modes have a non-smooth transition between them, stick-slip systems belong to the class of non-smooth systems, such as systems with stops, impacts, and hysteresis.

Depending on the values of the system parameters, the response of the mechanical part of the system can be composed of a sequence alternating stick and slip-modes. It is possible also to be composed of

just stick or just slip. The main motivation of this paper is to better understand what are the parameters that control the stick duration in an electromechanical system. We believe that the theoretical knowledge on the role of these parameters can provide improvements in the design of electromechanical systems and can help in the development of control techniques to mitigate the stick duration. These techniques could be implemented in many mechanical systems in which undesirable stick appears. Study of oscillatory conditions in dry-friction systems has practical significance for providing protection against vibrations, seismic isolation, reduction of noise, and friction-induced vibration, etc [12, 13]. Dry-friction could be the source of dynamic instability, noise, and reduction of performance.

Despite the great number of papers in the area of dry-friction, few of them address the problem in an electromechanical system. The majority of the references that characterizes dynamics with dry-friction only make it for a pure mechanical system.

2 DYNAMICS OF THE ELECTROMECHANICAL SYSTEM WITH DRY-FRICTION

The system analyzed in this paper is composed of a cart whose motion is driven by a DC motor. The motor is coupled to the cart through a pin that slides into a slot machined on a plexiglas plate that is part of the cart, as shown in Fig. 1. The pin hole is drilled off-center on a disk fixed in the axis of the motor, so that the motor rotational motion is transformed into horizontal cart motion over a rail. The dynamics

Figure 1: Electromechanical system with dry-friction between the cart and the rail.

of a DC motor is given by the following initial value problem (IVP). Given a source voltage v , find (α, c) such that, for all $t > 0$,

$$L\dot{c}(t) + r c(t) + k_e \dot{\alpha}(t) = v(t) , \quad (1)$$

$$j_m \ddot{\alpha}(t) + b_m \dot{\alpha}(t) - k_e c(t) = -\tau(t) , \quad (2)$$

with the initial conditions

$$\dot{\alpha}(0) = \dot{\alpha}_0 \quad , \quad \alpha(0) = \alpha_0 \quad , \quad c(0) = c_0 , \quad (3)$$

where t is the time, c is the electric current, $\dot{\alpha}$ is the angular speed of the motor, L is the electric inductance, j_m is the motor moment of inertia, b_m is the damping ratio in the transmission of the torque generated by the motor to drive the coupled mechanical system, k_e is the motor electromagnetic force constant and r is the electrical resistance. The magnitude of the available torque to the coupled mechanical system is τ . The source voltage is considered to be

$$v(t) = v_0 + v_1 \sin(\omega_v t) . \quad (4)$$

i.e., the source voltage oscillates around the level v_0 with amplitude v_1 and with frequency ω_v . The mass of the mechanical system is m and the horizontal cart displacement is represented by x . It is considered that the cart is not allowed to move in the vertical direction. Due to the problem geometry, and denoting $\|d\| = d$, the horizontal motion of the cart and the angular displacement α of the motor are related by the constraint

$$x(t) = d \cos(\alpha(t)). \quad (5)$$

In the model of the coupling between the motor and the mechanical system, it is assumed that the motor shaft is rigid. Thus, the available torque to the coupled mechanical system, τ , can be written as

$$\tau(t) = d(t) \times f(t), \quad (6)$$

where d is the eccentricity of the pin of the motor and f is the coupling force between the DC motor and the cart. The component of d , which is perpendicular to the plane of the cart movement, is always zero and, the others horizontal and vertical components can be calculated from the angular displacement α of the motor. Assuming that there is no friction between the pin and the slot machined on an acrylic plate, the vector f only has a horizontal component, called f , which is the horizontal force that the DC motor exerts on the cart. Thus, the magnitude of $\tau(t)$ is

$$\tau(t) = -f(t) d \sin \alpha(t). \quad (7)$$

Since the cart is modeled as a particle, its movement in the horizontal direction satisfies the equation:

$$m \ddot{x}(t) = f(t) + f_r(t), \quad (8)$$

where f_r is the dry-friction force between the cart and the rail. The initial value problem for the coupled motor-cart system with dry-friction is: given v , find (α, c) satisfying

$$I \dot{c}(t) + r c(t) + k_e \dot{\alpha}(t) = v_0 + v_1 \sin(\omega_v t), \quad (9)$$

$$\begin{aligned} \ddot{\alpha}(t) [j_m + m d^2 (\sin(\alpha(t)))^2] + \dot{\alpha}(t) [b_m + m d^2 \sin(\alpha(t)) \cos(\alpha(t))] \\ - k_e c(t) = -f_r(t) d \sin(\alpha(t)), \end{aligned} \quad (10)$$

for given initial conditions of electric current, angular speed and position of the motor.

3 DRY-FRICTION MODEL

The friction is modeled as Coulomb, which is a simple model, shown in Fig. 2.

The non-smooth behavior of the dry-friction force can induce stick-slip oscillations in the system. Depending on the values of the system parameters, the response of the system can be composed of a sequence of alternating stick and slip-modes.

During the stick-mode, the cart does not move, so the angle of disc is constant. The frictional force and the current can vary. Stick means no motion, the motor continues to change its state until it has enough power to move the car. The stick mode occurs when $\dot{\alpha} = 0$ in an interval and when the frictional force, which satisfies

$$k_e c(t) = f_r(t) d \sin(\alpha(t)), \quad (11)$$

Figure 2: Coulomb dry-friction.

is in the interval $-f_{max} \leq f_r \leq f_{max}$, where $f_{max} = \mu mg$, g is the gravitational acceleration and μ is the friction coefficient between the cart and the rail. Equation (11) is obtained considering $\dot{\alpha} = 0$ and $\ddot{\alpha} = 0$ in Eq. (10). Remark that during the stick-mode, the frictional force varies and depends on the angular position of the motor. There is a functional relation between these two variables. Besides this, the initial value problem that describes the dynamics of the coupled motor-cart system with dry-friction is reduced to just one differential equation, given by

$$l\dot{c} + rc = v_0 + v_1 \sin(\omega_v t), \quad (12)$$

where the initial condition of the current is its value in the beginning of the stick-mode. Observe that during the stick-mode, the sum of the forces that act over the cart is zero (it does not move). The horizontal coupling force between the DC motor and the cart, f , is balanced by the dry-friction force, f_r . This balance lasts until the frictional force, given in Eq. (11), reaches its maximum value, f_{max} . During the stick-mode, the dynamics of the system is governed only by the dynamics of the electrical circuit of the motor. Electrical and mechanical systems do not interact: the system is decoupled. During the slip-mode, the dry-friction force is

$$f_r(t) = -mg\mu \operatorname{sgn}(\dot{x}(t)) = -mg\mu \operatorname{sgn}(-\dot{\alpha}(t) d \sin(\alpha(t))). \quad (13)$$

4 NUMERICAL RESULTS

Once defined a time interval for analysis t_a , one of the variables of great interest in the analysis of systems with dry-friction is the total time of stick as function of the friction coefficient. For the electromechanical system analyzed in this work, this variable presents an interesting behavior, as shown in Fig. 3. When μ is lower than 0.57, there is no stick; when μ is greater than 2.84 the only mode is stick. For values of μ between 0.57 and 2.84, both can exist. For computation, duration t_a was chosen as 30 seconds. For the integration, it was used the function *ode45* of the *Matlab* software, which applies the Runge-Kutta 4th/5th-order method as time-integration scheme with a varying time-step algorithm. The maximal step size is equal to 10^{-4} seconds, and the relative and absolute tolerances are equal to 10^{-4} . The values of the parameters used in all simulations were $m = 5.0$ kg, $d = 0.01$ m, $v_0 = 4.0$ V, $v_1 = 4.0$ V and $\omega_v = 30$ rad/s. The motor parameters are given in Table 1 and the initial conditions of the system are $\alpha(0) = \pi/2$ rad, $\dot{\alpha}(0) = 0$ rad/s and $c(0) = v_0/r$ Amp.

Table 1: Values of the motor parameters used in simulations.

Parameter	Value
I	1.880×10^{-4} H
j_m	1.210×10^{-4} Kg m ²
b_m	1.545×10^{-4} Nm/(rad/s)
r	0.307 Ω
k_e	5.330×10^{-2} V/(rad/s)

**Figure 3:** Total time of stick as function of the friction coefficient.

5 CONCLUSIONS

In this article, it is analyzed the dynamics of an electromechanical system composed by a cart and a DC motor. The coupling between the motor and the cart is made by a mechanism called scotch yoke, so that the motor rotational motion is transformed into horizontal cart motion on a rail. It is considered the existence of dry-friction between the cart and the rail. The resulting motion of the motor can be characterized by stick- and slip-modes, with a non-smooth transition between them. A parametric analysis was performed numerically. It was analyzed the influence of the friction coefficient in the total time of stick. The results show that an increase of the friction coefficient does not assure an increase in the total time of stick.

Key words: Piezoelectric Absorber, Digital Vibration Absorber, Delayed System, Stability

Abstract. Digital piezoelectric vibration absorbers synthesizing passive shunt circuits may be subject to instabilities. This work investigates the cause for these instabilities, and highlights the role of sampling delays in their onset. If for practical reasons the sampling frequency cannot be increased, a stabilization procedure which anticipates the sampling delays is proposed. The theoretical developments in this work are experimentally validated on a piezoelectric beam.

1 INTRODUCTION

Engineering structures from various disciplines tend to be lighter or more slender. This trend usually goes along with smaller structural damping and increased susceptibility to vibrations. This in turn may shorten their lifespan, lower their performance or undermine their safety. Piezoelectric shunt damping is often considered as one potential solution to this issue. It was originally proposed by Forward [1], and formalized by Hagood and von Flotow [2]. The working principle of piezoelectric shunt damping is based on the transduction capability of piezoelectric materials: a piezoelectric transducer is able to convert a part of its mechanical energy into electrical energy. The latter can be dissipated by connecting a so-called shunt circuit to the electrodes of the transducer. A common type of shunt circuit is a resonant one, composed of a resistor and an inductor, arranged either in series or in parallel. The realization of this circuit may be challenging for several reasons. The first one is that the required inductance may be impractically large. A common workaround is to use virtual inductors or girators made up of analog electronics. Designing inductors with high inductances is not impossible though, as demonstrated by Lossouarn et al [3]. However, such components are not widely available and require some expertise to be built. The second reason is that the performance of the piezoelectric shunt is highly sensitive to the values

of the electrical components. Any misvaluation or time-variation of the system characteristics will result in sub-optimal performance, rectified by time-consuming modifications of the electrical parameters.

Fleming et al [4] introduced the concept of synthetic impedance as an alternative solution. The combination of a digital signal processor with a current source makes it possible to realize an arbitrary impedance. The synthetic impedance is an attractive option to realize shunt damping circuits owing to its flexibility. This nonetheless comes at the expense of the need for powering the digital unit and its associated electronics.

It was noted by the authors that instabilities of a system composed of a structure controlled by a synthetic impedance may arise. This work discusses the cause of these instabilities, namely, sampling delays, and proposes a stabilizing methodology. This paper is organized as follows. First, a digital vibration absorber is presented in Section 2. A simplified model is developed in Section 3, and the onset of instabilities is studied. Section 4 proposes a simple stabilization method to suppress these instabilities. The method is experimentally validated on a cantilever piezoelectric beam in Section 5. Finally, conclusions are drawn.

2 DIGITAL PIEZOELECTRIC VIBRATION ABSORBER

Connecting an electrical circuit to the electrodes of a piezoelectric transducer is equivalent to imposing a prescribed relation between the voltage across the electrodes and the current flowing through this transducer. This relation may be described by the impedance (voltage over current) or its inverse, the admittance. From the point of view of the transducer, any circuit which is able to impose this relation is equivalent to the original circuit.

The goal of the digital vibration absorber used in this work is to mimic a piezoelectric shunt circuit by measuring the voltage of a piezoelectric transducer and inject the desired current back into it. The voltage-to-current relation, i.e. the admittance, is programmed into a digital processing unit (DPU). The circuit layout of the digital vibration absorber used in this work is given in Figure 1, which is the same as that used by Matten et al [5].

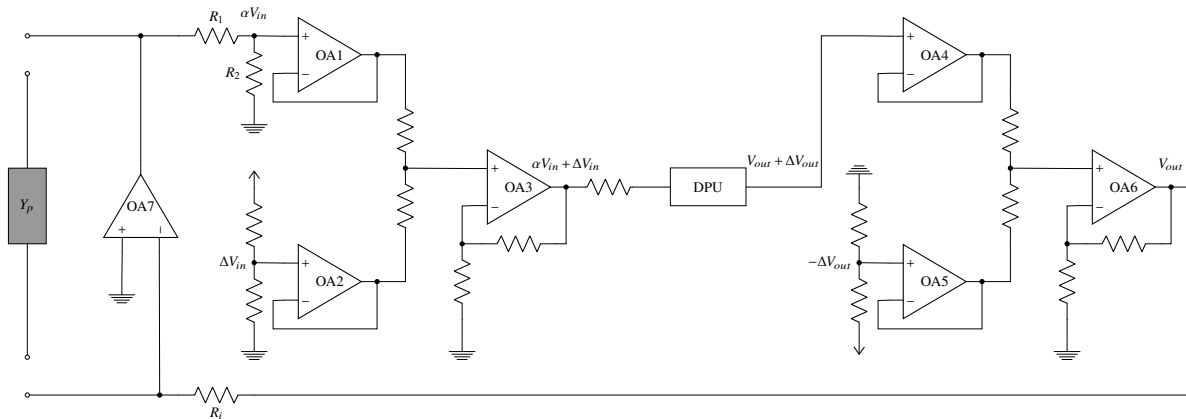

Figure 1: Layout of the digital absorber; the gray box represents a piezoelectric transducer.

The voltage divider composed of R_1 and R_2 is connected to the follower operational amplifier (Op-Amp) OA1, whose output is a scaled-down version of the piezoelectric voltage V_{in} by a factor $\alpha = R_2/(R_1 + R_2)$. OA2 follows a constant offset voltage ΔV_{in} which is added to the input by the summing amplifier OA3 before being fed to the analog to digital converter of the DPU. The DPU computes the

desired input-output relation and outputs via its digital to analog converter a voltage signal $V_{out} + \Delta V_{out}$, which is followed by OA4. A constant negative offset $-\Delta V_{out}$ followed by OA5 is added to the output by the summing amplifier OA6. This signal is applied to one pole of the resistor R_i , while the other is maintained to a virtual ground by OA7. Given the very high input impedance of OA7, the current injected into the piezoelectric transducer is thus V_{out}/R_i .

The input and output offset voltages are generated because the DPU used in this work can only work with positive input and output voltages. They are internally compensated for in the DPU software. An internal gain g is also applied to the transfer function programmed into the DPU for consistency. Indeed, if the desired relation between the piezoelectric voltage V_p and the current I_p is given by H_d , the digital absorber links these two quantities in the following way (assuming that the offsets are perfectly compensated)

$$I_p(s) = \frac{V_{out}(s)}{R_i} = \frac{g}{R_i} H_d(s) V_{in}(s) = \frac{\alpha g}{R_i} H_d(s) V_p(s) \quad (1)$$

where s is the Laplace variable. Assuming for now that the DPU is able to synthesize $H_d(s)$ exactly, a consistency relation is then derived

$$\frac{\alpha g}{R_i} = 1. \quad (2)$$

Typically, g can be computed from the measured values of α and R_i .

3 MODEL OF THE SYSTEM

3.1 Hardware model

The diagram shown in Figure 1 may be simplified while retaining the essential dynamical features of the digital absorber. Because of their large bandwidth (of the order of MHz), the followers and summing amplifiers (OA1 to OA6) are considered as ideal Op-Amps [6]. OA7 is modelled as a differential amplifier with one pole. This leads to the simplified circuit layout shown in Figure 2(a), which can be modelled according to Figure 2(b).

Figure 2: Feedback model of the voltage controlled current injector: simplified circuit layout (a) and equivalent block diagram (b).

From Figure 2(b), the following open-loop transfer function is derived

$$Y(s) = A(s) \frac{V_-(s)}{V_o(s)} = \frac{A_{OL}}{\frac{s}{2\pi f_0} + 1} \frac{V_-(s)}{V_o(s)}, \quad (3)$$

where A_{OL} is the Op-Amp open-loop gain, f_0 is its open-loop bandwidth, V_- is the voltage applied to its inverting input and V_o is its output voltage. Using Kirchhoff's voltage and current laws, the following relation can be derived

$$\frac{V_-(s)}{V_o(s)} = \frac{H_d(s) + Y_p(s)}{\frac{1}{R_i} + Y_p(s)} \quad (4)$$

where H_d is the transfer function synthesized by the DPU and Y_p is the admittance of the piezoelectric transducer, derived in the next subsection.

3.2 Piezoelectric admittance

The system composed of a structure coupled to a piezoelectric transducer may be modelled with the following set of equations

$$\begin{cases} \mathbf{H}_{sc}(s)\mathbf{x}(s) + \gamma\mathbf{B}V_p(s) = \mathbf{f}(s) \\ C_p^\varepsilon V_p(s) - \gamma\mathbf{B}^T \mathbf{x}(s) = q_p(s) \end{cases}, \quad (5)$$

where \mathbf{x} is the vector of generalized degrees of freedom, \mathbf{f} is the vector of conjugated generalized forces, \mathbf{H}_{sc} is the structural dynamic stiffness matrix when the piezoelectric transducer is short-circuited, C_p^ε is the piezoelectric capacitance at constant strain, $q_p = I_p/s$ is the electric charge flowing through the transducer and $\gamma\mathbf{B}$ is an electromechanical coupling vector [7]. The piezoelectric admittance is then found as

$$Y_p(s) = \left. \frac{s q_p(s)}{V_p(s)} \right|_{\mathbf{f}=0} = s C_p^\varepsilon + s \gamma^2 \mathbf{B}^T \mathbf{H}_{sc}^{-1}(s) \mathbf{B}. \quad (6)$$

The dynamic stiffness matrix may be expanded as

$$\mathbf{H}_{sc}^{-1}(s) = \Phi_{sc} \left(s^2 \mathbf{I} + s \mathbf{Z} \Omega_{sc} + \Omega_{sc}^2 \right)^{-1} \Phi_{sc}^T \quad (7)$$

where Φ_{sc} is the matrix of mass-normalized mode shapes when the piezoelectric transducer is short-circuited, \mathbf{I} is an identity matrix, \mathbf{Z} is a diagonal modal damping matrix and Ω_{sc} is a diagonal matrix containing the short-circuit resonance frequencies $\omega_{sc,i}$. The vector of modal strains in the piezoelectric transducer is given by

$$\mathbf{B}^T \Phi_{sc} = [\phi_1, \dots, \phi_N]. \quad (8)$$

Equations (6)–(8) give the following modal expansion

$$Y_p(s) = s C_p^\varepsilon \left(1 + \frac{\gamma^2}{C_p^\varepsilon} \sum_{i=1}^N \frac{\phi_i^2}{s^2 + 2\zeta_i \omega_{sc,i} s + \omega_{sc,i}^2} \right). \quad (9)$$

It is not straightforward to obtain the modal strains featured in Equation (9) experimentally. Further simplifying assumptions may be made to facilitate the experimental identification of the piezoelectric admittance. From Equation (5), the dynamic stiffness matrix when the piezoelectric transducer is open-circuited can be found to be

$$\mathbf{H}_{oc}(s) = \mathbf{H}_{sc}(s) + \frac{\gamma^2}{C_p^\varepsilon} \mathbf{B} \mathbf{B}^T \quad (10)$$

Equation (10) indicates that \mathbf{H}_{oc} and \mathbf{H}_{sc} only differ by a matrix independent of s . Assuming that this matrix is also diagonalized by the congruence transformation with Φ_{sc} ,

$$\Phi_{sc}^T (\mathbf{H}_{oc}(s) - \mathbf{H}_{sc}(s)) \Phi_{sc} = \frac{\gamma^2}{C_p^\varepsilon} \Phi_{sc}^T \mathbf{B} \mathbf{B}^T \Phi_{sc} \approx \Omega_{oc}^2 - \Omega_{sc}^2 \quad (11)$$

where $\mathbf{\Omega}_{oc}$ is a diagonal matrix containing the open-circuit resonance frequencies $\omega_{oc,i}$. Equating the diagonal entries in Equation (11) leads to the following relation

$$\frac{\gamma^2}{C_p^\varepsilon} \phi_i^2 \approx \omega_{sc,i}^2 K_{c,i}^2 \quad (12)$$

where

$$K_{c,i}^2 = \frac{\omega_{oc,i}^2 - \omega_{sc,i}^2}{\omega_{sc,i}^2} \quad (13)$$

is the square of the effective electromechanical coupling factor (EEMCF) [8]. Inserting Equation (12) into Equation (9), one gets the approximate piezoelectric admittance

$$Y_p(s) \approx sC_p^\varepsilon \left(1 + \sum_{i=1}^N \frac{\omega_{sc,i}^2 K_{c,i}^2}{s^2 + 2\zeta_i \omega_{sc,i} s + \omega_{sc,i}^2} \right) \quad (14)$$

Near the resonance frequency of a structural mode, the contribution from non-resonant modes may be neglected provided that the natural frequencies are well-separated. In this case, the piezoelectric admittance may be approximated as

$$Y_p(s)|_{s \approx j\omega_{sc,i}} \approx sC_p^\varepsilon \left(1 + \frac{K_{c,i}^2 \omega_{sc,i}^2}{s^2 + 2\zeta_i \omega_{sc,i} s + \omega_{sc,i}^2} \right) \quad (15)$$

3.3 Sampling delays model

The use of a DPU incurs delays associated with the sampling of input and output signals, as well as the clock frequency of the processor. The former (associated with frequencies of the order of kHz) being usually much slower than the latter (associated with frequencies of the order of MHz), only the delays induced by the sampling procedure are taken into account. They are simply modelled by a zero-order-hold operator [9]:

$$H_d(s) = \frac{1 - e^{-sT_s}}{sT_s} H(s), \quad (16)$$

where T_s is the sampling time and $H(s)$ is the synthesized transfer function. This model assumes that the DPU is able to compute the output instantaneously from the input, and keeps this output constant for one sampling period.

Now that all the terms involved in the open-loop transfer function (Equation (4)) are known, it is possible to assess the effect of these delays on the performance of the closed-loop system.

3.4 Delay-induced instabilities

As can be seen in Equations (3) and (4), the sampling delays only affect the zeros of the open-loop transfer function. As is well-known in feedback control theory [9], the zeros of the open-loop transfer function are asymptotic positions for the poles of the closed-loop transfer function as the open-loop gain tends to infinity. Hence, knowing their position is of paramount importance to assess the stability of the closed-loop system.

As an illustrative example, Figure 3 compares the poles and zeros of an ideal (i.e. without delays) transfer function and a delayed one. These transfer functions are computed from the characteristics of the experimental system described in Section 5, for which a shunt circuit is synthesized to mitigate the first then the second structural mode.

Figure 3: Poles (×) and zeros (○) of an ideal open-loop transfer function, and poles (+) and zeros (□) of a delayed open-loop transfer function: mode 1 (a) and mode 2 (b).

Figure 3(a) indicates that the delays effect is quite low for the first mode, although a small effect is visible on the zeros. In contrast, as seen in Figure 3(b), the delays cause a large shift of the zeros associated with mode 2 toward the right-half of the complex plane. The zeros almost become non-minimum phase, which signifies that the closed-loop system could be conditionally stable. As will be shown in Section 5, this estimate of the zeros is somewhat optimistic, and the closed-loop system is actually unstable.

3.5 Discussion

As the previous Subsection highlighted, the delays induced by the sampling procedure may lead to a destabilization of the vibration absorber, defeating completely its purpose. This destabilization is somewhat counter-intuitive, given that the DPU should synthesize a fully passive circuit, and that the sampling frequency is two orders of magnitude greater than the frequencies of interest. It should however be emphasized that this issue is solely hardware-related. A simple solution to this problem would be to increase the sampling frequency to a high enough value, but this is not always desirable for two reasons.

The first reason is linked to the power consumption of the DPU. The dynamic power consumption of an embedded system can be estimated by [10]

$$P = \beta C_L V_{cc}^2 f_{CPU} \quad (17)$$

where γ is the activity factor, C_L is the load capacitance, V_{cc} is the supply voltage and f_{CPU} is the clock frequency at which the DPU is operating. Increasing the sampling frequency will increase β and/or f_{CPU} , leading to a higher power consumption. Moreover, if f_{CPU} is increased, V_{cc} will also have to be increased, which leads to an actual power consumption proportional to f_{CPU}^3 [10].

The second reason is that the DPU sampling frequency may only be increased up to the hardware limits, which may be quickly reached. There could be the possibility to buy more powerful hardware, but the financial cost of such equipment could become prohibitive.

For these reasons, a stabilization method working for a given sampling frequency is proposed in the next section.

4 STABILIZATION PROCEDURE

The model developed in the previous section highlighted the role of sampling delays in the onset of instabilities. In this section, an anticipative method is proposed to cure the instability by placing the zeros of the delayed open-loop transfer function near or at the same location as those of the open-loop transfer function without delays.

The ideal transfer function of a hypothetical DPU without delays may be expressed as a rational transfer function

$$H(s) = \frac{\sum_{n=0}^N b_n s^n}{\sum_{m=0}^M a_m s^m} \quad (18)$$

and the zeros of the open-loop transfer function without delays satisfy

$$H(z_k) + Y_p(z_k) = 0, \quad \forall k \in [1, \dots, K] \quad (19)$$

The stabilization procedure consists in finding the modifications Δa_m and Δb_n to the coefficients a_m and b_n , respectively, such that the modified transfer function given as

$$\tilde{H}(s) = \frac{\sum_{n=0}^N (b_n + \Delta b_n) s^n}{\sum_{m=0}^M (a_m + \Delta a_m) s^m} \quad (20)$$

synthesized in the DPU give the same zeros as the idealized open-loop transfer function. In other words, the modifications should be such that the following equations are satisfied

$$H_d(z_k) + Y_p(z_k) = e^{z_k \beta T_s} \tilde{H}(z_k) + Y_p(z_k) = H(z_k) + Y_p(z_k) = 0, \quad \forall k \in [1, \dots, K]. \quad (21)$$

Using Equations (18) and (20), this equation becomes

$$e^{z_k \beta T_s} \frac{\sum_{n=0}^N (b_n + \Delta b_n) z_k^n}{\sum_{m=0}^M (a_m + \Delta a_m) z_k^m} = \frac{\sum_{n=0}^N b_n z_k^n}{\sum_{m=0}^M a_m z_k^m}, \quad \forall k \in [1, \dots, K]. \quad (22)$$

Carrying simple algebraic manipulations, Equation (22) can be recast into a linear system

$$\mathbf{M} \mathbf{\Delta} = \mathbf{r} \quad (23)$$

in which the unknowns are gathered in one vector

$$\mathbf{\Delta} = [\Delta a_0, \dots, \Delta a_M, \Delta b_0, \dots, \Delta b_N]^T \quad (24)$$

and \mathbf{M} and \mathbf{r} are deduced from Equation (22). Usually, $K \neq m + n + 2$ and the system is not square. A simple way of solving Equation (23) is to take its optimal solution in the least-squares sense

$$\mathbf{\Delta}^* = \left(\mathbf{M}^T \mathbf{M} \right)^{-1} \mathbf{M}^T \mathbf{r}. \quad (25)$$

The coefficients of a transfer function defined as in Equation (18) can all be multiplied by an arbitrary constant and still represent the same transfer function. This lack of unicity can lead to numerical issues. This can be fixed by setting one of the components of the vector $\mathbf{\Delta}$ to an arbitrary value. A simple choice is to choose one of the coefficients to be zero, which amounts to suppressing the corresponding column in the matrix \mathbf{M} .

5 EXPERIMENTAL VALIDATION

An experimental validation of the proposed approach is described in this section. A picture of the experimental setup is given in Figure 4. The structure is a cantilever beam with a thin, clamped lamina attached to its free end. The beam is covered with ten pairs of piezoelectric patches along its length. It is excited at midspan by an electrodynamic shaker (TIRA TV 51075) to which is also attached an impedance head (DYTRAN 5860B). An acquisition system (LMS SCADAS MOBILE) is used to record the signals. A more detailed description of the experimental setup can be found in Lossouarn et al [11].

Figure 4: Picture of the experimental setup.

Five of the ten pairs of patches are connected in parallel to the digital absorber. The two first bending mode of the beam are sequentially targeted for shunt damping. To identify the system, the frequency response functions (FRFs) when the patches are short-circuited and when they are open-circuited are measured. These FRFs, noted x/f , are obtained with a low-level broadband excitation and are displayed in Figure 5.

Figure 5: Experimental FRF of the beam when the piezoelectric patch are short-circuited (—) and open-circuited (---): close-up on mode 1 (a) and close-up on mode 2 (b).

The short-circuit and open-circuit resonance frequencies as well as the damping ratios are estimated by fitting the FRFs in Figure 5. The piezoelectric capacitance is measured with a multimeter (FLUKE 177). The parameters of the shunt circuit are then computed according to Soltani et al [12]. All these parameters are gathered in Table 1.

The DPU used in the digital absorber is an Arduino Due. The division ratio is given by $\alpha = 0.033$

Table 1: Identified and computed parameters.

Mode	f_{sc} (Hz)	f_{oc} (Hz)	ζ (-)	C_p^ε (nF)	L (H)	R (Ω)
1	30.35	30.47	0.24%	257	109.15	2,241.4
2	144.01	144.10	0.17%	257	4.8791	195.97

and the resistance of the current source is measured as $R_i = 265\Omega$. The series RL shunt circuit transfer function, theoretically given by

$$H(s) = \frac{1}{Ls + R} \quad (26)$$

is programmed into the DPU after discretizing it with Tustin's method, with a sampling frequency of $f_s = 10\text{kHz}$. The stabilizing method is used assuming that the approximation given in Equation (15) holds since the two modes are well-separated in frequency. The FRFs are compared when the transfer function is unmodified and when it is modified, with the coefficient of the numerator unchanged (i.e., $\Delta b_0 = 0$ is fixed). The open-loop transfer functions and experimentally obtained FRFs of the controlled structure are given in Figure 6, and the modified shunt circuit parameters are given in Table 2. Compared to the values given in Table 1, the synthesized inductances were empirically increased by 2% and 1% for mode 1 and 2, respectively, to obtain FRFs that exhibit equal peaks.

Table 2: Modified shunt circuit parameters.

Mode	\tilde{L} (H)	\tilde{R} (Ω)
1	109.09	2,440.1
2	4.868	395.49

As can be observed with the first mode in Figure 6(a), synthesizing the unmodified transfer function results in an already stable system which behaves as expected. The stabilization procedure brings negligible changes, as can also be observed in Figure 6(c). In contrast, a digitally synthesized shunt circuit for the second mode results in an unstable system, which is cured by the proposed procedure. The instability is confirmed by looking at the structural response in Figure 7: even when the structure is unforced, a significant acceleration is recorded. The system is thus self-excited, and its response is solely bounded thanks to the saturation of OA7. Figure 6(d) and Table 2 indicate that the physical action of the stabilization procedure is to increase the resistance in the shunt circuit, so as to bring the unstable poles back into the left-half complex plane.

6 CONCLUSIONS

Digital piezoelectric vibration absorbers are subject to instabilities caused by sampling delays. In the event of impossibility to increase the sampling frequency, a stabilization procedure was proposed. This method was experimentally validated on a piezoelectric beam. Future works may extend this method to discrete Laplace transform in order to work directly on the discretized transfer function.

Abstract. This paper is devoted to the construction of an electric analog for electromechanical systems, which contain elements made of viscoelastic energy dissipating materials and elastic piezoelectric elements. Two options of an electric analog in the form of an electric circuit are considered: a circuit made of elements with real-valued parameters of resistance inductance and capacitance and a circuit made of elements with complex-valued parameters. With these electric analogs it is possible to take into account the energy losses in an electromechanical system. The constructed electric analogs are used to find complex natural vibration frequencies, which are the dynamic characteristics of electro-viscoelastic systems. In this study the emphasis is placed on determining the values of such parameters as resistance, inductance and capacitance of the elements comprising the electric circuits.

1 INTRODUCTION

The analysis of the dynamic behavior of different engineering structures is associated with the evaluation of their dynamic characteristics, which can be determined by solving a number of relevant problems, such as the problem of steady-state vibrations, the problem of natural vibrations and the dynamic problem with initial conditions (transient analysis). The statement that the problem of natural vibrations is the most convenient and informative one from the viewpoint of the effectiveness of modeling the dynamic properties of a structure and optimisation of its dissipative characteristics has been considered and substantiated in [1]. Complex eigenvalues obtained by solving this problem define the frequencies of natural vibrations and their damping indices characterizing the damping rate of vibrations. The efficiency of the problem under consideration for optimization of the dynamic behavior of the structure can be judged by the independence of the obtained dynamic properties on the loading conditions.

Due to some peculiarities of the mathematical statement of the problem on natural vibrations of electro-viscoelastic bodies (viscoelastic structure with piezoelectric element), the numerical implementation of the algorithm for its solution using the finite element method is

a nontrivial task [2], and the search for the problem solution is a time-consuming process due to a large dimension of the resolving system of equations. At the same time, the mathematical equations, describing vibrations in the mechanical systems and current oscillations in the electric circuits demonstrate certain similarity. By this is meant that inductance is the analog of mass, resistance is the analogue of viscosity and capacitance is the analogue of stiffness. The coincidence of the mathematical descriptions suggests that in some cases we can use the electrical system instead of the mechanical one by substituting the equations for current oscillations in the equivalent electric circuit for the mechanical equations of motion [3-6]. In electrodynamics, there are also a number of well-defined approaches, for example, such as presented in [7-10], which are used to model the behavior of piezoelectric devices with the aid of their electric analogs in the form of equivalent electric circuits. However, in order to simulate the behavior of piezoelectric element attached to the structure, it is necessary to use a model, which can describe all resonant frequencies within a wide frequency range. This certainly generates the need for creating another model of electric circuit (equivalent circuit).

Representation of an electromechanical system in the form of discrete analog composed of the elements with lumped parameters allows us to significantly simplify the procedure of determining its dynamic properties. Nowadays, an approach, in which the structure is replaced by its electric analog in the form of equivalent electric circuit, is widely used especially in such applications, in which the understanding of the system performance determined by the interaction of its electrical and mechanical components is a question of utmost importance [11-12].

In the literature, there is a large number of options of electric analogs in the form of electric circuits, which are used for describing the electromechanical systems. In such systems, the parameters of the elements of electric circuits are represented both by the real (capacitance, inductance, resistance) and complex (complex inductance and capacitance) quantities [9].

The main problem is how to determine the values of the parameters for the elements of the electric circuit corresponding to the electric analog of the examined electro-viscoelastic system. The parameters of the elements comprising the examined electric circuit can be evaluated on the following basis: from the additional theoretical conditions and assumptions [5], from the data obtained from special experiments on the measurement of electric impedance of the system under consideration [3], or using the properties of the material, which are taken into account in designing an electric analog of the piezoelectric element with complex parameters [8].

It should be noted that the variety of existing approaches is explained by the complexity of the stated problem, the diversity of requirements specified for the electric analog being created, the necessity of an adequate description of the processes occurring in the system as well as the conformity to its dynamic characteristics

In this paper, we consider a method for constructing an electric analog for the examined electro-viscoelastic system and propose an approach for determining the parameters of the elements of electric circuit corresponding to the electric analog being created. The proposed techniques are based on the complex natural vibration frequencies, which are obtained from the experiment or by solving the natural vibration problem in a complete mathematical formulation.

2 MATHEMATICAL STATEMENT OF THE PROBLEM

The problem of natural vibrations for piecewise-homogeneous electro-viscoelastic bodies in the complete coupled mathematical formulation is considered in papers [13-14]. This problem is described by the following variational equation:

$$\int_{V_1} (\sigma_{ij} \delta \varepsilon_{ij} + \rho \ddot{u}_i \delta u_i) dV + \int_{V_2} (\sigma_{ij} \delta \varepsilon_{ij} - D_i \delta E_i + \rho \ddot{u}_i \delta u_i) dV = 0 \quad (1)$$

Here, the volume V_1 is related to a viscoelastic part of the structure; the volume V_2 is related to a piezoelectric part; D_i, E_i are the components of the vectors of electric flux density and electric field intensity, respectively; σ_{ij} are the components of the symmetric Cauchy stress tensor; ε_{ij} are the components of the linear strain tensor; u_i are the components of the displacement vector. The constitutive relations for the piezoelectric part of volume V_2 are written as follows:

$$\left. \begin{aligned} \sigma_{ij} &= C_{ijkl} \varepsilon_{kl} - \beta_{ijk} E_k \\ D_k &= \beta_{ijk} \varepsilon_{ij} + \varepsilon_{ki} E_i \end{aligned} \right\} \quad (2)$$

where C_{ijkl} are the components of the tensor of elastic constants; β_{ijk} and ε_{kl} are the components of the tensors of piezoelectric coefficients and dielectric coefficients, respectively ($i, j, k, l = 1, 2, 3$). Within the framework of this paper, we use the assumption that the behavior of viscoelastic material is described in terms of the complex dynamic moduli, as it was made in [14]. The dissipative mechanisms operating in the body of volume V_1 are described based on the model of linear hereditary viscoelasticity. The constitutive relations of this model can be written as

$$\begin{aligned} \sigma_{ij} - \sigma \delta_{ij} &= 2\tilde{G} \left(\varepsilon_{ij} - \frac{1}{3} \mathcal{G} \delta_{ij} \right) = 2(G_{\text{Re}} + iG_{\text{Im}}) \left(\varepsilon_{ij} - \frac{1}{3} \mathcal{G} \delta_{ij} \right), \\ \sigma &= \tilde{B} \mathcal{G} = (B_{\text{Re}} + iB_{\text{Im}}) \mathcal{G} \end{aligned} \quad (3)$$

where $\tilde{G} = G_{\text{Re}} + iG_{\text{Im}} = G_{\text{Re}} \left(1 - i \frac{G_{\text{Im}}}{G_{\text{Re}}} \right) = G_{\text{Re}} (1 - i\delta_g)$, $\tilde{B} = B_{\text{Re}} + iB_{\text{Im}} = B_{\text{Re}} \left(1 - i \frac{B_{\text{Im}}}{B_{\text{Re}}} \right) = B_{\text{Re}} (1 - i\delta_b)$ are the complex dynamic shear and bulk moduli; σ is the mean stress; \mathcal{G} is the volumetric strain; δ_g, δ_b are the mechanical loss tangents for the shear and bulk moduli, respectively; s_{ij}, e_{ij} are the components of deviatoric parts of the stress and strain tensors.

Let us consider the case, in which damping characteristics of the structure specified by the viscoelastic properties of the material it is made of are independent on the frequency, i.e. the shear and bulk moduli $G_{\text{Re}}, B_{\text{Re}}$ and the mechanical loss tangents δ_g, δ_b are constants. The solution to the problem of natural vibrations is sought in the form of $u(x, t) = u(x) e^{j\omega t}$, where $u(x) = \{u_1(x_1, x_2, x_3), u_2(x_1, x_2, x_3), u_3(x_1, x_2, x_3), \varphi(x_1, x_2, x_3)\}$ is the generalized state vector containing the components of mechanical displacements u_1, u_2, u_3 and electric potential φ ; $\omega = \omega_{\text{Re}} \pm i\omega_{\text{Im}}$ is the complex natural vibration frequency where ω_{Re} denotes the

angular natural frequency of vibrations and ω_{im} is the damping index characterizing the damping rate of vibrations.

The numerical implementation of the formulated problem is based on the finite element method (FEM). The application of the standard FEM procedures allows us to reduce the variational problem of natural vibrations described by equations (1-3) to the following matrix equation:

$$([K] - \omega^2 [M])\{\delta\} = \{0\} \quad (4)$$

where the stiffness matrix $[K]$ contains complex-valued coefficients [14].

The equivalent electric models including the elements with lumped parameters, such as the van Dyke model [4], are widely used for describing the dynamic behavior of piezoelectric element as an object with distributed parameters. The van Dyke model is represented by a series-connected elements of capacitance C , inductance L and resistance R and also the capacitance of the piezoelectric element C_0 connected in parallel to them (fig.1). This electric analog has a single resonance frequency of vibrations, which corresponds to the resonance frequency of mechanical vibrations of the piezoelectric element.

Let us consider each element of this model in detail. Here $C_0 + C$ is the inherent capacitance of piezoelectric element. The series-connected inductance element L and capacitance element C describe the resonant character of the process. The resistance element R describes losses, which occur due to the flow of electric current through the conducting elements [4].

Figure 1: Equivalent circuit of the quartz resonator proposed by van Dyke [4].

In paper [13], the van Dyke model was expanded to an elastic structure with a piezoelectric element attached to its surface (fig.2a). Here, the method proposed in [13] for constructing an electric analog for the electroelastic system makes it possible to take into account several natural vibration frequencies of the structure. However, in this case the energy losses which may occur in real structures made of viscoelastic materials are ignored.

To take into account the energy losses caused by vibrations of viscoelastic structures, the equivalent circuit represented in fig.2a is modified by introducing the resistance R_i in each resonant branch C_i, L_i (see fig.2b). This additional resistance is responsible for the energy dissipation in the vicinity of resonance. Here also C_{0n}, R_{0n} are the capacitance and the resistance in the non-resonant branch.

Figure 2: Equivalent circuits for electric analog of an electromechanical system without dissipation (a) and with dissipation (b)

According to the Kirghoff second law, the mathematical statement of the problem for the circuit represented in fig.2b is described by the following system of differential equations [13]:

$$L_i \frac{d^2 q_i}{dt^2} + R_i \frac{dq_i}{dt} + \frac{q_i}{C_i} + R_{0n} \sum_{k=1}^n \frac{dq_k}{dt} + \frac{1}{C_{0n}} \sum_{k=1}^n q_k = 0, \quad i = \overline{1, n} \quad (5)$$

Here n is the number of elementary closed electric circuits formed by the branch C_{0n}, R_{0n} and each of the resonant branches $R_i L_i C_i$; $n-1$ is the total number of parallel branches in the circuit. Representing the solution to the problem as $q_i = q_{0i} e^{j\lambda t}$, where $j^2 = -1$ is the imaginary unity, we reduce the system of differential equations (5) to the following form

$$-\lambda^2 L_i q_{0i} + j\lambda R_i q_{0i} + \frac{q_{0i}}{C_i} + j\lambda R_{0n} \sum_{k=1}^n q_{0k} + \frac{1}{C_{0n}} \sum_{k=1}^n q_{0k} = 0, \quad i = \overline{1, n} \quad (6)$$

Further, we construct the characteristic equation with respect to the unknown complex natural vibration frequency λ . The solution of this characteristic equation gives the spectrum of n complex natural vibration frequencies of the structure operating in the open circuit (o/c) mode. The spectrum of n complex natural vibration frequencies of the structure operating in the short circuit (s/c) mode can be obtained provided that each parallel branch of the circuit represented in fig.2 is short-circuited. In this case, each parallel branch is a closed oscillatory circuit. As a result, the terms containing multipliers $1/C_{0n}$ and R_{0n} are excluded from the systems of equations (5-6). Taking into account that the solution is represented as $q_i = q_{0i} e^{j\lambda t}$, the system of equations for determining the complex natural vibration frequencies of the structure operating in the short circuit mode can be written as:

$$-\lambda^2 L_i q_{0i} + j\lambda R_i q_{0i} + \frac{q_{0i}}{C_i} = 0, \quad i = \overline{1, n} \quad (7)$$

The problem of determining the parameters $R_i, R_{0n}, L_i, C_i, C_{0n}$ entering into the systems of equations (6-7) is discussed in Section 3. In the following, the values of complex natural vibration frequencies obtained on the basis of the complete mathematical formulation (1-4)

are denoted as ω . The values of complex natural vibration frequencies determined with the aid of the equivalent electric model (5-7) are denoted as λ .

3 THE CONSTRUCTION OF AN ELECTRIC ANALOG FOR ELECTRO-VISCOELASTIC SYSTEM

3.1 The circuit of an electric analog with real-valued coefficients

In order to determine the values of parameters $R_i, L_i, C_i, C_{0n}, R_{0n}$ (fig.3) for the electric analog of electro-viscoelastic system, we consider the part of the circuit, which corresponds to the vibration frequencies in the vicinity of the i -th resonance. In this case, in the short circuit mode at the i -th frequency, the electric current flows only through the R_i, L_i, C_i branch, whereas in the open circuit mode at the i -th frequency the current flows both through the branches R_i, L_i, C_i and R_{0i}, C_{0i} , which in this case are connected in series.

Figure 3: A part of the electric circuit corresponding to the system vibrations in the vicinity of the i -th natural vibration frequency.

By analogy with [13], the equations of balance of voltages are constructed according to the Kirghoff laws [15]. Here, the total capacitance of the electric circuit is assumed constant and equal to C_s :

$$C_s = \sum_{i=1}^n C_i + C_{0i} \quad (8)$$

$$L_i \frac{d^2 q_i}{dt^2} + R_s \frac{dq_i}{dt} + \frac{1}{C_i} q_i = 0 \quad \text{-- short circuit mode} \quad (9)$$

$$L_i \frac{d^2 q_0}{dt^2} + (R_i^s + R_{0i}^s) \frac{dq_0}{dt} + \frac{1}{C_i} q_0 + \frac{1}{C_s - C_i} q_0 = 0 \quad \text{-- open circuit mode} \quad (10)$$

where q_i is the variable charge in the i -th branch of the electric circuit.

The analysis of the solution of the natural vibration problem for electro-viscoelastic bodies obtained in the framework of a complete mathematical formulation (1-4) shows that when viscoelastic properties of the material are independent of frequency, the values of damping

indices are linearly dependent on the frequency of vibrations. Consequently, the damping coefficients $\xi_i = \omega_{Im}^i / \omega_{Re}^i$ have the same value for all frequencies. It means that the resistance of the electric circuit should be a variable quantity, i.e. should take different values at different frequencies of vibrations. Let this quantity be defined as $R_i^S = R_i / \lambda_i$, $R_{0n}^S = R_{0n} / \lambda_i$.

From condition (10) the following relation is obtained:

$$C_{0i} = C_s - C_i \quad (11)$$

The solution to equations (9-10) is sought in the form of $q_i = q_{0i} e^{j\lambda t}$, where $j^2 = -1$ is the imaginary unity. In view of equation (11), the equations (9) and (10) take the following form:

$$\left(-\lambda^2 L_i + j R_i + \frac{1}{C_i} \right) q_{0i} = 0 \quad (12)$$

$$\left(-\lambda^2 L_i + j(R_{0i} + R_i) + \frac{1}{C_i} + \frac{1}{C_s - C_i} \right) q_{0i} = 0 \quad (13)$$

In this case, the solution we are searching for are the eigenvalues $(\lambda)_k = (\lambda_{Re})_k + j(\lambda_{Im})_k$, which have positive imaginary parts $(\lambda_{Im})_k \geq 0$.

The values of complex natural vibration frequencies of unloaded electro-viscoelastic structure (in the case when the external circuit is absent) operating in the short circuit $(\omega_{s/c})_i = (\omega_{Re}^s)_i + j(\omega_{Im}^s)_i$ and open circuit $(\omega_{o/c})_i = (\omega_{Re}^o)_i + j(\omega_{Im}^o)_i$ modes are assumed to be known, since they can be obtained from the solution to the problem on natural vibrations of electro-viscoelastic system in the framework of a complete mathematical formulation of solid mechanics (1-4) [2]. Accordingly, the results of solution of equations (12) and (13) are expected to be the natural vibration frequencies $\lambda_i = (\omega_{s/c})_i$ and $\lambda_i = (\omega_{o/c})_i$.

It is necessary to determine four parameters: R_i , L_i and R_{0i} , C_i , which could be done with reference to condition (8). Equations (12) and (13) are the equations with complex-valued coefficients. Equality of the complex number to zero means that real and imaginary parts of this number must be equal to zero. Thus, we have four equations for four unknowns.

Let us consider equation (12), describing the short circuit mode at the i -th frequency. With regard to the relations for the known complex natural vibration frequencies, we can differentiate between the real and imaginary parts of the equation:

$$\begin{cases} -((\omega_{Re}^s)_i^2 - (\omega_{Im}^s)_i^2) L_i + \frac{1}{C_i} = 0 \\ -2(\omega_{Re}^s)_i (\omega_{Im}^s)_i L_i + R_i = 0 \end{cases} \quad (14)$$

From this it follows that:

$$R_i = 2(\omega_{Re}^s)_i (\omega_{Im}^s)_i L_i \quad L_i = \frac{1}{C_i ((\omega_{Re}^s)_i^2 - (\omega_{Im}^s)_i^2)} \quad (15)$$

By analogy, for the open circuit mode at the i -th frequency, after distinguishing the real and imaginary parts in the equation (13) we get:

$$\begin{cases} -\left((\omega_{\text{Re}}^o)_i^2 - (\omega_{\text{Im}}^o)_i^2\right)L_i + \frac{1}{C_i} + \frac{1}{C_s - C_i} = 0 \\ -2(\omega_{\text{Re}}^o)_i (\omega_{\text{Im}}^o)_i L_i + (R_i + R_{0i}) = 0 \end{cases} \quad (16)$$

Substituting in (16) the relations for R_i, L_i from (15) we obtain the relations for R_{0i} and C_i

$$R_{0i} = 2\left((\omega_{\text{Re}}^o)_i (\omega_{\text{Im}}^o)_i - (\omega_{\text{Re}}^s)_i (\omega_{\text{Im}}^s)_i\right)L_i \quad C_i = C_s \left[1 - \frac{\left((\omega_{\text{Re}}^s)_i^2 - (\omega_{\text{Im}}^s)_i^2\right)}{\left((\omega_{\text{Re}}^o)_i^2 - (\omega_{\text{Im}}^o)_i^2\right)} \right] \quad (17)$$

Thus, in the case when n resonant branches are retained in the numerical modeling, all parameters of the elements of the equivalent electric circuit can be evaluated using the relations (15) and (17). Here, the above parameters are determined in terms of the components of complex natural vibration frequencies, which are defined by the electric boundary conditions for the piezoelectric element of the system operating in the short circuit and open circuit modes.

Figure 4: Equivalent electric circuit of the electro-viscoelastic system containing an element with variable resistance

However, it remains to be seen how the elements with additional resistance should be fit into the electric circuit, to make sure that the latter could be described by the equations in the form of (17). Obviously, the resistive elements with lumped parameters are not suitable for this purpose, since they cannot describe the dependence of resistance on frequency. In order to provide the equivalent circuit with the resistance required for realization of the open circuit mode, it was decided to use the option, at which the resistive element has a variable resistance [15]. As the result, the diagram of the equivalent electric circuit with real-valued coefficients is of the form shown in figure 4. This electric circuit corresponds to an electric analog of the electro-viscoelastic system. The element with variable resistance is colored red.

3.2 The circuit of an electric analog with complex-valued parameters

Let us consider the second option of constructing an electric analog for the electro-viscoelastic system, in which the external circuit is absent. In this option, the parameters of the elements comprising the electric circuit (capacitance and inductance) take complex values. In this case, the electric circuit is of the form represented in fig.1a, which corresponds to the

examined electroelastic structure. The parameters of the elements included into this circuitry are determined by analogy with the technique described above:

$$\tilde{C}_i = C_s \frac{(\omega_{o/c})_i^2 - (\omega_{s/c})_i^2}{(\omega_{o/c})_i^2}, \quad \tilde{L}_i = \frac{1}{\tilde{C}_i (\omega_{s/c})_i^2}, \quad C_s = \sum_{i=1}^n \tilde{C}_i + \tilde{C}_{0n} \quad (18)$$

The difference is in fact that the frequencies of vibrations $(\omega_{o/c})_i$, $(\omega_{s/c})_i$ and the values of parameters of the elements \tilde{C}_i , \tilde{L}_i , \tilde{C}_{0i} included into the equivalent circuit, describing an electric analog for the examined electro-viscoelastic system without the external electric circuits, are the complex numbers, except for the total capacitance of the piezoelectric element C_s . Note however, that all parameters of the electric elements \tilde{C}_i , \tilde{L}_i , \tilde{C}_{0i} are determined on the basis of the complex natural vibration frequencies of the electro-viscoelastic system, which operates in the open circuit and short circuit modes and is not connected to any external electric circuit.

The systems of equations, which describe oscillations of the charge in the electric circuit, corresponding to the electric analog of the electro-viscoelastic system with the attached piezoelectric element, which is not connected to an external circuit, take the same form as for the case of electroelastic system:

$$\begin{aligned} \frac{d^2 q_i}{dt^2} \tilde{L}_i + \frac{q_i}{\tilde{C}_i} &= 0, \quad i = 1, n \text{ - open circuit mode;} \\ \frac{d^2 q_i}{dt^2} \tilde{L}_i + \frac{q_i}{\tilde{C}_i} + \sum_{j=1}^n \frac{q_j}{\tilde{C}_{0n}} &= 0, \quad i = 1, n \text{ - short circuit mode} \end{aligned} \quad (19)$$

4 DETERMINATION OF NATURAL VIBRATION FREQUENCIES OF ELECTRO-VISCOELASTIC STRUCTURE USING ITS ELECTRIC ANALOG

In this section, the efficiency and reliability of both options of the electric analogs (with real parameters and with complex parameters) will be demonstrated by solving the problem of determining complex natural vibration frequencies of the cantilever viscoelastic plate with the attached elastic piezoelectric element, which operates in the open circuit and short circuit modes (figure 5). The cantilevered plate has the following dimensions: $l_1 = 210$ mm, $b_1 = 26$ mm, $h_1 = 0.5$ mm. The material of the plate has the following viscoelastic properties: instantaneous moduli are $G_{Re} = 1.5385 \cdot 10^{11}$ Pa, $B_{Re} = 1.6667 \cdot 10^{11}$ Pa; tangents of mechanical losses are $\delta_g = 0.01$, $\delta_b = 0$; mass density is $\rho = 7800$ kg/m³.

The piezoelectric element has a rectangular form with the following dimensions: $l_p = 50$ mm, $b_p = 20$ mm, $h_p = 0.36$ mm. It is located symmetrically about the longitudinal axis at a distance of 12 mm from the rigidly clamped end. The piezoelectric element is made of piezoceramics PZT-4 polarized along the z-axis, which has the standard physical and mechanical properties similar to those presented in [2]. The upper and lower surfaces of the piezoelectric element are covered with electrodes and the lower surface is grounded.

Figure 5: Computational model of the cantilever plate with attached piezoelectric element

Now let us calculate the complex natural vibration frequencies of the system under consideration for two limiting cases of boundary conditions specified for the piezoelectric element - the short circuit operating mode (s/c, zero-valued electric potential on both electrode surfaces) and open circuit operating mode (o/c, zero-valued electric potential on the lower electrode surface and the upper one is free of loads). Table 1 represents the values of complex natural vibration frequencies of the structure for the s/c and o/c modes obtained on the basis of the finite element solution of the coupled problem on natural vibrations of electro-viscoelastic bodies, on the basis of the electric analogue with real-valued parameters and on the basis of the electric analogue with complex-valued parameters.

The following notations are used in the table : $f^o = \omega_{o/c} / 2\pi$, $f^s = \omega_{s/c} / 2\pi$. In table 1, from all possible natural vibration frequencies we present only those frequencies, at which the electric potential is generated on the electrodes of piezoelectric element (coupled frequencies). These frequencies of vibrations are numbered in the ascending order of magnitude. For the calculations made on the basis of the electric analogs the number of retained branches n is equal to 10. This number corresponds to the frequencies of the examined system ranging from 0 up to 3100 Hz. However, only the first five frequencies of the frequency range from 0 to 700 Hz are presented. All eigenvalues, which have positive imaginary parts $(\omega_{lm})_i \geq 0$, $i = 1, n$ are the sought solutions of the problem.

The analysis of the obtained results allows us to conclude that the electric circuits with real and complex parameters, which correspond to the electric analog of the examined electro-viscoelastic system without the external electric circuit, are quite reliable from the viewpoint of obtaining values of natural vibration frequencies. What is also important, one of the advantages of the proposed option of the electric circuit with complex parameters is that there is no need to supplement the circuit of the electric analog with additional resistance.

Table 1: Complex natural vibration frequencies of the structure under study for the s/c and o/c modes obtained on the basis of the solution to the coupled problem of continuous media mechanics; using the electric analog with real-valued parameters or using the electric analog with complex-valued parameters.

Moreover, the proposed model allows for such peculiarities of viscoelastic material of the structure as the dependence of material properties on frequency in the case when the external electric circuit is absent. However the question as to the advantages of using the electric circuit with complex parameters in the system connected to an external shunting electric circuit is still open to further investigation and discussion.

5 CONCLUSIONS

In this paper, we consider two options of constructing an electric analog in the form of electric circuits with real and complex-valued parameters for electro-viscoelastic systems. The both options of electric analogs allow describing the vibrations of electro-viscoelastic systems in the open circuit and short circuit operating modes. It is proposed that the element of an electric circuit with variable resistance should be used to describe the mechanism of energy dissipation in the framework of the model of linear hereditary viscoelasticity with complex dynamic moduli. This element allows taking into account the dissipative properties of the system, operating in the open circuit and short circuit modes. The results of numerical calculations showed the efficiency and reliability of the proposed method for determining the values of complex natural vibration frequencies of an electromechanical system including the elements of energy dissipation based on the construction of the electric analogs in the form of equivalent electric circuits.

Key words: piezoelectric shunt, negative capacitance, resonant shunt, vibration control

Abstract. This paper addresses the use of piezoelectric shunt for suppressing vibrations. The focus of the work is on the coupling between the classical resonant shunt and negative capacitances. General formulations are provided for the tuning of the elements composing the shunt impedance and the consequent vibration attenuation performances are investigated. Moreover, the paper explains which issues could be encountered in practical applications and how to overcome them. The theoretical results are validated by means of an experimental campaign.

1 INTRODUCTION

This paper addresses the use of negative capacitances (NC) for improving the vibration attenuation provided by the piezoelectric resonant shunt. Piezoelectric resonant shunt is a way of attenuating vibrations of the structures based on the shunt of a piezoelectric actuator, bonded to the structure, with an electrical impedance Z_{sh} made from a resistance R and an inductance L connected in either parallel or series (see Fig. 1a) [1, 2, 3, 4, 5, 6, 7, 8].

The attenuation performance provided by the shunt of piezoelectric actuators can be improved by adding in the shunt circuit one [9, 10, 11, 12, 13] or two [14, 15] NCs. NCs do not exist in nature but they can be built synthetically by means of operational amplifiers (OP-AMP) [16, 17]. Different works in the literature treat the coupling between NCs and resistive shunt impedances (e.g. [11, 18]), while few address the coupling with resonant impedances (e.g. [19]).

The purpose of this paper is to show how to optimise the values of L and R when NCs are added in the shunt circuit, giving general formulations. Furthermore, the consequent attenuation performance is

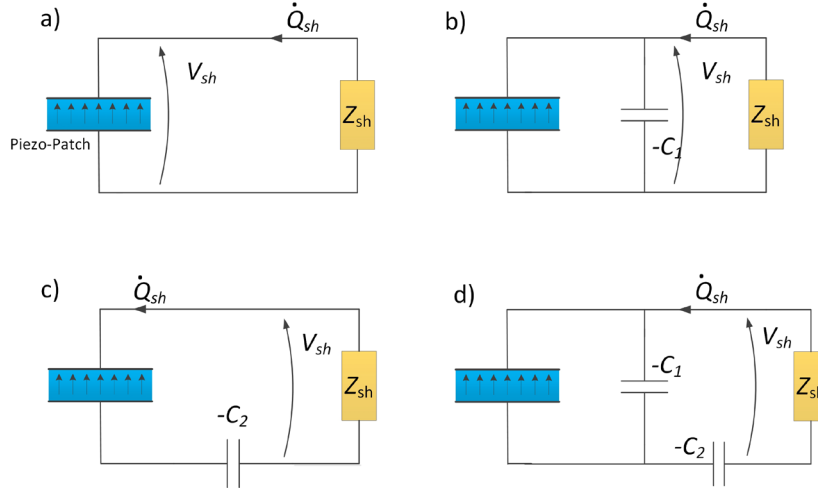

Figure 1: Piezoelectric shunt without NCs (a), with an NC ($-C_1$) connected in parallel (b), with an NC ($-C_2$) connected in series (c), with two NCs ($-C_1$ and $-C_2$) connected in series+parallel (SP) (d)

quantificated and analysed.

The second part of the paper then discusses the effect of the practical implementation of NCs on the stability of the whole system and hints are given to overcome possible problems. Therefore, the structure of the paper is as follows: Section 2 briefly describes the model employed in this paper to describe the electro-mechanical system. Then, Section 3 shows how to optimise the shunt circuit and provides estimates of the attenuations achievable with this type of vibration control strategy. Section 4 discusses practical issues related to the coupling between resonant shunt and NCs and explains how to solve them. Finally, Section 5 discusses an experimental campaign performed to validate the theoretical results.

2 MODEL OF THE ELECTRO-MECHANICAL STRUCTURE

The model used in this paper to describe the behaviour of the electro-mechanical system was developed in the works of Thomas et al. [20, 21] and Ducarne et al. [22] and then refined in the work of Berardengo et al. [18], where a detailed description of the dynamics of the electrical part of the system improves the accuracy of the whole model. These referenced works show that the dynamics of the electro-mechanical system in presence of NCs in the shunt circuit and in case of low modal density is described by the following equations at $\Omega \simeq \omega_i$ (where Ω is the angular frequency and ω_i is the i -th eigenfrequency of the system with the piezoelectric actuator short-circuited):

$$\ddot{q}_i + 2\xi_i \omega_i \dot{q}_i + (\omega_i^{\text{oc}})^2 q_i - \omega_i \tilde{k}_i \bar{Q}_{\text{sh}} = F_i \quad (1)$$

$$\bar{V}_{\text{sh}} - \bar{Q}_{\text{sh}} + \omega_i \tilde{k}_i q_i = 0 \quad (2)$$

Equation (1) describes the motion of the system, while Eq. (2) describes the dynamics of the electrical part of the system. Here, ξ_i is the non-dimensional damping ratio associated to ω_i and F_i is the modal forcing. ω_i^{sc} and ω_i^{oc} are the eigenfrequencies of the structure coupled to NCs when Z_{sh} is zero (SC) or $+\infty$ (OC), respectively; they can be written as functions of ω_i , $-C_1$, $-C_2$ (i.e. the NCs, see Fig. 1) and the capacitance of the piezoelectric patch (see [18]). Furthermore, q_i is the modal displacement. \bar{Q}_{sh} and \bar{V}_{sh} are the normalised charge and voltage seen by the impedance Z_{sh} ($\bar{Q}_{\text{sh}} = Q_{\text{sh}} / \sqrt{C_{\text{eq}}}$ and $\bar{V}_{\text{sh}} = V_{\text{sh}} \sqrt{C_{\text{eq}}}$),

respectively (see Fig. 1). Since the capacitance of the piezoelectric patch depends on the frequency, a particular capacitance value appears naturally in the equations: C_{pi} , which is the blocked capacitance corrected by a static term accounting for the higher modes (see [18]). C_{eq} is C_{pi} modified by the NCs. The expressions of C_{eq} , which are dependent on the type of connection of the NCs (see Fig. 1), can be found in [18]. \tilde{k}_i is the enhanced modal electro-mechanical coupling factor and it can be estimated as [18]:

$$|\tilde{k}_i| \simeq \sqrt{\frac{(\omega_i^{oc})^2 - (\omega_i^{sc})^2}{\omega_i^2}} \quad (3)$$

It is important to mention that, considering the elastic structure coupled to the NCs, the enhanced modal electro-mechanical coupling factor \tilde{k}_i appears naturally in the dynamical equations of the coupled system. \tilde{k}_i is the classical modal electro-mechanical coupling factor k_i increased by the effect of the NCs [9, 18]). This similarity enables to write the same model than for a classical shunt (see Eqs. (1) and (2)), with the effect of the NCs taken into account by \tilde{k}_i , ω_i^{sc} and ω_i^{oc} .

If the proper link between \bar{V}_{sh} and \bar{Q}_{sh} is derived, according to the type of connection between L and R (either parallel or series, see [5]), the frequency response function (FRF) of the system can be derived starting from Eqs. (1) and (2). The FRF in case of parallel connection between L and R is:

$$H_i^{par}(\Omega) = \frac{q_i}{F_i} = (-\Omega^2 + \omega_e^2 + 2j\xi_e\omega_e\Omega) \cdot [\Omega^4 - \Omega^2(\omega_e^2 + 4\xi_i\xi_e\omega_i\omega_e + (\omega_i^{oc})^2) + (\omega_i^{sc})^2\omega_e^2 + j\Omega[2\xi_e\omega_e((\omega_i^{sc})^2 - \Omega^2) + 2\xi_i\omega_i(\omega_e^2 - \Omega^2)]]^{-1} \quad (4)$$

while, for the series link, it is:

$$H_i^{ser}(\Omega) = \frac{q_i}{F_i} = (-\Omega^2 + \omega_e^2 + 2j\xi_e\omega_e\Omega) \cdot [\Omega^4 - \Omega^2(\omega_e^2 + 4\xi_i\xi_e\omega_i\omega_e + (\omega_i^{oc})^2) + (\omega_i^{sc})^2\omega_e^2 + j\Omega[2\xi_e\omega_e((\omega_i^{oc})^2 - \Omega^2) + 2\xi_i\omega_i(\omega_e^2 - \Omega^2)]]^{-1} \quad (5)$$

ω_e and ξ_e are the eigenfrequency and the non-dimensional damping ratio of the electrical circuit, respectively. They can be expressed as functions of L and R . The relationships, in case of parallel connection, are:

$$\omega_e = \frac{1}{\sqrt{LC_{eq}}}, \quad \xi_e = \frac{1}{2R} \sqrt{\frac{L}{C_{eq}}} \quad (6)$$

while, in case of a series link, they are:

$$\omega_e = \frac{1}{\sqrt{LC_{eq}}}, \quad \xi_e = \frac{R}{2} \sqrt{\frac{C_{eq}}{L}} \quad (7)$$

These FRFs are valid for all the types of NC connections, provided to use the proper formulation of the terms ω_i^{sc} and ω_i^{oc} , which are functions of the type of NC connection. The expressions of these two parameters for all the three NC links (parallel, series, and series+parallel (SP), see Fig. 1) can be found in [18, 19].

3 OPTIMISATION OF THE SHUNT AND ATTENUATION PERFORMANCES

To optimise the control system, the shunt network parameters (L , R and the NC) must be set. According to [18, 19], the value of the NC (in absolute value) must be set as close as possible to C_{pi} . However, a perfect equality between the NC (in absolute value) and C_{pi} is not possible because there are stability limits on the values of the NC. These stability limits are provided in [19]. It is noticed that the closer the value of the NC (in absolute value) is to the value of C_{pi} , the higher the value of $|\tilde{k}_i|$ is and, thus, the higher the attenuation performance is. High values of $|\tilde{k}_i|$ can be achieved thanks to the fact that the presence of NCs in the shunt circuit make the short- and open-circuit farther and farther (see Eq. (3), and refer to [18] for more details).

Relying on the FRFs of Eqs. (4) and (5), it is possible to optimise the values of L and R . The method used here is, indeed, a well-established approach already employed for optimising tuned mass dampers and passive (i.e. without NCs) piezoelectric shunts (e.g. [7, 21, 23, 24]), based on considerations on the shape of the transfer function of the controlled system. The value of L is set noticing that there exist two points of the FRF amplitudes, at ω_{F-} and ω_{F+} , respectively, at which all the curves obtained changing the ξ_e value, for a given value of ω_e , cross. Imposing the equality of the FRF amplitudes at ω_{F-} and ω_{F+} , the optimal value of ω_e (named here ω_e^{opt}) is derived, as well as that of L .

Then, the optimal value of ξ_e (named here ξ_e^{opt}), and thus that of R , can be found by imposing that the FRF amplitudes have a maximum first at ω_{F-} and, then, at ω_{F+} . The first condition allows to find a value of ξ_e named ξ_e^- , while the second condition allows to find a value of ξ_e , named ξ_e^+ . Then, the value of ξ_e^{opt} is derived as:

$$\xi_e^{\text{opt}} = \sqrt{\frac{(\xi_e^+)^2 + (\xi_e^-)^2}{2}} \quad (8)$$

The expressions of ω_e^{opt} and ξ_e^{opt} are provided in Table 1. Thanks to the general formulation used to model the system, these expressions are valid for all the NC configurations.

Table 1: Expressions of ω_e^{opt} and ξ_e^{opt}

parameter	L and R connected in parallel	L and R connected in series
$\omega_e^{\text{opt}} =$	$\sqrt{\frac{3(\omega_i^{\text{sc}})^2 - (\omega_i^{\text{oc}})^2}{2}}$	ω_i^{oc}
$\xi_e^{\text{opt}} =$	$\frac{\sqrt{3}}{2} \sqrt{\frac{(\omega_i^{\text{oc}})^2 - (\omega_i^{\text{sc}})^2}{3(\omega_i^{\text{sc}})^2 - (\omega_i^{\text{oc}})^2}}$	$\frac{\sqrt{3}}{2} \sqrt{\frac{(\omega_i^{\text{oc}})^2 - (\omega_i^{\text{sc}})^2}{(\omega_i^{\text{oc}})^2 + (\omega_i^{\text{sc}})^2}}$

The attenuation performance achievable by the optimised shunt can be measured by means of an index named A_{dB} and expressed in decibel, defined as:

$$A_{\text{dB}} = 20 \log_{10} \frac{H_{\text{sc}}}{H_{\text{shunt}}} \quad (9)$$

where H_{sc} is the maximum FRF amplitude value of the uncontrolled system (i.e. when the piezoelectric actuator is short-circuited without any NCs), while H_{shunt} is the FRF amplitude at ω_{F-} (this index is used because of the flat shape of the FRF amplitude around ω_i with the optimised shunt, see [21]).

Figure 2 shows the trend of A_{dB} as a function of the value of $|\tilde{k}_i|$ for an NC in either parallel or series. As for the SP configuration, the trends are not reported here because they are always between those of

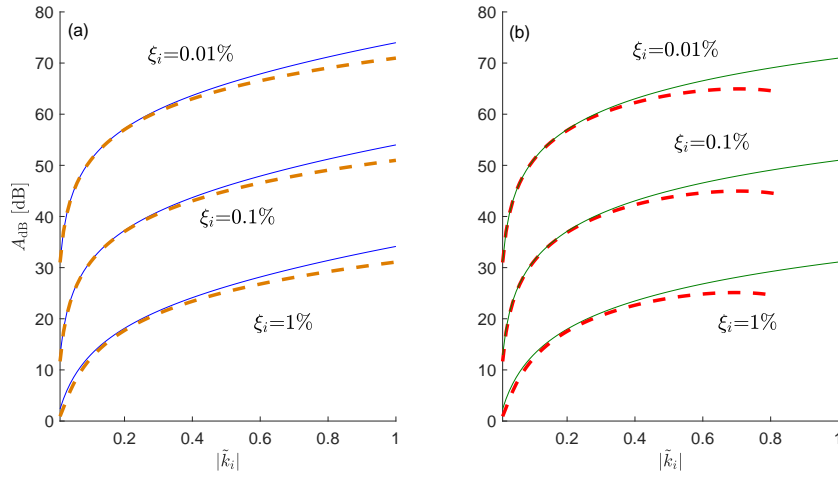

Figure 2: Trend of A_{dB} as a function of $|\tilde{k}_i|$ for an NC in parallel (a) and an NC in series (b) for different values of ξ_i . $k_i = 0.01$. Solid lines for R and L connected in series and dashed lines for R and L connected in parallel.

the parallel and the series. They slightly change according to the value set for the ratio C_{pi}/C_1 (where C_1 is the absolute value of the NC in parallel in the SP configuration, see Fig. 1).

The attenuation curves are close each other for all the NC layouts and the types of connection between L and R when the value of \tilde{k}_i is low. Conversely, when it increases, some differences become evident:

- the series connection between L and R offers higher attenuation levels compared to the parallel one;
- the NC in parallel offers slightly higher attenuations compared to the series NC. However, it is noticed that the parallel NC is usually used to attenuate high-order modes, while the series NC is employed for low-order modes. Thus, they must not be directly compared. Conversely, the SP configuration is suitable for all the modes;
- the curve of the NCs in series (and SP), when L and R are connected in parallel are stopped at $\tilde{k}_i \simeq 0.8$ because, over this threshold, the value of $[3(\omega_i^{sc})^2 - (\omega_i^{oc})^2]$ (see Tab. 1) becomes negative and ω_e^{opt} becomes imaginary;
- the A_{dB} values depend mainly on the values of $|\tilde{k}_i|$ and ξ_i and show a very small dependence on the ratio between the NCs and C_{pi} .

4 PRACTICAL ISSUES

This section analyses two different aspects related to possible issues which can arise in practical applications where piezoelectric shunt damping with NCs is employed. The two following subsections analyse them one by one.

4.1 The static gain for NCs in series and SP

When the value of $|\tilde{k}_i|$ is increased over about 0.8 using NCs in either series or SP, the curves shown in Fig. 2 can become non-accurate in describing the value of the actual attenuation provided by the shunt. Indeed, in these cases, the static gain of the FRF amplitude can become high, and even higher than the resonance peak (see, as an example, Fig. 3). Nevertheless, the curves of Fig. 2 are still able to properly

Figure 3: $|H_i|$ for $|\tilde{k}_i|$ equal to 0.7 and 0.9. $k_i=0.3$, $\omega_i/(2\pi)=30$ Hz and $\xi_i=0.1\%$

Figure 4: The electrical scheme for implementing a pure NC in series (a), the scheme with addition of \hat{R} , and the use of the compensation resistance R_s (c).

describe the attenuation if the interest is in the behaviour of the system at frequency values around ω_i . However, since the peak of the FRF amplitude is no more there, the A_{dB} curve is no more related to the maximum attenuation (which is worse). However, it must be highlighted that in many practical cases, like those discussed in this paper, the static gain is not so important and, thus, often this issue can be neglected.

Figure 3 also allows to evidence an important aspect: the use of NCs coupled to resonant shunt is potentially able to completely cancel a resonance peak. As an example, the curve related to $\tilde{k}_i = 0.7$ is almost flat up to about 40 Hz. This point will be addressed again in Section 5, where it will be shown that resonance cancellation is actually possible in practical applications.

4.2 The stability of NCs in series and SP

When NCs in either series or SP are used, sometimes the circuit used to build pure NCs (see, as an example, Fig. 4a) cannot be used because of electrical problems like bias currents. This requires the addition in the series NC, and in the NC in series in the SP configuration, of an additional resistance \hat{R} (see Fig. 4b). This additional component in the impedance makes it behave like the parallel of an NC

Figure 5: Trend of the attenuation as a function of $|\tilde{k}_i|$ for a system with $\omega_i/(2\pi)=30.5$ Hz, $\xi_i=0.1\%$, $k_i=0.2$ and different values of R_{eq} : -1 M Ω (solid curves), -10 M Ω (dashed curves) and -75 M Ω (dash-dotted curves). Thick lines for a series NC and thin lines for NCs in SP (with $C_1/C_{p_i}=0.5$). The trends of the theoretical A_{dB} curves are not reported because they have negligible differences compared to the curves with $R_{eq}=-75$ M Ω .

and a negative resistance [18]. This negative resistance has an influence on the attenuation performance at low frequency (e.g. below 20 Hz), thus changing the behaviour of the curves in Fig. 2b. However, the major problem caused by this layout is related to the fact that it has destabilising effects on the system [25]. Therefore, the theoretical stability limits do not hold anymore and the value of the NC must be moved away from that of C_{p_i} to guarantee system stability. This implies a worsening of the attenuation performance, even in case the vibration control is performed at high frequency.

There are two ways to prevent such a problem. The main one is the use of a compensation resistance R_s in parallel to the negative resistance (see Fig. 4c). If the values of R_s is chosen so that the total equivalent resistance becomes negative and with a high absolute value (e.g. -75 M Ω), then the problems related to the worsening of the attenuation performance at low frequency and the additional possibility of having system instability tend to disappear. This is because, with such a value of the total equivalent resistance, the electric circuit of Fig. 4c tends to behave like a pure NC.

The other way to overcome the mentioned problems is the use of the SP NC in place of the series NC. Indeed, with the same value of \tilde{k}_i and the same value of the equivalent resistance, the SP shows to be farther from instability than the series NC [19] and the achievable attenuation performance is higher (see Fig. 5, as an example).

5 EXPERIMENTS

This section aims at validating the previous theoretical outcomes by means of an experimental campaign. The set-up was made from a stainless steel cantilever beam (length 18 cm and thickness 1.1 mm) with two piezoelectric patches bonded at the clamped end (on opposite sides of the beam) and electri-

Figure 6: Numerical (dashed curves) and experimental (circles) for an NCs in parallel (a), series (b) and SP (c).

cally connected in series. The excitation to the structure was provided by a contactless electro-magnetic actuator [26] and the structural response was measured by means of a laser velocimeter. The NCs were built with OPA445 OP-AMPs, always supplied with a voltage of $\pm 30V$, as well as the inductance of the shunt due to its high values [27]. The layout used to build the inductance was the Antoniou's circuit [19, 21, 28].

The eigenmode chosen to carry out the tests was the first. Its modal parameters were estimated by means of an experimental modal analysis and their values for all the tests carried out are gathered in Tab. 2.

Table 2: Modal parameters identified experimentally

parameter	Test A	Test B	Test C
$\omega_i/(2\pi)$ [Hz]	34.42	34.45	34.50
ξ_i [%]	0.39	0.36	0.36
k_i	0.2618	0.2662	0.2603

Figure 6 shows the values of the A_{dB} index for NCs in parallel (plot a, test A), series (plot b, test B) and SP (plot c, test C) as a function of the value of $|\tilde{k}_i|$. The highest values of $|\tilde{k}_i|$ tested for the NCs in series and SP were much higher than in the case of the NC in parallel. This is due to the fact that, as mentioned, the parallel NC is used to control high order modes, while here the first mode is accounted for. This implies that it is not possible to achieve high values of $|\tilde{k}_i|$ with an NC in parallel due to stability limits, as demonstrated in [18, 19].

The plots of Fig. 6 show good agreement between theoretical expectations and experimental results.

Figure 7: Experimental FRFs for test B: piezoelectric patch in SC without any NCs (dashed line) and shunted (solid line, NC in series, $\tilde{k}_i = 0.69$)

This demonstrates the reliability and the accuracy of the model used. Furthermore, the same plots show that the attenuation achievable by coupling NCs to the classical resonant shunt is very high. More details about the test campaign can be found in [19].

Finally, Fig. 7 shows some experimental FRFs in the case of test B. The main outcome of this figure is that it is actually possible to achieve resonance cancellation, as already mentioned in Section 4.2. Indeed, the curve in the figure related to $\tilde{k}_i=0.69$ is almost flat up to about 40 Hz. This demonstrates the great potentiality of the coupling between resonant shunt and NCs in practical application, because it allows to achieve very high attenuation levels, even allowing for resonance cancellation.

6 CONCLUSIONS

This paper has addressed the use of piezoelectric shunt for attenuating mechanical vibrations. Particularly, the shunt impedance treated in the paper is made from the classical resonant shunt impedance (an inductance and a resistance connected in either series or parallel) coupled to one or two NCs.

Optimisation formulas are provided for all the possible layouts of the shunt impedance. This allows to have general formulations for the tuning of the values of the inductance and the resistance. With these optimisation formulae, it is shown that the attenuation achievable by using this type of suppression approach can be very high. Basically, the attenuation for the optimised shunt is function of the values of the enhanced electro-mechanical coupling coefficient and of the mechanical non-dimensional damping ratio.

Furthermore, the paper shows which practical problems could occur in real applications and provides methods for overcoming them.

The theoretical results have been validated by carrying out experimental tests on a cantilever beam provided of two piezoelectric actuators electrically connected in series. One of the main outcomes of the experiments is that the coupling between resonant shunt and NCs is able to achieve resonance cancellation in real applications, thanks to the very high achievable attenuation levels.

Key words: Piezoelectric materials, Nonlinear Dynamics, Internal Resonance

Abstract. Theoretical and experimental results tracing non linear behaviors of an electro-mechanic beam are presented. Two configurations for the beam are studied: a homogeneous beam with a single piezoelectric patch (the unilateral configuration (1)) and a homogeneous beam with two piezoelectric materials patched symmetrically on each side of the beam (the bilateral configuration (2)). It is shown that by changing the position of the piezoelectric materials, internal resonances 1 : 2 and 1 : 3 between two modes can be achieved for both configurations. Tracing the mode shapes of the composite beams demonstrate their modification due to the presence of the piezoelectric patches. The configurations are supposed to present quadratic and cubic non linearities, when the configuration (1) posses more quadratic non linear terms than configuration (2). This conclusion is made through the theoretical part and experimental results traced for the direct excitation of one mode. Experimental results when the configuration (2) is set in its 1 : 3 internal resonance and excited on its lower mode are presented and an energy transfer toward the upper mode is exhibited.

1 INTRODUCTION

Piezoelectric materials can be used for the aim of control [1] and energy harvesting [2]. Several studies showed the interest of using non linear circuit with those materials to enhance the efficiency of control process by the piezoelectric materials [3, 4, 5, 6].

On the contrary of linear systems, nonlinear systems can present mode coupling(s) and energy exchange(s) between different modes due to internal resonances. This phenomenon can be used for passive control and/or energy harvesting [7]. The creation of internal resonances in non linear systems is influenced by the degree of nonlinearity of the considered system: in systems which present cubic nonlinearities, the internal resonance can happen if we have: $\omega_q \simeq \omega_r$, $\omega_q = 3\omega_r$, $\omega_k \simeq |\pm 2\omega_q \pm \omega_r|$, where

Figure 1: Schemes of the unilateral configuration (1), composed of one piezoelectric material patched on an homogeneous beam, and the bilateral configuration (2) consisting in two piezoelectric materials patched symmetrically on an homogeneous beam. The beam is supposed clamped-free of length L_b , and the piezoelectric materials are patched between the positions $x = x_1$ and $x = x_2$.

ω_i is the i^{th} natural frequency of the system. In systems with quadratic non linearity, besides the above conditions, the internal resonance can emerge if $\omega_q \simeq 2\omega_r$ and $\omega_k \simeq \omega_q \pm \omega_r, \dots$ [8, 9]. When an internal resonance is reached, a strong energy exchange between the modes can happen depending on the non-linear coefficients of the system.

The aim of this work is to use the energy exchanges between modes of a multi-physics system (an homogeneous beam and piezoelectric materials), due to internal resonances, for control and/or energy harvesting. For our study two configurations of beam with piezoelectric materials are studied: a configuration with only one piezoelectric material patch on an homogeneous beam, called as the unilateral configuration (1), the other one is named the bilateral configuration (2), it consists of two piezoelectric materials placed symmetrically on each side of the beam, as seen in Fig.1. While both configurations present cubic and quadratic non linearities, the effect of quadratic terms in configuration (1) is more evident compare to the configuration (2). From the theoretical developments it is deduced that the position of the piezoelectric patches on the beam can be used to create internal resonances between modes[10]. For example, internal resonances 1 : 2 and 1 : 3 can be achieved as: $\omega_3 \simeq 3\omega_2$ and $\omega_3 \simeq 2\omega_4$. The focus of this paper is studying the 1 : 3 internal resonance happening between the second and the third mode. The paper is structured as it follows: theoretical developments are presented in Section 2. In detail, after presenting governing system equations, spatio-temporal variables of the system are separated leading to detection of frequency and mode shapes of the composite beams. Then governing system equations are projected on: (i) one mode when the system doesn't have any internal resonances and (ii) two modes presenting an internal resonance 1 : 3, and are treated via a multiple scale method. In Section 3 experimental results are provided: First, natural frequencies and mode shapes are detected and compared with the theoretical results. Then results of two cases are presented and commented, (i) a single mode excitation traced via a Phase-Locked-Loop (PLL) [11] method and (ii) we set the bilateral configuration in its 1 : 3 internal resonance, and we detect the equilibrium points through a synchronous detection method.

2 THEORETICAL DEVELOPMENTS FOR THE DIFFERENT CONFIGURATIONS

Let us denote by $v(x, t)$ the displacement in the \vec{e}_y direction as seen in Fig.1. The piezoelectric materials (PIC151) are supposed to be polarized in the \vec{e}_y direction and they are positioned between $x = x_1$ and $x = x_2$. Then their free electrical enthalpy $H(\epsilon, E)$, with ϵ_{xx} and E_y the strain and the electrical

field in the direction \vec{e}_x and \vec{e}_y respectively, is expanded until the order 3 [10, 12] in its variables as:

$$H(\epsilon_{xx}, E_y) = \frac{s_{11}}{2}\epsilon_{xx} + d_{31}\epsilon_{xx}E_y + \xi_{33}\frac{E_y^2}{2} + r_{331}\epsilon_{xx}E_y^2 + d_{311}\epsilon_{xx}^2E_y + \xi_{333}\frac{E_y^3}{3} + \frac{s_{111}}{3}\epsilon_{xx}^3 \quad (1)$$

where s_{11} , d_{31} , ... are some constants coming from the piezoelectric materials non linear behavior. Then, the electro-mechanical equations of the 2-dimensional multi-physics system can be written as [10]:

$$\begin{aligned} \mu(x)\ddot{v} + c_v\dot{v} - Q_v = EI(x)[-v^{(iv)} - (v'(v'v''))'] + [v' \int_x^{L_b} (-\mu(x)/2) [\int_x^0 v'^2 dx] dx]' \quad (2) \\ + \int_{\frac{h_b}{2}}^{\frac{h_b}{2}+h_p} \int_{-\frac{b_p}{2}}^{\frac{b_p}{2}} \left[\left((\mathcal{H}(x_1) - \mathcal{H}(x_2))v''^2 + 2(\delta(x_1) - \delta(x_2))2v''v''' + (\delta'(x_1) - \delta'(x_2))v''^2 \right) y^3 s_{111} \right. \\ \left. + \left((\mathcal{H}(x_1) - \mathcal{H}(x_2))v^{(iv)} + 2(\delta(x_1) - \delta(x_2))v''' + (\delta'(x_1) - \delta'(x_2))v'' \right) \frac{2d_{311}}{h_p} y^2 V + \right. \\ \left. + (\delta'(x_1) - \delta'(x_2)) \left(\frac{-d_{31}}{h_p} yV + \frac{r_{331}}{h_p^2} yV^2 \right) \right] dydz \\ Q = \int_{x_1}^{x_2} \int_{-\frac{b_p}{2}}^{\frac{b_p}{2}} (d_{31}yv'' - \xi_{33}E_y + 2r_{331}yE_y - 2d_{311}y^3v''^2 - \xi_{333}E_y^2) dx dz \end{aligned}$$

when \cdot and $'$ stand for time and space derivations of a variable respectively, and c_v is the damping of the system, \mathcal{H} and δ are the Heaviside and Dirac functions and s_{111} is a nonlinear piezoelectric coefficients [12, 13], taking into account a nonlinear stiffness behavior of the piezoelectric materials, and:

$$\mu(x) = \begin{cases} \mu_1(x) = \mu_b & x \in [0, x_1[U, x_2, L_b] \\ \mu_2(x) = \mu_b + \chi \mu_p & x \in [x_1, x_2] \end{cases} \quad (3)$$

where μ_b and μ_p are the mass densities of the beam and the piezoelectric materials respectively, and $\chi = 1$ or 2 depending if the unilateral or bilateral configuration is considered, and:

$$EI(x) = \begin{cases} EI_1(x) = E_b \frac{b_b h_b^3}{12} & x \in [0, x_1[U, x_2, L_b] \\ EI_2(x) = E_b \frac{b_b h_b^3}{12} + \chi E_p \frac{b_p h_p^3}{12} & x \in [x_1, x_2] \end{cases} \quad (4)$$

E_b , b_b , h_b and E_p , b_p , h_p are the Young modulus, the width and the thickness of the beam and the piezoelectric materials respectively.

2.1 Treatment of spatial system equations

A separation of the spatio-temporal variables of the displacement $v(x, t)$ is done, as it follows:

$$v(x, t) = \phi(x)r(t) \quad (5)$$

To detect the natural frequencies of the system, the linear part in time of Eq. (2) is taken:

$$\mu(x)\ddot{r}(t)\phi(x) = EI(x)r(t)\phi^{(iv)}(x) \quad (6)$$

$\mu(x)$ and $EI(x)$ are defined by parts as seen in Eqs.(3) and (4), because of the position of the piezoelectric materials, this is why the mode functions $\phi(x)$ are written as:

$$\phi(x) = (1 - \mathcal{H}(x_1))\phi_1(x) + (\mathcal{H}(x_1) - \mathcal{H}(x_2))\phi_2(x) + \mathcal{H}(x_2)\phi_3(x) \quad (7)$$

Then the following differential equations arise:

$$\begin{aligned} \mu_1(x)\phi_1(x) &= EI_1(x)\phi_1^{(iv)}(x) \quad \text{with } x \in [0, x_1[\\ \mu_2(x)\phi_2(x) &= EI_2(x)\phi_2^{(iv)}(x) \quad \text{with } x \in [x_1, x_2] \\ \mu_1(x)\phi_3(x) &= EI_1(x)\phi_3^{(iv)}(x) \quad \text{with } x \in]x_2, L_b] \end{aligned} \quad (8)$$

where:

$$\phi_j(x) = A_j \cos(K_j x) + B_j \sin(K_j x) + C_j \cosh(K_j x) + D_j \sinh(K_j x) \quad (9)$$

with $j = 1, 2$ and 3 .

The beam is supposed to be clamped-free, as seen in Fig. 1. Moreover, since piezoelectric materials are fully patched on the beam, one should impose continuity conditions on the system modes at $x = x_1$ and $x = x_2$.

Those conditions allow us to access a critical equation to find the natural frequencies and the mode functions of both configurations of the multi-physics system [14, 5, 10].

2.2 Treatments of temporal system equations

From the section 2.1, the mode functions of the system are found. To solve the problem in time, Eq. (2) is projected on the mode(s) of interest(s), and the following equations in time are solved with a Multiple Scale method [9]. Two different cases are considered: (i) we suppose that only one mode is excited by the external excitation, (ii) we suppose that two modes are in a 1 : 3 internal resonance and the lower one is directly excited by the external excitation.

2.2.1 Case (i): a single mode excitation

For the case (i), let us suppose the d^{th} mode is directly excited, this way $v(x, t)$ is expanded as:

$$v(x, t) = \phi_d(x)r_d(t) \quad (10)$$

Eq.(2) projected on the mode d^{th} can be written as:

$$\begin{aligned} 0 &= T_0 \ddot{r}_d + T_1 \dot{r}_d + T_2 \Omega^2 \cos(\Omega t) + T_3 r_d + T_4 r_d^3 + T_5 r_d \overbrace{r_d^2}^{..} + T_6 r_d^2 + T_7 r_d V + T_8 V + T_9 V^2 \\ 0 &= S_1 r_d + S_2 V + S_3 r_d V + S_4 r_d^2 + S_5 V^2 \end{aligned} \quad (11)$$

$T_0, T_1, \dots, T_9, S_1, \dots$ and S_5 are some constants coming from the projection on the d^{th} mode and Ω is the frequency of the external excitation. It should be noted that for the configuration (2), $T_6 = T_9 = 0$, removing most of the quadratic non linear terms for this configuration.

The Multiple Scale hypothesis are written as follow:

$$\begin{aligned} T_1 &= T_2 = T_4 = T_5 = T_6 = T_7 = T_8 = T_9 = O(\epsilon) \\ r_d &= r_{d0} + r_{d1}\epsilon + r_{d2}\epsilon^2 \\ V &= V_0 + V_1\epsilon + V_2\epsilon^2 n \\ \Omega &= \omega_d + \epsilon\sigma \\ \frac{\partial}{\partial t} &= D_0 + \epsilon D_1 + \epsilon^2 D_2 \end{aligned} \quad (12)$$

Figure 2: Theoretical curves for the second mode of $|A_{21}^2 + B_{21}^2|$ from the Cardano equation for both configurations: unilateral (1) (in green, on the left) and bilateral (2) (in blue, on the right). Nonlinear piezoelectric coefficients are taken from [15].

with σ a detuning parameter and ω_d the d^{th} frequency of the multi-physics system.

We then suppose that r_{d0} is expanded as:

$$r_{d0} = A_d + A_{d1} \cos(\Omega t) + B_{d1} \sin(\Omega t) \quad (13)$$

Studying system equations until $O(\varepsilon)$, a Cardano equation in $A_{d1}^2 + B_{d1}^2$ is obtained that can be solved and shows a Duffing behavior, and the quadratic nonlinear terms only allow to go from softening to hardening behavior [10] if those are high enough. Theoretical curves for both configurations are traced for the second mode in Fig. 2, nonlinear piezoelectric coefficients are taken arbitrarily from [15]. For the configuration (1), the effects of the quadratic non linear terms are not activated yet, but, [16, 17] show that the quadratic terms can be responsible for a change of curvature.

2.2.2 Case (ii): two modes in a 1 : 3 internal resonance with the lower one directly excited

For this problem, we suppose the n^{th} and the m^{th} modes to be in a 1 : 3 internal resonance ($\omega_m = 3\omega_n$), thus we suppose $v(x, t)$ expanded as:

$$v(x, t) = \phi_n(x)r_n(t) + \phi_m(x)r_m(t) \quad (14)$$

Projecting Eq. (2) on the n^{th} and the m^{th} modes, the following equations are found:

$$\begin{aligned} 0 = & N_0 \ddot{r}_n + N_1 \dot{r}_n + N_2 \Omega_2^2 \cos(\Omega_2 t) + N_3 r_n + N_4 r_n^3 + N_5 r_n^2 r_m + N_6 r_n r_m^2 + N_7 r_m^3 + N_8 r_n \overbrace{r_n^2}^{..} \\ & + N_9 r_n \overbrace{r_m^2}^{..} + N_{10} r_n \overbrace{r_n r_m}^{..} + N_{11} r_m \overbrace{r_n^2}^{..} + N_{12} r_m \overbrace{r_m^2}^{..} + N_{13} r_m \overbrace{r_n r_m}^{..} + N_{14} r_n^2 + N_{15} r_n r_m + N_{16} r_m^2 \\ & + N_{17} r_n V + N_{18} r_m V + N_{19} V + N_{20} V^2 \\ 0 = & M_0 \ddot{r}_m + M_1 \dot{r}_m + M_2 \Omega_2^2 \cos(\Omega_2 t) + M_3 r_m + M_4 r_n^3 + M_5 r_n^2 r_m + M_6 r_n r_m^2 + M_7 r_m^3 + M_8 r_n \overbrace{r_n^2}^{..} \\ & + M_9 r_n \overbrace{r_m^2}^{..} + M_{10} r_n \overbrace{r_n r_m}^{..} + M_{11} r_m \overbrace{r_n^2}^{..} + M_{12} r_m \overbrace{r_m^2}^{..} + M_{13} r_m \overbrace{r_n r_m}^{..} + M_{14} r_n^2 + M_{15} r_n r_m + M_{16} r_m^2 \\ & + M_{17} r_n V + M_{18} r_m V + M_{19} V + M_{20} V^2 \\ 0 = & L_1 V + L_2 r_n + L_3 r_m + L_4 V^2 + L_5 r_n^2 + L_6 r_m^2 + L_7 r_n r_m + L_8 r_n V + L_9 r_m V \end{aligned} \quad (15)$$

where $N_0, N_1, \dots, N_{16}, M_0, M_1, \dots, M_{16}$ and L_1, \dots, L_9 constants from the projection on the n^{th} and m^{th} modes respectively and Ω_2 is the frequency of the external excitation.

The hypothesis made for the Multiple Scale method are as follow:

$$N_1 = \varepsilon^2 N_{1p} \quad (16)$$

$$N_2 = \varepsilon^3 N_{2p}$$

$$M_1 = \varepsilon^2 M_{1p}$$

$$M_2 = \varepsilon^3 M_{2p}$$

$$N_{19} = \varepsilon N_{19p}$$

$$M_{19} = \varepsilon M_{19p}$$

$$r_n = r_{n1}\varepsilon + r_{n2}\varepsilon^2 + r_{n3}\varepsilon^3$$

$$r_m = r_{m1}\varepsilon + r_{m2}\varepsilon^2 + r_{m3}\varepsilon^3$$

$$\Omega_2 = \omega_n + \varepsilon^2 \sigma_2$$

$$\omega_m = 3\omega_n + \varepsilon^2 \sigma_3$$

$$\frac{\partial}{\partial t} = D_0 + \varepsilon D_1 + \varepsilon^2 D_2 \quad (17)$$

where σ_2 and σ_3 are detuning parameters.

We suppose r_{n1} and r_{m1} are expanded as:

$$r_{n1} = A_{n1} \cos(\Omega_2 t) + B_{n1} \sin(\Omega_2 t) \quad (18)$$

$$r_{m1} = A_{m3} \cos(3\Omega_2 t) + B_{m3} \sin(3\Omega_2 t) \quad (19)$$

At $O(\varepsilon^3)$, the solvability condition gives the following system of coupled equations:

$$0 = F_1(A_{n1}, B_{n1}, A_{m3}, B_{m3}) \quad (20)$$

$$0 = F_2(A_{n1}, B_{n1}, A_{m3}, B_{m3})$$

$$0 = F_3(A_{n1}, B_{n1}, A_{m3}, B_{m3})$$

$$0 = F_4(A_{n1}, B_{n1}, A_{m3}, B_{m3}) \quad (21)$$

This way, the amplitudes of r_{n1} and r_{m1} are coupled, meaning that although the n^{th} mode is directly excited, the m^{th} mode respond as well due to the mode coupling. From [10], supposing the piezoelectric materials linked to a resistor and an internal resonance 1 : 3 between the second and the third mode, we have Fig. 3, it shows that the first harmonic of the second mode and the third harmonic of the third mode are the ones responding as expected from the hypothesis Eq. (19). We can see that $|A_{21}^2 + B_{21}^2| \simeq 10|A_{33}^2 + B_{33}^2|$, showing that the nonlinear coefficients are not large enough to have a real exchange of energy between the modes.

3 EXPERIMENTAL RESULTS FOR BOTH CONFIGURATIONS

For the experimental set up, the multi-physics beams are fixed through a clamping system that is screwed on a shaker. The shaker is excited via an amplifier. An accelerometer is glued on the clamping system allowing us to monitor the input excitation given to the structure. Then, the velocity of a given

Figure 3: Theoretical curve for a problem with coupled modes and a electrical circuit solved with Manlab for r_n and r_m with three harmonics.

point of the structure is detected by a laser vibrometer. The software used allows us to find the different natural frequencies of the configuration and also to trace the modal deformations. A Phase-Locked-Loop (PLL) method [11] is also used, exciting one mode of the structure. Finally, a synchronous detection is performed on configuration (2) when set to present a 1 : 3 internal resonance between its second and third natural frequencies.

3.1 Experimentally results detected: frequencies and modal deformations

First, the Young Modulus E_b of the homogeneous beam is fixed thanks to a scaling between its theoretical and experimental frequencies. On both considered configurations, the piezoelectric materials are patched at a fixed position from the free end of the beam as $\Delta = L_b - x_2$ and their length is $x_2 - x_1 = 0.05 \text{ m}$. For the unilateral configuration (1), Δ is set equal to 0.06 m , as for the bilateral configuration (2), we have $\Delta = 0.07 \text{ m}$.

From the mechanical properties of the homogeneous beam and the piezoelectric materials (PIC151), detailed in Table 1 and 2, and knowing x_1 and x_2 for both configurations, theoretically and experimentally obtained frequencies of the fourth mode are compared in Fig. 4, for different length of the beam L_b . In Figs. 4 and 5, it is seen that experimental results are in a reasonable agreements with the theoretical ones.

Table 1: Mechanical properties of the homogeneous beam

$\mu_b \text{ (kg.m}^{-3}\text{)}$	$E_b \text{ (Pa)}$	$h_b \text{ (m)}$	$b_b \text{ (m)}$
7.8104×10^3	1.78881×10^{11}	0.5×10^{-3}	13×10^{-3}

Furthermore, the experiments showed that a 1 : 2 and 1 : 3 internal resonances can be created between the third and fourth modes and the second and third modes respectively, for a special length of the beam L_b . Figure 5 shows that mechanical (stiffness and mass addition) of the piezoelectric materials have an effect on the modal deformation, it also confirms that the function is different from the one of the beam only.

As a summary, the hypothesis that the modal deformation are modified by the presence of the piezoelec-

Figure 4: Theoretical (continuous line) and experimental (o) points where obtained for the fourth natural frequency of the unilateral configuration (1) (in green, on the left) and the bilateral configuration (2) (in blue, on the right) respectively, for different values of the length of the beam L_b .

tric patches and should be written by parts accordingly, is confirmed experimentally. Moreover, it is seen that the piezoelectric materials positions can help the creation of internal resonances.

3.2 Experimentally detected forced responses of the system

Two methods are used to study the behavior of the system excited around some of its natural frequencies by the shaker.

The first method is the PLL method [11]. For this method, the phase between the excitation and the vibration of the system is set to stay constant equal to 0 or $-\Pi$, depending on where the vibrometer laser is pointed on the structure. Then, starting around one of the natural frequency of the system, the forcing is gradually increased while the system keeps the difference of phase at 0 or $-\Pi$.

As for the synchronous detection, a loop is made to control the intensity given at the shaker in order to have the same excitation while a sweep in frequency is performed around a natural frequency of the system. For this excitation, the configuration (2) is set at a disposition where a 1 : 3 internal resonance is created between the second and third mode.

3.2.1 Single mode excitation, the Phase-Locked-Loop method

The PLL method is used to have the results for both configurations, at $L_b = 0.17$, assuring the configuration's natural frequencies are not in any internal resonances disposition.

It can be seen from Fig. 6, that for the unilateral configuration, there is a change of curvature that is not seen for the bilateral configuration. This can be explained by the presence of quadratic nonlinear terms in the unilateral configuration, that are less important for the bilateral configuration [16, 18], as it is supposed in the theoretical model, since $T_6 = T_9 = 0$ for the bilateral configuration in Eq. (12) removing most of the quadratic non linear terms.

Figure 5: Experimental points (o) and theoretical curves (-) of the modal deformations of the fourth mode are presented for different configurations at $L_b = 0.17$. In black is the modal deformation of the homogenous beam, in green the one of the unilateral configuration (1) and in blue the one of the bilateral configuration (2).

Figure 6: Forced response curves obtained via the PLL started around the second natural frequency of each configuration, the unilateral (in green, on the left) and the bilateral (in blue, on the right), respectively.

3.2.2 The 1 : 3 internal resonance with the lower mode excited, using a synchronous detection method

Here the second and the third mode are supposed to be in a 1 : 3 internal resonance, thus, from Eq. (17), $v(x, t)$ is expanded as:

$$v(x, t) = \phi_2(x)r_2(t) + \phi_3(x)r_3(t) \quad (22)$$

$$(23)$$

We develop $r_2(t)$ and $r_3(t)$ in Fourier Series of Ω_2 the frequency of excitation, as:

$$r_2(t) = \sum_{s=1}^{\infty} (A_{2s} \cos(s\Omega_2 t) + B_{2s} \sin(s\Omega_2 t)) \quad (24)$$

$$r_3(t) = \sum_{s=1}^{\infty} (A_{3s} \cos(s\Omega_2 t) + B_{3s} \sin(s\Omega_2 t))$$

Experimentally, we set the configuration (2) at a length $L_b = 0.12$ m allowing a resonance 1 : 3 between the second and the third mode. To compare the results of the experiment with what was expected from

Figure 7: Experimental points of the synchronous detection method around the second natural frequency of the bilateral configuration at $L_b = 0.12\text{ m}$, allowing a $1 : 3$ internal resonance between the second and the third mode. The experimental points (*) of the first harmonic of the second mode at $x = x_{f3}$, are traced for different amplitude of excitation of the system, on the left. The experimental points (+) of the first harmonic of the third mode (at $x = x_{f2}$), are traced for the same different amplitude of excitation of the system, on the right.

Figure 8: Experimental points of the synchronous detection method around the second natural frequency of the bilateral configuration at $L_b = 0.12\text{ m}$, allowing a $1 : 3$ internal resonance between the second and the third mode. The experimental points (*) of the third harmonic of the second mode (at $x = x_{f3}$), are traced for different amplitude of excitation of the system, on the left. The experimental points (+) of the third harmonic of the third mode (at $x = x_{f2}$), are traced for the same different amplitude of excitation of the system, on the right.

the Multiple Scale Method, the experiments are conducted at two different points on the system: $x = x_{f2}$ a node of the second mode and $x = x_{f3}$ a node of the third mode. This way, it can be written:

$$\text{At } x = x_{f2} \quad v(x = x_{f2}, t) \simeq \sum_{s=1}^{\infty} (A_{3s} \cos(s\Omega_2 t) + B_{3s} \sin(s\Omega_2 t)) \quad (25)$$

$$\text{At } x = x_{f3} \quad v(x = x_{f3}, t) \simeq \sum_{s=1}^{\infty} (A_{2s} \cos(s\Omega_2 t) + B_{2s} \sin(s\Omega_2 t)) \quad (26)$$

Thus, at $x = x_{f2}$ we trace the third harmonic of the response which correspond to $|A_{33}^2 + B_{33}^2|$ from the Multiple Scale comparison, and at $x = x_{f3}$ the first harmonic of the response which relates to $|A_{21}^2 + B_{21}^2|$. In Fig. 7, we trace the first harmonic of the second (at $x = x_{f3}$) and third mode (at $x = x_{f2}$) and in Fig. 8, we trace the third harmonic of the second (at $x = x_{f3}$) and third mode (at $x = x_{f2}$), respectively for the bilateral configuration. Figures 7 and 8 shows that $|A_{33}^2 + B_{33}^2| > |A_{31}^2 + B_{31}^2|$ and $|A_{21}^2 + B_{21}^2| > |A_{23}^2 + B_{23}^2|$ confirming the hypothesis from Eq. (17) that the first harmonic of the second mode and the third harmonic of the third mode are the one that are mainly responding. We also have $|A_{21}^2 + B_{21}^2| \simeq 6 \times |A_{33}^2 + B_{33}^2|$, this confirms the behavior from Fig. 3. Thus, we confirmed that the $1 : 3$ internal resonance is activated but there is no extreme exchange of energy between the modes. This assumption could be verified by trying to see which of the theoretical equations found from the Multiple

Scale method, with one mode excited or two modes in a 1 : 3 internal resonance is the best fit with the experimental results.

4 CONCLUSIONS

Experimental and theoretical results of dynamics and modal interactions of a multi-physics system, an homogeneous beam with piezoelectric materials, are presented. Two configurations are considered: the configuration (1) consists of an homogeneous beam with a single piezoelectric patch, and the configuration (2) has two piezoelectric materials patched symmetrically on the beam.

After separation of spatio-temporal variables of governing system equations, the equations in space provided natural frequencies and mode shapes of the system showing possibilities of 1 : 2 and 1 : 3 internal resonances, corresponding to $\omega_4 \simeq 2\omega_3$ and $\omega_3 \simeq 3\omega_2$ for both configurations ((1) and (2)) as investigated in experimental tests. As for the modal deformations, experimental results confirmed that the presence of the piezoelectric materials changes the mode shapes, and that the theoretical formulation of the functions expressed by parts for each segment of the beam, coupled to each other via continuity conditions are relevant.

As for the effects of the coefficients of the piezoelectric material, it is shown that non linear coefficients are responsible of the quadratic terms in the unilateral configuration, that decreased for the bilateral configuration, from the theoretical part. Tracing the responses of both configurations excited on one of their mode, a change of curvature in the frequency response curve is observed for the unilateral configuration, due to the quadratic non linear terms confirming their presence for configuration (1) and their almost absence for configuration (2).

Investigating the internal resonance 1 : 3, the bilateral configuration set on its resonance showed that although the lower mode is excited, the higher mode is also responding. Thus, the non linear coupling of those modes exist and is expressed.

To conclude, this paper highlighted that the presence of the piezoelectric materials on the beam play an important role on the creation of internal resonances and energy exchanges between modes. Meanwhile, in our experimental studies, the non linear coefficients of the piezoelectric material weren't sufficient to create visible energy exchanges between the modes. Thus, the experiments will be used to re-scale the theoretical model. Then, the model will be studied to enhance the non linear terms and design the exchange of energy between the modes.

Key words: Vibrations, Smart Structures, Piezoelectrics, Shunt Circuits.

Abstract. Smart structures, in general, have the ability to respond and reduce vibrations which are caused by external forces. The self-monitoring capability of smart structures is due to the properties of the involved materials, such as piezoelectric sensors or actuators. Passive damping of vibrations using shunted piezoelectric elements is quite common for structures such as beams, plates, smart panels, etc. In fact, shunted piezoelectric circuits can consume the kinetic energy of the controlled system by transferring it to a suitably defined electric impedance. The present investigation focuses on the control of the oscillations of a smart composite plate equipped with shunted piezoelectric transducers. Namely, resonant shunt circuits, i.e. circuits with a resistor and an inductor, which can deteriorate the vibrations near the resonant frequencies, are considered. The structural model of the plate is discretized by using the finite element method yielding to a smart laminate composite model with elastic and piezoelectric layers. For a laminate composite plate, a parametric analysis was performed to evaluate optimal locations along the plate plane (xy) that maximize the effective modal electromechanical coupling coefficient. Then, the particle swarm optimization (PSO) method was used to find the optimum values of resistance and inductance of each circuit for a network of optimally located shunted piezoelectric patches bonded to the plate. Numerical examples validate and demonstrate the potential of the proposed approach for the design of piezoelectric shunt devices. A vibration amplitude reduction for the first four vibration modes was observed.

1 INTRODUCTION

As piezoelectric effect is called the phenomenon where electrical voltage is produced under the application of mechanical stress or pressure. Etymologically, the term piezoelectricity is of Greek origin and namely, it is derived from words piezo ($\pi\acute{\epsilon}\zeta\omega$), which means to press, and electron ($\acute{\eta}\lambda\epsilon\kappa\tau\rho\nu$), which stands for amber. This phenomenon was discovered in Paris at August the 2nd 1880 by Pierre and Jaques Curie [1] and it mainly appears on certain crystal-like materials and ceramics, which, in turn, are called piezoelectric and piezoceramic materials respectively. Among others, the Quartz crystal (SiO_2), the Rochelle salt (Potassium Sodium Tartrate), the Ammonium Dihydrogen Phosphate ($\text{NH}_4\text{H}_2\text{PO}_4$), the Lithium Sulphate (Li_2SO_4), the Tourmaline, the Polyvinylidene Difluoride polymer $(\text{CH}_2\text{CF}_2)_n$ and the ceramic Lead Zirconate Titanate (PZT) are known materials which present piezoelectric properties. The piezoelectric effect can be explained by the transfer of free electric charge to the edges of the crystalline grid. The reverse phenomenon also exists, and it is realized with the appearance of deformation of the material when it is subjected to an electric voltage.

Shunt piezoelectric damping is a vibration suppression method, suitable for the control of smart flexible structures. The method is mainly characterized by the connection of an electric impedance (e.g. an electric resistance, an inductance or a capacitance) to a piezoelectric transducer. Thus, the concept behind these systems lies to the construction of an electric network, which can reduce mechanical vibrations on smart structures, such as beams [2,3], plates [4], smart panels [5], etc. An advantage of this method is that it does not need external sensing, and, if designed properly, it can guarantee the stability of the whole system [6].

The simplest shunt circuits -however, of low efficiency- are the so-called resistive shunts, which consist of an electric circuit of one or more resistors in series or in parallel. On the other hand, resonant shunts, i.e. circuits of one or more resistors and inductors in various combinations, are very powerful in terms of vibration suppression near resonant frequencies. These two techniques were introduced by Hagood and Von Flotow, in a pioneering work [7]. Of course, there are several more complicated systems, capable of multi-mode damping. In this case, the shunt circuits consist of combinations of resistors, capacitors and inductors, either in series or in parallel. These systems include, among others, online tuned systems, current block circuits and Holkamp current flow circuits [8]. A detailed literature review on the several types of shunt circuits is available in [9].

The performance of shunt circuits, designed for vibration suppression, is discussed in [10]. Namely, A reduced-order model is considered, and both resistive and resonant shunt circuits were tested. Numerical, along with experimental results, showed that both circuits are efficient, especially for low structural damping cases, which means that, as the damping increases, the performance of such circuits deteriorates. In a recent work which is described in [11], the optimization of the parameters of absorbers, which consist of shunted piezoelectric circuits is presented. A hybrid system, which is based on piezoelectric shunts in combination with conventional tuned-mass dampers is proposed in [12].

In this work the finite element model of laminate composite plates with bonded piezoelectric patches or layers that are connected to passive resonant shunt circuits is presented. The model is based on an equivalent single layer theory combined with FSDT. For a Graphite-Epoxy laminate composite plate, a parametric analysis is performed to evaluate optimal locations along the plate plane (xy) that maximize the effective modal electromechanical coupling coefficient.

Next, the optimum values of resistance and inductance are obtained for maximum reduction of vibration level at the first four target excitation frequencies using particle swarm optimization.

2 THE PLATE MODEL

The host structure consists of a smart composite plate based on the first-order shear deformation theory for laminated composite plates (FSDT), simply known as Mindlin theory. The elastic core of the plate is made of T300/976 graphite-epoxy composite material, which stacking sequence is antisymmetric angle-ply $([-45^\circ/45^\circ/-45^\circ/45^\circ])$ as seen in Figure 1. The structure is discretized by using the finite element method. The plate is of square shape and the length of each side is 0.2 m. The model is also equipped with piezoelectric elements, which are made by PZT G1195N material and they can be placed on one or more finite elements at a time.

Figure 1: The plate model

The detailed material properties are given in Table 1. More information about this model can be found in [13,14].

Table 1: Material properties

Property	T300/976	PZT
Young's moduli (GPa)		
E_1	150	63
$E_2 = E_3$	9.0	63
Shear moduli (GPa):		
$G_{12} = G_{13}$	7.1	24.2
G_{23}	2.5	24.2
Poisson's ratio: $\nu_{12} = \nu_{13} = \nu_{23}$	0.3	0.3
Density: ρ (kg/m ³)	1600	7600
Piezoelectric constants (m/V): $d_{13} = d_{32}$	-	$254 \cdot 10^{-12}$
Electrical permittivity (F/m):		
$\xi_{11} = \xi_{22}$	-	$15.3 \cdot 10^{-9}$
ξ_{33}	-	$15.0 \cdot 10^{-9}$
Ply thickness (mm)	0.25	0.1

By using a set of practical assumptions (see ref. [3]) we can obtain an original variation formulation and then an efficient finite element formulation of the electromechanical problem:

$$\begin{bmatrix} M & 0 \\ 0 & 0 \end{bmatrix} \begin{Bmatrix} \dot{w} \\ \ddot{\phi} \end{Bmatrix} + \begin{bmatrix} K_{uu} & K_{u\phi} \\ -K_{u\phi}^T & K_{\phi\phi} \end{bmatrix} \begin{Bmatrix} w \\ \phi \end{Bmatrix} = \begin{Bmatrix} F_m \\ q \end{Bmatrix} \quad (1)$$

where $\{w\}$ is the column vector of nodal values of mechanical displacement of length N (N is the number of mechanical degrees of freedom); $[M]$ and $[K_{uu}]$ are the global mass and mechanical stiffness of the system of size $N \times N$ and $\{F_m\}$ is the column vector of mechanical force of length N . Moreover, $\{q\} = [q^{(1)}, q^{(2)}, \dots, q^{(P)}]^T$ and $\{\phi\} = [\phi^{(1)}, \phi^{(2)}, \dots, \phi^{(P)}]^T$ are the column vectors of electric charges (contained in the upper electrode) and potential differences in each patch; $[K_{u\phi}]$ is the electromechanical coupling matrix of size $N \times P$; and $[K_{\phi\phi}] = \text{diag}(C^{(1)}, C^{(2)}, \dots, C^{(P)})$ is a diagonal matrix filled with the P capacitances of the piezoelectric patches where $C^{(p)} = \xi_{33} S^{(p)} / h^{(p)}$, ξ_{33} being the piezoelectric permittivity in the direction normal to the electrodes and $S^{(p)}$ the area of the patch electrodes surfaces.

The above discretized formulation (1) can be used to the case where the piezoelectric patches are ‘shunted’, that is to stay connected to a passive electrical network. In this case, neither $\{\phi\}$ nor $\{q\}$ is prescribed by the electrical network but the latter imposes only a relation between them [7], where for the case of a resonant shunt composed of a resistor R and an inductor L in series, connected to the p th patch, can be written as

$$\phi^{(p)} - L\ddot{q}^{(p)} - R\dot{q}^{(p)} = 0 \quad (2)$$

Combining equations (1) and (2) and considering a mechanical viscous damping in the system, we finally obtain the general FE formulation of the electromechanical spectral problem when the piezoelectric patches are shunted

$$\begin{bmatrix} M & 0 \\ 0 & L_e \end{bmatrix} \begin{Bmatrix} \ddot{w} \\ \ddot{q} \end{Bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & R_e \end{bmatrix} \begin{Bmatrix} \dot{w} \\ \dot{q} \end{Bmatrix} + \begin{bmatrix} K_{uu} + K_{u\phi} K_{\phi\phi}^{-1} K_{\phi u} & K_{u\phi} K_{\phi\phi}^{-1} \\ K_{\phi\phi}^{-1} K_{\phi u} & K_{\phi\phi}^{-1} \end{bmatrix} \begin{Bmatrix} w \\ q \end{Bmatrix} = \begin{Bmatrix} F_m \\ 0 \end{Bmatrix} \quad (3)$$

where $[R_e]$ and $[L_e]$ are the diagonal matrices filled with the electrical resistances R and the electrical inductances L of the shunt circuits.

There exist two possible configurations for the piezoelectric patches, namely the short-circuit ($\{\phi\} = \{0\}$) and open-circuit ($\{q\} = \{0\}$) configurations. The electromechanical coupling coefficient (EMCC) of the piezoelectric patches is defined as:

$$K_j^2 = \frac{f_{oc}^{j^2} - f_{sc}^{j^2}}{f_{oc}^{j^2}} \quad (4)$$

where f_{oc}^j and f_{sc}^j is j -th eigen-frequency of the plate in open- and short-circuit respectively. The EMCC is used here as a metric to perform the positioning of four symmetric pairs of

patches throughout the plate, via parametric analysis, such that each patch maximizes the EMCC of one of the first four vibration modes of the laminate plate.

3 PARTICLE SWARM OPTIMIZATION

For the optimization of the parameters of the resonant shunt circuit, i.e. for the values of the resistance R and the inductance L , the particle swarm optimization (PSO) method was considered. More specifically, this nature-inspired algorithm imitates the movement of particles, i.e. birds or fish, towards the search of food, i.e. the optimal solution. PSO is a very powerful optimization method and it has been used in vibration suppression of smart structures [15]. The optimum is reached through an iterative process, until a criterion of performance is met. Several variations of the classical PSO method have been proposed. One of the most efficient is called inertia PSO and it was introduced by Shi and Eberhart in [16]. The main feature of this method is that it includes an inertial weight, influencing this way the convergence of the algorithm.

Inertia particle swarm optimization algorithm can be modeled considering the position and the velocity of the particles. The position is given by:

$$x_{ij}(t+1) = x_{ij}(t) + u_{ij}(t+1) \quad (5)$$

The velocity of the particles, in the case of inertia PSO is given by:

$$u_{ij}(t+1) = w u_{ij}(t) + c_1 r_1 (p_{best\ ij} - x_{ij}(t)) + c_2 r_2 (g_{best\ j} - x_{ij}(t)) \quad (6)$$

where r_1 and r_2 are random values in the interval $[0, 1]$ and c_1 and c_2 are the so-called cognitive and social parameters respectively. The values of these parameters can be calculated through modal analysis. The inertia w reads:

$$w = w_{max} - \frac{w_{max} - w_{min}}{max_iteration} t \quad (7)$$

where typical values of w_{max} and w_{min} are 0.99 and 0.01 respectively.

The personal best of each particle and the global best of the whole swarm are also kept:

$$p_{best\ ij} = \begin{cases} x_{ij}(t+1), & \text{if } f(x_{ij}(t+1)) < f(x_{ij}(t)) \\ p_{best\ ij}, & \text{elsewhere} \end{cases} \quad (8)$$

$$g_{best\ j} = \min\{f(p_{best\ 1j}), f(p_{best\ 2j}), \dots, f(p_{best\ nj})\}$$

where with n is denoted the total number of the iterations of the algorithm.

4 NUMERICAL RESULTS

As mention above, the optimal position of the piezoelectric patches is found taking into account the value of the EMCC [4]. Namely, a parametric investigation is carried out in order to find the positions where the coupling coefficient is maximized for each eigen-frequency. The optimal positions for the piezoelectric patches and the system response for the first four eigen-frequencies are given schematically in Figure 2 and 3 respectively.

The parameters of a resonant shunt circuit, i.e. the values of resistance R and inductance L are optimized using the inertia variation of the particle swarm optimization algorithm. The objective is the maximization of the attenuation, due to the electric circuit. The results for the optimal R, L values, along with the best position for the PZT patches is given in Table 2.

Mesh Discretization

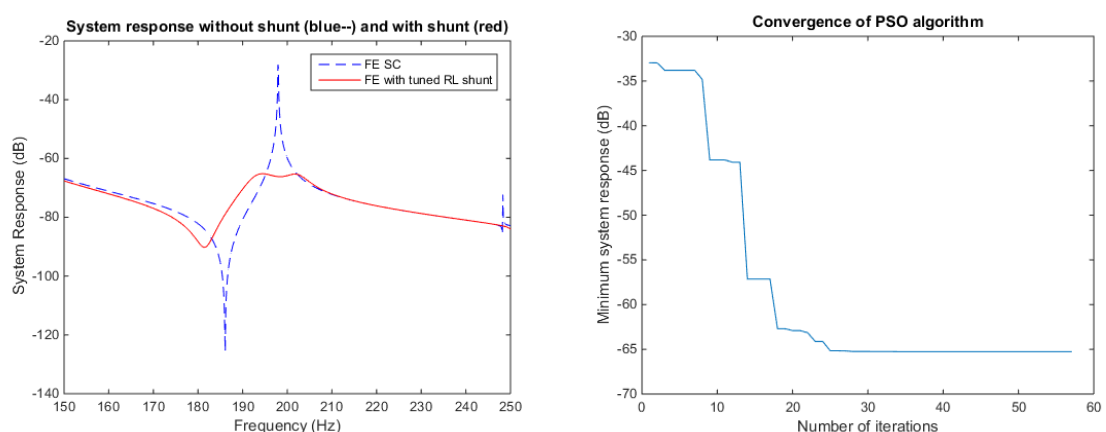

Figure 6: (a) Response of the system for the third eigen-frequency and (b) convergence of PSO algorithm

Figure 7: (a) Response of the system for the fourth eigen-frequency and (b) convergence of PSO algorithm

5 CONCLUSIONS

Resonant shunt circuits are proved to be very efficient in vibrational control of smart composite plates with piezoelectric elements. However, the calculation and fine-tuning of the values of the electrical parameters, i.e. the resistance and the inductance, is not always an easy task to perform.

From the numerical results of the present investigation, it is clearly shown that the inertia particle swarm optimization method is very powerful in terms of estimating the optimal values of the electric parameters of the resonant shunt circuit. More specifically, the occurrence of a second peak near each eigenfrequency, due to the presence of an extra electrical equation, along with the maximization of the attenuation, validate the feasibility and the effectiveness of the method. In most cases, the inertia PSO algorithm converged quite fast, i.e. before 20 iterations, except of the fourth case, where nearly 40 generations were required. It is possible to achieve faster convergence with modification of optimization parameters or by using other variations of the PSO algorithm. The selection of the positions of the PZT patches was also efficient, however, it could be further optimized in future investigations, by its inclusion as an extra design variable in the optimization scheme.

Abstract. The objective of this work is to investigate the interest of analogous piezoelectric networks for vibration mitigation of multiple nonlinear resonances. An electrical network providing a similar dynamics as the considered structure is first designed according to linear considerations. Then, a nonlinear electrical component is added to the network to ensure both a spatial analogy and a principle of similarity regarding the mathematical form of the mechanical nonlinearity. Once the electrical network and the mechanical structure are coupled through an array of piezoelectric elements, it is shown that such an analogous coupling offers strong benefits for vibration mitigation over a broad frequency range and a broad range of excitation amplitudes.

1 INTRODUCTION

Tuned vibration absorbers [1, 2] usually provide effective solutions for passive vibration mitigation. However, mechanical nonlinearities generate a detuning that seriously affects damping performance. A solution to this issue consists in the introduction of an additional nonlinearity in the absorber [3]. The interest of nonlinear piezoelectric shunts has already been proven for vibration mitigation of single nonlinear resonances [4, 5]. The concept was then extended to the design of a nonlinear and multi-branch piezoelectric shunt [6]. The present work addresses the development of a multimodal and fully passive piezoelectric analogous network that mitigates several resonances of a nonlinear structure.

An electrical network can be assembled to reproduce the dynamics of a cantilever beam in the linear regime of motion. In this case, several electrical resonances are simultaneously tuned to the mechanical resonances, thus providing the equivalent of a multimodal vibration absorber from electromechanical coupling through an array of piezoelectric patches [7, 8]. This allows broadband vibration mitigation at low forcing amplitudes. Yet, higher amplitudes still lead to a serious detuning of the absorber when considering nonlinear structures.

By extending a principle of similarity to spatial considerations, a nonlinear component is placed in the electrical network in order to mimic the dynamics of the mechanical structure. The electromechanical

analogy is thus ensured beyond the linear regime. In this work, the use of a nonlinear capacitor generates an autonomous adjustment of the electrical resonances for a wide range of excitation amplitudes. The interest of this method is investigated numerically and experimentally by focusing on structural vibrations over a broad frequency range that covers the first three modes of a beam with localized cubic nonlinearity.

2 SINGLE MODE DAMPING WITH A PIEZOELECTRIC TUNED VIBRATION ABSORBER

2.1 For linear and nonlinear resonances

The resonant piezoelectric shunt, also called piezoelectric tuned vibration absorber, is commonly used to reduce the vibration amplitude of a single linear resonance. It is made of a piezoelectric transducer of capacitance C at zero strain connected to an inductor and a resistor whose values are typically obtained from

$$L = \frac{1}{C\omega_0^2} \quad \text{and} \quad R = \sqrt{\frac{3}{2}} \frac{k_c}{C\omega_0}, \quad \text{where} \quad k_c = \sqrt{\frac{\omega_0^2 - \omega_s^2}{\omega_s^2}}. \quad (1)$$

The angular frequencies ω_s and ω_0 corresponds to the resonances in short- and open-circuit, respectively. This formulation highlights a coupling factor k_c , which is usually considered for the positioning of the piezoelectric elements. Indeed, since k_c is directly related to damping performance [9], maximizing the coupling factor implies minimizing vibration amplitude for an adequate tuning of the electrical circuit. As seen in Eq. (1), part of the tuning procedure is to ensure that the electrical resonance at angular frequency $1/\sqrt{LC}$ matches the open-circuit natural frequency. As a consequence, it is clear that a mechanical nonlinearity altering the angular frequency ω_0 would deteriorate the tuning of the piezoelectric shunt and thus the damping performance.

A solution to overcome the influence of mechanical nonlinearities on piezoelectric tuned vibration absorbers is to introduce nonlinearities in the electric shunt itself. Following a principle of similarity, the added nonlinearity should possess the same mathematical form as the one in the mechanical system. For example, if a nonlinear force is modeled by a cubic function of the displacement u ,

$$f_{NL} = K_{NL}u^3, \quad (2)$$

it has been shown that the required additional voltage in the shunt is also a cubic function of the electric charge q [4, 5]:

$$v_{NL} = \frac{1}{C_{NL}}q^3 \quad \text{with} \quad \frac{1}{C_{NL}} = 2 \left(\frac{L}{m} \right)^2 K_{NL}, \quad (3)$$

where m corresponds to the modal mass of the mechanical structure. This theoretical nonlinear capacitance in series with the inductor would ensure an adequate tuning of the resonant shunt by maintaining an equal-peak condition over a broader range of excitation amplitudes [4]. While the nonlinear voltage in Eq. (3) could be synthesized with a numerical controller, find a passive electrical component able to satisfy this purely nonlinear condition is not obvious [10]. In order to circumvent this limitation, it has been proposed to rather introduce the nonlinearity in the inductor [5]. Indeed, a one-term harmonic balance approximation shows that Eq. (3) is close to

$$v_{NL} = L(1 - \alpha \dot{q}^2) \ddot{q} \quad \text{with} \quad \alpha = 6 \frac{LK^{NL}}{m^2\omega_0^4}. \quad (4)$$

While no passive inductors seems to be able to precisely satisfy this nonlinear relation, the next experimental section still shows that it is possible to benefit from saturation of magnetic circuits to approximate the required nonlinearity.

Figure 1: Beam covered with an array of piezoelectric patches; half of the patches are connected to a single resonant shunt for vibration damping of the first mode [5].

(a)

(b)

Figure 2: Piezoelectric tuned vibration absorber – (a) physical inductor, (a) experimental frequency response function around the first mechanical resonance, with short circuit (\cdots), with open circuit (\cdots) or with an optimal linear shunt (—).

2.2 Experimental validation of the principle of similarity

The experimental setup is based on a cantilever beam involving a cubic nonlinearity. As shown in Fig. 1, a thin lamina is clamped at the left end of the beam, which generates the hardening nonlinearity. The structure is covered with an array of piezoelectric patches in order to mitigate vibration with a piezoelectric tuned vibration absorber. The passive inductor in Fig. 2(a) is realized by winding copper wire around a magnetic circuit in ferrite material. When connected to the piezoelectric patches, Fig. 2(b) demonstrates that the passive inductor allows a strong reduction of the vibration amplitude at low excitation levels. However, Fig. 3(a) shows that an increasing forcing amplitude leads to a complete detuning of the resonant shunt because of the mechanical nonlinearity.

As mentioned previously, a solution to overcome this effect is to introduce in the absorber a nonlinearity similar to that of the primary structure. Here, the electrical circuit is made of an inductor whose inductance value depends on the current flowing through it. An approximation of the nonlinear relation in Eq. (4) is obtained by choosing a magnetic circuit that provides an adequate magnetic saturation.

Figure 3: Experimental frequency response functions for various forcing amplitudes, $F = 0.2$ N (—), $F = 0.4$ N (— · —), $F = 0.6$ N (— · · —) and $F = 0.8$ N (···) – (a) linear shunt, (b) nonlinear piezoelectric tuned vibration absorber [5].

Restraining the analysis to the first harmonic, a decrease of the equivalent inductance value leads to an increasing electrical resonance frequency that follows the increase of the mechanical natural frequency due to the cubic stiffness. As shown in Fig. 3(b) this solution is able to maintain vibration mitigation performance compared to a case involving a linear shunt.

3 MULTIMODAL DAMPING WITH AN ANALOGOUS PIEZOELECTRIC NETWORK

3.1 Broadband damping in the linear regime

The extension of resonant piezoelectric shunts to multimodal structures consists in designing a multi-resonant circuit whose electrical natural frequencies are sufficiently close to the mechanical resonances to be controlled. With a single piezoelectric transducer, the most direct approach is the so-called multi-branch shunt [11, 12] made of inductors and capacitors organized with just as many branches as the target mechanical resonances. The main limitation is that this solution does not optimize the coupling factor k_c for all the considered modes. The first reason concerns the addition of external capacitors in the shunt which decreases electromechanical coupling [13]. The second reason is related to the positioning of the single piezoelectric patch that is generally not optimal for different mode shapes.

Another solution for multimodal damping is based on analogous piezoelectric coupling. This requires several piezoelectric transducers that are interconnected with electrical components so as to build a multi-resonant network with modal properties similar to that of the considered structure. The analogy is no more restrained to the natural frequencies as with the multi-branch shunts because similar mode shapes are also ensured. The design of the electrical analogue of a beam has been fully described in Ref. [8]. The first step consists in discretizing the bending wave differential equation from a finite difference approximation. Then, a direct electromechanical analogy is applied to find the unit cell of the electrical network. The complete network is built by reproducing this unit cell along one direction, taking into account that the number of unit cells per wavelength has to be sufficiently large to approximate the continuous mechanical medium. For the case of a beam, the electrical unit cell is made of an inductance L^* representing the analogue of a point mass, a capacitance C^* that represents the inverse of a bending

Figure 4: Electrical analogue of a cantilever beam.

Figure 5: Beam coupled to its electrical analogue through an array of piezoelectric patches.

stiffness and a transformer of ratio \hat{a} that is analogous to a mechanical lever of length a .

A beam electrical analogue involving 10 unit cells is represented in Fig. 4. In order to approximate the mode shapes of a cantilever beam, we need to ensure analogous boundary conditions. This is realized by short-circuiting one end of the network (equivalent to zero force and moment), while leaving open the other end (equivalent to zero displacement and angle). Another critical condition is the tuning of the dispersion relation in the electrical waveguide. From the discrete model, it can be shown that the electrical parameters need to satisfy

$$\frac{1}{\hat{a}^2} \frac{1}{L^* C^*} = \frac{1}{a^2} \frac{K_\theta^*}{m^*}, \quad (5)$$

where K_θ^* is the bending stiffness of the mechanical unit cell, m^* is its mass and a its length [8].

Considering the practical example described in the last section, one wants to couple a clamped beam to its analogous electrical network with an array of piezoelectric patches. Thanks to the inherent capacitance C^* of the piezoelectric patches, there is no need for external capacitors for the analogue of the bending stiffness. Only transformers and inductors satisfying Eq. (5) are required for the analogue of a clamped beam. In the present case, however, one has to take into account the clamping through the thin lamina. In the linear regime, the lamina can be modeled by a linear spring of stiffness K^{end} . So, its analogue is a capacitor to be placed at the end of the electrical network, as shown in Fig. 5. Considering the nondimensionalized equations in the two domains when no coupling occurs, one can find a relation between the end capacitance and its analogous linear stiffness:

$$C^{\text{end}} = \frac{K_\theta^*}{K^{\text{end}}} \frac{\hat{a}^2}{a^2} C^*. \quad (6)$$

A last step consists in introducing appropriate damping in the electrical network. Coming back to Eq. (1), remark that the optimal electrical quality factor at ω_0 is $Q = L\omega_0/R = \sqrt{2/3}/k_c$. A similar damping ratio can be obtained with a resistance R_{L^*} in series with the inductance L^* or a resistance R_{C^*} in series with the capacitance C^* when

$$R_{L^*} = \sqrt{\frac{3}{2}} k_c \omega_0 L^* \quad \text{or} \quad R_{C^*} = \sqrt{\frac{3}{2}} \frac{k_c}{\omega_0 C^*}. \quad (7)$$

The dependence on ω_0 in those equations shows that using a resistance R_{L^*} that is optimal for the first mode of the structure would be too low for the next modes leading to an underdamped case. On the other hand an optimal resistance R_{C^*} for the first mode would lead to overdamped highest modes. In the present

Figure 6: Simulated frequency response function of the beam with short-circuited patches (\cdots) and with the analogous electrical network ($—$).

case focusing on the first three modes of the beam which are fully separated, it is decided to benefit from both damping configurations by tuning R_{L^*} for the first mode and R_{C^*} for the third mode. This requires the computation of individual coupling factors for each modes by comparing natural frequencies when $L^* = 0$ and when this inductance tends to infinity. In the end, both resistances are reduced by 10% to be closer to the optimal damping because R_{C^*} still has a slight influence on the damping of the first mode. The resulting linear frequency response functions of the beam are represented in Fig. 6 with and without coupling. One can see the simultaneous vibration mitigation of the first three modes of the beam through the equivalent of a multimodal tuned mass damper. Note that damping of the second mode is not optimized (underdamped) because the considered tuning of two electrical quality factors on L^* and C^* only allows optimal damping at two specific frequencies around the first and third modes. A last remark concerns the third mode which does not ensure an equal peak condition. This is directly due to the fact that the discrete network only involve 10 unit cells inducing a slight mismatch between the mechanical and electrical resonances.

3.2 Damping of multiple nonlinear resonances

Although analogous piezoelectric coupling provides broadband damping in the linear regime, higher vibration amplitudes still lead to the undesired behavior illustrated in Fig. 3(a) if only linear electrical components are considered. The next objective is thus to find the adequate nonlinearity to be introduced in the electrical network. Here, contrary to the previous experimental validation involving a nonlinear inductor [5], a nonlinear capacitor is incorporated at the end of the electrical network to ensure a strict analogy with the nonlinear stiffness at the end of the beam. This actually combines the principle of similarity used for nonlinear control [3] and the spatial analogy used for multimodal damping [8].

Still, it remains the question of the numerical value for the nonlinear capacitance. Focusing on Eq. (3), it can be remarked that the nonlinear capacitance depends on the ratio of the inductance L over the modal mass m , which can be seen as a mass ratio between the absorber and the main structure. Using a single mode piezoelectric shunt $L/m = 1/CK$ where K is the open-circuited modal stiffness, which depends on the considered mode. However, considering two modal systems with similar mode shapes, all modal mass ratio L/m becomes equal to the same local mass ratio L^*/m^* , which does not depend on the mode of interest anymore. This is a critical point because Eq. (3) then leads to a tuning of the capacitance nonlinearity at the end of the network that does not depend on frequency:

$$\frac{1}{C_{NL}} = 2 \left(\frac{L^*}{m^*} \right)^2 K_{NL}. \quad (8)$$

Figure 7: Simulated frequency response function of the nonlinear beam for $F = 0.8$ N without nonlinear capacitance (\cdots) and with nonlinear capacitance ($—$).

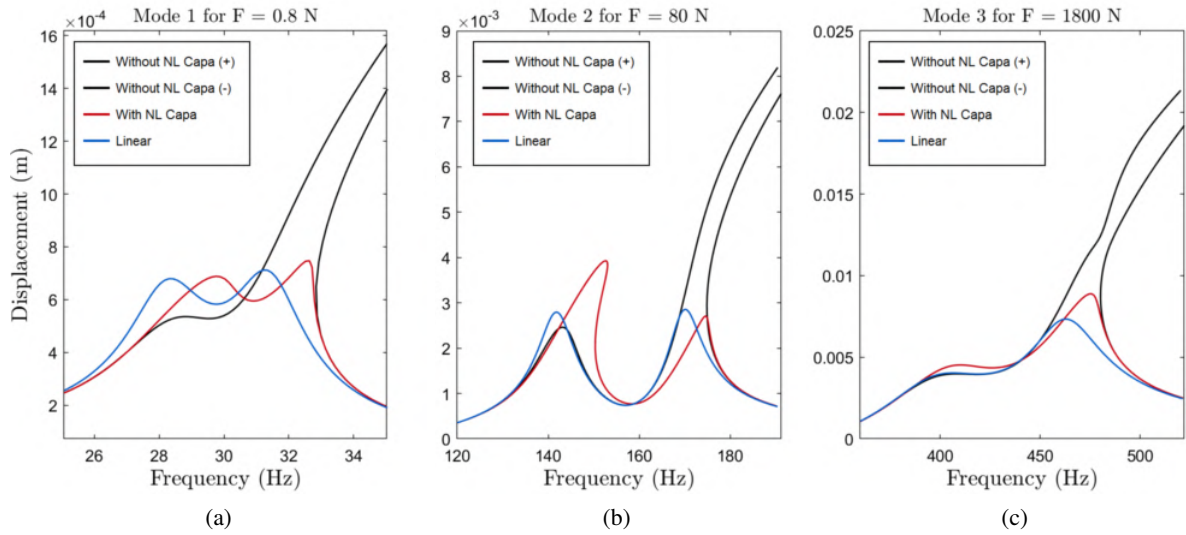

Figure 8: Simulated frequency responses for the first three modes – (a) mode 1 for $F = 0.8$ N, (b) mode 2 for $F = 80$ N, (c) mode 3 for $F = 1800$ N.

With the proposed nonlinear capacitor, the analogy is not only valid in the linear regime but also in the nonlinear regime. Damping performance is thus maintained over an extended range of forcing amplitudes. This is first observed in Fig. 7 which compares frequency responses with and without nonlinear capacitance. The results are obtained from a harmonic balance with three harmonics and a forcing amplitude equal to 0.8 N. This level of excitation does not induce a significant nonlinearity for the second and third modes but the first mode is seriously affected. In Fig. 8, the excitation amplitude is set independently for all three modes so as to provoke the merging of the right local maximum with a detached resonance curve when no nonlinearity is introduced in the electrical network. The addition of the nonlinear capacitance in Eq. (8) significantly reduces the vibration amplitude of all the considered modes. While we are close to an equal peak condition for mode 1, the responses for modes 2 and 3 are further from the linear case. Those differences are definitely due to the lack of damping for mode 2 and to the imprecise linear tuning for mode 3.

Figure 9: Electrical analogue of the cantilever beam with passive inductors, transformers and capacitors.

Figure 10: Experimental (—) and simulated (---) frequency response functions of the electrical network.

3.3 Development of the multi-resonant network

Starting with the linear case, assembling the previously described electrical network requires 9 inductors, 10 transformers and one capacitor as shown in Fig. 5. The magnetic components are specifically designed for this application. In order to first validate the electrical dynamics alone, the piezoelectric patches are replaced by ceramic capacitors. Then, an impedance meter is placed at the end of the network in order to measure the frequency response function of the current over the voltage that actually corresponds to the end admittance of the circuit.

Figure 10 shows the good agreement between the experimental results and the numerical simulations computed from the discrete set of equations that describe the electrical circuit. Note that the resistance of copper wire in the inductors and transformers has been added to the model because of its strong influence on the electrical quality factor. Even so, one can easily detect the three resonances corresponding to the first three modes of the electrical network. The distributions of the electrical current are then plotted at frequencies corresponding to those three maxima of admittance. As represented in Fig. 11, the electrical distributions are similar to mode shapes of a clamped beam which definitely validate the topology of the analogous network.

While those results validate the analogue of a beam that is clamped at one end, one has to remember that we also need to take into account the weak clamping through the thin lamina at the other end. As it can be modeled by a capacitor in the electrical domain, the influence of such a passive component at

Figure 11: Experimental distributions of the electrical current – (a) mode 1 , (b) mode 2, (c) mode 3.

Figure 12: Choice of the capacitor at the end of the electrical network – (a) experimental frequency response function of the electrical network for various end-capacitors: 166 μF ($-\cdot-$), 266 μF ($—$) and infinite capacitance (\cdots), (b) objective for the nonlinear capacitor (\cdots) and measurement on a physical capacitor ($—$).

the end of the electrical network is investigated. The experimental admittance around the first resonance is plotted in Fig. 12(a) for various end capacitors. We note that a capacitance equal to 266 μF places the electrical resonance around the first natural frequency of the beam, which is consistent with Eq. (6).

While the considered end capacitor ensures modal coupling at low excitation level, it should also offer a nonlinear contribution in order to ensure a similarity with the nonlinear lamina. This contribution has to satisfy Eq. (3) whose first-harmonic approximation is $V_{\text{NL}} = \frac{3}{4C_{\text{NL}}}Q^3$, where V_{NL} is the amplitude of the nonlinear voltage contribution and Q is the amplitude of the electric charge. Supposing that the component that provides this nonlinear voltage is in series with a linear capacitor C^{end} , the equivalent variable capacitance is defined as

$$C_{\text{NL}}^{\text{end}}(Q) = \frac{1}{\frac{1}{C^{\text{end}}} + \frac{3Q^2}{4C_{\text{NL}}}}. \quad (9)$$

The variation of this capacitance as a function of the electrical charge is plotted in Fig. 12(b). This

Figure 13: Experimental setup involving the beam coupled to its analogous electrical network.

Figure 14: Frequency response functions at low excitation levels with short-circuited patches (\cdots) and with coupling to the analogous electrical network: model ($---$), experiment ($—$).

provides the objective function when looking for an appropriate nonlinear capacitor. Some multilayered ceramic capacitors offer saturation at relatively low voltage levels leading to a decrease of the equivalent capacitance. Unfortunately, up to now, no passive component has been found to correctly approximate the prescribed nonlinear function. Investigations are in progress to define if a non-passive numerical impedance is required or if a fully passive component can still be found.

3.4 First experimental results on multimodal damping of the nonlinear beam

The electrical network in Fig. 9 is coupled with the nonlinear beam through the array of piezoelectric patches. The full setup is seen in Fig. 13 that also shows the electromechanical shaker and the impedance head used for drive-point measurement at the end of the beam. The experimental and numerical frequency response functions appear in Fig. 14. First, the experimental response with short-circuited patches clearly shows the first and second modes of the beam but the third mode comes after two unpredicted resonances. Those extra resonances are finally related to the mounting system and this point will be corrected in the next version of the setup. In any case, multimodal damping is clear for the first three modes of the beam, which also validates the numerical model.

Concerning the tuning of the electrical network, note that it is slightly underdamped for modes 2 and 3 but it is overdamped for the first mode. This excessive damping is clearly observed on the first response in Fig. 15 that does not offer the local minimum normally observed with optimized tuned vibration absorbers. This shows a limit of the present analogous network whose copper losses in the magnetic components are not optimal for a broad frequency range. A new design of the electrical circuit will

Figure 15: Experimental frequency response functions around the first mode for various forcing amplitudes, $F = 0.05$ N (—), $F = 0.1$ N (---), $F = 0.2$ N (- · -) and $F = 0.4$ N (···).

address this issue by providing optimal damping for the first mode and external resistors will be used to slightly lower the electrical quality factor at higher frequencies.

Another limitation of the present network is the lack of an adequate nonlinear capacitor. Consequently, the effect of the mechanical nonlinearity on the tuning of the piezoelectric vibration absorber is observed in Fig. 15. Increasing the forcing amplitude moves the mechanical resonance to higher frequency without similar adjustment of the corresponding electrical resonance. This results in an increase of the vibration amplitude similar to what has been observed in Fig. 3(a) for single mode control with optimized damping. The next step thus consists in finding an adequate nonlinear capacitor and place it in an optimally damped electrical network so as to retrieve similar results as in Fig. 3(b).

4 CONCLUSIONS

This work aims to show that the principle of nonlinear similarity can be extended to multimodal damping with piezoelectric networks. To this end, an analogous electrical circuit is proposed in order to reproduce the dynamics of the considered structure. A multimodal coupling offers vibration mitigation over a wide frequency range. For higher forcing amplitudes, however, a mechanical nonlinearity leads to a serious increase of the vibration amplitude. A nonlinear capacitor is thus placed in the electrical network at an analogous position. Numerical results show that using an electrical nonlinearity similar to the mechanical one can lead to a substantial gain in terms of damping performance around several modes of the mechanical structure. This definitely proves that broadband damping of a nonlinear structure can be achieved with a fully passive vibration absorber. Experiments will be conducted to obtain further results with an improved analogous electrical network.

Abstract. Sandwich panels exhibit outstanding mechanical performances due to their high bending-stiffness-to-weight ratio. However, a high specific rigidity has usually negative impact on vibroacoustic performances. In the current industrial scenario, acoustic comfort is a fundamental quality criterion and it is vital to start to include vibroacoustic design rules at early stages of products development. The aim of this work is the design of a sandwich panel with enhanced vibroacoustic performances in the low-to-mid frequency range. Novel materials and manufacturing techniques are adopted to develop the sandwich panel: flax fibers in poly furfuryl alcohol for the square-cell core and the skins; carbon-nanotube reinforced resin as viscoelastic inserts. The results of material characterization tests are presented in this work, as well as the application of a design procedure for the viscoelastic inclusions.

1 INTRODUCTION

Object of this work is the design of a sandwich panel with enhanced vibroacoustics characteristics. More in detail, the main target is to delay the panel's bending-shear transition frequency, ω_T , towards higher values by embedding viscoelastic depositions within the core, with the main limitation of keeping the added mass to low percentages. The bending-shear transition identifies the shift from the low frequencies range, where sandwich panels dynamic behaviour is governed by the whole section bending stiffness, to higher frequencies, where core shear effects become dominant [1]. The latter regime is usually associated with a lower transmission loss, leading to unsuitable acoustic comfort. Shifting ω_T towards higher frequencies mirrors an improvement in the sound transmission loss through the panel in the mid frequencies range [2] and allows an easier control of the acoustic transmission e.g. by adopting porous inclusions. This is why ω_T is becoming a vibroacoustic indicator of great interest [3] [4]. Figure 1 shows typical dispersion curves of sandwich panels, highlighting the above-mentioned transition.

Figure 1: Typical sandwich panels dispersion curve [1]

Novel materials and manufacturing techniques are adopted to develop a multi-scale reinforced sandwich panel: flax fibers in poly furfuryl alcohol (PFA) resin for core walls and skins; carbon-nanotube (CNT) reinforced bio-resin for the viscoelastic depositions. Natural fibers provide lower environmental impact, higher vibration damping and lower density than traditionally used materials, i.e. polymers, aluminium. PFA is an eco-friendly, 100% bio-derived resin. Finally, viscoelastic inserts are deposited at the square-cell core walls junctions by means of a Liquid Resin Printing (LRP) technique. Other than offering core strengthening and vibration damping, their main purpose is increasing the out-of-plane shear stiffness of the sandwich panel, which has a direct impact on ω_t . Figure 2 shows the Finite Element model of a quarter of unit cell with no skins and the resin deposition at the corner [5].

This paper is structured in two main sections: firstly, the results of materials mechanical characterization tests are shown; then, the design procedure of viscoelastic inclusions described in [5] is applied to our case, taking into account the actual measured properties of core, skins and inserts' materials.

2 MATERIALS MECHANICAL CHARACTERIZATION

2.1 Core and skins: Biotex Flax

As introduced in the previous paragraph, the material chosen for the core walls and skins of the sandwich panels consists of natural fibers in a bio-derived epoxy resin. More in detail, the composite is a prepreg provided by Composites Evolution Ltd, Biotex Flax 400 g/m² 2x2 twill pre-impregnated in PFA resin. Flax fibers provide good performance, together with a combination of sustainability and processability. Moreover, they offer reduced weight, lower environmental impact, higher vibration damping and safer handling compared to traditionally used fibers, such as glass. On the other hand, PFA is a thermosetting bioresin derived from crop waste. It resembles phenolic resins, but with lower volatile organic compounds (VOC) emissions. Indeed, PFA presents fire retardant properties equivalent to phenolics, other than very good temperature and chemical resistance.

Laminates consisting of four layers of prepreg were cured in autoclave at a temperature of 140°

Figure 2: FE model of one-quarter unit cell in case of hyperbolic insert profile [5] - ANSYS® Mechanical APDL

degrees and a pressure of 100 psi. Two fibers orientations were considered: one with the twill at 0/90 degrees, the other at 45 degrees. Tensile tests specimens were cut from the final 2.2-mm-thick laminates according to the ASTM D3039 standards. Tensile tests were performed by means of a Shimadzu testing machine with 10 kN load cell. Emery cloth was used for the gripping of the samples, once checked that it was a valid and more practical substitute to end tabs. Finally, a video gauge was adopted for the measurements of longitudinal and transverse strains.

Data were post-processed in Matlab. Linear regression curves were calculated from the video gauge data in the material's elastic range and were used to evaluate the Poisson's ratio. The in-plane shear modulus was found by post-processing the data of tensile tests on specimens with fibers orientation at 45 degrees (ASTM D3518). All data underwent the Chauvenet criterion, in order to define the outliers to be discarded in the evaluation of the batches' statistic properties.

Figures 3 and 4 show the curves of tensile tests on the 0/90 degree and 45 degree fiber orientation samples.

Table 2.1 reports a summary of the Biotex Flax average in-plane mechanical properties, together with the statistic characteristics of data.

Table 1: Summary of in-plane elastic properties of autoclave-cured Biotex Flax laminates

	Mean Value	Standard deviation	Coefficient of variation
Elastic Modulus 0/90 deg	4.03 GPa	0.121 GPa	3.01%
Poisson's ratio	0.336	0.114	33.9%
Shear Modulus	0.957 GPa	0.0656 GPa	6.86%
Elastic Modulus 45 deg	2.93 GPa	0.100 GPa	3.42%

2.2 Viscoelastic inserts: CNT-reinforced resin

As mentioned in the first paragraph, viscoelastic inclusions will be injected at the junction corners of the sandwich core's walls. Their main purpose is increasing the bending-shear transition frequency, by increasing the shear stiffness of the core itself. However, they also contribute to strengthen the panel and

Figure 3: Tensile tests on flax fibers and PFA resin composite. Twill fabric, fibers orientation 0/90 degrees.

Figure 4: Tensile tests on flax fibers and PFA resin composite. Twill fabric, fibers orientation 45 degrees.

to the vibration damping and energy absorption.

The resin adopted for the inserts is SuperSap (SS) CLV, a special formulation of the highly regarded SuperSap resin system from Entropy Resins. SS CLV is a bio-derived epoxy resin, combining good mechanical properties with high levels of UV stability, clarity and a low viscosity. The low viscosity made it ideal for our purposes. Indeed, the inserts will be injected at the corners by means of a specifically designed injection mould applied to a medical syringe, and the narrow channels through which the resin flows made low viscosity a requirement. On the other hand, as the resin itself is reinforced with Carbon Nanotubes, it is also enough viscous so that once applied to the corners it does not flow too much under the effect of gravity. The resin was mixed to EPOCYL 128-06, a multi-walled-carbon-nanotube (MWCNT) Bis-A epoxy resin concentrate for high mechanical performances provided by Nanocyl SA, by means of a high shear rotor/stator laboratory mixer at 50 rpm. The heat generated in the stirring process helped to obtain a more homogeneous resin. The CNT weight percentage in the final resin is 0.477 wt%.

Specimens of the CNT-reinforced resin for tensile characterization were cured in a silicone mould for dumbbell-shaped specimens according to ASTM D638-14. Once again, tensile tests were performed

Figure 5: Tensile tests on CLV SS resin reinforced with MWNTs.

using a Shimadzu testing machine with 10 kN load cell and all data underwent the Chauvenet criterion, in order to define the outliers. The results of the tensile tests show a Young Modulus of 1.99 GPa, with a good statistic relevance (0.0655 GPa standard deviation and 3.29% coefficient of variation) - Figure 5.

The same tests were performed on pristine resin samples and in this case the results show a Young Modulus of 1.82 GPa.

In Figure 6, the experimental results are compared to the analytic prediction according to Halpin-Tsai formulation [6] with Thostenson correction [7]. For the resin of interest (Young Modulus of pristine resin of 1.82 GPa and 0.477 wt% - 0.0027 Volume fraction) the formulation predicts a Young Modulus of the resulting composite resin of 1.92 GPa, showing in fact a small error with respect to the measured value.

3 SANDWICH PANEL DESIGN PROCEDURE

The design steps of the viscoelastic inclusions follow the procedure developed in [5]. However, while in [5] the materials properties were assigned from literature values, the analytic and numerical models were here updated with the actual properties measured experimentally, so that the final curves of added mass and transition frequency in function of the inserts dimension are different from those presented in [5] - Figures 7 and 8. Furthermore, the transition analytic expression that was used in this work is the one derived in [8], where the transition phenomenon's definition results from the conversion of the flexural waves in the sandwich panel waveguide. Thus, the transition frequency formulation used here is:

$$\omega_T = \frac{2S}{\sqrt{3\mu D}} \quad (1)$$

where

$$S = h_c G_c \left(1 + \frac{h_s}{h_c} \right)^2 \quad (2)$$

and

$$D = E_s h_s \left(\frac{h_c^2}{2} + h_c h_s + \frac{2h_s^2}{3} \right) \quad (3)$$

Figure 6: Halpin-Tsai prediction of the composite material's Young Modulus, Y_C , in function of the MWCNTs Volume fraction, V_{NT} , and the pristine resin's Young Modulus, E_{resin} .

are the transverse shear rigidity of the plate and its bending stiffness, respectively, and μ its mass per unit area. On the other hand, in [5] Guillaumie formulation was adopted [9], where the transition frequency is defined from the geometric intersection of the asymptotic bending and shear wavenumbers. This results in a further difference of the graphs presented here from those presented in [5].

Following, a summary of the sandwich panel design steps:

1. The insert's thickness is set to 1.4 mm by defining a limit on the desired added mass to 5% and by considering a cylindrical shape for the insert itself - Figure 7;
2. The inserts resin Young Modulus is a result from the Young Modulus of the pristine resin and the percentage of CNTs dispersed in it - about 2 GPa (3.9% error with the analytic prediction) - Figures 5 and 6;
3. Following the first two steps, the transition frequency is estimated according to [8], with the value of G_c evaluated numerically. Figure 8 shows the ratio between the transition frequency of the reinforced panel and the one of the bare panel. For our configuration, it is expected to be 1.07 (increment of 6.58% with respect to the base configuration).

4 CONCLUSIONS AND FUTURE WORK

This work presented the design of CNT-reinforced inserts of a sandwich panel for vibroacoustic purposes, following its constituent materials mechanical characterization. The design steps developed in a previous work were here updated according to the measured core, skins and inserts' materials properties. The design procedure aims to increase the sandwich panel's transition frequency by means of the

Figure 7: Estimated percentage of added mass in function of the insert dimensions.

viscoelastic inclusions, but at the same time setting limits to the added mass. Indeed, the final inserts thickness is set to 1.4 mm by taking into account a limit of 5% on the added mass to the panel, and an increment of about 7% to the transition frequency is estimated from the numerical/analytic models.

Future work will include the manufacturing of two large-scale sandwich panels of $700 \times 700 \text{ mm}^2$ - one with the viscoelastic inserts and one control panel without - and vibroacoustic numerical investigation and testing. Finally, samples for out-of-plane flatwise compression tests will be manufactured in order to define the inserts contribution to the strength of the panel.

Abstract. Metamaterials are artificial, engineered materials with properties that are not found in nature. They are typically formed by an assembly of reoccurring patterns whose scale is (generally) smaller than the phenomena they influence. In the vibro-acoustic community metamaterials are mostly known for their stopband behavior that can be used to reduce noise and vibrations beyond what is dictated by the mass law. This behavior can be predicted during the design stage using unit cell modeling techniques such as the Wave Finite Element Method (WFEM) and the Shift Cell Operator Method to compute the propagation constants of the relevant waves. As a consequence, most design optimization schemes have focused solely on maximizing the spatial attenuation of targeted waves. However, dispersion characteristics alone cannot predict the performance of metamaterial solutions once deployed because they neglect their operating environments, finiteness and boundary conditions applied. For instance, the presence of edge modes may result in increased and localized vibration energy, deteriorating the effect of the treatment. This paper presents a second order optimization scheme based on the 1D WFEM framework enabling the optimization of the response of finite metamaterial solutions. The proposed methodology is validated on a simple model updating case and subsequently applied to the design of a resonant metamaterial.

1 INTRODUCTION

As constraints on the weight and volume of vibro-acoustic packages become more important, the interest in metamaterial based solutions increase. This interest is mostly driven by the stopband behavior exhibited by some periodic structures enabling attenuation properties that

go beyond the mass law. So far, the Wave Finite Element Method and the Shift Cell Operator Method have been the most popular tools to study and engineer smart structures based on this concept because they allow the computation of the dispersion characteristics of a periodic medium by the discretization of a single unit cell (UC). Studies based on the analysis of dispersion curves and band diagrams have become standard and designs including perforations or resonant add-ons have been used to open bandgaps around targeted frequencies [1]–[3]. More recently, numerical methods have been used to obtain bandgaps with maximal width and attenuation properties in phononic crystals [4], [5] or specific anisotropic behavior in meta-structures [6]. However, most of the studies in the literature stop their analysis at the stop band level without investigating the impact of boundary conditions, operating environment, load characteristics and finite size effects on the performance of metamaterial solutions. While research targeted those topics from a theoretical or qualitative point of view [7]–[10], not many studies deal with those topics applying detailed numerical modeling [11]. This paper presents a second order optimization scheme based on the 1D WFEM framework that accounts for load characteristic, boundary conditions and finiteness of metamaterial solutions.

2 FORCED RESPONSE OF A 1D WAVEGUIDE USING THE WFEM

Given the unit cell of a 1D periodic structure, its mass, damping and stiffness matrices, K , M and C are considered. A partition of its degrees of freedom (dofs) U is also established following the spatial structure of the UC:

$$U = \begin{bmatrix} U_L \\ U_I \\ U_R \end{bmatrix} \quad (1)$$

The subscripts R , L and I are used for variables associated with the right, left and internal dofs of the UC. Additionally, the subscript B will be used for quantities associated to all interface dofs.

The first step in the direct WFEM scheme is to form the dynamic stiffness matrix G for a given circular frequency ω :

$$G = K + i \omega C - \omega^2 M \quad (2)$$

The internal dofs of the UC are then condensed in order to form D the condensed dynamic stiffness matrix:

$$D = G_{BB} - G_{BI} G_{II}^{-1} G_{IB} \quad (3)$$

Applying the Floquet-Bloch boundary conditions leads to an eigenvalue problem with propagations constants and waveshapes as solutions:

$$\left(\lambda D_{LR} + (D_{LL} + D_{RR}) + \frac{1}{\lambda} D_{RL} \right) \Psi = 0 \quad (4)$$

The eigenvalue problem of equation (4) yields the wave shapes Ψ_k and propagation constants λ_k of free waves in the periodic medium at the circular frequency ω . It should be noted that the propagation constants come in pairs $(\lambda_k, \frac{1}{\lambda_k})$ with eigenvectors (Ψ_k^+, Ψ_k^-) that correspond to waves traveling in the positive and negative direction. Using this information, it is possible to compute the forced response of a finite waveguide comprised of N UCs by relating the wave amplitudes to the excitations and boundary conditions. In case of a Clamped-Free waveguide, the following equations are given:

$$\begin{pmatrix} \Psi^+ & \Psi^- \Lambda^N \\ D_{RL} \Psi^+ \Lambda^{N-1} + D_{RR} \Psi^+ \Lambda^N & D_{RL} \Psi^- \Lambda + D_{RR} \Psi^- \end{pmatrix} \begin{bmatrix} q^+ \\ q^- \end{bmatrix} = \begin{bmatrix} U_L \\ F_R \end{bmatrix} \quad (5)$$

The displacement at the i^{th} section of the waveguide being given by:

$$V_i = \Psi^+ \Lambda^i q^+ + \Psi^- \Lambda^{N-i} q^- \quad (6)$$

3 SECOND ORDER NON-LINEAR OPTIMIZATION

This Section describes the second order optimization strategy used in the examples presented in Section 4. The strategy is developed to account for two characteristics of the WFEM. Firstly, obtaining accurate derivatives by numerical differentiation is very hard because of the low numerical accuracy of the WFEM as compared to usual FEM modeling [12]. Secondly, computing the response of a waveguide is relatively cheap because all computations are done on a single UC. It follows that semi-analytical gradients and Hessians of C^2 objective functions can be computed at an acceptable cost. Making use of the available second order information, an algorithm that combine both line search and trust region methods is proposed.

Let's note f an objective function and $p \in \mathbb{R}^n$ the vector of optimization variables. The variables may be subject to a set of n_e convex equality constraints $\forall i \in \llbracket 1, n_e \rrbracket E_i(p) = 0$ and n_c convex inequality constraints $\forall j, \llbracket 1, n_c \rrbracket C_j(p) \leq 0$. For a starting point p_0 , the function value $f(p_0)$, the gradient $\nabla f(p_0)$ and the Hessian $\nabla^2 f(p_0)$ are computed. A surrogate function \tilde{f} that approximates f around p_0 is then used.

$$f(p) \approx \tilde{f}(p) = f(p_0) + \nabla f(p_0)(p - p_0) + \frac{1}{2}(p - p_0)^T \nabla^2 f(p_0)(p - p_0) \quad (7)$$

If the Hessian is positive definite. A line search method is used:

$$v = \operatorname{argmin}\{\tilde{f}(p_0 + v), E_i(p_0 + v) = 0, C_j(p_0 + v) \leq 0\} \quad (8)$$

Equation (8) can be solved using the interior point method [13] or analytically when there are no constraints. Once the search direction v is obtained. f is minimized in the v direction:

$$\alpha_m = \operatorname{argmin}\{f(p_0 + \alpha v), \alpha \in [0; 1]\} \quad (9)$$

Defining the next iteration:

$$p_1 = p_0 + \alpha_m v \quad (10)$$

When the Hessian is not positive definite, a trust region method [13]–[16] is used. The first step is to define $|\nabla^2 f(p_0)|$. This matrix is obtained by keeping the eigenvectors of $\nabla^2 f(p_0)$ and taking the absolute value of all its eigenvalues. A supplementary constraint is then introduced:

$$T(p) = (p - p_0)^T |\nabla^2 f(p_0)| (p - p_0) - R_0^2 \leq 0 \quad (11)$$

The trust region's radius R_0 is updated at each iteration to make sure that the surrogate function can be trusted. In practice it is adjusted so that decreases or increases in the objective function are correctly predicted by the surrogate model:

$$\forall p \in \mathbb{R}^n, \quad T(p) \leq 0, \quad \frac{f(p) - f(p_0)}{\tilde{f}(p) - f(p_0)} > \frac{1}{4} \quad (12)$$

Guidelines and algorithms about how to update the trust region radius R_i at each iteration can be found in [13]. Summarized, the optimization algorithm consists of the following steps:

1. Select an initial point p_0 .
2. Compute $f(p_0)$, $\nabla f(p_0)$ and $\nabla^2 f(p_0)$
3. Assume: $f(p) \approx \tilde{f}(p) = f(p_0) + \nabla f(p_0)^T (p - p_0) + \frac{1}{2} (p - p_0)^T \nabla^2 f(p_0) (p - p_0)$
- 4.a If $\nabla^2 f(p_0) > 0$ use line search with Newton direction v .
Find an approximate the minimizer α_m of : $\{f(p_0 + \alpha v), \quad \alpha \in [0 ; 1]\}$
Define $p_1 = p_0 + \alpha_m v$
- 4.b Else a trust-region method is used to take the step:
Define $p_1 = \operatorname{argmin}\{\tilde{f}(p), T(p) \leq 0, E_i(p) = 0, C_j(p) \leq 0\}$
5. Iterate steps 2 to 4 until convergence.

4 NUMERICAL EXAMPLES

4.1 Application to parameter identification

In this subsection the method is used in a parameter identification scheme as mean of validation. A 1m meter long beam with a 1cm by 3cm rectangular cross-section and unknown material properties is considered. Assuming a Poisson's ratio of 0.3, the cross section of a beam with unitary density ρ and unitary Young's modulus E is modeled using ANYS APDL 17.0 to serve as the basis for a parametric model. The corresponding UC is shown in Figure 1. The mass matrix M_0 and stiffness matrix K_0 are then used in a model for which the density, the real part and the imaginary part of the Young's modulus are the parameters as specified in equation (13).

$$\begin{cases} K(p) = (E_r + iE_i)K_0 \\ M(p) = \rho M_0 \\ p = \begin{bmatrix} E_r \\ E_i \\ \rho \end{bmatrix} \end{cases} \quad (13)$$

Figure 1: Unit cell for the cross-section of the beam (1cm by 3cm by 0.556mm)

Clamped-Free boundary conditions are used and a unit force of 1N is applied at the free end of the beam. The direct forced response is computed on the 10Hz-1000Hz frequency range for material parameters values corresponding to those of aluminum:

- Real part of the Young modulus $E_r^0 = 69.10^9 Pa$
- Hysteretic damping $\eta_0 = 0.3\%$
- Imaginary part of the young modulus: $E_i^0 = E_r^0 \eta_0 = 2,07.10^9 Pa$
- Density $\rho^0 = 2700$
- Poisson's ratio $\nu = 0.3$

This response, $X_0(\omega)$, is used to build an error function f that evaluates the difference between the reference and a response obtained using a material property vector p .

$$f(p) = \frac{1}{\omega^+ - \omega^-} \int_{\omega^-}^{\omega^+} \|\log(|X_0(\omega)|) - \log(|X(\omega, p)|)\|^2 d\omega \quad (14)$$

In equation (14) the logarithm ensures that the objective function is sensitive to the information available on the full frequency range. Without this precaution, modal frequencies

would dominate the error evaluation because this is where most of the signal's energy is located.

The optimization process is started with material properties $\rho = 1300 \text{ kg.m}^{-3}$, $E_r = 90.10^9 \text{ Pa}$ and $E_i = 1,08.10^9 \text{ Pa}$. The optimization path of each variable is given in Figure 2.

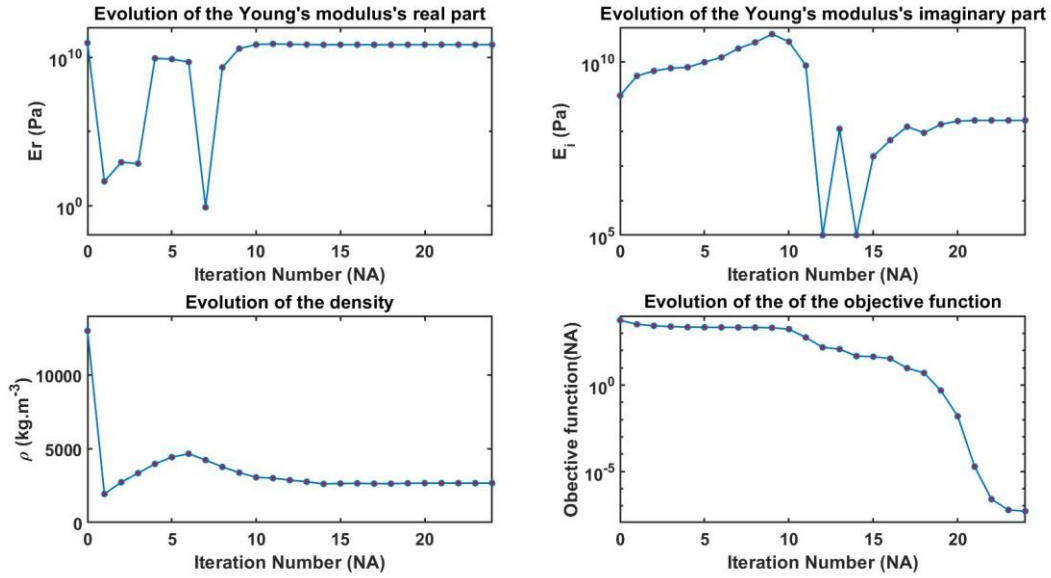

Figure 2: Evolution of the material properties and the objective function

Convergence to the original material properties is reached in 24 iterations validating the method and its implementation.

4.2 Optimization of a metamaterial design

In this subsection, the wave-based methodology is applied to the optimization of the mean square velocity of a 1 m long steel beam with a square section of side length 1cm and Clamped-Free boundary conditions, subjected to a 1N force applied on its free side. The optimization variables are the mass, stiffness and damping parameters of the periodic resonant add-ons used to treat the host structure. The length of the UC is decided beforehand and fixed to 5cm, hence the beam contains 20 UCs.

The variables of the problem are:

- The added mass to the UC (cannot be negative and shall not exceed 20% of the host structure).
- The stiffness of the spring (cannot be negative)
- The damping of the spring (cannot be negative and shall not exceed 10%)
- The position of the resonator in the UC (should be between 5mm and 4.5cm). The corresponding optimization variable is normalized to be in the $[0, 1]$ interval.

The objective function takes the form:

$$f(p) = \frac{1}{\omega^+ - \omega^-} \int_{\omega^-}^{\omega^+} \frac{1}{N} \sum_i \omega^2 |X_i(p, \omega)|^2 d\omega$$

Where $X_i(p, \omega)$ is the frequency forced response of the i^{th} section of the waveguide for a unitary load on the free side and N is the number of UCs.

The derivatives of the resonator's position are computed by taking advantage of the fact that length appears explicitly in the formula for Euler-Bernoulli elements. However, elements size do not change at each iteration. Instead, re-meshing occurs when different parameter values are used. For the optimization, the 5th mode of the bare structure around 712Hz is targeted. The frequency band of optimization, 648Hz-919Hz, is defined by the two anti-resonances surrounding the 5th mode in the direct forced response of the bare structure. The second order optimization methodology described in Section 2 is applied for a random starting p_0 in the design space and the results obtained are presented in Figure 3 and Figure 4.

Figure 3: Response of the bare structure (direct), starting point (direct and far field) and optimum (direct and far field). The vertical dashed lines indicate the frequency band of optimization

In Figure 3 the direct forced response for the bare structure, the starting point of the optimization, and the optimum are shown. Additionally, the response at section 1 (near the clamped side) is presented for the starting point and the optimum so that the stopband behavior can be evaluated in both cases. The value of the optimization variables at each iteration can be observed in Figure 4.

Figure 4: Optimization path in the design space

Unsurprisingly, maximizing the added mass and loss factor results in optimal performances. However, having the tuned resonance frequency on the targeted mode or at the center of the targeted frequency band does not. Similarly, the resonator's position in the UC is not a neutral parameter. These observations cannot be predicted from simple dispersion analysis and highlight the need to account for boundary conditions, finiteness and source location properties during the design phase.

5 CONCLUSIONS

A second order optimization scheme for 1D WFEM analysis was presented. The scheme accounts for both strong and weak points of the WFEM namely the decoupling of the computation cost from the size of the waveguide and the lower accuracy of the WFEM as compared to FEM. The method is versatile and can be used in a range of applications including parameter identification, homogenization, model updating and design optimization.

Key words: Meta-porous material, Biot-Allard poroelastic model, Mass-spring effect

Abstract. In this paper the possibility of enhancing the absorption coefficient of a poro-elastic material using small, elastic mass inclusions in frequencies lower than the quarter-wavelength resonance of the porous material is discussed. We show that absorption peaks can be achieved not only by what is known in literature as the trapped mode effect, but also by the resonance of small elastic inclusions at low frequencies, which can be interpreted as a mass-spring effect. In this work, the inclusion and the porous skeleton is considered elastic and fully coupled to each other, therefore accounting for all types of energy dissipation i.e. viscous, thermal, and structural losses and energy dissipated due to the relative motion of the fluid phase and the frame excited by the resonating inclusion. Additionally, the inclusions are also modeled as motionless and rigid to distinguish between the trapped mode and/or the modified frame mode effect and the mass-spring effect. Moreover, the distinction between these two effects are explained in more detail by comparing the dissipated energy by each mechanism (viscous, thermal and structural effect).

1 INTRODUCTION

Porous materials are proved to be efficient absorbers in the mid- and high-frequencies, where their thickness is equal/higher than quarter wavelength in the medium. On the other hand, they suffer from lack of efficiency in low-frequencies. A common solution to this problem is to use multi-layered structures, which is, however, limited by the allowable thickness [1]. In the past years, many researchers have been seeking to find alternative solutions to improve the absorption of poro-elastic materials at low-frequencies. One example is using periodic rigid inclusions with the size in the same order of the acoustic wavelength Groby et al. [2] proved that by trapping the energy between the motionless inclusion and the rigid backing, perfect absorption can be achieved under the quarter-wavelength limit. Another

alternative solution was suggested by Lagarrigue et al. [3], who used periodic array of rigid split-ring resonator inclusions to create a meta-porous system to increase the absorption coefficient of the foam with motionless frame significantly near the resonant frequency of the inclusions.

Complementary to the works mentioned above, Zieliński [4] showed that the absorption coefficient of the porous materials can also be improved by small periodic mass inclusions. Inspired by [4], in this paper we investigate the absorption enhancement of poro-elastic materials with small mass inclusions due to the mass-spring effect. Moreover, it is shown that at the resonant frequency of the inclusions, the elastic frame of foam is excited leading to an increase in the phase difference of the solid and fluid part, which results in viscous loss increase at low-frequency. The mass-spring effect is demonstrated by decomposing the absorption coefficient into the three different energy dissipation mechanisms [5] (the viscous, thermal, and structural loss). It is worth mentioning that this effect can be captured, when the targeted frequency lies in the viscous region, and therefore is only applicable to the foams with high value of flow resistivity and/or very small characteristic viscous length.

This paper is structured in four sections. In the second section, the modeling technique used for the porous material and the inclusion is explained. The third section is focused on describing the mass-spring effect by introducing the inclusion in the foam and comparing the acoustic behavior of the homogeneous porous foam layer to the foam layer with inclusion. At last, the paper is concluded in the forth section.

2 Modeling technique

This section consists of two parts. The first part explains the modeling technique used for the poro-elastic material, while the second part describes the models used for the inclusion.

2.1 Poro-elastic material modeling

As mentioned in the previous section, the mass-spring effect can be captured in foams with high viscous loss at low-frequencies, which translate to high value of flow resistivity. Therefore, the effect appears under the decoupling frequency, which requires using the theory of Biot [6] to model the porous material. In this paper the classical $u - p$ formulation [6] of the Biot theory, where the field variables are the displacements of the elastic frame (\mathbf{u}) and the pressure in the pores (p), is used. The Biot poro-elasticity equations in terms of $u - p$ variables are given in the equations below:

$$\nabla \cdot \boldsymbol{\sigma} + \omega^2 (\tilde{\rho}_{11} - \frac{\tilde{\rho}_{12}^2}{\tilde{\rho}_{22}}) \mathbf{u} + \tilde{\gamma} \nabla p = \mathbf{0}, \quad (1)$$

$$\nabla^2 p + \omega^2 \frac{\tilde{\rho}_{22}}{\tilde{R}} p - \omega^2 \tilde{\gamma} \frac{\tilde{\rho}_{22}}{\phi^2} \nabla \cdot \mathbf{u} = 0, \quad (2)$$

with

$$\tilde{\gamma} = \phi (\frac{\tilde{\rho}_{12}}{\tilde{\rho}_{22}} - \frac{\tilde{Q}}{\tilde{R}}). \quad (3)$$

The total inertial and viscous energy dissipation due to relative motion of the two phases is described by $\tilde{\rho}_{11}$, $\tilde{\rho}_{12}$, and $\tilde{\rho}_{22}$, see [6]. Moreover, $\boldsymbol{\sigma}$ is the stress tensor of the solid phase for the frame in vacuum; therefore, it is independent on the displacement (nor rather volumetric strain) in the fluid phase and related purely to the strain of the solid phase:

$$\boldsymbol{\sigma} = (A - \frac{\tilde{Q}^2}{\tilde{R}}) \text{tr}(\boldsymbol{\epsilon}) \mathbf{I} + 2N\boldsymbol{\epsilon}, \quad (4)$$

where $\boldsymbol{\epsilon}$ is the solid phase strain tensor, N is the second Lamé coefficient (the shear modulus of the material of visco-elastic frame), and \mathbf{I} is the second-order identity tensor. Additionally, the fluid stress dependency on the solid displacement and respectively the opposite is accounted for with the dilatational coupling factor i.e. \tilde{Q} . Moreover, \tilde{R} can be described as the fluid phase bulk stiffness at zero frame dilatation. The detail description of A , \tilde{Q} , and \tilde{R} can be found in [6].

2.2 Inclusion modeling

In this paper the inclusion is modeled in three different ways to differentiate between the different effects which may play a role, being the mass-spring effect and the trapped mode effect and/or modified mode of the frame. In the first approach the inclusion is considered as point mass, therefore accounting only for the effect caused by the concentrated mass (m_0) addition to the frame. As a result, it is modeled by adding an inertial weak contribution to the variational formulation of the poro-elastic material:

$$\mathcal{W}_{\mathcal{F}_p} + \int_{\Omega_p} \omega^2 m_0 \delta(\mathbf{x} - \mathbf{x}_0) \mathbf{u} \cdot \mathbf{w} = 0. \quad (5)$$

$\mathcal{W}_{\mathcal{F}_p}$ is the weak form for a poro-elastic material in the domain Ω_p , m_0 is the point mass of inclusion at the point \mathbf{x}_0 , δ is the Dirac delta function, and \mathbf{w} is the test function for \mathbf{u} .

In the second approach, the inclusion is considered as rigid and motionless, however, now it has a finite (small) volume, and the interface between the rigid motionless inclusion and the poroelastic domain Ω_p is denoted by Γ_{p-r} . The presence of such inclusion is modeled simply by applying the fixed-frame boundary conditions on this interface, i.e.:

$$\mathbf{u} = \mathbf{0} \quad \text{on} \quad \partial\Gamma_{p-r}. \quad (6)$$

Considering the inclusion as motionless results in capturing the trapped mode effect and/or modified mode of the frame with rigid backing.

In the third approach, which is the most complete one of all, the inclusion is considered to be elastic and it is fully coupled to the poro-elastic material accounting for the inertial, trapped mode effect, and modified mode of the frame all together. Therefore, the inclusion is modeled as an isotropic elastic medium and its displacement is fully coupled to the frame's displacement at the interface Γ_{p-e} between the both media, namely,

$$\mathbf{u} - \mathbf{u}^e = \mathbf{0} \quad \text{on} \quad \partial\Gamma_{p-e}. \quad (7)$$

3 Results and discussion

In this section the absorption enhancement of a poroelastic foam layer due to the mass-spring effect is illustrated by investigating three cases: the foam without inclusion and the foam with inclusion at two different positions. For each case, the three modeling approaches mentioned in previous section are applied. In the first and second part of this section the partial absorption coefficient due to each dissipation mechanism is shown for the three cases. The third part elaborates more on the dynamic behavior of the meta-porous system and its connection with the increase in sound absorption. In the third part, the average phase difference between the fluid and solid phases is calculated over the frequency range of interest and the results discussed.

3.1 Sound absorption for the foam without inclusion

A polyurethane foam with poro-elastic parameters given in Table 1 is used in these investigation. Firstly, a 24 mm layer of the foam (case 0) is considered, which is shown in Figure 1, as a reference in order to compare to the cases of the foam with inclusion.

Figure 1: Schematic view of the cases considered in this paper.

$E[kPa]$	η	ν	$\rho[kg/m^3]$	ϕ	α_∞	$\Lambda[\mu m]$	$\Lambda'[\mu m]$	$\sigma[Pa.s/m^4]$
143	0.055	0.3	31	0.97	2.52	37	119	87000

 Table 1: The Biot parameters of the foam. E , η - the Young modulus and loss factor of the material of frame, ν - the bulk Poisson ratio, ρ - the bulk density, ϕ - the porosity, α_∞ - the tortuosity, Λ , Λ' - the viscous and thermal characteristic lengths, σ - the airflow resistivity.

Figure 2: Partial absorption coefficient for different dissipation mechanisms for the foam without inclusion.

A 2D model of the foam is considered and it is clamped at the base in the y direction, and is excited by a plane wave at the other end in the normal direction. The foam is assumed periodic in the x direction, which is modeled as sliding boundary condition due to symmetry. The partial acoustic absorption coefficient of the foam due to three different energy dissipation mechanism (viscous, structural, and thermal) are calculated according to the expressions given in [5], and are shown in Figure 2.

To better understand Figure 2, the resonance frequency of the frame with rigid backing [6] is calculated, i.e. $f_r = \frac{1}{4l} \sqrt{\frac{Re(K_c)}{\rho_1}} \approx 820$ Hz, where l is the layer thickness (see Figure 2, $K_c = \frac{2(1-\nu)N}{(1-2\nu)}$, and ρ_1 is the bulk density of the solid phase. Figure 2 shows that at the resonance frequency of the frame there is a dip in the viscous loss, and simultaneously there is a peak in the structural loss. The mentioned behavior is due the fact that the viscous loss depends on the out-of-phase movement of the fluid and solid phase, while the structural loss depends on the solid phase strain. At the resonance frequency of the frame, the frame is excited and moving in-phase with the fluid part, therefore there is a decrease in phase difference of the solid and fluid part. Additionally, the dip is followed by a peak in viscous loss, which is due to the

out-of-phase displacement of the frame and the fluid part above the resonance of the frame.

3.2 Sound absorption for the foam with inclusions

Next, two cases of a foam with steel rod inclusions of diameter of 0.8 mm periodic in the x direction with the periodicity length of 8 mm are studied. In the first case (case A) the inclusion is located at $y_1 = 4 \text{ mm}$ from the rigid backing, while in the second case (case B) the inclusion is located at $y_2 = 20 \text{ mm}$ from the rigid backing, see Figure 1. The partial absorption coefficient for each case is calculated using the three different models for the inclusion i.e. elastic, rigid, and point mass, see Figure 3.

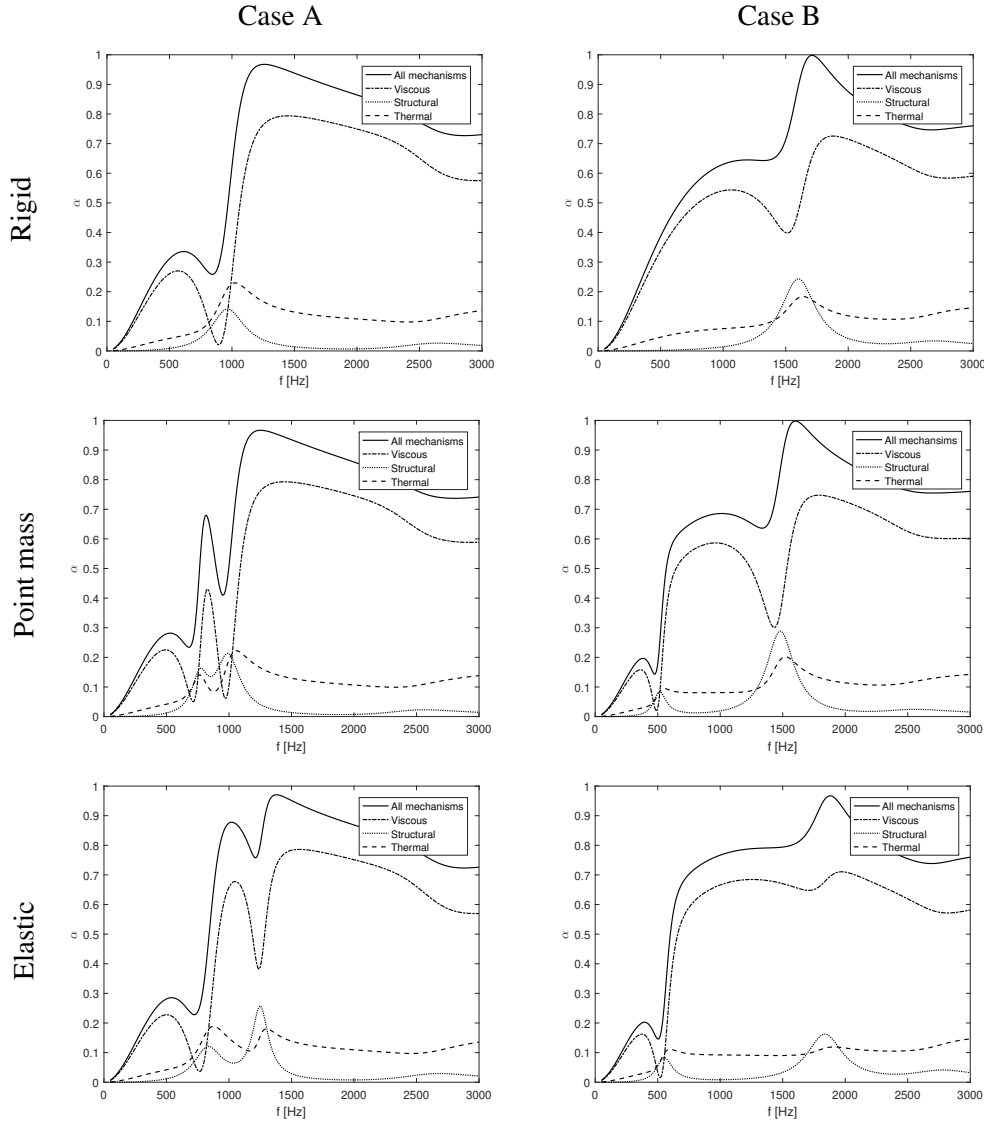

Figure 3: Partial absorption coefficients for different mechanism for case A(left) and case B(right), considering the inclusion as rigid(top), point mass(middle), and elastic(bottom).

Several conclusions can be drawn based on Figure 3. Firstly, different models of case A are compared to each other. It is clear that the rigid inclusion model misses the effect of inclusion, when it is close to

rigid backing. The only difference between the absorption coefficient of the rigid inclusion compared to the foam without inclusion (cf. Figure 3 (top) to Figure 2) is that the foam is slightly stiffened and the resonance frequency of the frame shifted to higher frequency (from 820 Hz to 910 Hz). Comparing the point mass inclusion model to the elastic inclusion model, it is observed that the effect is more localized, and is less pronounced, which is due to the fact that in the elastic inclusion model the effect of the inclusion size is also considered. Another remark is that the modified mode of the frame due to elastic inclusion is higher in frequency as compared to the point mass inclusion (from 1000 Hz for point mass inclusion to 1250 Hz for elastic inclusion) because the elastic inclusion model accounts for the stiffness of the inclusion, which leads to stiffening of the frame.

Secondly, different models of case B are compared to each other. In this case, the larger distance of inclusion and rigid backing leads to a shift of the frame mode to higher frequencies (from 820 Hz to 1600 Hz). The rigid inclusion model shows an absorption improvement, which is also noticeable in the point mass and elastic inclusion models (at 1500 Hz for point mass inclusion, and at 1850 Hz for the elastic inclusion). Moreover, in this case absorption enhancement is achieved over a broader frequency range because the two effects (the mass-spring effect and the modified mode of frame) are located further apart in frequency, creating a combined effect. On the other hand, since the modified mode of the frame is shifted to higher frequencies, the frequency at which the perfect absorption is reached is also moved to higher frequencies, creating a zone (from 980 Hz to 1750 Hz) with absorption reduction of maximum 17%. This behavior is the trade off between enhancing the absorption coefficient at lower frequencies and creating a zone of absorption reduction at higher frequencies.

Thirdly, when case B is compared to case A, we can see that the resonance frequency of the inclusion (the first peak of in the structural loss for the two cases) is shifted down, since the elastic foam between the inclusion and the rigid backing wall acts as the spring in the so-called mass-spring system. Therefore, by increasing the length of the foam below the inclusion, the stiffness of the spring is decreased, and consequently the resonance frequency is decreased.

At last, to show that the absorption improvement at higher frequencies for both cases, A and B, is due to the modified mode of the frame and not the trapped mode effect, we draw readers' attention to the peak appearing in structural loss at those frequencies (around 1000 Hz to 1250 Hz for case A, and around 1500 Hz to 1850 Hz for case B). A peak in structural loss relates to a resonance of the frame, while the trapped mode effect corresponds to trapping of the energy between the rigid backing and the inclusion, which is also apparent under the motionless frame assumption when the equivalent-fluid model is used instead of the poro-elastic one.. To further illustrate this reasoning, the absorption curve of the two cases are calculated using the equivalent fluid model with the same transport parameters ($\phi, \alpha_\infty, \Lambda, \Lambda^{prime}$, and σ) from Table 1 and representing the inclusion with rigid boundary conditions. As expected, the equivalent fluid model doesn't capture the mass-spring effect of the inclusion, and the shift in the frame resonance frequency due to the inclusion.

3.3 Phase difference of the fluid and solid part

The phase difference between the motion of the solid and fluid phase is calculated as follows:

$$phase(\mathbf{U}^f - \mathbf{u}) = \text{imag}(\log(\frac{\frac{\phi}{\bar{\rho}_{22}\omega^2} \nabla p - \frac{\bar{\rho}_{12}}{\bar{\rho}_{22}} \mathbf{u}}{\mathbf{u}})), \quad (8)$$

in order to demonstrate the increase in viscous loss due to the presence of inclusions. In the equation above $\frac{\phi}{\bar{\rho}_{22}\omega^2} \nabla p - \frac{\bar{\rho}_{12}}{\bar{\rho}_{22}} \mathbf{u}$ is the fluid displacement. For the sake of completeness, also the amplitude difference of the fluid and solid phase motion i.e. $\int_{\Omega_p} |\mathbf{U}^f - \mathbf{u}|$ is shown in Figure 6.

Figure 4: Absorption coefficient (for cases A and B) computed using the equivalent fluid model and the Biot-Allard model with elastic inclusions.

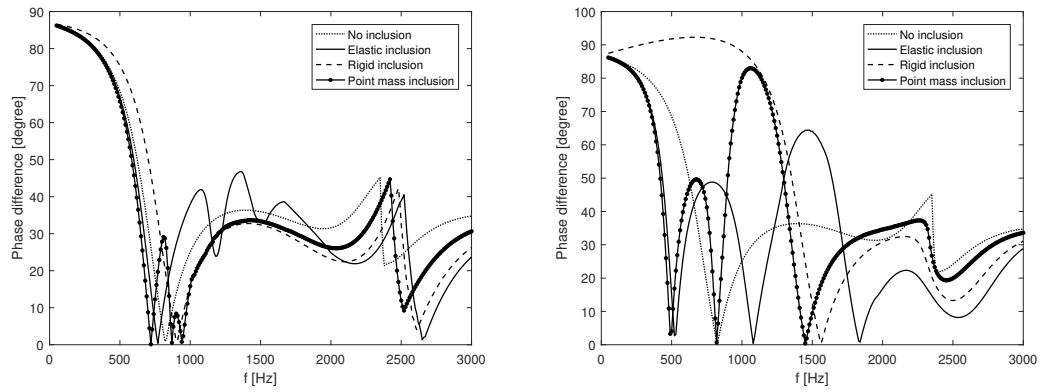

Figure 5: Average phase difference between the fluid and solid part for the case A(left) and B(right).

Figure 6: Amplitude difference between the fluid and solid phase motion for the case A(left) and B(right).

Considering the phase difference and the amplitude difference in case A and case B, it is clear that the peaks in Figure 5 and 6 corresponds to the peaks appearing in the partial absorption coefficient due to the viscous loss. Moreover, there is an additional peak for the point mass and elastic inclusion model

as compared to the rigid-motionless inclusion model for both cases, which is induced by the resonating inclusion, which creates an additional mode in the frame, therefore increasing the out-of-phase movement of the frame with fluid part.

4 Conclusion

In this paper, the absorption enhancement of poro-elastic material with small rod inclusions is studied. It is shown that the absorption coefficient can be improved under the quarter-wavelength frequency exploiting a mass-spring effect of the inclusions, when the porous medium is considered viscoelastic and fully coupled to the inclusion. By decomposing the absorption coefficient into energy dissipated by three mechanisms (viscous, structural, and thermal), it is illustrated that the resonating mass excites the frame and increases the out-of-phase movement of the frame and fluid, and consequently leads to an increase in viscous loss. Moreover, the inclusions were modeled using three different assumptions i.e. elastic, rigid, and point mass to differentiate between the mass-spring effect and what is known in literature as the modified mode of the frame. As it was expected, while the rigid model was able to illustrate the modified mode of frame effect, it came short in showing the mass-spring effect. Moreover, it was shown that by changing the location of the inclusion, which translates to changing the spring stiffness, the resonance frequency of the inclusion is changed, and therefore the absorption peak is shifted in frequency. This behavior shows that such meta-porous systems can be tuned to improve absorption coefficient at targeted frequencies below the quarter wavelength frequency, which can be also effectively used in active sound absorbing meta-porous treatments [7].

Key words: Quasi-periodic structures, band diagram, frequency stop-band, forced response, metamaterials

Abstract. The vast majority of structures introduce symmetry in one or two dimensions, which can be a periodicity in the case of constructing several identical unit cells. Periodic structures have found a big interest in engineering applications because they introduce frequency band effects, due to the impedance mismatch generated by periodic discontinuity in the geometry, which can improve the vibroacoustic performances. However, the presence of imperfections i.e. (defects, irregularity) in the structure, leads to a partial loss of regular periodicity (called quasi-periodic structure) that can have a noticeable impact on the vibrational and/or acoustic behaviour of the elastic system. The tailored irregularity, which is a designed loss of periodicity, can be used, therefore, to improve the dynamic behaviour of structures. In the present paper numerical studies on the vibrational analysis of two-dimensional non-planar periodic and quasi-periodic structures have been performed. The content deals with finite and infinite systems. The finite element models of solid structures focused on the band diagram analysis of the infinite systems and the forced responses of the finite structures. The quasi-periodicity is defined by invoking the Thue-Morse sequence for building the assigned variations (geometry) along the domain of finite element model. The wave characteristics in quasi-periodic panels, present some elements of novelty and could be considered for designing structural filters and controlling the properties of elastic waves.

1 INTRODUCTION

Periodic metamaterials are one of the central topics in vibration and acoustics domain. A degree of regular periodicity in arrays of engineered metamaterials, always leads to design and create frequency stop bands (i.e. waves cannot freely propagate in these frequency ranges). One of the main features associated with the periodic distribution of mechanical devices is the ability of the system to block the propagation of waves in specific frequency ranges [1]. Such structures behave as filtering systems, since in some ranges of frequencies waves propagate without attenuation (if damping is neglected), while in

others decay exponentially [2, 3]. They are also very well known metamaterials and phononic materials for exhibiting frequency band gaps, that can improve the vibroacoustic response of structures [4, 5]. Recent studies show interesting topics on architected material like phononic crystals, metamaterials, and auxetic sandwich cores [6] to control the propagation of elastic waves. These architected material rely on two mechanisms for forming band gaps. Phononic crystals can form Bragg type band gaps, but are limited in the low-frequency regimes because their unit cell size scales with wavelength. In contrary metamaterials overcome this size, because they rely on resonances, but the resulting band gaps are narrow [7, 8].

Numerical analyses lead to the design of nominally perfect periodic structures. However, the presence of imperfections i.e. defects or irregularities in post-manufacturing are highly likely to be occurred in regular periodic designs. Recent studies show that there are effects on random variability due to the additive manufacturing process on the performance of the elastic band gap behaviour in creating a stop band effect in the forced response of the waveguide [9]. On the contrary, the present work is focused on tailored irregularities, which is called (quasi-periodicity), which are considered to have impacts on dynamical behaviour of the structures. The first challenge is how to predict the frequency band gap in infinite quasi-periodic systems. In fact, the design of periodic configurations is usually based on the use of Floquet-Bloch (FB) theorem which considers a single cell with adequate boundary conditions [10, 11].

To design an enhanced quasi-periodic structure and analyse the impact of this design in terms of dynamics response, two methods are under investigation. A forced response of the finite quasi-periodic structure and a periodic panel which has commonality in terms of in-plane dimensions. In the second method in order to predict the frequency stop band zones a dispersion analysis of the infinite periodic structure is designed. In this design two meso-scale unit cells, which represent the dispersion analysis of the infinite periodic structures are considered. The predicted dispersion curves can be directly compared with its finite periodic counter parts for frequency band gaps prediction. In the forced response, those two meso-scale cells are combined using Thue-Morse morphism series in order to tailor a quasi-periodic panel. The FRFs of the quasi-periodic panel show effective results compared to strictly periodic panels in terms of band gaps width enlargement and level of attenuation.

2 MODEL AND LEXICON

2.1 Infinite structure

The model consists of a metamaterial waveguide. Metamaterials in the present investigation are an engineered sets of multiple elements to show some filtering properties. The waveguide consists of two different unit cells in meso-scale. The unit cells are made of polymers materials and the mechanical properties are given in Tab.1.

The unit cell is made of two sub-parts, on-board panel, and a resonator. The dimension of the meso-scale wave-guide is detailed in the Fig.1. The information of the control volume of the both unit cells are taken into account for modelling a lightweight, easy-to-manufacture metamaterial [12]. The on-board panel has a thickness of $2mm$ with an area of $35 \times 35 mm^2$. The resonator shape has a height of $17.5mm$ and a lateral and horizontal span of $30mm$. Cell A and cell B have two different shapes with approximated equal control volumes. The wall thickness of the cell A is $4.8mm$ and the circular hole in cell B has a radius of $8mm$.

Figure 1: Meso-scale unit cells of infinite periodic panels

Table 1: Material properties of the metamaterial

Material	Polymer
Modulus of elasticity(Pa)	2.32×10^9
Density ($\text{kg} \cdot \text{m}^{-3}$)	1050
Poisson's ratio	0.34

2.2 Finite structure

In the finite panel two perfectly periodic and two quasi-periodic structure are considered. In the last two models specific Thue-Morse sequences are used to generate impedance mismatches in the view of desired degree of quasi-periodicity. The degree of quasi-periodicity might be controlled with mathematical rules that are introduced in the next section.

2.2.1 Thue-Morse sequence

A Thue-Morse sequence is binary sequence (an infinite sequence of 0s and 1s). The sequence starts with 0 then 01, 0110, 01101001, and so on, [13]. For the simplicity, let us define the Thue-Morse morphism to be the function s from the set of binary sequences to itself by replicating every 0 in a sequence with 01 and every 1 with 10 [14]:

$$s(x, y) = s(x)s(y) \quad (1)$$

Eq.1 defines a map s for all strings x, y . Defining the Thue-Morse morphism $s(0) = 01, s(1) = 10$ leads to the relations for increasing the quasi-periodicity pattern in two directions:

$$\begin{aligned} s(0) &= 01 = AB \\ s^2(0) &= s(s(0)) = 0110 = ABBA \end{aligned}$$

$$s^3(0) = s(s(s(0))) = 01101001 = ABBABAAB$$

Each 0 and 1 represents cell A and cell B respectively. In the present finite element model only 8 combined unit cells are used, it means that the Thue-Morse morphism map stops at s^3 .

Two types of quasi-periodic finite panels are considered. The first one is a pure quasi-periodic panel (8×8 unit cells) and the second quasi-periodic panel is designed similar to the first one with an addition of two bare panels without resonators in the right and left sides of the quasi-periodic one. These two bare panels are used as an input zone in the left and output zone in the right side of filtering domain shown in Fig.2.

Figure 2: Quasi-periodic panel with the combination of cell A and B

2.2.2 Periodic sequence

The two periodic panels have a repetition of single cell A for first panel, and single cell B for second panel respectively with the dimensions of 8×8 shown in Fig.3. According to the Fig.3, the panel has a thickness of 2 mm, and the hollow resonator has a wall thickness of 4.8 mm.

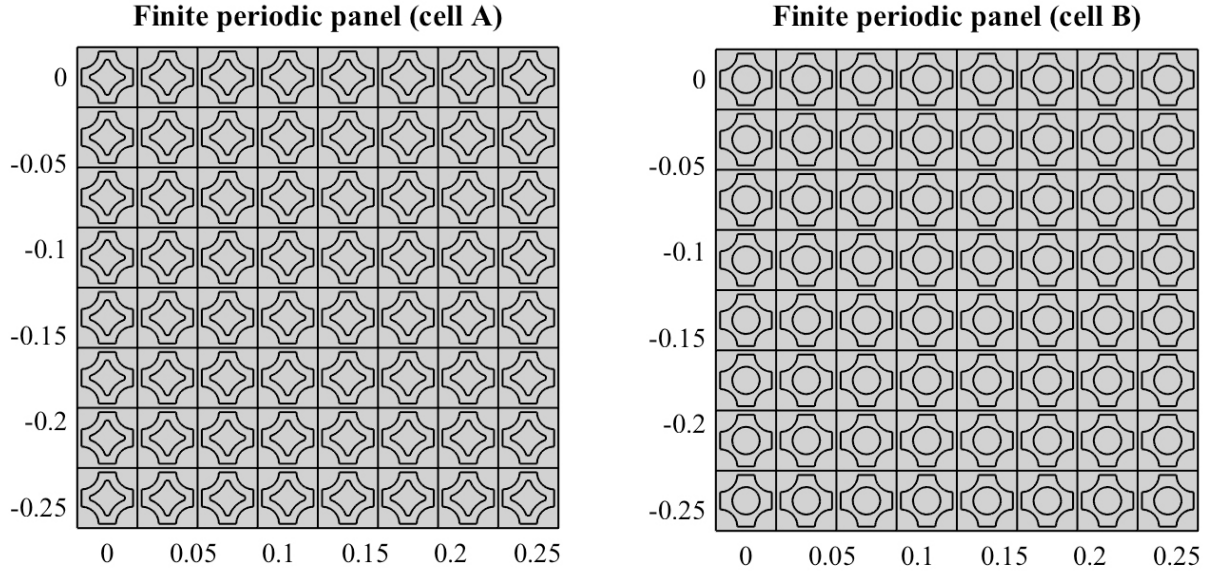

Figure 3: Two strictly periodic panels, left with cell A periodicity and right with cell B

3 STRUCTURAL DYNAMICS

3.1 Dispersion analysis

Classical FB method is used for the band diagram analysis of the strictly periodic infinite panel. The Floquet-periodicity is defined in the four side boundaries of the unit cell. The unit cell represents a bi-directional spatial periodicity in the given infinite structure. The band diagram is computed along the three symmetry directions of the first Brillouin zone shown in Fig. 4. Classical (FB) Floquet-Bloch theory is used as a periodic boundary condition using COMSOL Multiphysics for the analysis of dispersion curves. The periodicity boundary conditions in four sides of the lattice are

$$\mu_R = e^{-jk_x L} \mu_L \quad (2)$$

$$\mu_U = e^{-jk_y L} \mu_B \quad (3)$$

where, μ_R and μ_L are the displacement in the right and left side of the x axis and μ_U and μ_B are the displacement in the upper and bottom of the y axis. L is the length of reciprocal element, k_x and k_y are the wavenumbers in the x and y directions. Band diagrams are analysed by setting up eigensolver analysis as a parametric sweep using one parameter, k , which varies from 0 to π . The range of the k parameter spans three wave vectors starting from (A to R to S and back to A), covering the edges of the first irreducible Brillouin zone Fig. 4.

Two different unit cells are considered for the dispersion analysis. First cell A and second cell B. Both cells have commonalities in terms of mass, volume fraction, material and structural properties in order to be useful periodic tool to be compared with the quasi-periodic counter part. The results predicted by these two cells could lead to design a quasi-periodic lattice, which is a finite panel with a tailored irregularity that is invoked by Thue-Morse morphism deterministic approach. The results of the band diagram is plotted in Fig. 5 There are two complete frequency band gaps in each sub-figure. The first band gaps with small $\Delta\omega = 570$ Hz that represents the (resonance band gaps) following the larger Bragg

Figure 4: Diagram of the first irreducible Brillouin zone for a square lattice

band gaps $\Delta\omega = 2.9$ kHz around 11 kHz is predicted for the cell A. Cell B in the right hand side of the Fig.5 shows almost similar dispersion behaviour but with a wider resonance band gaps $\Delta\omega = 754$ Hz around 4 kHz and a slight wider Bragg band gaps 3.1kHz compared to cell A. According to a sensitivity analysis on both cells, the compromised wall thickness of the cell A = 4.8 mm and radius of the resonator shape cell B = 8 mm is selected to isolate the maximum vibration level.

Figure 5: Band diagram of infinite panels with a representative, left cell A and right cell B

3.2 Finite element analysis

In this part, four types of investigations, on periodic and quasi-periodic panels; specifically, the aim is to apply on a finite structure the results obtained with a infinite periodic sequence.

Fig. 6 show three curves; by focusing on the Bragg type band gaps zone, the blue curve with dash lines corresponds to the cell B. It has thinner stop band wide compared to the other curves and there is also a slight shift in the stop bands towards the higher frequencies compared to the two cell A and combined (A, B). Despite of that cell A has a shift of the same band gaps zone towards the lower frequency ranges. Paying attention to the dark green solid curve that corresponds to the combined cell A and cell B, it has wider band gaps compared to both blue dash curve and dotted orange curve almost around 10.5 – 14.2 kHz. Also it should be mentioned that in the velocity amplitude response it has the lowest pick in comparison of two other curves. The highest picks could be seen at around 8.25 kHz, and the orange has the highest pick with the amplitude of 20dB.

Figure 6: FRFs of three finite structures in terms of velocity amplitude in dB response

In conclusion of the first part, it could be predicted that the combination of two unit cells in finite quasi-periodic panel (8×8 unit cells) is a compromise model and it has impacts on the dynamic behaviour of panel compared to the two other strictly single periodic panels in terms of wide of band gaps and lower attenuation level.

In the second part of the finite element analysis, an FRF of the quasi-periodic structure with ($840 \times 280 \times 2 \text{ mm}^3$) is taken into account. This meta-structure shown in Fig.7 is made of three sub-parts. The middle part is a quasi-periodic panel of combined cell A and cell B and the two other parts in the left and right hand side bare panels with no resonators on it.

The panel has a cantilever constraint (fixed boundary condition) marked blue in Fig.7. A unit white spectrum force is applied to the input zone right left hand side bare panel (marked with red arrow) and the response is observed in terms of Root Mean Square (RMS) with the average node points in the input and output zones.

Figure 7: Geometry of meta-structure (filter)

Fig.8 shows FRF response in terms of velocity amplitude in dB. Practically, this type of panel is used as a junction filter between two bare panels. The induced vibration energy transfers through this junction, and it acts as a meta-material filtering property to the elastic waves due to the impedance mismatch in the shape of resonators embedded in the bare panels.

The FRF shows two types of curves, the blue one corresponds to the the average of the 64 nodes in the input zone, where all the elastic waves are confined in the zone and there is no sign of frequency stop bands. The orange curve corresponds to the response of the output zone. The frequency stop bands starts from 10.36 kHz and continues to 13.6 kHz. There are some picks around 12 kHz inside the band gap in shaded area. Three frequencies are chosen inside the shaded area and their operative modes or forced deflections are plotted in Fig. 9.

A similar procedure for the numerical modelling of filtering effects has been done in the paper of Billon et al [10]. They basically selected 4 points in the FRFs. Two points are located in the inside the predicted band gap and two outside the band gap. One point inside the band gap does not really reflects good response despite of being in the predicted band gaps. In fact, in the present FRFs only three points are considered, two of them are on the lower and upper bound of the band gaps and the third one is taken in the middle of the attenuation zone.

As it can be seen from the results in the paper of Billon et al [10], the average squared amplitude velocity around 43.3 kHz which is inside the predicted band gap zone, has visible deformed shapes over $-20dB$. In contrary, although there are some picks in the middle of band gap in the present result but they are bellow $-25dB$ with less deflections.

Figure 8: FRFs of the meta-structure in terms of RMS of velocity amplitude in dB

The operative modes in Fig.9 shows the deformation of the panel in 10.36 kHz, the start point of band gaps, 11.36 kHz middle of the band gaps, and 13.12 kHz almost at the finishing point of the band gaps. It can be seen that the panel has an efficient filtering effects by using quasi-periodic pattern.

Figure 9: Operative modes of the meta-structure with three selected frequencies in the upper, lower and middle position of the attenuation level

4 CONCLUSIONS

The first aspect is formulating fundamental procedures to design a quasi-periodic meta-structure using Thue-Morse morphism sequence. The second aspect is dedicated to analysis of the impact of this design in terms of dynamical behaviour. The results of FRFs and dispersion analysis shows that quasi-periodic pattern have impact on dynamic behaviour of panels, especially in terms of isolating unwanted vibrational behaviour all over the metamaterial part of the span, specifically inside the attenuation level.

In this analysis, the presented tailored irregularity, which in higher extent is a designed loss of periodicity in finite structure has influential access to extend the attenuation level to lower velocity amplitude-dB and slightly increase the wide of the band gaps. These impact came due to the impedance mismatch of the combined (resonators) embedded on the bare panel. There are some points to be highlighted in the below:

The quasi-periodicity (Thue-Morse morphism) in two directions shows lower frequency band gaps compared to the one direction ones like Fibonacci sequences. Quasi-periodic panel in the present article has an efficient impacts on the vibrational analysis compared to the single periodic panels. In general quasi-periodic pattern is capable of confining the energy in some modes, and in higher extends there are possibilities to shift those localised modes in desired frequency bands.

Abstract. Experimental vibroacoustic measurements are very common for the study of emitted noise reduction and vibration energy isolation of structures. The most important case is when structures are subjected to an aerodynamic excitation as Turbulent Boundary Layer (TBL). In this paper, a preliminary study is performed on the energy transmission between subsystems of a structure subjected to TBL. A numerical test is developed on a three-plates-in-row system at high frequencies, through the application of Statistical Energy Analysis (SEA). Parameters such as surface dimensions, thickness and damping loss factor are evaluated in different configurations for a first design of a testbench used for vibroacoustic measurements in a wind tunnel.

1 INTRODUCTION

In the aerospace engineering field, the study of vibroacoustic behaviour of complex structures is very popular as academic research, as well as for industrial purposes.

In fact, main topics are the emitted noise and the structural vibration of systems which are subjected to an aerodynamic excitation (i.e. Turbulent Boundary Layer, TBL), with the aim of guarantee a good comfort in terms of reduced emitted noise and isolation of structural vibration. Focusing the attention on the effect of a TBL at high flow speeds, it is important to have a relevant testbench, mounted in the wind tunnel that, for this specific excitation, can guarantee the quality and robustness of the measured experimental data. In other words, it is required that ideally no contamination effects, related to the impedance breaks between testbench and sample panel, affect the measurements.

For this reason, the decoupling of energy transmission between subsystems of a structure is the main topic of this paper. A similar work is done by Finnveden in [1,2]. The wind tunnel, at KTH laboratories, consists in a suspended flow duct in which an air flow is blown; the test panel is mounted on the wall of the above-mentioned duct. The validation of the wind tunnel,

which Finnveden [1,2] proposed through the application of the Statistical Energy Analysis (SEA), assumed that it is possible to consider the vibration of the test panel decoupled by the vibration of the flow duct.

In the present paper, a verification of the prior assumption is made, followed by a numerical procedure based only on SEA. The procedure uses the description of an aerodynamic excitation, such as TBL, as an equivalent “rain on the roof” excitation in the mid-high frequencies [3,4].

The following sections are organized in this order: first, the presentation of the adopted SEA method, second, the presentation of the Equivalent TBL model, and finally the presentation of results per categories: influence of surface, thickness and damping, respectively

2 STATISTICAL ENERGY ANALYSIS

Statistical Energy Analysis is based on the principle of energy balance between subsystems which are assumed to be linearly coupled. This energetic method has been studied and theorized by Lyon [5]. Among the assumptions thus theorized, it is considered the one for which the excitation spectrum is broadband, and the excitation forces are statistically independent: there are no pure tones in the input spectra.

The energy balance between two subsystems i and j can be expressed as

$$P_{in,j,i} = P_{diss,i} + (P_{ij} - P_{ji}) \quad (1)$$

$$P_{in,j,i} = \omega \eta_i E_i + \sum_{j=1}^2 \omega \eta_{ij} n_i \left(\frac{E_i}{n_i} - \frac{E_j}{n_j} \right) \quad (2)$$

where η_{ij} is the coupling loss factor (CLF), n_i is the modal density, E_i and E_j are the uncoupled total subsystem energies (Fig. 1).

Figure 1: Simple SEA system.

SEA affirms that power always flows from the subsystem which has a higher energy to the one having lower energy

$$P_{ij} = \omega (\eta_{ij} E_i - \eta_{ji} E_j) = \omega \eta_{ij} n_i \left(\frac{E_i}{n_i} - \frac{E_j}{n_j} \right) \quad (3)$$

$$\eta_{ij} n_i = \eta_{ji} n_j \quad (4)$$

For a complex structure, the relation between the injected powers and the modal energies can be written as follows

$$\begin{Bmatrix} P_{inj,1} \\ \vdots \\ P_{inj,s} \end{Bmatrix} = \omega \begin{bmatrix} \eta_1 n_1 + \sum_{j=1}^s \omega \eta_{1j} n_1 & \cdots & -\eta_{1s} n_1 \\ \vdots & \ddots & \vdots \\ -\eta_{s1} n_s & \cdots & \eta_s n_s + \sum_{j=1}^{s-1} \omega \eta_{sj} n_s \end{bmatrix} \begin{Bmatrix} E_{m,1} \\ \vdots \\ E_{m,s} \end{Bmatrix} \quad (5)$$

$$\{P_{inj}\} = \omega[L]\{E_m\} \quad (6)$$

The energy distribution inside the subsystems of a complex structure is the result of a simple algebraic matrixial equation in which it is needed to know only three parameters, which are the injected powers in terms of Power Spectral Densities (PSD), the modal densities and the CLFs.

However, SEA presents some limitations of applicability, defined by Mace in [6,7]. It is here mentioned the modal overlap factor

$$m(\omega) = \eta \omega n(\omega) \quad (7)$$

as instrument for SEA validity. If $m \gg 1$ for all subsystems of the structure, in fact, it can be said that it is possible to use SEA. The frequency for which the modal overlap factor is equal to unity, is the limit frequency for SEA validity.

3 EQUIVALENT TBL EXCITATION

With the aim of designing a testbench for vibroacoustic measurements in wind tunnel, it is necessary to describe the effect of an aerodynamic load as a TBL excitation. But, as mentioned in the previous section, the type of excitation applied to a structure in SEA method should be a broadband statistically independent excitation, such as ‘rain on the roof’ excitation (ROF). For this reason, the Equivalent TBL presented by Ichchou in [3] is considered.

Referring to the Corcos model described as

$$C(x - x', y - y'; \omega) = e^{-\delta_x |x - x'|} \cos(\gamma_x (x - x')) e^{-\delta_y |y - y'|} \quad (8.a)$$

$$\begin{cases} \gamma_x = \omega / U_c \\ \delta_{x,y} = a_{x,y} \gamma_x \end{cases} \quad (8.b)$$

where U_c is the convective speed and $a_{x,y}$ are empirical coefficients, it is possible to define the Equivalent TBL auto-spectrum (Eq. 10) in function of an equivalent correlation function $C^{eq}(\omega)$ (Eq. 9) and ROF auto-spectrum

$$C^{eq}(\omega) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} e^{-\delta_x |\zeta|} \cos(\gamma_x \zeta) e^{-\delta_y |\chi|} d\zeta d\chi = \frac{4\delta_x}{\delta_y (\delta_x^2 + \gamma_x^2)} \quad (9)$$

$$S_{pp}^{ETBL}(\omega) = C^{eq}(\omega) S_{pp}^{ROF}(\omega) = \frac{4\delta_x}{\delta_y (\delta_x^2 + \gamma_x^2)} S_{pp}^{ROF}(\omega) \quad (10)$$

In this way, it is possible to describe at high frequencies, the effect of an aerodynamic load on a structure as vibration levels, thanks to the application of Equivalent TBL (ETBL) excitation in a SEA approach.

4 NUMERICAL APPLICATIONS OF EQUIVALENT TBL (ETBL)

4.1 Generalities

Ref. [2] shows how to evaluate the modal density of a flow duct. Particularly at high frequencies, it has been observed that the dispersion curves of the flow duct follow the analytical thin-plate theory. At high frequencies, this means that it is possible to approximate a complex structure as an ensemble of thin plates.

According with this assumption, the energy transmission between a flow duct and a test panel can be described as an energy transmission among simple plates: the energy transmission between a testbench and a test panel can be also simplified as said before. Therefore, the preliminary study of energy transmission between three plate in a row (Fig. 3) is carried out.

Figure 2: Equivalent SEA model.

Three is the lowest number of plates that can be chosen for the first study of energy flow direction among subsystems: the energy transmission referred to a test panel would be analyzed between more than one interface.

The plates of equivalent SEA system (Fig. 2) have the characteristics described in Table 1.

Table 1: Geometry and physical properties of the plate.

Geometry: Plate	Material: Aluminium
$L_x = 1.5m$	$E = 7.1e10 Pa$
$L_y = 0.9m$	$\nu = 0.33$
$h = 5mm$	$\rho = 2500 kg/m^3$
	$\eta = 0.005 (0.5\%)$

The energy transmission analysis of the equivalent SEA system is organized as follows.

A first solution has been evaluated keeping all three plates with the same identical properties; the other solutions calculated for different configurations would be compared with this as reference case ('case 0'). The SEA frequency limit for this configuration is 2500Hz. The first comparison is in function of difference of surface: the middle plate – which represents the test

panel – would have a reduced length $L_x = 0.5m$, having a consequential reduction of surface of 33% respect to the side plates surfaces.

The second comparison is in function of difference of thickness: the middle plate would have a reduced thickness $h = 1mm$, 1/5 of the side plates thickness.

The third and last comparison is in function of the damping loss factor: the side plates would present an increase of damping from 0.5% to 7%.

All the cases described above will be compared with ‘case 0’ in terms of: (i) Vibration velocity levels S_{VV} , in order to obtain a velocity gap between middle plate and side plates of at least 20 dB; (ii) Powers levels which act on subsystem ‘plate 2’, in order to understand how the energy spreads inside the system. The power levels are not presented as absolute values, but as ratio with the injected power on ‘plate 2’.

4.2 SEA Test-Cases

4.2.1 Surfaces

As first case, the length of middle plate is reduced from the initial value $L_x = 1.5m$ to $L_x = 0.5m$, as mentioned above. The reduction of surface applied at the middle plate changes its modal overlap factor and, consequently, increases the value of SEA frequency to ≈ 7000 Hz. The velocity gap obtained for a surface reduction of 33% is only of 6 dB (Fig. 3), which is too low for an energy isolation of the middle plate in terms of vibration velocity.

Figure 3: Vibration velocities of three plate in row subjected to an Equivalent TBL: same properties (-), subsystem ‘plate 2’ with $L_x = 0.5m$ (--).

The consequences of surface reduction of the middle plate can be seen in Fig. 4: the dissipated power, $P_{diss,2} = \omega \eta_2 E_2 = f[\langle v_2 \rangle^2]$, of ‘plate 2’ has reduced, while the transmitted energy of side plates has increased. This is not an acceptable configuration, because the aim is the reduction of the transmitted power from the other subsystems to the test panel, not the

opposite.

Figure 4: Difference of powers calculated in function of injected power acting on the subsystem 'plate 2': same properties (-), subsystem 'plate 2' with $L_x = 0.5m$ (--).

4.2.2 Thicknesses

In this second configuration, the middle panel had a reduction of thickness from $h = 5mm$ to $h = 1mm$. With this change of thickness, the modal overlap factor of the middle plate leads to a wider frequency range in which the SEA method is valid. But, because it must be considered the modal overlap factors of all the subsystems, the SEA frequency limit still remains over 2500Hz. The reduction of thickness leads also to a velocity gap between the middle plate and the side plates of 20 dB and more (Fig. 5), which can ensure an energy isolation of the middle plate from the side plates.

Observing Fig. 6, it is possible to notice that the dissipated power of 'plate 2' reaches almost the same value of the injected power; this could mean that the energy flows inside the middle plate and then it is directly dissipated without almost any transmission to the near subsystems. Moreover, the values of the transmitted energy by side plates is consistently reduced, which could mean that the velocity response of the middle plate it is a direct effect of the TBL.

Hence, it can be said that a change of thickness can ensure the energy isolation of a test panel from its testbench.

4.2.3 Damping loss factors

The last comparison refers to a change of damping loss factor; this has been increased in side plates, to see the effect of energy transmission between a high damped subsystem with a low damped subsystem. The increase of damping loss factor in a subsystem has a direct effect on the modal overlap factor, which even this time ensures a wider frequency range of SEA validity. But, because the modal overlap factor of the middle plate must be considered too, the SEA frequency limit still remains 2500 Hz.

In Fig. 7, a velocity gap of nearly 4 dB is shown. While the vibration velocity of the middle plate remains the same, the side plates present a reduction of vibration velocity. Considering the case of the testbench, it means that a damped frame system does not ensure a huge difference of vibration velocities between itself and the test panel. On the other hand, it is shown in Fig. 8 that an increase of damping loss factor in the side plates ensures a reduction of transmitted energy from them to the middle plate. As expected, the dissipated power of ‘plate 2’ seems not changed.

Figure 5: Vibration velocities of three plate in row subjected to an Equivalent TBL: same properties (-), subsystem ‘plate 2’ with $h = 1mm$ (--).

Figure 6: Difference of powers calculated in function of injected power acting on the subsystem ‘plate 2’: same properties (-), subsystem ‘plate 2’ with $t = 2.5mm$ (--).

Figure 7: Vibration velocities of three plate in row subjected to an Equivalent TBL: same properties (-), subsystems 'plate 1' and 'plate 3' with $\eta = 0.07$ (7%) (--).

Figure 8: Difference of powers calculated in function of injected power acting on the subsystem 'plate 2': same properties (-), subsystems 'plate 1' and 'plate 3' with $\eta = 0.07$ (7%) (--).

5 CONCLUSIONS

From the above numerical tests based on SEA, it can be seen that there are different ways of changing the energy transmission between subsystems of a structure. Reducing the surface of the middle plate does not ensure its energetic isolation, but it implies only an increase of the energy transmission from the side plates to the middle one. On the other hand, the reduction of thickness is the best solution for a large velocity gap between the subsystems; in fact, the change

of thickness influences directly the impedance values of the subsystems, which consequently alters the way the energy is transmitted. Finally, modifying the damping loss factor only leads to a reduction of the transmitted energy; it could be taken in consideration as final option for the optimization of the structure in terms of energy isolation of the test panel.

This is only a preliminary study which can be conducted for a first design of a testbench. As following step, it is necessary to consider the indirect energy transmission between subsystems which are not physically connected each other. This second test can be carried on through the utilization of SEA-like method, which not only is able to estimate the indirect CLF, but it can also extend the study of energy transmission in the middle frequency range.

Abstract. *The exploitation of non-trivial topological properties of band structures in Phononic Crystals has recently proved to be a proficient way to obtain robust waveguides showing immunity to backscattering at defects and capability to overcome sharp bends without reflections. This manuscript shows how it is possible to design an elastic waveguide that exploits the promising features of topological protection and at the same time achieves reconfigurability in the path followed by the carried signal. This is accomplished by integration in the structure of piezoelectric smart devices with negative capacitance shunting circuits. Moreover, the design of a mechanism to switch between different edge channels to convey at need elastic energy to distinct points of the structure is presented.*

1 INTRODUCTION

The design of engineered periodic lattices has become of great interest during the past decades as a means to obtain wave propagation control in elastic structures [1]. The exploitation of Bragg scattering at periodic discontinuities or the use of patterns of resonators are now established ways to shape phononic dispersion branches. In this context, the opportunity to observe and take advantage of topological phases in elastic systems has recently driven a growing interest to the subject. Such topological properties were firstly introduced in quantum systems of condensed matter [2, 3, 4] and have quickly spread to other fields of studies such as optics [5] and acoustics [6, 7] for the new promising ways of wave manipulation they offer. Indeed, the systematic study of the geometrical properties of band structures is now a powerful tool to predict the occurrence of efficient energy transport showing certain degree of immunity to backscattering. As a matter of fact, each topological phase can be indexed by a topological invariant. Moreover, the bulk-edge correspondence principle ensures that at the shared edge between two distinct phases a number of topologically protected states equal to the difference of their topological invariants will occur. In particular, in the following we will consider periodic mechanical structures establishing analogy with the quantum valley Hall effect (QVHE). This phenomenon can be obtained exploiting the valley degree of freedom as a pseudospin, given that inter-valley scattering is suppressed. Valley Hall phases have been successfully observed both in discrete mechanical lattices [8, 9, 10], and in continuum periodic structures [11, 12, 13]. A profitable way to obtain such Valley edge states is to lift the Dirac degeneracy occurring in Kagome lattices by break of spatial inversion symmetry (SIS). Exploiting

this design procedure, the aim of this paper is to show how it is possible to combine the unique features of topologically protected edge waves with adaptivity, achieved introducing piezoelectric inserts in the unit cell. Indeed, such patches are adopted to locally alter the stiffness of the unitary elements, using series negative capacitance shunting circuits [14, 15, 16]. In this way, the designed elastic structure is capable to route elastic energy along different paths, in addition to showing all the interesting features of topological protection. The manuscript is organized as follows: in the second section the design of the unit cell of the proposed structure is discussed. The occurrence of a topological phase transition when the elastic properties of the unit cell are smoothly changed by use of the shunting circuits is also underlined. In section 3 an analysis of the edge states occurring at interfaces created between topologically distinct lattices is performed. The design of a quantum point-like device capable of redirecting elastic energy in different directions is also added. Conclusions are drawn in the last section.

2 UNIT CELL ANALYSIS

A sketch of the Kagome geometry is provided in Figure 1(a) along with the selected unit cell of direct lattice and a drawing of its Brillouin zone. In its discrete version it can be obtained joining lumped masses with linear springs. By lowering the symmetries of the lattice it is known that the Dirac degeneracy occurring at K/K' points can be lifted and a topological bandgap opened [8]. This can be done by alternating soft and stiff springs as highlighted with different colors in Figure 1(a). This consideration provides the guidelines for the design of the unit cell that is employed in the following to realize the tunable waveguide.

Figure 1: 1(a): Spring-mass discrete Kagome lattice, unit cell and Brillouin Zone. 1(b): Sketch of the continuum implementation of the tunable unit cell. Scheme of synthetic negative capacitance shunting circuit.

A schematic of such unit cell is shown in Figure 1(b): it is made by an Aluminum substrate and comprises three circular mass-elements connected by beam-elements acting as springs. Piezoelectric

Physical prop.	Substrate	PZT-5A	Geometrical prop.	
E	70 MPa	61.9 MPa	d	27.5 mm
ν	0.33	0.33	L	23 mm
ρ	2700 kg/m ³	7750 kg/m ³	$w = t$	6 mm
k_{31}		0.34	a	100 mm
ϵ_{33}^s		$13.3 \cdot 10^{-9}$ F/m	$h_s = h_p$	1 mm

Table 1: Unit cell physical and geometrical properties.

 Figure 2: Dispersion diagram for Kagome lattice: $\beta = 0$ (Left), $\beta = \pm 0.14$ (right).

patches are attached on both sides of the connecting elements, resulting in a bimorph configuration: h_s and h_p are the substrate and piezo thickness respectively (see Table 1 for all physical and geometric properties). Each patch is connected to a series negative capacitance shunting circuit. The resulting effective elastic modulus reads as [15, 16]:

$$E_p^{E*} = E_p^E \left(\frac{C_N - C_p^T}{C_N - C_p^S} \right) \quad (1)$$

considering E_p^E as the Young's Modulus at constant electric field and C_n the *negative capacitance* (NC) value. $C_p^{T,S}$ are the equivalent capacitance under free and blocked conditions, respectively:

$$C_p^T = \epsilon_{33}^T \frac{A}{h_p} \quad C_p^S = \epsilon_{33}^S \frac{A}{h_p} \quad (2)$$

being A the surface of the piezo patch and h_p its thickness. The piezoelectric coupling coefficient k_{31} relates ϵ_{33}^T and ϵ_{33}^S :

$$\epsilon_{33}^T = \frac{\epsilon_{33}^S}{(1 - k_{31}^2)} \quad (3)$$

The equivalent properties of the sandwich are obtained by the nominal ones of its sub-elements:

$$E_{eq} = \delta E_p^{E*} + (1 - \delta)E \quad \rho_{eq} = \delta \rho_p + (1 - \delta)\rho \quad (4)$$

with $\delta = \frac{2h_p}{h_s} = \frac{2}{3}$. Positive and negative modulation of the equivalent stiffness of the beam elements are

Figure 3: Band structure evaluated for the super cell depicted in Figure 4. Gap-less states are highlighted with different colors: red one appears at a Hard (H) interface, yellow ones a Soft (S) interface

achieved upon the application of a negative capacitance such as:

$$\frac{C_N}{C_P^T} = 1.25(1 \pm \beta) \quad (5)$$

where the constant 1.25 is required for stability reasons [15]. The value of β is tailored to obtain alternate soft and stiff spring elements, in analogy with the discrete case [8]. In particular, $+\beta$ is used for the three internal beams, and $-\beta$ for the remaining three. Figure 2 shows the dispersion diagram of the unit cell along the irreducible Brillouin zone, for $\beta = 0$. When no bias in the stiffness of the connecting elements is introduced, a degeneracy can be observed between the eighth and ninth branches at the high symmetry point K. Switching from $\beta = 0$ to $\beta = \pm 0.14$, a bandgap is opened between approximately 16 and 17 KHz, as a consequence of SIS break. In particular, the same stop band is obtained for $\beta = \pm 0.14$: despite representing two different unit cells (one has three internal soft springs, the other has three internal stiff springs) when repeated in infinite patterns the two lattices cannot be distinguished. Nevertheless, the band structures for $\beta > 0$ and $\beta < 0$ show different topological invariants: lattices with positive value of β cannot be smoothly deformed in ones with negative β without band-gap closing and reopening at $\beta = 0$. This witnesses the occurrence of a topological phase transition [8, 9]. That is, adjusting the value of the negative capacitance by switching from $\beta > 0$ to $\beta < 0$ causes the topological order of the structure to be changed.

3 TUNABLE TOPOLOGICALLY PROTECTED WAVEGUIDE

Figure 4: Finite strip made of 15 unit cell of type A followed by 15 B type elements. A so called Hard (H) interface is created in the middle: two hard connectors (highlighted in red) are facing at the discontinuity.

According to the bulk-edge correspondence principle, localized edge states are expected to occur at the interface between topologically distinct lattices having $\beta = \pm 0.14$. To observe their occurrence, a ribbon is made by $N_1 = 15$ unit cells with $\beta = 0.14$ (type A) and $N_2 = 15$ ones characterized by $\beta = -0.14$ (type B). This means that two halves built with different topological phases are joined together. If A-type unit cells are followed in the strip by B ones, a domain wall (DW) is created comprising two subsequent

Figure 5: Figure 5(a): Frequency response function evaluated when two edge channels are kept apart. Seven rows of A type unit cells constitute the slice. Loading point is indicated with a red dot. K and K' -polarized modes are indicated with arrows. Figure 5(b): Energy is transferred between upper and lower edge channels if the number of rows in the slice is reduced.

stiff elements (Figure 4). A second kind of DW can be created reversing the order of the unit cells in the ribbon. This latter will be called S interface, consisting of two consequent soft connectors, while the former type will be indicated as H (hard) interface. The dispersion analysis of the super-cell is conducted letting the wave-vector vary between $\kappa_x \in [0, \pi/a]$. The resulting band structure is depicted in Figure 3. S-interface state is represented by the continuous yellow curve, while the red one describes the H-interface mode. In accordance with the bulk-edge correspondence principle, only one mode is obtained at each valley for each type of DW, being each phase indexed by a Valley Chern number $C_v = \pm 1/2$ [8]. Moreover, as long as inter-valley scattering is forbidden, forward and backward propagating modes cannot couple. This makes the topological waves protected against backscattering. As a consequence, the interface created facing two distinct phases constitutes an ideally perfect waveguide. It is worth noticing that the shape of such waveguide only depends on the spatial arrangement of A and B-type of unit cells inside the structure. Adaptivity is thus achieved considering that a topological phase transition from A cells to B ones and vice-versa can be induced manipulating the shunting circuits, upon variation of the parameter β which defines the value of the negative capacitance [16].

An interesting way to exploit such adaptivity is to design switch mechanisms in analogy with the quantum point-like devices developed in the context of QSHE [17]. Indeed, the coupling between topological states at different DWs can be exploited to switch edge channel. Consider a narrow bar made by A units surrounded at both sides by B elements: an H interface is obtained above such slice, while an S one is produced below (Figure 5(a)). On the former interface, the K polarized state is characterized by positive group velocity (forward propagation), while it exhibits negative group velocity on the other edge channel (backward propagation, see red arrows in Figure 5(a)). Upon tuning of the NC value inside the narrow slice, its width can be reduced or increased by inducing a phase transition of rows of unit cells. Until the width of the point contact is sufficiently opened, the two edge channels cannot couple, thus if excitation is applied to the H domain wall the forward propagating wave can reach the other end of the structure (Figure 5(a)). On contrast, a reduction of the width of the slice induces the forward state propagating on a DW to couple with the one which possesses the same valley index on the other, and the elastic signal is stirred back to the same side of the device (Figure 5(b)). In this way a switch is obtained between two possible paths, involving a reduced number of unit cells which need to be adjusted.

4 CONCLUSIONS

In this manuscript the design of a tunable topological waveguide was discussed. Adopting piezo-electric inserts it was possible to obtain semi-active control on the stiffness properties of the unit cell of the Kagome lattice, thus giving the opportunity to switch a topological phase into another at need. This allows to re-shape the interface constituting the waveguide itself. An example of switch mechanism between edge channels that exploits valley coupling was also shown, in analogy with quantum point-like structures.

Key words: vibroacoustics, periodic structure, shift cell, foam, inclusion

Abstract: The main advantage of designing sound packages with periodic arrangements is that they can provide a combination of absorption effects, resonance effects and wave interferences effects. This offers different applications in transportation (aeronautics, space, automotive, railway), energy and civil engineering sectors, where both weight and space, as well as vibroacoustic quality of performance and comfort, still remain as critical issues. The application of shift cell technique is presented and discussed for periodic porous media described with equivalent fluid models: it consists in a reformulation of classical Floquet-Bloch (F-B) conditions, whose major advantage stands in allowing the introduction of any frequency dependence of porous material behavior, through the resolution a quadratic eigenvalue problem, providing an efficient way to compute the dispersion curves of a porous material modelled as an equivalent fluid. The central part of this work shows the results, in terms of absorption coefficient and transmission loss curves, obtained through a numerical test campaign involving different melamine and polyurethane foams. The 48 test cases involve a cubic unit cell of porous material with a cylindrical inclusion. Furthermore, some absorption coefficient and transmission loss comparisons are shown, between a homogeneous unit cell and a unit cell with a perfectly rigid inclusion; the comparisons are carried out at fixed dimensions, then at fixed mass and then at fixed performance in the periodicity peak range. The results clearly point out the advantage of designing foam layer with periodic inclusion patterns in order to improve the performances in a specific range of frequencies, allowing a save both in terms of thickness and, most of all, mass, respect to a classical homogeneous foam layer.

1 INTRODUCTION

The inclusion of vibroacoustic treatments at early stage of product development, through the use of porous media with periodic inclusions, is a powerful strategy for the achievement of lightweight sound packages and represents a convenient solution for manufacturing aspects.

Indeed, although porous materials are commonly used for vibroacoustic applications, they suffer from a lack of absorption at low frequencies compared to their efficiency at higher ones; this difficulty is usually overcome by multi-layering [1]. However, while reducing the

impedance mismatch at the air-material interface, the efficiency of such devices relies on the allowable thickness [2].

A more efficient way to enhance the low frequency performances of sound packages consists in embedding periodic inclusions in a porous layer [3] in order to create wave interferences or resonance effects that may play a positive role in the dynamics of the system.

The classical approach, known as Floquet-Bloch (F-B) theory, provides a strategy to analyze the behavior of systems with a periodic structure.

In layered systems, due to the heterogeneity of the relevant elastic properties or to particular geometric features, or to both, only certain wave modes can physically propagate inside the structure. Each of these modes can be identified by a determined (generally nonlinear) function relating the time frequency and the spatial frequency (or wave number). These relationships are called dispersion curves and they summarize all the dynamic behavior of the system [4]. Therefore, dispersion curves offer a better perspective to explain the wave field behavior inside bodies.

For instance, the Helmholtz equation is a known example of equation describing the spatial behavior: there, the physical periodic structure of the studied object translates into spatial periodicity of its coefficients. Therefore, the F-B theory can be applied to obtain the dispersive properties of different mechanical periodic systems, reducing the problem to the calculations performed in the so-called unit cell under to certain specific boundary conditions derived from the F-B theory itself [5].

In order to develop efficient numerical techniques to handle the problem, the shift cell operator technique is presented. It allows the description of the propagation of all existing waves from the description of the unit cell through the resolution of a quadratic eigenvalue problem, in which the phase shift of the boundary conditions related to wave propagation is integrated into the partial derivative operator; consequently, the periodicity is included in the overall behavior of the structure, while continuity conditions are imposed at the edges of the unit cell. This is done through a $k(\omega)$ (wave number as a function of the angular frequency) method, which allows computing dispersion curves for frequency-dependent problems; instead of using the classical $\omega(k)$ (angular frequency as a function of wave number) that leads to non-linear eigenvalue problems.

Similar techniques, which use a modified F-B approach in order to handle a $k(\omega)$ problem, can be found in literature ([6]–[8]). The main reason why the shift cell method differs from them is that it consists in a reformulation of classical F-B conditions, in which the phase shift of the boundary conditions related to wave propagation is integrated into the partial derivative operator; consequently, the periodicity is included in the overall behavior of the structure, while continuity conditions are imposed at the edges of the unit cell. This technique has been successfully applied for describing the mechanical behavior of periodic structures embedding visco-elastic materials ([9], [10]) or piezoelectric materials [11]. Here it is proposed an extension to equivalent fluid models: this makes possible to overcome the limits of existing approaches by a more specific design of the system, through a process of optimization and testing of different inclusions, in order to obtain a device whose frequency efficiency outperforms existing designs.

The behavior of the porous materials is described by Johnson-Champoux-Allard (JCA) model ([12], [13]) in the following sections, but one can identically use any other equivalent fluid model ([14]–[16]).

2 SHIFT CELL OPERATOR TECHNIQUE

In this paper, a periodic arrangement of porous materials is considered. For a more detailed discussion, one can refer to [17]. The behavior of each material is described by an equivalent fluid model in the frequency domain, i.e.:

$$\rho \frac{\omega^2}{K} p + \Delta p = 0, \quad (1)$$

where $p = p(\mathbf{x}, \omega)$ is the acoustic pressure, $\mathbf{x} = (x, y, z)$ is the coordinate vector, ω is the angular frequency, $\rho = \rho(\mathbf{x}, \omega)$ is the equivalent fluid density and $K = K(\mathbf{x}, \omega)$ is the bulk modulus [18]. The periodicity is described by $\rho(\mathbf{x} + \mathbf{r}\mathbf{n}) = \rho(\mathbf{x})$ and $K(\mathbf{x} + \mathbf{r}\mathbf{n}) = K(\mathbf{x})$, $\forall \mathbf{x} \in \Omega$, where \mathbf{n} is a vector of integers normal to the face considered, $\mathbf{r} = (\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3)$ is a matrix containing the three vectors defining the cell periodicity directions and lengths, and Ω is the domain of interest.

For the purpose of the shift cell technique development, considering Eq. 1 and applying the Bloch theorem such as $p(\mathbf{x}, \omega) = p(\mathbf{x})e^{j\mathbf{k}\mathbf{x}}$, where \mathbf{k} , for a 3D application, is

$$\mathbf{k} = k \begin{pmatrix} \cos\theta\cos\phi \\ \cos\theta\sin\phi \\ \sin\theta \end{pmatrix} \quad (2)$$

one can obtain

$$\rho \frac{\omega^2}{K} p + (\nabla + j\mathbf{k})^T (\nabla + j\mathbf{k}) p = 0. \quad (3)$$

$p(\mathbf{x})$ being periodic, the Dirichlet boundary conditions imply $p(L) = p(0)$.

Figure 1: Reciprocal lattice vector in a 3D unitary cell.

2.1. Weak formulation

The aim of this section is the development of the weak formulation of the problem, in order to obtain a matrix equation that fully describes what happens inside a periodic unit cell of equivalent fluid. A weak formulation of Eq. (3) consists in finding p such that $\forall \tilde{p}$, which obeys to the periodic boundary conditions, one has:

$$\begin{aligned} \omega^2 \int_{\Omega} \frac{1}{K} \tilde{p} p \, d\Omega + \int_{\Omega} \frac{1}{\rho} \tilde{p} \nabla^T \nabla p \, d\Omega + j\mathbf{k} \int_{\Omega} \frac{1}{\rho} \tilde{p} \nabla^T p \, d\Omega + \\ + j\mathbf{k}^T \int_{\Omega} \frac{1}{\rho} \tilde{p} \nabla p \, d\Omega - k^T \mathbf{k} \int_{\Omega} \frac{1}{\rho} \tilde{p} p \, d\Omega = 0. \end{aligned} \quad (4)$$

After several passages, considering that $\boldsymbol{\varphi}$ is the eigenvector, the equation can be written in its matrix form

$$(\mathbf{K} + j\mathbf{k}\mathbf{L} + k^2\mathbf{H} - \omega^2\mathbf{M})\boldsymbol{\varphi} = \mathbf{0} \quad (5)$$

with the following matrices:

- $\mathbf{K} \propto \int_{\Omega} \frac{1}{\rho} \nabla \tilde{p} \nabla p \, d\Omega;$
- $\mathbf{L} \propto \int_{\Omega} \frac{1}{\rho} (\nabla \tilde{p} p - \tilde{p} \nabla p) \, d\Omega;$
- $\mathbf{H} \propto \int_{\Omega} \frac{1}{\rho} \tilde{p} p \, d\Omega;$
- $\mathbf{M} \propto \int_{\Omega} \frac{1}{K} \tilde{p} p \, d\Omega.$

Here, \mathbf{M} and \mathbf{K} are respectively the standard symmetric definite mass and symmetric semi-definite stiffness matrices, \mathbf{L} is a skew-symmetric matrix and \mathbf{H} is a symmetric semi-definite positive matrix. In this formulation, all matrices are frequency dependent.

3 NON-RIGID INCLUSIONS NUMERICAL TEST CAMPAIGN

Herein, all results are related to a 3D unit cell constituted by a cube with side equal to 2 cm (homogeneous case) and with a 0.5 cm radius cylindrical inclusion (cases with inclusion).

The analyses are carried out in the frequency range 0–17000 Hz. It is well known that the parameters of the equivalent fluid models can have a strong impact on the performances of the acoustic device [19], hence they should be determined in a confident way.

In the current case, the characteristics of the materials called “Melamine” and “Black PU” are experimentally determined, while those of the materials called “P1” and “M10” are taken from the work performed by Doutres et al. [20] and those related to “Melamine 173” and “P60” from a paper by Deckers et al. [21]. Except for the “Melamine” and “Melamine 173” materials, all the others are polyurethane foams. While dispersion curves are computed for an infinite repetition of unit cells, absorption coefficient and transmission loss are calculated for a finite repetition of five unit cells, using the same domain and boundary conditions of the infinite periodic system. This, in a first approximation, allows comparing the dispersion relations and the acoustical characteristics of the equivalent finite medium. Indeed, it has been noted that a further increasing in the number of repeated cells would lead to a change in the mean value of absorption coefficient and transmission loss respectively below 2% and 20% compared to the usage of a repetition of five unit cells.

The general definition of the sound absorption coefficient is the fraction of incident energy propagating into a sample material versus the energy propagating out. A part of the incident energy will be absorbed into the sample material, or rather dissipated inside it. The absorption coefficient α can be computed starting from the reflection coefficient R as

$$\alpha = 1 - |R|^2, \quad (16)$$

where R depends on the surface impedance Z_s . The surface impedance of the material is often presented in real and imaginary terms respectively; the real part describes the energy losses whereas the imaginary part describes the phase changes caused by the material [22]:

$$Z_s = \frac{p(L)}{v(L)} = Z_0 \frac{1+R}{1-R}. \quad (6)$$

This technique is only valid for plane waves impinging upon homogeneous media, and just at low frequencies for non-homogeneous ones. In a more general way, that is always correct, the absorption coefficient can be computed as [23]

$$\alpha = \frac{\Pi_{dissipated}}{\Pi_{incident}} \quad (7)$$

where

$$\Pi_{dissipated} = \Pi_{thermal} + \Pi_{viscous} \quad (8)$$

The terms can be expressed as [23]

$$\Pi_{incident} = \frac{S|p_{inc}|^2}{2\rho_0 c_0}, \quad (9)$$

$$\Pi_{thermal} = \frac{1}{2} \Im \left(-\omega \int_{\Omega_p} \frac{\phi^2}{K} p p^* d\Omega \right), \quad (10)$$

$$\Pi_{viscous} = \frac{1}{2} \Im \left(\int_{\Omega_p} \frac{\phi^2}{\omega \bar{\rho}_{22}} \underline{\nabla} p \cdot \underline{\nabla} p^* d\Omega \right), \quad (11)$$

where

- S = surface interested by incident pressure;
- p_{inc} = amplitude of the excitation mode (incident pressure);
- ρ_0 = density of the interstitial fluid (air);
- c_0 = sound speed in the interstitial fluid (air);
- Ω = poro-elastic volume;
- $p^* = conj(p)$;
- $\underline{\nabla}$ operator = gradient.

The transmission loss is numerically computed as

$$TL = 10 \log_{10} \frac{\Pi_{incident}}{\Pi_{transmitted}} \quad (12)$$

where $\Pi_{incident}$ and $\Pi_{transmitted}$ represent the incident and transmitted power, respectively.

Table 1: Non-acoustic parameters of the foams used for the numerical test campaign.

	Porosity	Tortuosity	Resistivity [Pa*s/m ²]	Viscous characteristic length [mm]	Thermal characteristic length [mm]
Melamine	0.99	1.02	8430	0.138	0.154
P1	0.956	1.06	3490	0.187	0.250
Black PU	0.96	1.075	5815	0.102	0.269
M10	0.982	1.25	3670	0.240	0.310
Mel. 173	0.98	1.01	9500	0.166	0.249
P60	0.98	1.17	3750	0.110	0.742

These values are obtained using an implementation of the plane wave forced response of the periodic cell accounting for fluid loading [24]. For a plane wave configuration, the value computed through Eq. (12) for homogeneous flat configurations is equivalent to the one obtained with the Transfer Matrix Method [1]:

$$TL = 10 \log \left(\frac{1}{4} \left| T_{11} + \frac{T_{12}}{\rho_0 c_0} + \rho_0 c_0 T_{21} + T_{22} \right|^2 \right), \quad (13)$$

$$\text{with } \begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix} = \begin{bmatrix} \cos(kd) & j \sin(kd) Z_0 \\ \frac{j \sin(kd)}{Z_0} & \cos(kd) \end{bmatrix}. \quad (14)$$

3.1. Results

The JCA-modeled 3D unit cell that is described in the previous sections can be tested with some perfectly rigid and non-rigid inclusions. In particular, 48 setups are discussed here (Table 2), whose fundamental parameters are reported in Table 1.

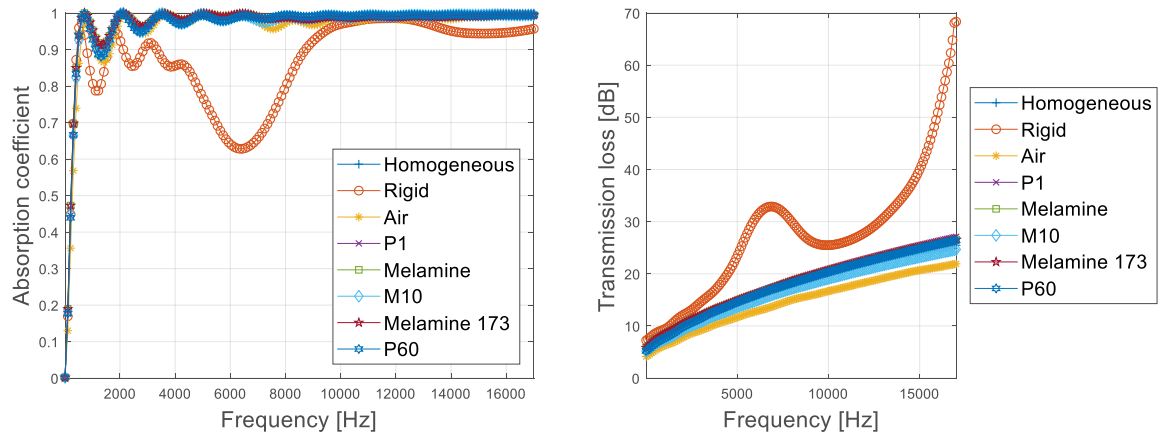

Figure 4: Comparison between absorption coefficient (on the left) and TL (on the right) curves for cases 17-24.

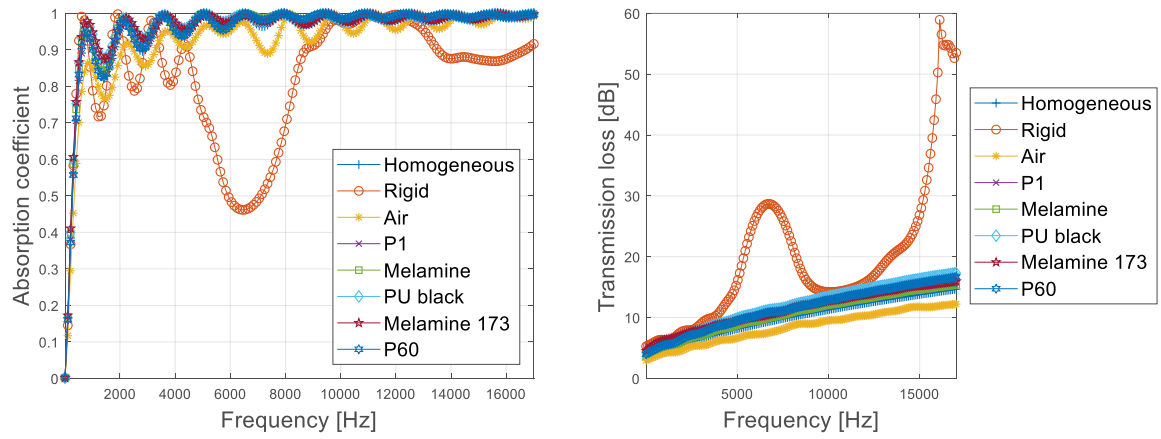

Figure 5: Comparison between absorption coefficient (on the left) and TL (on the right) curves for cases 25-32.

Figure 6: Comparison between absorption coefficient (on the left) and TL (on the right) curves for cases 33-40.

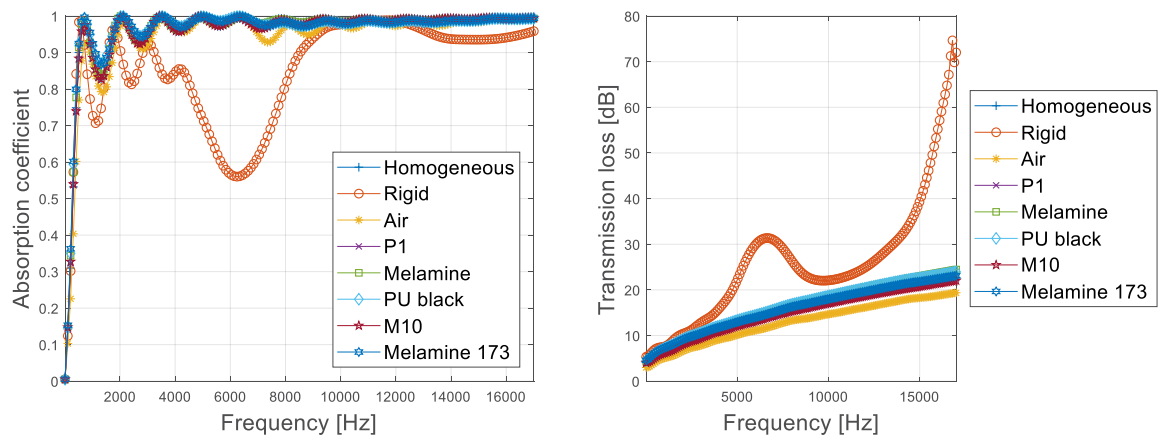

Figure 7: Comparison between absorption coefficient (on the left) and TL (on the right) curves for cases 41-48.

In Figures 2-7, some comparative absorption coefficient and transmission loss plots are shown for each of the 48 cases of study: in particular, each of the six foams is tested using eight different inclusions, according to the combinations reported in Table 2.

It can be noticed that, for what concerns the transmission loss, the effect of the inclusion is not particularly advantageous in these situations: in the case of the air, indeed, there is a drop of performances at all frequencies while, in the case of a foam inclusion, only a slight change of the values can be seen, as well as a very small effect of the periodicity when this is equal to half of the wavelength (around 7000 Hz).

Anyway, some different cases, that may be more interesting from the practical point of view, can be studied by modelling the foam unit cell through the use of the Biot model [25], instead that as an equivalent fluid; doing so, indeed, allows to take into account the elasticity of the skeleton and the entire problem formulation depends not anymore only on the pressure, but on the skeleton displacements too: this means that it should be possible to properly write the coupling conditions between the foam and an eventual (non-perfectly rigid) solid inclusion.

4 COMPARISON OF ACOUSTIC PERFORMANCES BETWEEN A HOMOGENEOUS UNIT CELL AND AN UNIT CELL WITH INCLUSION WITH FIXED MASS

In the previous sections, all the comparisons between homogeneous cases and cases with inclusions are made considering unit cells with the same dimensions; in other words, it means that the performances of a layer with periodic inclusions are estimated assuming that it has the same thickness of the related homogeneous one.

One may want also to compare absorption coefficient and transmission loss plots for the case in which the unit cell with inclusion has the same mass (and therefore different dimensions) respect to the homogeneous one. For example, considering an unit cell made of Melamine and with a perfectly rigid inclusion (Configuration 2 of Table 2), when comparing it to the homogeneous case with fixed dimensions, it obviously has a lower mass (75.56% of the homogeneous unit cell value); therefore, in order to perform a comparison with fixed mass respect to the homogeneous case, one should increase each dimension of the unit cell with inclusion of a certain quantity that, for the specific case, is equal to the 7.56%.

At this point, making some considerations based on the results shown in Figures 8 and 9, one may notice that the curve with fixed mass, respect to the one with fixed dimensions, has a performance peak caused by periodicity effect that is shifted at lower frequencies (this is due to the different dimensions between the two cases with inclusion) and also of different amplitude (due to the different mass of the compared unit cells).

Furthermore, in order to obtain the same transmission loss performances in the periodicity peak range (between 6000 and 8000 Hz, for the specific cases considered) by the use of a simple homogeneous layer made of the same foam, one should use a thickness that is around twice the one required for the cases with inclusion, therefore leading to an increment of the mass of about 100%. This clearly points out the advantage of designing foam layer with periodic inclusion patterns in order to improve the performances in a specific range of frequencies, allowing a save both in terms of thickness and, most of all, mass, respect to a classical homogeneous foam layer.

Figure 8: Comparison of absorption coefficient curves between the homogeneous case, the case with inclusion with fixed dimensions and the case with inclusion with fixed mass.

Figure 9: Comparison of transmission loss curves between the homogeneous case, the case with inclusion with fixed dimensions, the case with inclusion with fixed mass and the homogeneous case with fixed performance in the 6000-8000 Hz frequency range.

5 CONCLUSIONS

The shift cell technique has been presented, providing details on its numerical formulation.

Numerical results have been shown, in terms of absorption coefficient and transmission loss curves obtained through a test campaign involving 48 different JCA-modelled melamine and polyurethane foam unit cell configurations.

Furthermore, it has been shown the comparison between absorption coefficient and transmission loss plots for the case in which the unit cell with inclusion has the same mass (and therefore different dimensions) respect to the homogeneous one.

Further developments of the work will include the implementation of the shift cell technique using Biot model, for both 2D and 3D geometries, as well as the design and experimental tests of a specific unit cell configuration, chosen accordingly to an optimization process that will involve geometry, foam and inclusion material.

Key words: Periodic Structures, Metamaterials, Curved Panels, Turbulent Boundary Layer

Abstract. The effects of embedded resonators on the sound transmission loss of sandwich curved structures is investigated. The simulated loading is aerodynamic (turbulent boundary layer excitation), to simulate in-flight operational conditions for fuselages and nacelle fairings. The study is conducted numerically on double wall panels and auxetic-cored sandwiches, with periodic embedded resonant elements. A two-dimensional wave finite element method is used to model the metamaterial with a single periodic cell. The resonant elements are analysed in different tuning combination to investigate the effect on the aerodynamic coincidences and the ring frequency of the shell. The advantages regarding the sound transmission and the cost associated to the added-masses of the periodic resonators, are also discussed.

1 INTRODUCTION

While it is hard to renounce to the lightness of sandwich panels, proper counter-measures must be adopted to avoid high vibrational and noise levels which characterise this type of structures.

Many authors in the literature tried to optimize pre-existent sandwich panels' designs for acoustic purposes. For example, the shear-core effects on the larger acoustic radiation of sandwich panels, has been investigated by describing the panel using an equivalent shear core.¹⁻⁵ Palumbo et al.⁶ and Grosveld et al.,⁷ for example, experimentally studied honeycomb-cored sandwich plates with periodic voids in the core original geometry. Even though this creates a localised reduced bending stiffness, a strong benefit is observed in the sound transmission loss.

On the other hand, with the rise of modern numerical techniques as the Wave Finite Element Method (WFEM), detailed investigations on shear-core transitions and the acoustic radiation of sandwich structures, have been conducted easily by working with single elementary cells.⁸⁻¹⁰ In this context, the core geometry effects on the shear-core transition and sound transmission loss of honeycomb sandwich plates, were investigated in.¹¹ Zergoune et al.¹¹ showed the transmission loss sensitivity to most of the classic topological parameters of honeycomb cored sandwich panels, such as angles between walls, thickness and deformation of hexagonal core cells.

Alternative approaches, are connected to the use of periodically distributed resonant elements on a host plate.^{12–15} Even though, in this case, the addition of mass can not be avoided, some difficulties persist in targeting broadband enhancements of the acoustic performance of the panels. Particularly interesting is the work from Liu et al.¹⁴ which focuses on tuning spring-mass elements (the resonators) around the first coincidence region of the original panel to avoid the transmission loss drop typical in that regions. However, the work is mainly conducted, as for other works in the literature, for simplified excitation models or single acoustic plane-waves. Differently, the resonators are also used to target the ring frequency of shells, which is typically a tonal problem.¹⁵

In this work, some simple models of mechanical resonators embedded in curved sandwich/double-wall host plates are analysed under a turbulent boundary layer excitation. The idea is to approach more realistic operation conditions for curved sandwich plates commonly used in aerospace and in automotive industry. Simplified studies are also presented to understand how to set the first resonator's resonance frequency depending on the excitation model assumed.

The paper is structured as follows: Section 2 describes the numerical approach followed; Section 3 discusses about the use of embedded resonant elements to target acoustic and convective coincidences, as well as ring resonances and shows the different resonators designs used here; Section 4 shows the results in terms of dispersion curves and sound transmission loss.

2 NUMERICAL APPROACH

A 2D periodic structure is composed by an assembly, along arbitrary, even curved, directions, of identical elementary cells. The procedure used here is WFE-based and makes use of periodic links among degrees of freedom of finite element models of elementary cells. The mass and stiffness matrices of the cell, modelled with meshing convergence considerations for appropriate wavelengths description, can be extracted and post-processed. With reference to Fig. 1, the dynamic stiffness equation of the segment can be written as

$$[\mathbf{K} - \omega^2 \mathbf{M}] \mathbf{q} = \mathbf{D} \mathbf{q} = \mathbf{f} + \mathbf{e} \quad (1)$$

where \mathbf{q} , \mathbf{f} and \mathbf{e} are respectively the nodal vectors of degrees of freedom (DoFs), internal and external forces; \mathbf{K} , \mathbf{M} and \mathbf{D} are the stiffness, mass and dynamic stiffness matrices. The vectors and matrices are ordered as in Fig. 1. The wave motion through a periodic media can be analysed by imposing the Bloch-Floquet conditions^{8,9} to the finite element (FE) of a periodic cell, assuming time and space harmonic excitation. The periodicity conditions are translated in a magnitude and phase link among each point belonging to the periodic pattern, using a complex propagation constant for each wave type. Displacements and forces at any point of the cell can be connected, as follows (see Fig. 1):

$$\mathbf{q}_A = \mathbf{I} \lambda_Y \mathbf{q}_F; \quad \mathbf{q}_R = \mathbf{I} \lambda_X \mathbf{q}_L; \quad \mathbf{q}_2 = \mathbf{I} \lambda_X \mathbf{q}_1; \quad \mathbf{q}_3 = \mathbf{I} \lambda_Y \mathbf{q}_1; \quad \mathbf{q}_4 = \mathbf{I} \lambda_X \lambda_Y \mathbf{q}_1; \quad (2)$$

with

$$\lambda_{X,j} = e^{-ik_{X,j} L_X} \quad \lambda_{Y,j} = e^{-ik_{Y,j} L_Y} \quad (3)$$

where $k_{X,j}$ and $k_{Y,j}$ are wavenumbers of the propagating wave-type j in the periodicity directions X and Y , while L_X and L_Y represent the cell lengths along the same directions; \mathbf{I} is the identity matrix. In general a periodicity matrix Λ (see Eq. 2) can be built to link the whole set of degrees of freedom to a specific subset; i.e. the ones in one corner. Pre-multiplying Eq.1 by Λ^H , where H stands for the hermitian operator, the dynamic stiffness matrix of the reduced model is given by Eq. 4.

$$\mathbf{D}_S = \Lambda^H [\mathbf{K} - \omega^2 \mathbf{M}] \Lambda \quad (4)$$

Figure 1: Example of a FE cell model with periodicity along the X-Y directions. a) Isometric view; b) Top view with nodes' subsets.

For the equilibrium of the internal forces between neighbouring cells, only external forces are considered (\mathbf{e} in Eq. 1). At this stage, different eigenvalue problems can be solved, if the target is the estimation of the dispersion curves of the periodic structure.¹⁰

2.1 Curvature Simulation

Being interested here in curved structures, with reference to Fig. 2, the idea is to rotate the local reference for each node belonging to the cell finite element model. This way, imposing the periodicity conditions, as shown in Eq. 3 and 4, the wave propagation is automatically analysed along the imposed curved path. Each translational DoF is rotated depending on its distance from the axis of rotation. In order to achieve the model of the curved cell, a rotational matrix \mathbf{r} is defined and assembled in a block

Figure 2: Rotation of the local system of reference for each node of the periodic cell FE model

Figure 3: Scheme of the acoustic field and load approximations used within the numerical method described in section 2

diagonal matrix, **Rot**. The mass and stiffness matrices of the curved waveguide are obtained as:

$$\begin{aligned} \mathbf{M}_c &= \mathbf{Rot}^T \mathbf{M}_f \mathbf{Rot} \\ \mathbf{K}_c &= \mathbf{Rot}^T \mathbf{K}_f \mathbf{Rot}. \end{aligned} \quad (5)$$

where **Rot** is the rotation matrix, while the subscript *fl* refers to the FE matrices of the periodic cell being modelled as flat and the subscript *c* to the ones calculated simulating the curvature of the system. Forcing wavenumbers, imposed after Eq. 5, represent, in general, helical waves exciting the semi-infinite cylinder (see Fig. 3).

2.2 Fluid-Structure Coupling

Let us assume a forcing wave impinging on one face of the structure, with an amplitude p_I . The structure, as a result, transmits and reflects waves in the fluid adjacent to the top and bottom surfaces. On the excited side (subscript 1), the sound field is the superposition of the incident and reflected acoustic sound waves, while, in the receiver side (subscript 2), it is given by the transmitted waves assuming a semi-infinite fluid termination (see Fig. 3). Here, in the case of curved surfaces, as described also in subsection 2.1, the assumed plane wave is approximated through its projection components on the locally curved surface (Fig. 3):

$$HW = p_I e^{-i(k_{X'}X' + k_Y Y - k_{Z'}Z')} \approx p_I e^{-i(k_\theta \theta + k_Y Y - k_R Z')}, \quad (6)$$

where $k_{X'}$, k_Y and $k_{Z'}$ are the wavenumber components in the new locally rotated reference (see Fig. 2) and are directly proportional to the circumferential, axial and radial wavenumber components, respectively. It is worth to emphasize that a typical decomposition in cylindrical waves, implying the use of Bessel functions, is not necessary when using a locally rotated reference system as the one in Fig. 3: Eq. 6 depicts helical waves in cylindrical coordinates and the equivalent plane waves in Cartesian coordinates, respectively.^{10, 16–18} When non-homogenised periodic cells are considered, multiple harmonics are added to the k_X and k_Y terms;¹⁹ these are numerically accounted in the structural response of the radiating side

(subscript 2). In fact, when applying the WFE, discrete periodic conditions are applied for the forcing wavenumbers couple k_X and k_Y (Eq. 6) and a semi-infinite fluid termination is assumed to the domain 2 (see Fig. 3)

To express the nodal forces on the periodic cell as a function of the pressure amplitudes in the forcing and radiating side of the structure, the dynamic stiffness of the fluids can be used. From continuity of the normal particle velocity on the excited and radiating surfaces:

$$\begin{bmatrix} \mathbf{e}_T^{red} \\ \mathbf{e}_I^{red} \\ \mathbf{e}_B^{red} \end{bmatrix} = \begin{bmatrix} \mathbf{S} \cdot (\mathbf{p}_I + \mathbf{p}_R) \\ \mathbf{0} \\ \mathbf{S} \cdot \mathbf{p}_T \end{bmatrix} = \begin{bmatrix} \mathbf{S} \cdot (2\mathbf{p}_I - \mathbf{D}_{f,1}\mathbf{q}_{inc}) \\ \mathbf{0} \\ -\mathbf{S} \cdot \mathbf{D}_{f,2}\mathbf{q}_{rad} \end{bmatrix} \quad (7)$$

where:

$$D_{f,1} = \frac{-i\rho_1\omega^2}{k_{Z,1}}; \quad D_{f,2} = \frac{-i\rho_2\omega^2}{k_{Z,2}}, \quad (8)$$

where \mathbf{S} is vector of the free nodal surface of each excited node and \mathbf{p}_I , \mathbf{p}_R and \mathbf{p}_T are the nodal pressure vectors, ρ_1 and ρ_2 are the fluid densities, $D_{f,1}$ and $D_{f,2}$ the dynamic stiffness of the fluid in the incident and radiating domains; q_{in} and q_{rad} are the out-of-plane displacements, respectively of the incident and radiating surfaces.²⁰ The lumped-on-nodes forces act on the degrees of freedom of out-of-plane displacements, identified with the subscript T (top) and B (bottom), while all other degrees of freedom (not excited) are identified by I (internal).

The dynamic stiffness matrix and the reduced displacement vector can be rearranged in the same way as in Eq. 7, condensing all the non-excited (internal) nodes.²¹ Including the relations of Eqs. 4, 7 and 8, in the initial dynamic stiffness equation, the problem can be solved in \mathbf{p}_R and \mathbf{p}_T obtaining the power transmission coefficient τ associated with the couple of forcing wavenumbers k_X and k_Y .

$$\tau(k_X, k_Y) = \frac{(k_{Z,2}/\rho_2)\mathbf{S}|\mathbf{p}_T|^2}{(k_{Z,1}/\rho_1)\mathbf{S}|\mathbf{p}_I|^2}. \quad (9)$$

Finite size effects, can be included through correction factors, in order to increase the accuracy at low frequencies.^{22,23} The sound transmission to plane wave excitation, as discussed in Sec. 2, is not sufficient for many applications. A wavenumber-space load approximation to take into account a general type of excitation is proposed in²⁰ and is used here. The final sound transmission coefficient will be given by a weighted integration scheme:²⁰

$$\tau_{TOT}(\omega) = \frac{\int \int \tau(k_X, k_Y) \times W_A(k_X, k_Y, \omega) dk_X dk_Y}{\int \int W_A(k_X, k_Y, \omega) dk_X dk_Y} \quad (10)$$

where W_A is the matrix of the normalized amplitude function, of the wall surface waves, for all the wavenumber couples involved in the integration process.²⁰

3 STRUCTURAL DESIGNS ANALYSED

3.1 Resonators' Efficiency for Different Excitation Models

Depending on the excitation model assumed, the sound transmission loss of a panel changes. Similarly, the exotic nature of some excitation models might reduce the efficiency of the use of resonators. With reference to Eq. 10, each couple of forcing wavenumbers k_X and k_Y , contributes to the final transmission coefficient as a function of the weighting factors $W_A(k_X, k_Y, \omega)$. For a diffuse acoustic field, the integration scheme is equivalent to integrating all plane-wave inclinations.²¹ In Fig. 4a, some acoustic plane-wave trace wavenumbers versus frequency are plotted with the flexural ones of a 2mm-thick

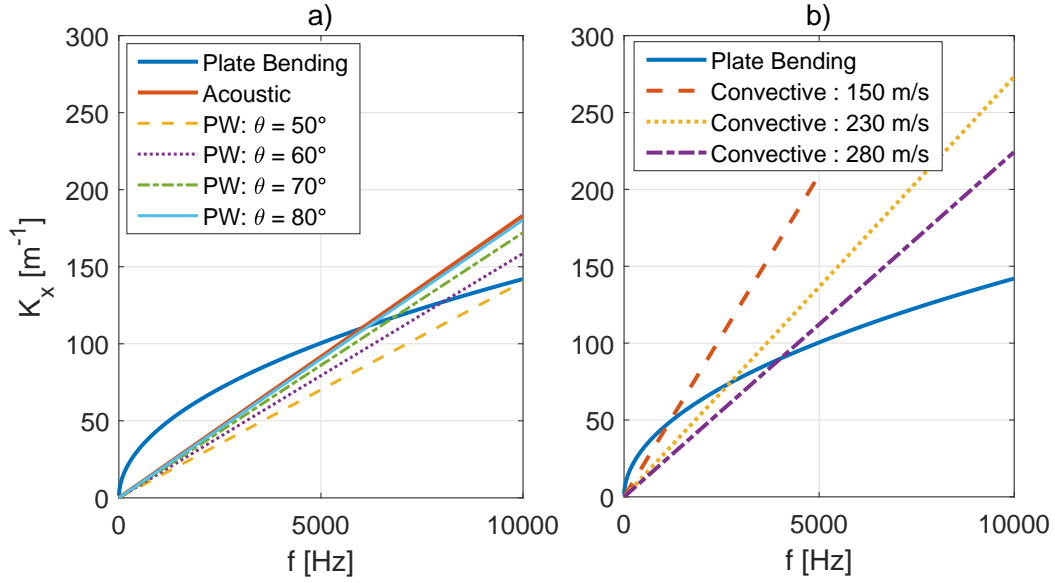

Figure 4: Dispersion Curves - The bending wavenumbers of a flat isotropic plate with: a) acoustic wavenumbers for different plane wave angles. b) convective wavenumbers for different flow speeds

aluminium plate; the coincidences shift depending on the inclination angle and the final coincidence we would obtain from integrating on every angle (Eq. 10), thus simulating a diffuse acoustic field, is the one give by assuming the acoustic wavenumber ω/c_0 , where c_0 is the speed of sound in the media analysed.

This means that tuning a single resonator on a specific coincidence/inclination, even if the global one, means, then, averaging its increased sound transmission losses over a large number of cases where the resonator is "mis-tuned" and thus induces a lower transmission loss, as shown in.¹⁴ The global advantages in using the resonant elements are attenuated (cancelled, in the worst cases), by the diffusiveness of the loading model.

Differently, for a turbulent boundary layer model, the aerodynamic coincidence (or critical frequency; see Fig. 4b) is stream-wise filtered by the physical nature of the load itself. Similarly, the structural-induced acoustic drops, as for the ring frequency of shells/curved panels, are not dependent on any inclination. For these reasons, the use of simple resonant elements (as beams) to contrast these frequency-fixed issues, can be a valid approach; the resonators "mis-tuning" effects are somewhat damped with respect to the ones integrated for a diffuse acoustic field.

3.2 Metamaterial Designs Analysed

The original panel designs analysed in this work are a double-wall with mechanical link (see Fig. 5a) and an auxetic-cored sandwich (see Fig. 6a). In both cases resonant laminas/beams are attached to the core walls (see Figs. 5b and 6b,c) and case-by-case tuned considering the first cantilever-beam-like mode. Both the models are made with skins in aluminium. The double-wall panels have a core in aluminium too and both skins and core walls are 0.6mm-thick, while the global thickness is 15mm. The auxetic core of the sandwich plates, which have a total thickness is 14mm, is instead made of an isotropic material with the following properties: $E = 1.45 \text{ GPa}$, $\nu = 0.27$, $\rho = 1100 \text{ Kg/m}^3$. In this case, the skins are 1mm-thick and the core walls are 0.5mm-thick.

Depending on the tuning and the number of the resonant elements, different configurations are stud-

Figure 5: The periodic cell extracted from the double-wall panel with mechanical links. a) Standard design; b) Designs with Resonant Elements.

Figure 6: The periodic cell extracted from the Auxetic-Cored Sandwich Plate. a) Standard design; b) Designs with single Resonant Elements; c) Designs with triple Resonant Elements.

ied: for the double-wall plate three configurations are analysed and reported in Table 1; for the auxetic-cored sandwich panel four configurations are analysed instead and are reported in Table 2.

Considering the mass ratio influence, as discussed in,¹⁴ the effects of the resonant elements should be strongly visible for the double-wall panels, where the added masses are largely superior to the ones added in the auxetic-core configurations (see Tables 1 and 2)

4 RESULTS

The approach described in Sec. 2 is applied to simulate the sound transmission loss of the panel designs described in Sec. 3 under a turbulent boundary layer excitation (TBL). The Corcos model^{24,25} is used in these cases; the flow data are: $\delta = 0.027$ m, $\alpha = 0.125$ and $\beta = 0.83$.

Table 1: Double-Wall plate with mechanical links: Configurations Info

ID	Number of Resonant Elements	Added Mass [%]	Target Coincidence	Curvature [m]
Standard	0	0	N/A	1.6
Resonant (Ring) - D1	1	6	Ring Mode	1.6
Resonant (Aero)- D2	1	15	Aerodynamic	1.6
Doubly-Resonant (Aero)- D3	2	18	Aerodynamic	1.6

Table 2: Auxetic-Cored Sandwich Plate: Configurations Info

ID	Number of Resonant Elements	Added Mass [%]	Target Coincidence	Curvature [m]
Standard	0	0	N/A	1.0
Resonant (C1)	1	0.78	Ring Mode	1.0
Resonant (C2)	3	2.36	Ring Mode	1.0
Resonant (C3)	2	1.49	Ring Mode	1.0
Resonant (C4)	1	0.52	Aerodynamic	1.0

4.1 Dispersion Curves

First, the dispersion curves of the panel designs described in Sec. 3 are plotted in Figs. 7 and 8. In Fig. 7, the double-wall panel with mechanical links is analysed imposing a 1.6m curvature; due to the typical low core-shear stiffness of these types of structures, the presence of the resonant beam (see Fig. 5) seems to strongly influence even the ring frequency zone and, as shown later for the transmission loss, this will cause a shift of the ring frequency to lower values. For the resonant configurations targeting the aerodynamic coincidence (see Table 1 and Figs. 7a,b), resonance-induced band-gaps appear around the critical frequency.

Differently, in Fig. 8, the dispersion curves of three configurations presented in Table 2 for the auxetic-cored sandwich plate with a 1.0m curvature, are compared to the standard circumferential waves. In these cases, the presence of the resonant beams embedded in the auxetic core, does not influence the wave propagation in the original structure in frequency regions outside the resonance modes of the beams, as happens for the double-wall panel. This effect is connected to the reduced mass addition of this test-cases (see Table 2).

4.2 Sound Transmission Loss

Here, the sound transmission loss is finally calculated and compared, for all the configurations analysed, using the approach of Section 2. Infinite shells made with the elementary cells of Figs. 5 and 6 are simulated under an axial turbulent boundary layer flow. As a rule of thumb, the lower the mass addition

Figure 8: Dispersion curves for the Auxetic-cored sandwich panel with a 1.0 m curvature. With reference to Table 2: a) C1; b) C2; c) C4. Legend: Or) Standard Configuration; .b) Resonant Configurations; -) Convective Wavenumbers for $U_c = 285$ m/s.

the lower should be the advantages of the resonant elements around their frequency of resonance, in terms of sound transmission loss; with reference to Table 1 and 2 the addition of mass is between 6-18% for the double wall panel and between 0.5-2.4% for the auxetic-cored sandwich panel.

In Fig. 9 the sound transmission loss for the double-wall panel under a 160 m/s flow is presented. As evidenced also in the dispersion curves, the presence of the resonators shifts the ring frequency of the modified configurations and, thus, a mis-tuning of the resonance frequency of the embedded beams appears when targeting the original ring frequency of the shell. Differently, for the other configurations targeting the aerodynamic coincidence, a strong increase of the sound transmission loss is observed; a narrower band is targeted when using a single resonant beam, while a larger one, with a reduced peak of STL, is targeted when using two beams with a slightly different natural frequency. It is worth notice that the bands of increase of the sound transmission loss, when targeting the aerodynamic coincidence, are larger than expected by looking at the free wave propagation of the dispersion curves. This effect is attributable to the flow-induced increase of damping around the critical frequency (typical of TBL;^{20,26}), usually larger than the one observed for the acoustic coincidences.

On the other hand, in Fig. 10 the sound transmission loss for the sandwich panel with auxetic core, under a 285 m/s flow, is presented. Differently from the previous case, the increases of the STL are reduced because of the minimum addition of mass. Still, the configurations C1, C2 and C3 (see Table 2) induce a non-negligible increase of performance around the ring frequency region, as observed in Fig. 10. The use of three resonant elements with slightly shifted first natural frequencies (see C2 in Table 2 and Fig. 6c) helps in enlarging the coverage in frequency of the resonance-induced band-gaps and, thus, also the region of STL increase. Differently, the resonant configuration targeting the aerodynamic frequency (see C4 in Table 2) gives a relatively good increase of sound transmission loss even being single-element based and adding less than 1% of mass to the system.

5 CONCLUDING REMARKS

The effects of embedded resonators on the sound transmission loss of two types of sandwich cylindrical structures is numerically investigated under a turbulent boundary layer excitation. A two-dimensional wave finite element method is used to model the metamaterial with a single periodic cell, including the configurations with embedded resonant elements. The curvature of the models is simulated rotating the translations degrees of freedoms of the finite element model of the cells. A set of helical waves is used instead to simulate the random external pressure fluctuations and relate them to the periodic structural scale.

The resonant elements are analysed in different resonance tuning combination to investigate the effect on the aerodynamic coincidences and the ring frequency of the shell. A discussion on the use of such devices to target specific coincidences or resonances is also given. The effects of the resonant structural configurations with respect to the wave propagation, sound transmission and added-masses are observed and discussed.

Key words: Periodic structure, wavenumber, damping loss factor, dispersion curves

Abstract. The physical characteristics of periodic structures are employed to analyze the vibro-acoustic response of several complex structures in the wavenumber domain. This work is focused on the analysis of elastic periodic structures, designed in order to obtain a wave attenuation in certain frequency bands, generating the so-called band-gaps (mainly related to the Bragg's effect), and on the identification of the material properties of complex structures. In this context, an inverse wavenumber correlation method is developed to obtain the dispersion characteristics and the damping information of complex periodic structures. The wavenumbers and the damping loss factor are identified exciting the structure by a unit harmonic force and using the complete vibrational field as primary input.

1 INTRODUCTION

In literature, the complex wavenumber recovery of a vibrating structure is an open issue. Several methods are available to correctly extract the real part of the wavenumber, but the estimation of the related damping information is still an open challenge. In the domain of punctual harmonic excited structures, McDaniel et al.^{1,2} developed a semi-analytical approach based on damped plane wave propagation (1D guided waves), using an expression of the plane wave

of type $e^{\pm ikx}$, where i is the imaginary unit, k is the complex wavenumber and x is the spatial coordinate. Different methods based on Prony series have been developed over the past years; Grosh et al.³ applied their method on cylindrical shells subjected to point harmonic excitation, obtaining a good estimation of the dispersion relation. Using a similar approach presented by Grosh et al.,³ another method, called *Inhomogeneous Wave Correlation* (IWC) method has been developed by Berthaut et al.;⁴ the proposed approach estimates the flexural wavenumber and the dispersion relation of a vibrating plate under punctual harmonic excitation, correlating the complete displacement field and a damped traveling plane wave, of the type $e^{\pm ik(x\cos\theta+y\sin\theta)}$, where θ is the propagation angle of the inhomogeneous wave. An interesting application of the IWC method is presented in Ichchou et al.,⁵ obtaining the complete θ -dependent dispersion relation of a ribbed plate. The presented approaches based on plane waves propagation suffered of a disadvantage related to plane wave hypothesis: the vibrational field should be acquired in a steady state condition, trying to avoid the excitation region where the plane wave assumption is not valid. One of the main advantage of the IWC method is the estimation of the complex wavenumber, with the related damping information; Cherif et al.⁶ applied the IWC method to an aluminum panel and to a two different laminated composite panels with honeycomb core, correlating the measured vibrational field and the damped inhomogeneous wave; the flexural wavenumber and the damping loss factor are both successful estimated. Van Damme et al.^{7,8} obtained the dispersion relation and the complex wavenumber for complex 1D structures, showing a good description of the Bragg's band gaps, adopting a 1D formulation of the IWC method. An enriched formulation of the IWC method is shown in Van Belle et al.,⁹ where they obtained the dispersion relation of a metamaterial plate with periodic resonators; this formulation takes in account the location of the force to have a better estimation of the wave attenuation. An IWC formulation for curved and axial-symmetric structures is shown in Tufano et al.,¹⁰ obtaining a good description of the k -space domain.

To describe the vibrational field of a structure subjected to punctual harmonic excitation, the Green's functions and the related image source method are widely used in literature. An application of the method of images is shown in Gunda et al.¹¹; the authors used this approach to describe the harmonic response of beams and rectangular plates. Based on the method of the images, Cuenca et al.¹² described the vibrational field of a finite plate with simply supported boundary conditions by the reconstruction of the Green's function of a point excited plate. The same method has been applied by Cuenca et al.¹³ to estimate the equivalent material properties of a plate covered by a viscoelastic layer. Recently, Roozen et al.¹⁴ used the Green's function of a point excited plate, by using a set of Hankel's functions, into a complex wavenumber fit procedure, making a comparison between the acquired vibrational field and the Green's function; the procedure here described allows to retrieve the complex wavenumber and the equivalent material properties.

All the methods based on plane wave assumption are affected by some limitations due to the nature of the plane wave itself. The vibrational field should be acquired in a steady-state condition, sufficiently far from the excitation location (this is a singularity point where the plane wave hypothesis is not valid) and trying to distinguish between the direct, reflected and evanescent fields. In this paper, a method is proposed to combine advantages of the IWC method and of the image source method, which uses a set of Hankel's functions to obtain the vibrational

field of a point excited structure. The main advantage of this approach is the possibility to be close the excitation region, avoiding the problems related to the plane wave assumption. The proposed approach estimates the complex wavenumber and the dispersion relation of several complex structures, showing a good description of the periodicity effect (Bragg's band gaps); the damping loss factor is also well estimated.

2 METHODOLOGY

The complex dispersion relation of different structures is here estimated by a wave correlation method. The presented approach estimates, at each frequency f_0 , the complex wavenumber as the point of best agreement between the acquired vibrational field and the Green's function of the point excited structure. The Green's function is derived by the classical Kirchhoff's thin plate theory¹⁵; according to this theory, for an isotropic, homogeneous plate and of a constant thickness h , the flexural vibration, in terms of transverse displacement w , is expressed as follows

$$D\nabla^4 w(\vec{x}, t) + \rho h \frac{\partial^2 w(\vec{x}, t)}{\partial t^2} = P(\vec{x}_0, t) \quad (1)$$

where $D = \frac{Eh^3}{12(1-\nu^2)}$ is the bending stiffness, E is the Young's modulus, ν is the Poisson's coefficient, ρ is the mass density, ∇^4 is the biharmonic operator, t is the time variable, P is the force per unit area and \vec{x} , \vec{x}_0 are the position vectors of the acquisition and excitation points, respectively. Assuming an harmonic point excitation, the expression of the force becomes $P(\vec{x}_0, t) = F(\vec{x}_0)e^{i\omega t}$, being ω the angular frequency; consequently, the steady state response of the transversal vibrational field is $w(\vec{x}, t) = u(\vec{x})e^{i\omega t}$. Substituting these two expressions in Eq. 1, the governing equation assumes the following form

$$D\nabla^4 u(\vec{x}) - k^4 u(\vec{x}) = F(\vec{x}_0) \quad (2)$$

where $k^4 = \rho h \omega^2 / D$ is the flexural wavenumber.

For a plate of infinite lateral dimensions, the solution of Eq. 2 is given by

$$G_\infty(x, y) = \frac{1}{8k^2 D} \left[H_0^1(kr) - H_0^1(ikr) \right] \quad (3)$$

with G_∞ the Green's function of the infinite plate, H_0^1 the Hankel's function of first kind and order 0 and $r = \|x - x_0, y - y_0\|$ is the distance between the acquisition (x, y) and excitation (x_0, y_0) points.

At each frequency f_0 , the complex flexural wavenumber is found as the point of best agreement between the measured vibrational field and the Green's function expressed in the Eq. 3. Considering an acquisition region of area S in the plane (x, y) , indicating with \tilde{w} and w the measured vibrational field and the one described by Eq. 3, respectively, the normalized correlation function has the following expression

$$\mathcal{F}(k_{\mathbb{R}}, k_{\mathbb{I}}) = \frac{\left| \iint_S \tilde{w} \cdot w(k_{\mathbb{R}}, k_{\mathbb{I}})^* dx dy \right|}{\sqrt{\iint_S |\tilde{w}|^2 dx dy \cdot \iint_S |w(k_{\mathbb{R}}, k_{\mathbb{I}})|^2 dx dy}} \quad (4)$$

where $*$ denotes the complex conjugate. For discrete points measurement, the integrals in Eq. 4 are replaced by summations over the entire domain. The complex wavenumber is identified as the location of the maximum of the correlation function. From the estimated wavenumber amplitude, an estimation of the damping loss factor can be obtained, at each frequency, by the following relationship²

$$\eta = \left| \frac{\Im(k^4)}{\Re(k^4)} \right| \quad (5)$$

By choosing a proper direction of propagation, Eq. 3 can be applied to a narrow beam subjected to punctual harmonic excitation. Keeping the same notation and indicating with L the length of the acquisition region, the correlation function showed in Eq. 4 becomes

$$\mathcal{F}(k_{\mathbb{R}}, k_{\mathbb{I}}) = \frac{\left| \int_L \tilde{w} \cdot w(k_{\mathbb{R}}, k_{\mathbb{I}})^* dx \right|}{\sqrt{\int_L |\tilde{w}|^2 dx \cdot \int_L |w(k_{\mathbb{R}}, k_{\mathbb{I}})|^2 dx}} \quad (6)$$

The dispersion curves of the different structures have been validated using the Wave Finite Element Method (WFEM)^{16–18} ; this method is not here described.

3 NUMERICAL RESULTS AND VALIDATIONS

The proposed approach is applied on different structures. Firstly, two different beams are taken in account: isotropic and periodic (with varying material and cross-section along the length). Then, application cases on two different plates are shown, taking in account an isotropic and homogeneous plate and a composite one, made of three different layers in the thickness direction.

3.1 Isotropic and periodic narrow plates

The first application of the proposed approach has been conducted on a simple isotropic beam. The total length of the beam is 1.0 m and the cross-section has dimensions 10 x 1 mm²; the finite element model of the beam is shown in Fig. 1a. The employed material is a general thermoplastic polymer (ABS) with Young's modulus $E = 1.0 \text{ GPa}$, density $\rho = 980.0 \text{ kg m}^{-3}$ and Poisson's coefficient $\nu = 0.35$; two constant values of structural damping η are assumed: 2% and 4%. An analytical expression of the dispersion relation can be derived using Timoshenko's model for vibrating beams, resulting in

$$EIk^4 - \rho A \omega^2 - \left(\rho I + \frac{EI\rho}{KG} \right) k^2 \omega^2 + \frac{\rho^2 I}{KG} \omega^4 = 0 \quad (7)$$

where G is the shear modulus, $I = bh^3/12$ is the second moment of area, A is the beam's cross-section area and $K = 5/6$ is a constant to take in account the shear force variation.

A periodic beam is also investigated, to prove the feasibility of the proposed approach in describing the band-gaps due to the geometric periodicity of the structure. The finite element model of the unit cell of the considered structure is shown in Fig. 1b. The unit cell has total length of 0.04 m and it's characterized by a double periodicity: material and cross-section. The

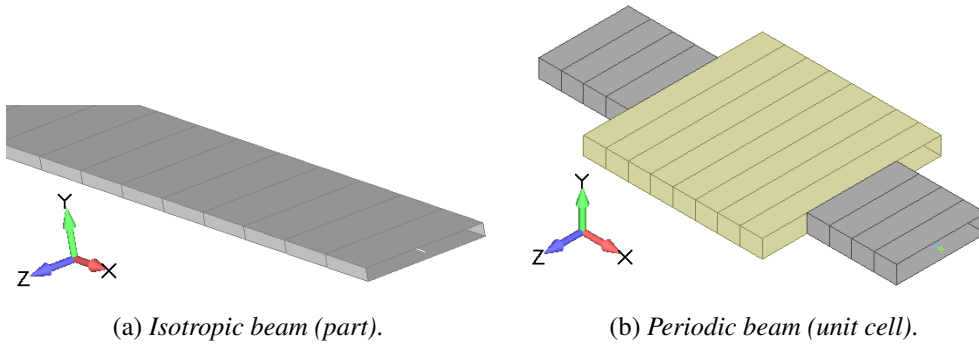

Figure 1: Finite element models of the isotropic and periodic beams

Figure 2: Dispersion curve and Damping Loss Factor estimation for the isotropic beam

Figure 3: Real and imaginary dispersion curves of the periodic beam

employed materials are a standard aluminum alloy, with Young's modulus $E = 70.0 \text{ GPa}$, density $\rho = 2700.0 \text{ kg m}^{-3}$ and Poisson's coefficient $\nu = 0.33$, and the ABS previously described. The aluminum part has a cross-section of dimensions $10 \times 2 \text{ mm}^2$; the ABS part has dimensions $20 \times 2 \text{ mm}^2$. The propagative part of the dispersion curve for the isotropic beam is shown in Fig. 2a; the proposed IWC approach exhibits a very good agreement with the analytical model (cfr. Eq. 7) and the WFE method. In Fig. 2b is shown the damping loss factor estimation; in both cases, the identified complex wavenumbers give a reasonable estimation of the structural damping previously introduced.

The dispersion curve of the periodic beam are shown in Fig. 3; the dispersion curve calculated with the WFE method are limited to the first Brillouin zone, where the wavelengths are longer than one period of the structure (Fig. 3a). The real part of the wavenumber has periodicity π/Δ , with Δ the length of the unit cell, showing multiples band-gaps, but always with $k_{\Re} \in [0, \pi/\Delta]$. The dispersion curve estimation with the proposed approach is shown in Fig. 3b, being in good agreement with the one calculated with the WFE method, identifying the same wide band-gaps zone. The proposed IWC approach takes in account the whole structure, avoiding the periodicity issue previously described in the wavenumbers estimation.

3.2 Isotropic and laminated plates

The proposed approach has been extended to 2D structures, an isotropic plate, made of ABS, and a composite one, constituted of three layers: aluminum-ABS-aluminum, of thickness 1 - 8 - 1 mm, respectively; both plates have geometrical dimensions $1.0 \times 0.6 \times 0.01 \text{ m}^3$. The finite element models of the two unit cells are shown in Fig. 4; both unit cells are used in the WFE method to validate the results obtained with the proposed IWC approach. For both test cases, two different constant values of structural damping η are assumed: 2% and 5%.

For what concern the isotropic plate, an analytical expression of the dispersion relation can be derived by Kirchhoff's thin plate theory, obtaining the following expression for the flexural wavenumber

$$k = \sqrt{\omega} \left(\frac{\rho h}{D} \right)^{1/4} \quad (8)$$

The propagative part of the dispersion curve is shown in Fig. 5a; the proposed approach is in good agreement with the analytical formulation of Eq. 8 and the WFE method, showing a low overestimation in the high-frequency region. In Fig. 5b, the damping loss factor estimations are shown; the relation of Eq. 5 is used, based on the estimated complex wavenumbers.

The propagative part of the dispersion curve for the composite plate is shown in Fig. 6a; a good agreement between the proposed approach and the WFE method is obtained in the whole frequency band of investigation. A very good identification of the damping loss factor is performed, and shown in Fig. 6b. Using an inverse approach based on the estimated wavenumber, the equivalent bending stiffness and the equivalent Young's modulus of the structure have been calculated by the following formulas, directly derived from Eq. 2

$$D_{eq} = \frac{\omega^2 \rho h}{k^4} \quad \text{and} \quad E_{eq} = \frac{D_{eq} 12(1 - \nu^2)}{h^3} \quad (9)$$

4 CONCLUDING REMARKS

In this work, different ideas are successfully implemented in this extended IWC approach, showing a very good prediction of the complex dispersion relation of periodic narrow plates and laminated structures. An estimation of the damping loss factor is obtained; the calculated values of η fast converge to the structural damping introduced. The feasibility of this method in estimating the wave attenuation in a structure is successfully demonstrated.

The proposed approach allows to identify the resonance zones (stop-bands) due to the geometrical periodicity of the structure, showing a good agreement with the WFE method, based on

the unit cell theory, avoiding some limitations related to the latter method.

The proposed approach can be used in an inverse way to estimate the frequency dependent equivalent material properties of complex structures, when analytical models are not available or difficult to obtain.

Key words: metamaterials, impact damper, nonlinear vibration

Abstract. The emergence of metamaterials as an alternative concept for the mitigation of structural vibration is increasingly attracting the interest of scientists and engineers. Recent studies confirm that the development of periodic structures assembled on the basis of unit cells of favourable properties, results in a filtering effect, preventing the propagation of vibration lying within a specific frequency band. The, so called, meta-structures are thus characterized by a frequency bandgap. For the purposes of structural vibration attenuation, two main interrelated challenges are currently associated with the conceptual design of such structures: the first corresponds to the feasibility of reducing the lower threshold of the band gap within a practical setting, while the second pertains to increasing the breadth of the bandgap. One approach to addressing these challenges lies in the use of the so-called “rainbow traps”, i.e., meta-structures consisting of unit cells with different properties. An alternative strategy pertains to use of nonlinear unit cells. Both schemes are so far little unexplored in terms of applicability for structural vibration mitigation. This study attempts to contribute to this research path, by exploring the nonlinear approach, by assessing the properties of finite lattices with unit cells composed of impact dampers. These devices have already demonstrated their attenuation potential, yet, their investigation has been mostly limited to systems of single, or two-degrees-of freedom. To this end, a one-dimensional finite lattice is herein considered, and the analysis is conducted over critical structural parameters, including the number and the individual stiffness properties of unit cells, the mass ratios, etc. The preliminary results demonstrate the potential of meta-structures composed of properly-designed impact dampers for vibration attenuation.

1 INTRODUCTION

Engineering vibration has traditionally comprised a very active research area, motivated by the abundance of associated technological applications. In this domain, the safety margins associated with the protection of humans, machines and structures, from undesired/uncontrolled motions of diverse frequency characteristics dictate design.

The attenuation of engineering vibration has been mostly treated using a mix of linear, passive, active and even semi-active methods. Passive vibration control typically dominates its active counterpart, for being simple, mature and of sufficiently lower lifecycle costs. Since structures are usually characterized by light damping (0.5% to 7%), the majority of actions for passive vibration control aims at integrating additional damping mechanisms that increase damping capacity up to 30%-40%. These include viscous and hysteretic energy dissipaters [1, 2, 3], friction dissipaters [4], oil dampers [5], visco-elastic dampers [6, 7, 8, 9], as well as tuned-mass and tuned-liquid dampers [10, 11, 12, 13, 14]. An inherent disadvantage, however, of passive devices is their inability to adapt, or at least to perform on par in wide frequency ranges; their properties remain fixed to their initial design and implementation. Tuned-mass dampers are a notable example of such a limited performance. To address this issue, semi-active and hybrid methods have been introduced, with promising results [15, 16, 17]. The effectiveness of active control is considerably improved with respect to its passive counterpart, as it can be adapted to an arbitrary set of specifications. However, they are significantly more expensive, they require continuous maintenance, and they are amenable to own faults, while the introduction of external energy to the structure raises stability issues. To cope with this, among available alternatives, devices relying on semi-active control schemes, such as magnetorheological dampers, are drawing increasing attention in real-time vibration mitigation and structural control [18, 19, 20, 21, 22, 23]. The increasing adoption of such systems may be attributed to the fact that semi-active control devices seem to gather the best features of both passive and active control systems and seem able to match adaptability of the active class without the associated large power requirements.

As an alternative to active control, a new concept for passive vibration mitigation has emerged by the exploration of metamaterials [24, 25]. The latter comprise a special class of periodic structures, characterized by fascinating filtering effects: when the frequency of the incoming excitation falls into their blind zone, the propagation of motion is arrested in any direction, thus forming a “band-gap”. An associated challenge, however, lies in the size of the band-gap, as well as in the arbitrary selection of the low-frequency threshold, which is critical in many engineering applications [26, 27, 28, 29, 30, 31]. In general, low wave speeds are required for obtaining a low-frequency band-gap, which may be succeeded via heavy inclusions in a soft medium and/or a large lattice constant [32, 33]. Weight, low stiffness and large size are unfavorable for lattices that are to be used for practical purposes.

In addressing this challenge, this study introduces strong nonlinearities to the finite lattice. In more detail and relying on the local resonator approach, a novel nonlinear neutralizer is thus proposed herein for passive vibration control. The envisaged periodic structure comprises an impact damper [34, 35, 36] as the unit cell. Impact dampers are studied since many years and their favorable properties have been already demonstrated [37, 38, 39, 40]. Still, their behavior in periodic configurations remains largely unexplored. To this end, a one-dimensional finite lattice is herein considered as a mean for the vibration attenuation of a linear oscillator that is amenable to harmonic excitation.

2 THE META-IMPACTOR

2.1 The impact damper

Figure 1 displays a schematic layout of an impact damper. It consists of an external mass, henceforth referred to as the container, which is attached to linear elastic and dissipative elements, of equivalent stiffness k and viscous damping c , respectively. Within the container, an auxiliary mass μ , herein corresponding to a frictionless solid particle, is constrained to oscillate with clearance D . The total length of the impact damper is L .

The nonlinearity of the impact damper stems from the successive impacts between the auxiliary mass

Figure 1: The impact damper (top view).

Figure 2: A periodic finite lattice of impact dampers attached to a linear oscillator (top view).

and the container, every time the former reaches the clearance limits of the latter. Under the assumption that the impulse duration is sufficiently smaller, compared to the natural frequency of the system, it can be deduced that the displacements of the container and the auxiliary mass right before and after the impact remain the same, while their velocities are discontinuously changed (see below). It is noted that, under the harmonic excitation that is considered in the current study, no prior assumption on the number of impacts per cycle at the steady state is adopted.

2.2 A finite lattice of impact damper unit cells

Consider now a structure that can be effectively described by a single degree of freedom linear oscillator of mass M , stiffness K and damping C , excited by a harmonic input force $F(t) = A \sin(2\pi ft)$. In reducing the effects of the external excitation, a periodic, finite lattice of N identical impact dampers is integrated as illustrated in Figure 2.

The equations of motion for the first (e.g. far left) unit cell of the lattice are

$$m\ddot{x}_1(t) = -kx_1(t) - c\dot{x}_1(t) - k[x_1(t) - x_2(t)] - c[\dot{x}_1(t) - \dot{x}_2(t)] \quad (1a)$$

$$\mu\ddot{y}_1(t) = 0, \quad |x_1 - y_1| < D/2 \quad (1b)$$

Similarly, the equations of motion for the i -th unit cell, $i = 2, \dots, N-1$, read

$$m\ddot{x}_i(t) = k[x_{i-1}(t) - x_i(t)] + c[\dot{x}_{i-1}(t) - \dot{x}_i(t)] - k[x_i(t) - x_{i+1}(t)] - c[\dot{x}_i(t) - \dot{x}_{i+1}(t)] \quad (2a)$$

$$\mu\ddot{y}_i(t) = 0, \quad |x_i - y_i| < D/2 \quad (2b)$$

while the ones for the last (N -th) unit cell of the meta-impactor and the linear oscillator are

$$m\ddot{x}_N(t) = k[x_{N-1}(t) - x_N(t)] + c[\dot{x}_{N-1}(t) - \dot{x}_N(t)] - K[x_N(t) - X(t)] - C[\dot{x}_N(t) - \dot{X}(t)] \quad (3a)$$

$$\mu\ddot{y}_N(t) = 0, \quad |x_N - y_N| < D/2 \quad (3b)$$

and

$$M\ddot{X}(t) = K[x_N(t) - X(t)] + C[\dot{x}_N(t) - \dot{X}(t)] + f(t) \quad (4)$$

respectively.

Under the assumptions adopted in Sec. 2.1, the states of the i -th unit cell, $i = 1, \dots, N$, immediately after the impact are calculated as

$$x_i^+ = x_i^-, \quad y_i^+ = y_i^- \quad (5a)$$

$$\dot{x}_i^+ - \dot{y}_i^+ = -r[\dot{x}_i^- - \dot{y}_i^-] \quad (5b)$$

where the superscripts \pm refer to time immediately after and before the impact, respectively, and r is the coefficient of restitution. Moreover, the conservation of momentum implies

$$m\dot{x}_i^+ + \mu\dot{y}_i^+ = m\dot{x}_i^- + \mu\dot{y}_i^- \quad (6)$$

From Eqs. 5b, 6, it follows that the velocity states of the i -th unit cell are computed from the following system of linear equations

$$\begin{bmatrix} m & \mu \\ 1 & -1 \end{bmatrix} \begin{bmatrix} \dot{x}_i^+ \\ \dot{y}_i^+ \end{bmatrix} = \begin{bmatrix} m\dot{x}_i^- + \mu\dot{y}_i^- \\ -r\dot{x}_i^- + r\dot{y}_i^- \end{bmatrix} \quad (7)$$

2.3 Simulation

For the parametric analysis that is carried out in the next section the system is brought into the form $\dot{\xi}(t) = g(\xi(t), f(t))$, where $\xi(t)$ is the state vector defined as (temporal variable is temporarily omitted for clarity)

$$\xi = \left[x_1, \dot{x}_1, y_1, \dot{y}_1 \mid \dots \mid x_N, \dot{x}_N, y_N, \dot{y}_N \mid X, \dot{X} \right]^T \quad [4N + 2 \times 1] \quad (8)$$

Based on Eq. 8, the equations of motion are now transformed as

$$\dot{\xi}_1(t) = \xi_2(t) \quad (9a)$$

$$\dot{\xi}_2(t) = -\frac{k}{m}\xi_1(t) - \frac{c}{m}\xi_2(t) - \frac{k}{m}[\xi_1(t) - \xi_5(t)] - \frac{c}{m}[\xi_2(t) - \xi_6(t)] \quad (9b)$$

$$\dot{\xi}_3(t) = \xi_4(t) \quad (9c)$$

$$\dot{\xi}_4(t) = 0, \quad |\xi_1 - \xi_3| < D/2 \quad (9d)$$

for the first unit cell, as

$$\dot{\xi}_{4(i-1)+1}(t) = \xi_{4(i-1)+2}(t) \quad (10a)$$

$$\begin{aligned} \dot{\xi}_{4(i-1)+2}(t) = & \frac{k}{m}[\xi_{4(i-2)+1}(t) - \xi_{4(i-1)+1}(t)] + \frac{c}{m}[\xi_{4(i-2)+2}(t) - \xi_{4(i-1)+2}(t)] \\ & - \frac{k}{m}[x_{4(i-1)+1}(t) - \xi_{4i+1}(t)] - \frac{c}{m}[\xi_{4(i-1)+2}(t) - \xi_{4i+2}(t)] \end{aligned} \quad (10b)$$

$$\dot{\xi}_{4(i-1)+3}(t) = \xi_{4(i-1)+4}(t) \quad (10c)$$

$$\dot{\xi}_{4(i-1)+4}(t) = 0, \quad |\xi_{4(i-1)+1} - \xi_{4(i-1)+3}| < D/2 \quad (10d)$$

for the i -th unit cell, $i = 2, \dots, N-1$, and as

$$\dot{\xi}_{4N-3}(t) = \xi_{4N-2}(t) \quad (11a)$$

$$\begin{aligned} \dot{\xi}_{4N-2}(t) = & \frac{k}{m}[\xi_{4N+1}(t) - \xi_{4N-3}(t)] + \frac{c}{m}[\xi_{4N+2} - \xi_{4N-2}(t)] \\ & - \frac{K}{m}[\xi_{4N-3}(t) - \xi_{4N+1}(t)] - \frac{C}{m}[\xi_{4N-2}(t) - \xi_{4N+2}(t)] \end{aligned} \quad (11b)$$

$$\dot{\xi}_{4N-1}(t) = \xi_{4N}(t) \quad (11c)$$

$$\dot{\xi}_{4N}(t) = 0, \quad |\xi_{4N-3} - \xi_{4N-1}| < D/2 \quad (11d)$$

and

$$\dot{\xi}_{4N+1}(t) = \xi_{4N+2}(t) \quad (12a)$$

$$\dot{\xi}_{4N+2}(t) = \frac{K}{M}[\xi_{4N-3}(t) - \xi_{4N+1}(t)] + \frac{C}{M}[\xi_{4N-2}(t) - \xi_{4N+2}(t)] + \frac{1}{M}f(t) \quad (12b)$$

for the last (N -th) unit cell of the meta-impactor and the linear oscillator, respectively. The post-impact velocity states of the i -th unit cell are computed by

$$\begin{bmatrix} m & \mu \\ 1 & -1 \end{bmatrix} \begin{bmatrix} \xi_{4(i-1)+1}^+ \\ \xi_{4(i-1)+2}^+ \end{bmatrix} = \begin{bmatrix} m\xi_{4(i-1)+1}^- + \mu\xi_{4(i-1)+2}^- \\ -r\xi_{4(i-1)+1}^- + r\xi_{4(i-1)+2}^- \end{bmatrix} \quad (13)$$

3 PARAMETRIC ANALYSIS

The behaviour of the meta-impactor is studied in the MATLAB[®] environment using the ode45 function (AbsTol=eps, RelTol=eps^(2/3), Refine=4 and MaxStep=0.01/sqrt(K/M), with eps corresponding to the *machine epsilon*). Impacts are being detected by an appropriate multiple event function. For each such impact, the simulation halts, the post-impact velocity states of the corresponding unit cell are calculated and the simulation continues from the same time instant by keeping all other states unaltered. A linear oscillator with $M = 1$ kg, $f_n = 1$ Hz and $\zeta_n = 2\%$ is chosen, subject to a harmonic excitation of unit amplitude ($A = 1$ N). For all the individual investigations the meta-impactor damping is selected to be zero ($c = 0$ Ns/m), while the coefficient of restitution remains constant ($r = 0.6$). Unless otherwise specified, the clearance is set at $D = 0.1$ m.

Following the findings of Dertimanis *et al.* [31], regarding the significance of the mass and stiffness ratios in the vibration attenuation performance of a linear, periodic, mass-in-mass lattice, a first insight is gained by varying these quantities of the meta-impactor. In specific, the ratios μ/m and K/k are varied within $[0.1, 1.0]$ and $[10, 100]$, respectively, at three fixed m/M ratios (namely, 1%, 50% and 100%) and for $N = 1, 2, 5$ and 10. For each realization, the maximum absolute vibration displacement response of the linear oscillator is recorded for a 10 s simulation time and an excitation frequency $f = f_n = 1$ Hz.

The results are expanded over Figs. 3– 6 and show that when $m/M = 0.01$ (e.g. far left plots in Figs. 3– 6), the performance of the meta-impactor is mainly dominated by the stiffness ratio. This is confirmed by the distinct vertical zones of the corresponding surf plots, inside which the variation of the vibration response due to different μ/m ratios is negligible. The addition of unit cells increases the vibration displacement response amplitude, as can be observed by the relative colobars on the right of each plot. This is attributed to the introduction of additional degrees of freedom, which most likely lead to higher transient response times (recall that the simulation is only 10 s). Yet, regardless the unit cell number, the vibration displacement response reaches its lowest levels (below 0.1 m) when $m/M = 1$ and for low μ/m and K/k ratios.

Figure 3: Maximum absolute displacement at 1 Hz for $N = 1$ and varying masses/stiffness ratios.

Figure 4: Maximum absolute displacement at 1 Hz for $N = 2$ and varying masses/stiffness ratios.

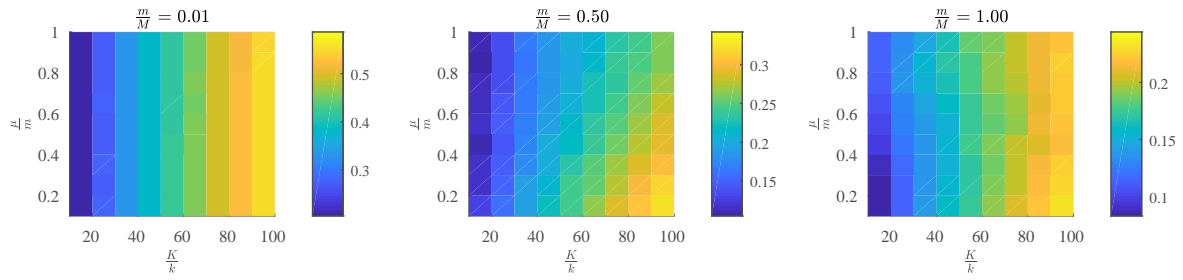

Figure 5: Maximum absolute displacement at 1 Hz for $N = 5$ and varying masses/stiffness ratios.

Figure 6: Maximum absolute displacement at 1 Hz for $N = 10$ and varying masses/stiffness ratios.

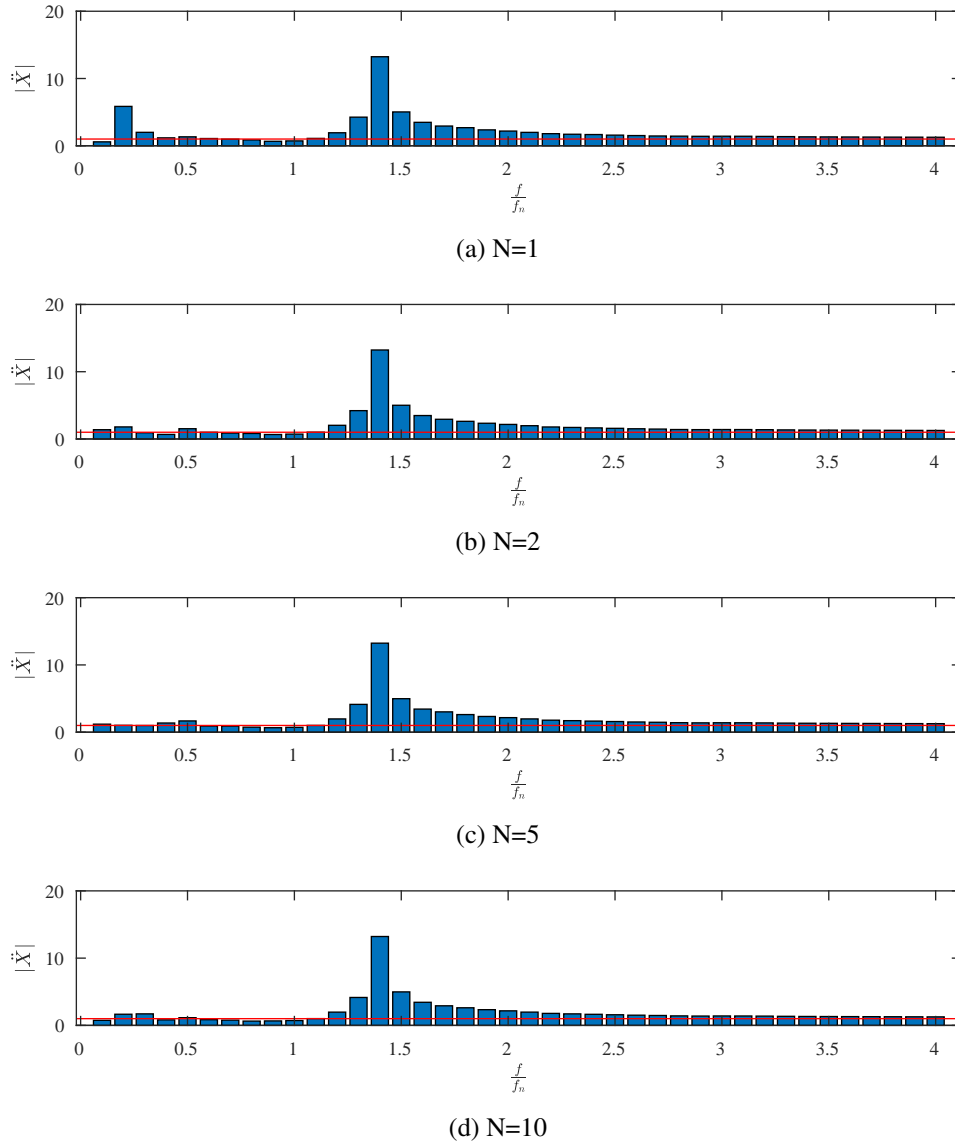

Figure 7: Maximum absolute acceleration of the linear oscillator for various unit cells of the meta-impactor, as a function of the frequency ratio. The red lines correspond to $|\ddot{X}| = 1$.

Based on these findings, a subsequent series of simulations is carried out for $m/M = 1$, $\mu/m = 0.1$, $K/k = 10$ and for the same number of unit cells as before. The simulation time is now increased to 50 s and the vibration acceleration response (maximum absolute value) of the linear oscillator is calculated for a frequency ratio f/f_n that varies in $[0.1, 4.0]$. As Fig. 7 indicates, there's a certain suppression of the response up to around 1.2 Hz (recall that the damping of the meta-impactor is zero). Increasing the number of unit cells does not significantly alters the suppression properties of the meta-impactor, yet, it is shown that when $N = 1$ there's a distinctive peak at 0.2 Hz, which does not appear in higher unit cell numbers.

A final investigation pertains to the coefficient of restitution. Figure 8 illustrates the maximum absolute vibration acceleration response of the linear oscillator for an excitation frequency $f = 1$ Hz, as a

function of r ranging from 0.1 (almost plastic collision) to 1 (perfectly elastic). It can be observed that the response is not much sensitive to low values of the coefficient of restitution, yet it is getting larger when the collision goes close to the perfectly elastic range, while at the limit it is even amplified, compared to the excitation amplitude.

4 CONCLUSIONS

This study investigated a nonlinear device for vibration attenuation, the meta-impactor, consisting of impact dampers as unit cells. Critical parameters of the structure, including mass and stiffness ratios, as well as the coefficient of restitution and the number of unit cells were explored. The results indicate

a certain degree of effectiveness, yet, they have also shown that proper tuning of the meta-impactor is a highly non trivial problem. The authors are currently performing research on this direction, trying to gain more insight on the theoretical and design aspects of this nonlinear device, yet also to establish a series of experiments for assessing more thoroughly its actual behaviour.

Keywords: multi-layer core, sandwich panels, transmission loss, periodic structures.

Abstract. In the last decades, the main issue concerning structures is related to weight constraint. Many solutions are available as composites or sandwich panels. Nevertheless, it seems that metamaterials such periodic structures focus a specific attention nowadays. In this field, honeycomb structures remain wide used solutions especially in the aerospace industry, but they exhibit a high stiffness-to-weight ratio leading to poor acoustic properties. Consequently, some new designs are created to obtain better acoustic indicators. In this context, this paper proposes to study a new kind of periodic structures using multi-layer core topology systems consisting on stacking layers made of different geometry of cores (auxetic, hexagonal, rectangular...). Several new parameters should be considered to fully understand the dynamic and acoustic behaviour. In this paper we will limit the study to rectangular core combined with a random core located in between. Consequently, we will stack 3 kind of cores: Rect-Random-Rect. The main objective of this study is to analyse the results of the parametric survey. All configurations are constraint to have the same surface density. The chosen acoustic indicator is the Sound Transmission Loss (STL). The transition frequency will be also investigated as well as the compression and shear modulus and the bending waves. Modelling these structures is possible using either Wave Finite Element Method (WFEM) only or combining WFEM and the Transfer Matrix Method (TMM). We assume an infinite panel, real wavenumbers and that the structure is excited by plane waves with the angles of incidence and reflection equal. The model is implemented using MATLAB and ANSYS apdl. Because such structures are made using a 3D printer, the ABS is used as the material for the study. From the parametric study, it turned out that multi-layer core systems correspond to relevant solutions to highly improve the STL. Moreover, it is possible to find out an optimized design giving the best STL. However, as it will be shown, it goes along with less efficiency in terms of mechanical properties and thus should be relevant for some specific applications.

1 INTRODUCTION

Lightweight structures including composite panels, sandwich panels or porous media are still widely used in the industry due their low mass. Besides, sandwich panels made of periodic cores exhibit a great interest having a low stiffness to weight ratio but leading to unsatisfactory acoustical properties. Many researches are carried out to provide them better mechanical and acoustical performances according to the industrial application. Proposed designs in the literature begin from simple cases as composite panels, studying the stacking sequences between layers to improve their mechanical efficiency [1,2], up to more complex structures using more exotic shapes and/or adding add-ons [3,4,5,6], especially within the periodic media field. More recently, multi-layer core topology systems have been developed by stacking different layers of cores (auxetic, hexagonal, rectangular, random geometry) to operate with new parameters. A double-layer honeycomb panel has been studied in [7] to drastically reduce the effect of the critical frequency of the Sound Transmission Loss (STL). Besides, corrugated and truss cores are stacked for building applications [8,9,10] trying to reach a more desirable impact resistance. Most of time, authors add damping layers separating the cores. These last designs are mainly considered for their capacity to absorb energy for specific mechanical applications but not employed as concerns acoustics. It is then clearly expected that more complex structures will continue to be investigated in the future to obtain improved properties. Consequently, this paper intends to analyze multi-layer core topology systems within the framework of periodic structures and to perform a parametric survey with the involvement of new parameters. Such approaches have been already completed for vibroacoustic properties in standard cases using honeycomb cores [11,12] or by changing gradually the core from a honeycomb to an auxetic unit cell [13, 14]. They have shown up the influence of geometrical parameters on vibroacoustic indicators (transition frequency, the modal density, the group velocity) and the STL. All these indicators reveal a better comprehension of the phenomenon leading to the improvement of the acoustical performances. In this paper, the parametric survey will be characterized by a study of the geometrical parameters of one layer over three opening new configurations and new perspectives not limited as one-core unit cell structures and leading to a high improvement of the STL.

2 MULTI-LAYER CORE TOPOLOGY SYSTEMS

2.1 Description

Multi-layer core topology systems are made of several layers of periodic structures (hexagonal, auxetic, rectangular, ...), Fig. 1.

Figure 1 : Multi-layer core topology systems

Such structures involve new parameters to be considered to figure out the dynamic and the acoustic behavior. These parameters are listed as following:

1. The phase shift between layers
2. The rotation between layers
3. The interaction between geometrical parameters of each layer giving the possibility to modify the shape of the unit cell for each layer.
4. The size of the unit cell for each layer.
5. The periodicity of each layer.

The phase shift and the rotation make occur lower rigid contacts between layers leading to new phenomena which tend to affect the transition frequency and decrease the compression modulus of the structure. Nevertheless, their impact on the STL still need to be verified. The phase shift is possible along the direction x and y . In addition, the rotation between layers produces a non-periodic structure. The existing methods using the Wave Finite Element Method (WFEM) for the calculation of vibroacoustic indicators are not applicable. Finally, they offer a great added value by keeping the mass constant.

Changing the geometrical parameters for each layer turns out the possibility to have different shape for each layer, and then, combining a hexagonal core with an auxetic or a rectangular core, or more generally random cores and increasing the number of possibilities and the complexity of the unit cell.

Ultimately, the size of the unit cell and the periodicity for each layer are linked. Indeed, the only way to extract a unit cell in this configuration comes out when each layer has a unit cell size multiple to each other and without rotation.

Resulting from these parameters, it is then not always possible to extract the unit cell through the depth of the structure. The entire sandwich panel must be modeled and a high computational is expected. Therefore, some listed parameters will be constrained to have the opportunity to use the WFEM and to apply the model allowing to obtain the STL.

2.2 Parametric model

The illustrated parametric model (Fig. 2) will be used for the study. Each layer has the same unit cell size and no rotation is considered. The main purpose in this study is to identify the geometrical influence of the shape of the core. The thickness of the core and the skins as well as the height of each layer will be not altered since it is shown in [4] that they have a strong influence on the mechanical and acoustical properties. Thereby, by keeping the mass constant, only parameters defined in the parametric model influence the STL. An algorithm, developed in the lab, gives the possibility to obtain all configurations having the same surface density for a given size of unit cell. Since the size of the unit cell is maintained and the depth of each layer are equal and the parameter n is set to $1/2$, only 5 parameters are modified: a_1 , a_2 , a_3 , α and β . However, to represent correctly the result coming from the parametric survey it is necessary to reduce the number of parameters. Consequently, it is decided that $a_1 = a_2$.

The size of the unit cell is fixed to $L_x = 15$ mm and $L_y = 15$ mm. A sandwich panel with 3 layers is considered. The top and bottom layers correspond to a rectangular core while the middle core is a random core defined by the set of parameters. The depth of each layer is 5 mm. The thickness of the skins and the core is 0,6 mm. The sandwich panel is made of ABS since the 3D

printing technic is commonly used to manufacture these structures, with $E = 1,8 \times 10^9$ Pa, $\rho = 985$ kg/m³ and $\nu = 0,33$. The damping η is evaluated at 2 %. These values were acquired using a DMA test. From the algorithm, the number of configurations is obtained (Fig. 3) given a certain range of surface density with $a_3 = L_x/4$. They will be compared to a standard periodic structure with a rectangular core whose surface density is equal to 0,57 kg/m². Thereby, 216 configurations are possible. The parameter a_3 is then used to be shifted in the along x with 6 different values between 0 and L_x . Consequently, 1296 configurations in total will be computed. For each configuration the STL is calculated. A wise choice for the model must be done to avoid high computational cost.

Figure 2 : Parametric model

Figure 3 : Number of configurations with $L_x = 15$ mm and $L_y = 15$ mm and $a_3 = L_x/4$.

By taking this range of surface density and having all the possibilities for each parameter, it is possible to plot each parameter as a function of others. It occurs that the angle α and β are linked by a logarithmic function as shown in Fig. 4. Consequently, the set of parameters could be reduced to a_1 , a_3 and α since $\alpha = f(\beta)$.

Figure 4 : $\alpha = f(\beta)$

3 MODELLING

During the last decade many models were developed to calculate vibroacoustic indicators. This paper is mainly focused on the STL as the acoustic indicator. Considering an incident plane wave impinging a structure with a specific angle, this will create 3 other waves corresponding to a reflected, transmitted and absorbed wave as illustrated in Fig 5. The STL is defined with the ratio $\tau = |W_t / W_i|$ which is the ratio between the acoustic power of the transmitted and incident wave and could be obtained for specific angles (Eq. 1).

$$STL(\theta, \phi, \omega) = -10 \log_{10} \frac{W_t}{W_i} \quad (1)$$

The STL is also calculated for a diffuse field by the integration over all angles $\theta \in [0^\circ, 90^\circ]$ and $\phi \in [0^\circ, 360^\circ]$ and yield to Eq. 2.

$$STL_d(\omega) = \frac{\int_0^{2\pi} \int_0^{\theta_{max}} \tau(\omega, \theta, \phi) \sin(\theta) \cos(\theta) d\theta d\phi}{\int_0^{2\pi} \int_0^{\theta_{max}} \sin(\theta) \cos(\theta) d\theta d\phi} \quad (2)$$

In 2016, two methods released [15, 16] using the nodal surfaces and the Transfer Matrix Method (TMM) concept combined with the WFEM respectively. They allow to model complex

structures without homogenization. More recently, [17] added their contribution by developing a hybrid wave-based method with finite element to add more complexity to the structure as resonators. It is possible to model other type of fluid on both sides of the structure such as strong fluid-structure interaction. In this paper, the method developed in [16] will be used. Indeed, the computational cost is drastically reduced since the skins are modeled using the analytical formulation for simple plate. The core is modeled with Ansys apdl using SHELL elements and MATLAB for post processing. It is assumed an infinite panel, real wavenumbers and that the structure is excited by plane waves with the angles of incidence and reflection equal. The principle of this method is illustrated in Fig. 6.

Figure 5 : Plane wave incidence, reflection, transmission and absorbed at the interface of a sandwich panel.

Figure 6 : Procedure for applying the method developed in [16]

Finally, to perform the parametric analysis two options are chosen for simplification. Firstly, due to the orthotropy of the structure resulting from the honeycomb core, it is not necessary to calculate the diffuse field. From the dispersion curves of the standard case corresponding to the rectangular core, bending waves reveals the direction x as critical to determine the acoustic efficiency of the structure. It is shown that the intersection with the acoustic wavenumber and bending waves occurs in the direction x . Thus, the STL will be calculated for an angle $\varphi = 0^\circ$ and $\theta = 45^\circ$ exciting the structure in its x -direction only. In addition, the target indicator is

defined as the integration of the STL over the frequencies as it is done in [18]. The more the value is high the more the structure is considered acoustically efficient.

Figure 7 : Bending waves of the standard case (rectangular core)

3 PARAMETRIC SURVEY

The first result was obtained having all configurations with different values of a_3 . It is shown in Fig. 8 that a quasi-symmetry occurred related to the chosen parametric model. As it can be noticed, the parameter a_3 has a strong influence on the STL and the highest values of STL is obtained when $a_3 = Lx/4$. The next steps of the parametric analysis are carried out with $a_3 = Lx/4$.

Figure 8 : Effect of the parameter a_3 on all configurations

Fig. 9 shows the effect on the STL of the angles α and β for different values of a_1 . The influence of the angles is highly dependent on the value of the parameter a_1 . The angles α and β become critical parameters when $a_1 = Ly/4$. Consequently, for such configuration it is necessary to make a wise choice on the angles. The highest values of the STL are obtained with $a_1 = 1,25$ mm and $a_1 = 6,25$ mm.

Figure 9 : Effect of the angles of the core α and β with specific values of the parameter a_1 .

Finally, the effect of the pair (α, β) is illustrated in Fig. 10. It is shown that depending on the value of the STL, the pairs (α, β) correspond to a linear function in which the value of the intercept has a critical influence. The highest value of STL occurs when the intercept is the lowest and the pairs (α, β) are highlighted in Fig. 10.

From this parametric study the optimized configuration can be listed in the following Tab. 1. with a_1 and a_2 equal to 1,25 mm or 6,25 mm and $a_3 = Lx/4$. Since the unit cell size is 15 mm by 15 mm, the angles are almost neglectable and could be considered as 0° . Nevertheless, the optimized unit cell with the highest STL value correspond to $(1,4^\circ, 0^\circ)$.

Table 1: Pairs of (α, β) for the optimized unit cell.

α (°)	-4,9	-3,3	-1,6	0	1,4	3	4,8
β (°)	-6,5	-4,9	-3,2	-1,6	0	1,4	3

Figure 10 : Influence of the pair (α, β) given with $a_1 = 1,25$ mm and $a_1 = 6,25$ mm.

4 OPTIMIZED VS STANDARD STRUCTURE

Thanks to the parametric survey, it is then possible to compare the optimized structure with the standard rectangular core. The Fig. 11. shows the great improvement obtained with the multi-layer core system in all the frequency range. The coincident frequency is shifted to higher frequencies.

Figure 11 : Comparison of the STL ($\theta = 45^\circ$ and $\varphi = 0^\circ$) of the optimized structure with the standard case.

This result is confirmed with the comparison of bending waves in Fig. 12. The multi-layer core has lower equivalent mechanical properties in both direction x and y and lead to an intersection with the acoustic wavenumber to a higher frequency. The acoustic wavenumber is calculated for a diffuse field and the intersection correspond to the critical frequency. Consequently, the optimized structure should be still acoustically efficient in a diffuse field.

Figure 12 : Bending waves comparison of the optimized and standard structure.

Finally, the mechanical and acoustical properties for both structures are summarized in the following table (Tab. 2).

Table 2: Mechanical and acoustical properties.

	standard	optimized
Compression modulus (MPa)	227	92
Transition Frequency (Hz) (ftx, fty)	(2910, 1694)	(1388, 251)
STL integration (dB)	26,71	32,88

The compression modulus is calculated along z-axis. As it is noticed, the improvement of the STL goes along with a reduction of the compression modulus and the transition frequency in both directions. Multi-layer core systems show a great interest in terms of acoustic properties while mechanical properties seem to be lower than a standard one core unit cell. These results were obtained without altering the mass which is a critical parameter especially in the aerospace industry.

5 CONCLUSIONS

This paper has been focused on the study of multi-layer core topology systems made of 3 layers with a top and bottom rectangular core and a random middle core. It has been shown that this new kind of structure involves new geometrical parameters to be considered. A parametric survey has been suggested to study the influence of this geometrical parameters on the random core. The parameter a_1 and a_2 were considered equal. The STL has been chosen as the target acoustic indicator and a WFEM combined with the TMM method has been used to model the unit cell.

It occurs through the analysis that all parameters seem to have an interaction with the other and could become critical in some configurations. The parameter a_3 have a strong effect on the STL and is maximum when $a_3 = Lx/4$. In addition, the pair (α, β) have an impact on the STL when $a_1 = a_2 = Ly/4$ and their influence decrease when a_1 get close to 0 or $Ly/2$. Moreover, after fixing $a_1 = 1,25 \text{ mm}$ or $6,25 \text{ mm}$, it was shown that the pair (α, β) turned out a linear relationship according to the value of STL. Thereby, the optimized pair (α, β) corresponded to the equation with the lowest intercept. Consequently, an optimized structure with the same surface density of the standard rectangular core was obtained as well as the comprehension of the influence of each parameter of the parametric model.

Ultimately, the parametric analysis may introduce new target indicators as mechanical and vibroacoustic indicators. In addition, this parametric model proposes some tools to verify the influence of each parameter and could be applied to other standard structure as hexagonal and auxetic core widely spread in the industry. Finally, some vibroacoustic indicators as the transition frequency seems to be strongly influenced by the geometry of the multi-layer core and should be studied.

ABSTRACT

To predict the wave characteristics of the periodic media in the presence of fuzzy uncertainties, the wave finite element method in conjunction with fuzzy logic and algebra has been applied. For one-dimensional wave propagation, firstly, the most significant input parameters such as Young's modulus and mass density are identified and then *fuzzified* using the membership functions. Then, the fuzzy variable is propagated through the numerical model of interval analysis. The dispersion curves for flexural and longitudinal waves with fuzzy parameters have been used to illustrate the generality of the proposed approach also looking at the possibility to have frequency region in which those waves cannot propagate (frequency band gaps). The triangular membership functions have been used in the numerical examples and the obtained results are compared against the classical Monte Carlo simulations (MCS). The approach was presented for very simplified test-cases but it is found to be more efficient when compared with the conventional MCS approach in terms of computational cost.

Key words: WFEM, uncertainty modeling, periodic media, bandgap, fuzzy analysis.

1 INTRODUCTION

In recent years the propagation of elastic waves in periodic media with periodic material and geometrical properties has been extensively studied. These periodic media offer property known as band gaps where the propagation of the elastic wave is restricted in all the directions. Such properties are demanded for the vibroacoustic performance and dynamics of the structure and especially sought in aeronautics, transport, energy and space for vibration reduction, acoustic blocking, acoustic channeling and acoustic cloaking [1].

Three different frequency ranges identified: at the low-frequency range, because of the low order modes and low sensitivity to variability generally, the finite element approaches are applicable; and high frequency, energy-based methods (e.g. Statistical Energy Analysis (SEA))

are well suited because of the involvement of many high order modes; finally the mid-frequency range affected by the variability of the model parameter and wave-based approaches has been developed by increasing computational efficiency [2].

The design of periodic media is generally based on deterministic models without considering the effect of intrinsic uncertainties existing in these media. In general, the design is aimed at controlling as much as possible the mechanical waves; however, inherent uncertainty may affect their characteristics. Periodic media are diffused in all the transportation engineering and demand a high level of robustness, which can be ensured with the careful consideration of the presence of uncertainty in the numerical models. The uncertainties, in terms of material properties and geometrical parameters, are mostly exhibited in both the manufacturing and assembly processes. To address this unavoidable actuality, the effects of uncertainties need to be considered when analyzing band structures (pass and stop bands). Generally, the stochastic characteristics of the periodic media can be determined by studying the design parameter uncertainties which are often modeled by random variables with consideration for spatial variability of the material and geometrical properties.

Manohar et al. studied the randomness in the wave propagation in waveguides using spectral element analysis [3]. Ichchou et al. proposed a numerical approach using the Wave Finite Element Method (WFEM) considering spatially homogeneous variability in waveguides using a first and second order perturbations are proposed [4][5]. Recently Rayleigh quotient method introduced to investigate the symplectic eigenvalue problem of random symplectic matrix [6]. The material or geometrical uncertainty often displays spatial correlation, in layered structures. There, random fields theory can be used to model spatially distributed variability with probability measure [7]. Also, this would be an approximate representation for the spatially varying system [8].

The probabilistic models to account for these uncertainties employ probabilistic methods which require a wealth of data on probabilistic parameters. The exact sources of uncertainty are rarely found since their identification represents a difficult task. Furthermore, even small inaccuracies in the data can lead to large errors in the computed probability of response [9].

When faced with incomplete information such as, “*Young’s modulus of the material lies between 70 GPa to 72.4 GPa,*” “*mass ration is about 4%,*” and “*lenght of side slightly larger than 1.2m,*” cannot be accomdated by deterministic model[10]. In fact, statements as “*the mean are approximately equal to..*” and “*the variance lies in the range..*” are typical when handling real mechanical data and by virtue of their subjective nature they deal with fuzzy uncertainties[11]; the adoption of the probabilistic approach can result in very challenging evaluations. In this scenario, the fuzzy set theory offers a way to approximating the uncertainty distribution in the form of the confidence interval through fuzzy membership functions. These are equivalent representations for the characterization of the linguistic, vague and missing data uncertainties.

The work reported so far in the literature with the best of the author's knowledge, is limited to wave propagation in elastic media and random media with probability method. In this work, a possibilistic method developed for the fuzzy uncertainty modeling and propagation in conjunction with WFEM and named as FWFEM (fuzzy wave finite element method). The approach was presented for a very simplified test-case 1D periodic bar and beam model with

fuzzy uncertainty. It is modeled using triangular membership function and uncertainty bound are computed with fuzzy arithmetic steps and α -cut method. The results of FWFEM formulation are compared to those obtained from MCS.

2 FORMULATION OF FWFEM

Firstly the definition of the fuzzy membership function is revisited [12]. Let U is a classical set of objects, it is called the universe. The generic elements of U are denoted u . Then the membership in a classical subset A of U can be viewed as a characteristic function μ_A from U to $\{0, 1\}$ such that

$$\mu_A(u) = \begin{cases} 1, & \text{if } u \in A \\ 0, & \text{if } u \notin A \end{cases} \quad (1)$$

The set $\{0, 1\}$ is called a valuation set. A set A is called a fuzzy set if the valuation set is allowed to be the real interval $[0, 1]$. The fuzzy set A is characterized by the set of pairs

$$A = \{[u, \mu_A(u)], u \in U\}$$

where $\mu_A(u)$ is called the grade of the membership function.

Figure 1: Triangular membership function

α - Cuts: When an element $u \in U$. The α -cut A_α of A , which is a fuzzy set of crisp values U and is the original set of membership values greater than some threshold $\alpha \in [0, 1]$.

If triangular fuzzy set A shown in Fig.1 is denoted by $A = \langle a, b, d \rangle$ then the α -cuts of the A can be shown as:

$$[a + \alpha(b - c), d - \alpha(d - b)], \quad \alpha \in [0, 1] \quad (2)$$

To propagate the fuzzy uncertainty in the dynamic model, the α -cut method is adopted. In this method, fuzzy membership function is discretized to different interval using α -cut level concept. For each α -cut, the interval analysis is performed with Sobol sequence to get the maximum and minimum bound of the response.

One dimensional periodic media obtained by formulating the unit cell and then repeating in the propagation direction. Then, the study of this media can be converted into a study of unit cell based on the Floquet-Bloch theorem [13]. The schematic representation is shown in Fig. 2.

Figure 2: Schematic representation of periodic structure

The WFEM is used to study the behavior of periodic media. This is extended to apply the WFEM for the fuzzy uncertainty modeling. This starts with consideration of the fuzzy membership function as a supplementary dimension through the fuzzy arithmetic using fuzzy set theory. Which start from the discretization of one sub-element of length (d). This discretization leads to fuzzy dynamic equilibrium of any substructure. The imprecise or vague variables are modeled using the triangular membership function, such that the dynamical equilibrium is expressed as:

$$[-\omega^2 M(+)K(1+i\eta)](\cdot) \begin{pmatrix} q_L \\ q_R \end{pmatrix} = \begin{pmatrix} F_L \\ F_R \end{pmatrix} \quad (3)$$

The (\cdot) symbol denotes the fuzzy arithmetic.

The dynamic stiffness matrix is condensed into the left and right side denoted by L and R respectively.

$$\begin{pmatrix} D_{LL} & D_{LR} \\ D_{RL} & D_{RR} \end{pmatrix}(\cdot) \begin{pmatrix} q_L \\ q_R \end{pmatrix} = \begin{pmatrix} F_L \\ F_R \end{pmatrix} \quad (4)$$

By defining two state vectors in the left and right side of each element and are related by symplectic matrix S as:

$$u_R = S(\cdot)u_L \quad (5)$$

Where

$$S = \begin{pmatrix} -D_{LR}^{-1}(\cdot)D_{LL} & D_{LR}^{-1} \\ D_{RL} - D_{RR}(\cdot)D_{LR}^{-1}(\cdot)D_{LL} & -D_{RR}(\cdot)D_{LR}^{-1} \end{pmatrix}$$

Then using the periodicity and Bloch's theorem, spectral eigenvalue problem is expressed as

$$S(\cdot)\Phi_i = \mu_i(\cdot)\Phi_i \quad |S - \mu_i(\cdot)I_{2n}| = 0 \quad (6)$$

The solution of the above equation leads to identify the propagation constant and mode shapes. The considered structure is dissipative and the wave classified as incident ($|\mu_i^{inc}| < 1$) and reflected ones ($|\mu_i^{ref}| > 1$). Considering the above classification the wave basis Φ composed by eigenvectors in following form:

$$\Phi = \begin{pmatrix} \Phi_q^{inc} & \Phi_q^{ref} \\ \Phi_F^{inc} & \Phi_F^{ref} \end{pmatrix} \quad (7)$$

Where q and F are the displacement and force component of eigenvectors with $\Phi_q^{inc}, \Phi_F^{inc}, \Phi_q^{ref}, \Phi_F^{ref}$ of the size of $n \times n$ matrices.

To obtain the harmonic response, The amplitude of wave at the first element obtained using

$$\begin{pmatrix} Q^{inc(1)} \\ Q^{ref(1)} \end{pmatrix} = \begin{pmatrix} I_n & 0 \\ 0 & \mu^N \end{pmatrix} (.) \begin{pmatrix} \Phi_F^{inc} & \Phi_F^{ref} \mu^N \\ \Phi_q^{inc} \mu^N & \Phi_q^{ref} \end{pmatrix}^{-1} (.) \begin{pmatrix} -F \\ q \end{pmatrix}$$

Projection of kinematic variable on wave basis and compute the displacement at the m^{th} element by relation

$$(Q)^m = \begin{pmatrix} \mu^{inc} & 0 \\ 0 & \mu^{ref} \end{pmatrix}^{(m-1)} (.) \begin{pmatrix} Q^{inc(1)} \\ Q^{ref(1)} \end{pmatrix} \quad (8)$$

3 RESULTS

This section shows the validation of FWFEM formulation presented in the previous section. The analysis is performed for the periodic rod and beam. Periodic rod and beam consist of section A of length l_1 and section B of length l_2 with different materials as depicted in the Fig. 3. Firstly, the longitudinal wave studied for the band gap and frequency response function (FRF) then flexural wave in the beam is studied.

3.1 Periodic rod with fuzzy uncertainty

In this subsection, the FWFEM is used to study the effect of fuzzy parametric uncertainty on the band diagram and FRF of a longitudinal wave in the periodic rod. The section of periodic

Figure 3: Symmetric unit cell

rod namely A and B made of aluminum and steel respectively. The length of section A is l_1 and section B is l_2 with 1m each with circular cross section of radius of 0.0644m.

To validate FWFEM results, a comparison made between the result from the proposed method and upper and lower bound obtained from MCS.

The uncertainty effect is studied considering fuzzy uncertain material properties modeled with triangular fuzzy membership function with lower and upper variation fixed at ± 10 percent of the nominal value. The considered frequency range for the numerical experiment from 1 Hz up to 5500 Hz. This frequency range considered to get the four complete band gap. The MCS

with 10000 samples is used to get the reference wave characteristics lower and upper bound of wave number.

In FWFEM formulation, stiffness and mass matrix of the two-node rod elements are considered.

The global stiffness and mass matrices formed with 100 elements in the unit cell of periodic rod in the MATLAB environment. The input material and geometric properties are shown in Table 1. It is to be mentioned that the material properties are chosen arbitrary for the test case.

Table 1: Geometric parameters and material properties of periodic rod

Geometrical and Material property	Nominal value
Rod length (A)	1 m
Rod length (B)	1 m
Radius of rod	0.0644 m
Young's modulus (A)	210 Gpa
Young's modulus (B)	70 Gpa
Mass density (A)	7800 kg/m ³
Mass density (B)	2700 kg/m ³
Loss factor (A) and (B)	0.001

The variation of fuzzy Young's modulus of section A (material 1) and section B (material 2) is considered as furnished in Fig.4.

FWFEM result at α -cut=0 (largest interval) in terms of upper and lower bounds of the wave number is compared with sampling upper and lower bound with 5000 samples. The comparison is shown in Fig.5. The results are in good agreement. The band gap envelopes for each value of the fuzzy elasticity in every α -cut can be extracted shown in Fig.6. It is visible that the effect of uncertainty (at the fixed level of uncertainty) on band gap bound is increasing with increasing frequency. The variation bound of the wave number at α -cut=0 is shown in Fig.7 and it can be inferred that the response membership function is not always symmetric about mean/crisp value. The upper bound of wave number is more sensitive to the uncertain elasticity.

Figure 4: Membership function for the fuzzy parameter

Figure 5: Upper and lower bound comparison

The FRF of a periodic rod of the finite extent of 20 m excited by unit force on the left end is furnished in Fig. 8 indicating the upper and lower bounds comparison at α -cut=0 (maximum bound). In Fig. 9 fuzzy bound of the FRF for the different value of α -cut is plotted. It can be seen that as the value of α -cut increase the fuzzy bound of FRF also decreases and finally at $\alpha=1$, without any simulation bound as expected, $\alpha=1$ represent the deterministic value.

3.2 Periodic beam with fuzzy uncertainty

In this subsection, the study of the fuzzy uncertainty effect on the flexural wave in the periodic beam is performed. For numerical simulation, Euler-Bernoulli beam theory is considered. The input material and geometrical properties are listed in Table 2.

For the fuzzy uncertainty propagation, the elasticity of material 1 and material 2 is fuzzified using triangular membership function and shown in Fig.4.

A two-node beam element with two degrees of freedom per node is considered. The global matrices (stiffness and mass) formed with 20 elements in the unit cell of the periodic beam in the MATLAB environment with input material and geometric properties given in Table 2.

FWFEM result at α -cut=0 is computed and compared with upper and lower bound obtained with MCS sampling (10000 samples) of the WFEM result and shown in Fig. 10. The frequency range of computation is 1-2000 Hz. The results are in good agreement. The variation bound of the wave number at a different frequency for the 11 α -cut levels is shown in Fig.11. it showed that at the same level of the α -cut upper bound of wave number is more sensitive to the uncertain elasticity.

Table 2: Geometric parameters and material properties of the periodic beam

Geometry/Property	Value
Beam length	0.5m
Height of beam	0.003m
Width of beam	0.003m
Young's modulus (A)	210 Gpa
Young's modulus (B)	70 Gpa
Mass density (A)	7800 kg/m ³
Mass density (B)	2700 kg/m ³
Loss factor (A) and (B)	0.01

Figure 6: Band gap bound

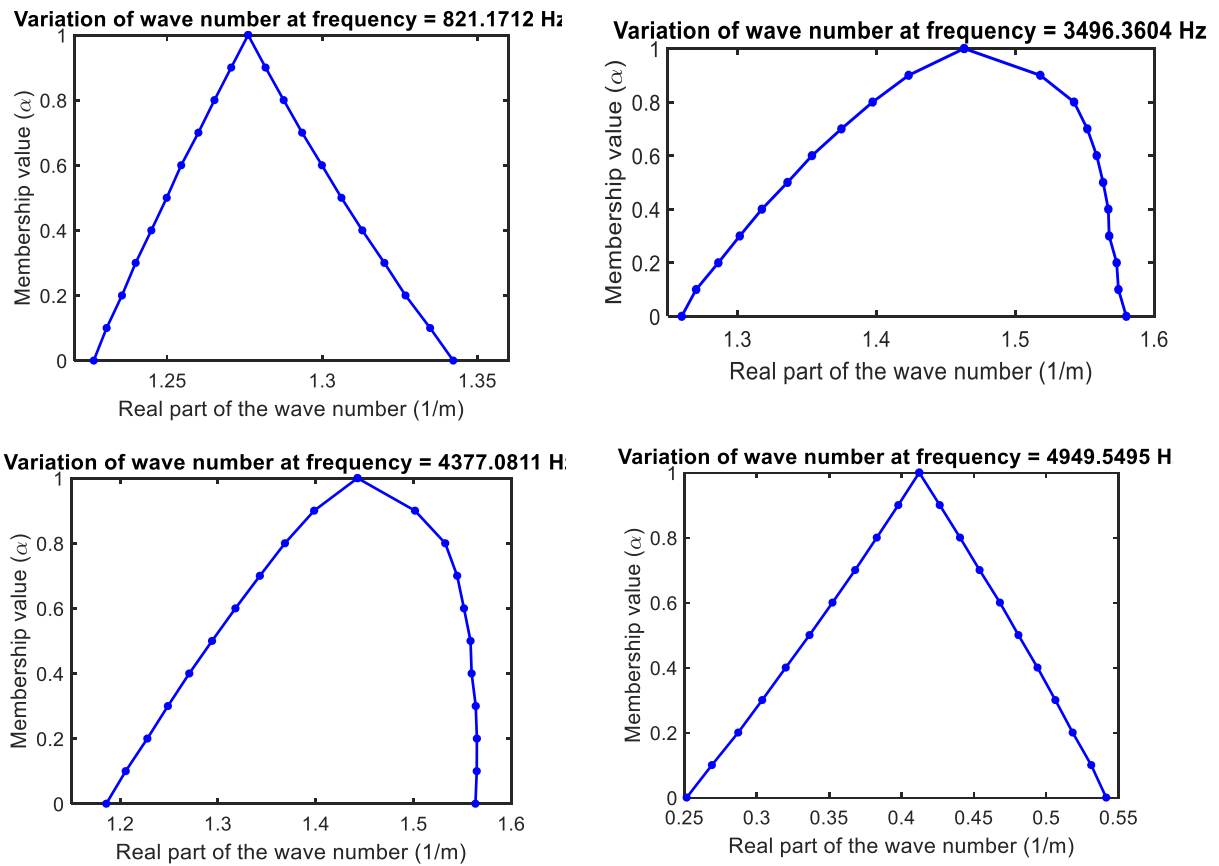

Figure 7: Variation bound of wave number at 11 α -cut level

Figure 8: Upper and lower bound comparison of FRF

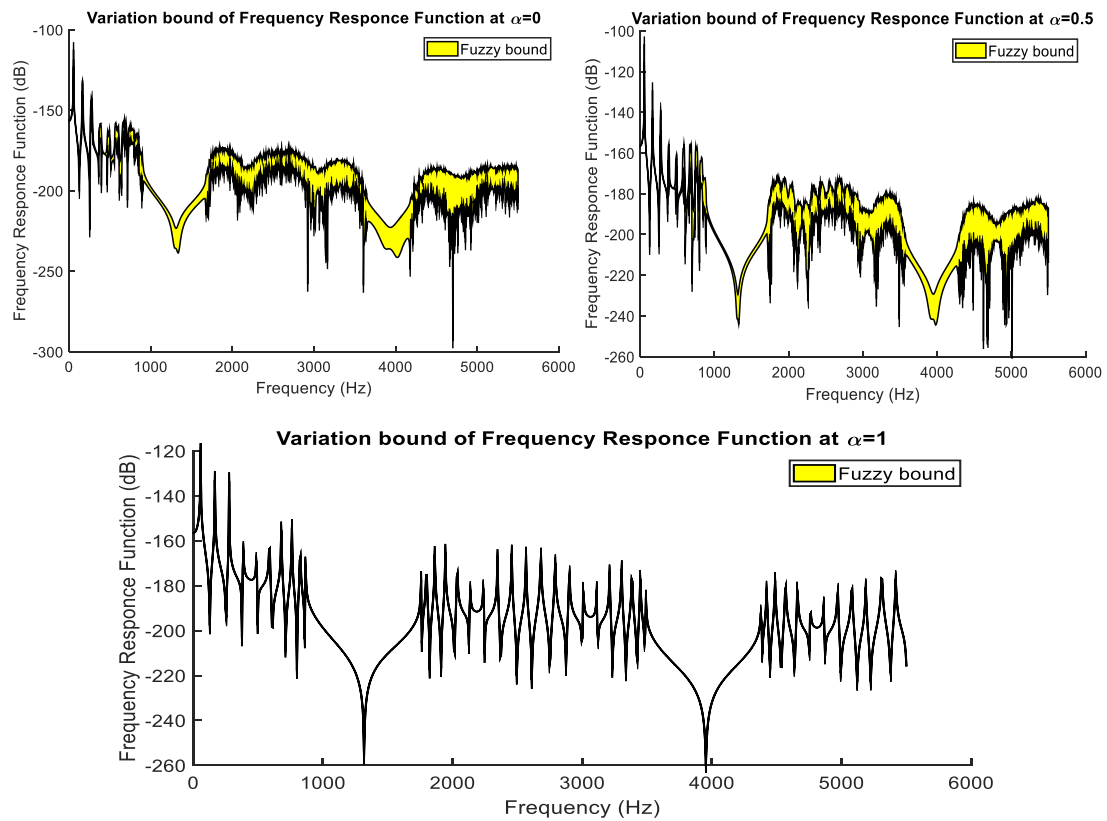

Figure 9: Fuzzy bound of FRF for the different value of α -cut

Figure 10: Upper and lower bound comparison

The FRF bound is shown in Fig. 12 representatives the bound at the different α -cut level. As α -cut value increase the fuzzy bound of FRF is expected to decrease. same can be seen from Fig. 13 as the value of membership increase the fuzzy bound is decreasing and lowest at $\alpha=0.9$.

For the computation cost comparison, elapsed time for the MCS and FWFEM obtained using homemade WFEM code which exploits the resources of the workstation with following characteristics, Intel® Core™i7 7820 HQ CPU@2.90GHz with 32 GB RAM and data storage using solid state drive. The comparison is presented in Table 3.

Table 3: Elapsed time comparison

Figure 11: Variation bound of wave number at 11 α -cut level

CONCLUSION

This paper provides a computationally inexpensive possibilistic numerical method for uncertainty propagation in 1D periodic media in conjunction with WFEM. This study proposes a new approach to predict uncertainty bounds of the band gap and FRF of periodic

rod and beam with fuzzy variations. The uncertainty quantification of wave number and frequency response function with fuzzy variables are derived using WFEM.

The approach was presented for very simplified test-cases, but it is found to be more efficient when compared with the conventional MCS approach in terms of computational cost. The present study can be extended for the future investigation for the complex unit cell and a large number of fuzzy variables.

Abstract. Space-time varying phononic materials have drawn great interest in the research community, due to their ability to break time reversal symmetry, therefore achieving one-way wave propagation in elastic structures. In analogy with their electric counterparts, these new devices are generally referred as acoustic wave diodes. In this manuscript we study discretely modulated beams, whose spatiotemporal unitary cells are made of sub-cells with time-varying elastic modulus. This new class of materials is able to break the mirror symmetry in the momentum space, which is necessary to achieve the acoustic wave-diode effect. Non-reciprocal Bloch diagram is computed using a generalization of the Plane Wave Expansion Method (PWEM) which can be applied to any modulation that can be written in a space-time Fourier basis. In this context, we show that the frequency spectrum is characterized by full and directional bandgaps, that are linked with the harmonic content of the spatiotemporal unit cell.

1 INTRODUCTION

Phononic crystals (PnCs) and acoustic metamaterials have been widely studied during the past years [1]. The growing interest in this field is motivated by the possibility to manipulate wave propagation in elastic media. That is, PnCs are characterized by spatial periodicity able to generate frequency bands - or bandgaps - in which waves cannot propagate. This feature can be exploited to design acoustic insulators [2], waveguides [3] and super-lenses [4], to name a few.

All these examples comply with the reciprocity principle, which means that waves propagate in the same manner from a point A to B and vice-versa. One possibility to achieve one-way wave propagation is to combine space and time varying material properties, mimicking the propagation of a wave [5, 6, 7, 8]. This new modulation concept is able to break the mirror symmetry in the momentum space, therefore generating bandgaps at different frequencies for left and right traveling waves. Although several works explain how time-space modulated waveguides support one-way wave propagation, there is no efficient and generally accepted method for the computation of the band diagram. Two valid alternatives are finite element Bloch-based method [9] and the *Plane Wave Expansion Method* (PWEM) [10]. If on the one hand the former, based on FEM, can be applied to a wide class of modulations (but to the expenses of computational resources and times), on the other hand the latter, based on PDEs, is faster but limited to plane wave modulations of material properties.

The first goal of this paper is to extend the formulation of the PWEM in order to make it applicable to a more general class of spatiotemporal materials, involving all the possible modulations in space and time. Once this new analysis tool is available, the second target of the work is to exploit the generalized PWEM for the analysis of discretely modulated periodic structures. In this context, we demonstrate that this new class of materials is characterized by full (reciprocal) and directional (non-reciprocal) bandgaps [11]. Specifically, linking the harmonic content of the unit cell to the symmetric and asymmetric parts in the frequency-momentum space.

2 Analytical procedure for band diagram computation

Consider an Euler-Bernoulli beam whose elastic and physical properties are spatially and temporally periodic, such that:

$$\begin{aligned} E(x, t) &= E(x + \lambda_m, t + T_m) \\ \rho(x, t) &= \rho(x + \lambda_m, t + T_m) \end{aligned} \quad (1)$$

where λ_m and T_m are spatial and temporal periods respectively. The governing equation describing longitudinal and transversal wave propagation writes:

$$\begin{aligned} \frac{\partial}{\partial x} \left\{ E(x, t) \frac{\partial u(x, t)}{\partial x} \right\} &= \frac{\partial}{\partial t} \left\{ \rho(x, t) \frac{\partial u(x, t)}{\partial t} \right\} \\ R_g \frac{\partial^2}{\partial x^2} \left\{ E(x, t) \frac{\partial^2 w(x, t)}{\partial x^2} \right\} &= - \frac{\partial}{\partial t} \left\{ \rho(x, t) \frac{\partial w(x, t)}{\partial t} \right\} \end{aligned} \quad (2)$$

being $R_g = J/A$ the radius of gyration and $u(x, t)$, $w(x, t)$ longitudinal and transversal displacement fields. The wave propagation characteristics of the medium can be computed exploiting a generalization of the PWEM. That is, material properties are written in terms of exponential functions:

$$\begin{aligned} E(x, t) &= \sum_{m=-M}^M \sum_{n=-N}^N \hat{E}_{m,n} e^{-j(m\kappa_m x - n\omega_m t)} \\ \rho(x, t) &= \sum_{m=-M}^M \sum_{n=-N}^N \hat{\rho}_{m,n} e^{-j(m\kappa_m x - n\omega_m t)} \end{aligned} \quad (3)$$

where the Fourier coefficients are computed performing a double integration in the time $[-\frac{T_m}{2}, \frac{T_m}{2}]$ and space $[-\frac{\lambda_m}{2}, \frac{\lambda_m}{2}]$ domains:

$$\begin{aligned} \hat{E}_{m,n} &= \frac{1}{T_m} \frac{1}{\lambda_m} \int_{-\frac{\lambda_m}{2}}^{\frac{\lambda_m}{2}} \int_{-\frac{T_m}{2}}^{\frac{T_m}{2}} E(x, t) e^{j(m\kappa_m x - n\omega_m t)} dx dt \\ \hat{\rho}_{m,n} &= \frac{1}{T_m} \frac{1}{\lambda_m} \int_{-\frac{\lambda_m}{2}}^{\frac{\lambda_m}{2}} \int_{-\frac{T_m}{2}}^{\frac{T_m}{2}} \rho(x, t) e^{j(m\kappa_m x - n\omega_m t)} dx dt \end{aligned} \quad (4)$$

The wave solution is therefore sought with the same associated periodicity, thus:

$$\begin{aligned} u(x, t) &= \sum_{p=-P}^P \sum_{q=-Q}^Q \hat{U}_{p,q} e^{j(p\kappa_m x - q\omega_m t)} e^{j(\kappa x - \omega t)} \\ w(x, t) &= \sum_{p=-P}^P \sum_{q=-Q}^Q \hat{W}_{p,q} e^{j(p\kappa_m x - q\omega_m t)} e^{j(\kappa x - \omega t)} \end{aligned} \quad (5)$$

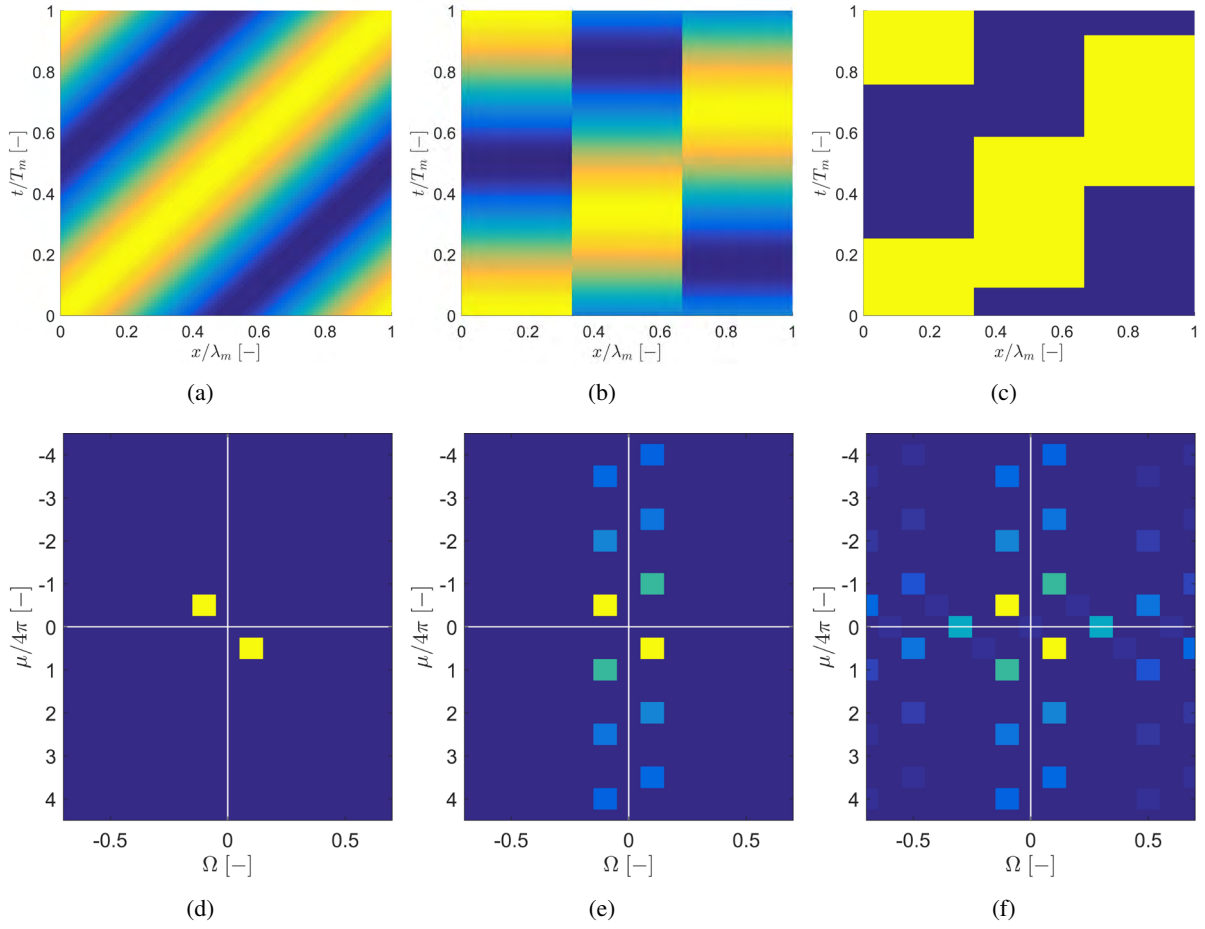

Figure 1: Plane Wave modulation 1(a) and corresponding 2D Fourier transform 1(d) in the wavenumber-frequency $\mu - \Omega$ plane. Here $\mu = \kappa\lambda_m$ and $\Omega = f\lambda_m/c_0$ are dimensionless quantities. Spatially discrete and temporally continuous unit cell 1(b) and associated spectral content 1(e), which includes more wavenumber components compared to plane wave modulation. Fully discrete space-time modulation 1(c) and 1(f). The spectral content is characterized by multiple wave components, which propagate along different directions.

Merging Eqs. 2-5 and enforcing orthogonality of exponential functions, the dispersion relation $\omega = \omega(\kappa)$ yields:

$$\begin{aligned} (\tilde{\mathcal{L}}_0^u(\kappa) + \tilde{\mathcal{L}}_1(\kappa)\omega + \tilde{\mathcal{L}}_2(\kappa)\omega^2) \tilde{\mathbf{u}} &= 0 \\ (\tilde{\mathcal{L}}_0^w(\kappa) + \tilde{\mathcal{L}}_1(\kappa)\omega + \tilde{\mathcal{L}}_2(\kappa)\omega^2) \tilde{\mathbf{w}} &= 0 \end{aligned} \quad (6)$$

which is a Quadratic Eigenvalue Problem (QEP) of size $\gamma = (2P + 1)(2Q + 1)$ being P, Q the Fourier series truncation orders.

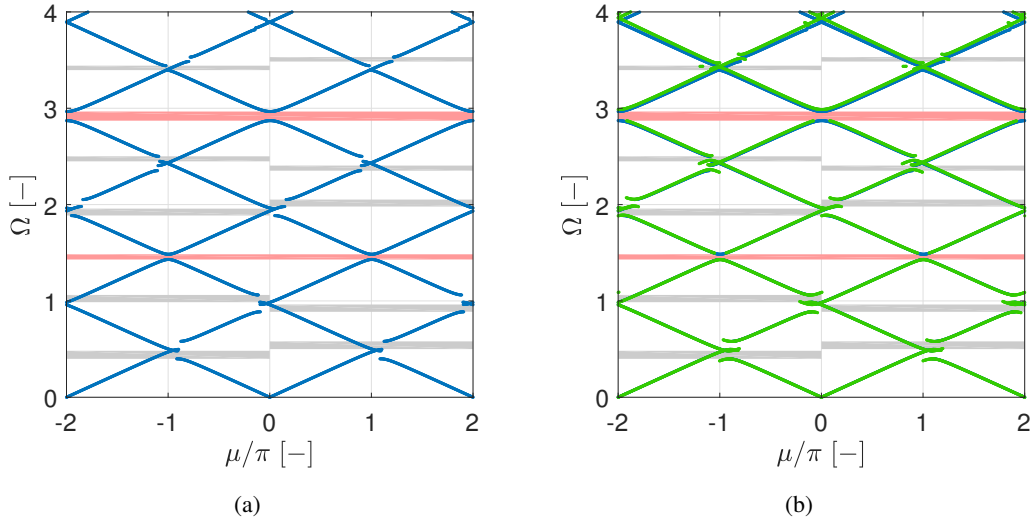

Figure 2: Bloch diagram for spatially discrete and temporally continuous unit cell 2(a) and comparison between generalized PWEM (blue line) and FE Bloch procedure (green line) 2(b). $\mu = \kappa\lambda_m$ and $\Omega = \omega\lambda_m/2\pi c_0$ are the dimensionless wavenumber and frequency respectively. Directional and full gaps are highlighted with colored bands.

3 Wave propagation in discretely modulated beams

Consider the longitudinal wave propagation problem in a discretely modulated beam, whose elasticity comply the following law:

$$E(x, t) = E_0 \left\{ 1 + \alpha_m \cos \left[-\omega_m t + (k(x) - 1) \frac{2\pi}{R_s} \right] \right\} \quad k(x) = \begin{cases} 1 & \text{if } 0 \leq x < \frac{\lambda_m}{R_s} \\ 2 & \text{if } \frac{\lambda_m}{R_s} \leq x < \frac{2\lambda_m}{R_s} \\ \dots & \\ R_s & \text{if } \frac{(R_s - 1)\lambda_m}{R_s} \leq x < \lambda_m \end{cases} \quad (7)$$

that is, spatially discrete and temporally continuous function. E_0 is the mean Young's Modulus value, α_m is the dimensionless modulation amplitude, R_s is the number of sub-elements constituting the spatio-temporal unit cell ($\alpha_m = 0.4$ and $R_s = 3$ in the remainder of this section). $v = \omega_m t / (\kappa_m c_0)$ is the dimensionless modulation speed which is set to 0.1 and $c_0 = \sqrt{E_0/\rho}$. The elasticity profile is represented in Figure 1 and compared with plane wave and fully discrete modulations, in terms of time-space and frequency-wavenumber domains. It is worth mentioning that discrete modulation is characterized by more spectral components having different propagation speed and direction. Specifically, one space-time harmonic for plane wave modulations and more components for discrete profiles.

The corresponding filtered ¹ dispersion relation (blue line) is represented in Fig. 2 which shows good agreement with the FE-based method (green line) described in Ref. [9]. Interestingly, the frequency spectrum is characterized by many directional gaps as the number of spatiotemporal harmonics owned by the unit cell Fourier decomposition in Fig. 1(e). Indeed, directional bandgap and unit cell spectral content share same periodicity, suggesting a direct relationship between them. The interaction between

¹i.e. only the leading component of the dispersion branches is plotted

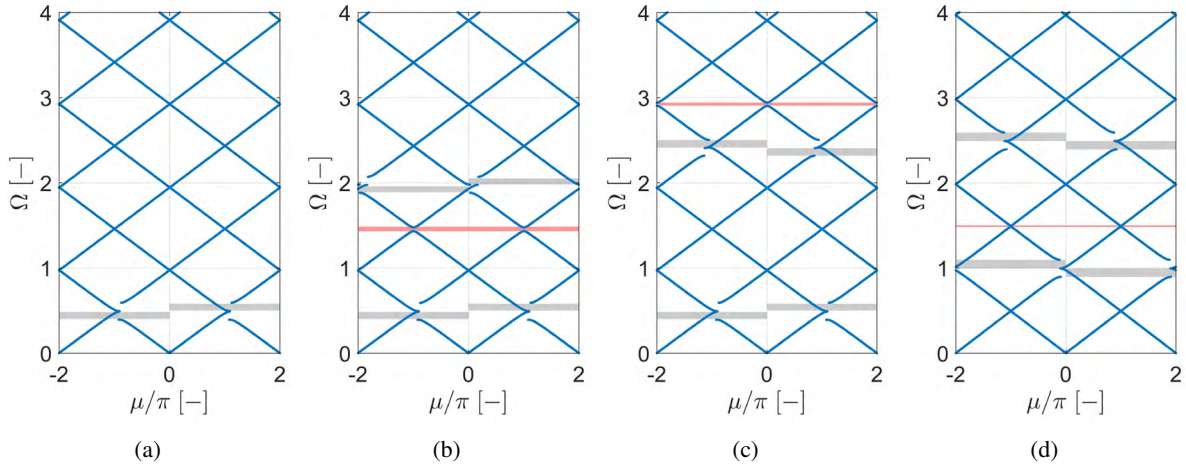

Figure 3: Filtered Bloch diagram for a plane wave modulation (1st harmonic only) 3(a). As a result, only a pair of directional gaps is supported by the media. Bloch diagram for a modulation given by the superposition of 1st and 4th unit cell spectral components 3(b). In addition to the first bandgap pair, full and directional gaps are present in the frequency domain. 1st and 5th 3(c). 2st and 5th 3(d).

spectral components - instead - generates full gaps at given frequencies. This is confirmed upon evaluation of the band diagram associated with a unit cell characterized by two plane wave components picked up from Fig 1(e). The result is shown in Fig. 3. When the unit cell is characterized by the first and fourth harmonics (both negative traveling pump waves), one gets two directional gaps at $\Omega = 0.5$ and $\Omega = 2$, plus one full gap centered at $\Omega = 1.5$, as shown in Fig. 3(b). Similar behavior is observed for the remaining pairs: first and fifth harmonics (which have negative and positive velocity sign respectively) generate first and fifth gaps, which are flipped to each others, see Fig 3(c) and one full gap for $\Omega = 3$.

4 Conclusion

In this work we presented a generalization of the PWEM which allows to study a wider class of spatiotemporal material. This new analysis tool has been exploited to study wave propagation in discretely modulated waveguides, demonstrating that this class of materials support one-way wave propagation at bandgap frequencies. Moreover, we demonstrated that the unit cell spectral content can be decomposed in plane waves, responsible for the generation of directional gaps. Their interaction instead lead to the formation of full bandgaps.

Key words: Artificial Intelligence, Machine Learning, Structural Health Monitoring, Support Vector Machine, Support Vector Classifier

Abstract. Artificial intelligence methods have been successfully used to solve complex problems in a wide variety of engineering fields. Support Vector Machine (SVM) is recognized as a reliable and efficient tool among current machine learning techniques, and is here adopted to automatize a Structural Health Monitoring (SHM) method aiming to detect and isolate the onset of damage. In a supervised learning approach, an experimental dataset is used to train the SVM algorithm so it would be able to predict the structural integrity of a target by means of new input data obtained during the inspection phase. A Lamb wave based effective monitoring uses the pitch-catch approach to generate the signals, and the SVM algorithm assesses the structures' integrity. The inspection is performed by means of an arrangement of piezoelectric transducers forming a circular array of eight sensors with a centered actuator, dividing the monitored area into eight regions. Damage presence causes waves scattering, which influences the amplitude of the measured signals, which differs from its respective regular behaviour. Discrete wavelet and Hilbert transform are applied to the raw signals in order to minimize noise and dispersion effects, and to propitiate clear damage indicators. Processed peak amplitudes from each of the eight signals are used as attribute axis for an eight-dimension SVM algorithm based on a Gaussian Radial Basis Function (RBF) kernel. Using a punctual mass placed on different positions inside the plate regions to simulate damage, a set of labeled measurements is obtained in order to train and test the SVM algorithm. Posterior experimental application of the classifier shows its effectiveness to automatically isolate the respective a damaged region.

1 INTRODUCTION

SHM systems aim at the continuous monitoring of structure areas prone to damage in order to detect, isolate and assess the severity of the damaged region. In this way, it is possible to repair or replace parts of the structure before any type of fault occurs. One has applied composite materials in a wide range of engineering systems, such as aircraft, automobiles and trains, due to their durability, strength and low density. This type of material may have defects inherent to their manufacturing process, such as delamination and voids, or damage like chemical corrosion and cracks that may arise during its use. Thus, many research has been conducted to develop reliable SHM systems to assess the integrity of structural parts made of composite material. Non-destructive evaluating (NDE) techniques are a key part in SHM systems. One of the most used approaches to assess the integrity of structures is through the Lamb waves propagation. These waves can be generated and received using piezoelectric transducers, which may be installed temporarily or permanently in the structure to be monitored. The information about the presence of damage, its location and its severity can be obtained by analyzing the parameters of the reflected and transmitted waves resulting from the interaction between the incident wave and the damage. Wang et al.[1] investigated the behavior of a glass fiber reinforced epoxy composite laminate plate subjected to damage like chemical corrosion, impact hole and crack, using Lamb waves to inspect and Gaussian Mixture Model to classify such kinds of damages. Huang et al.[2] used the time reversal method to detect impact damage on CFRP plate. An image of the plate showing the damage location was built using damage indexes based on the deviation between the reconstructed and the excitation signals.

Lamb waves propagation in composites exhibit a complex behavior, due to anisotropic properties and inhomogeneous composition of these materials. In order to properly evaluate structural integrity, some type of intelligence is necessary to analyze the extracted parameters of the signals obtained from the NDE technique applied. Recently, a new approach has been developed, with the use of artificial intelligence to automate the diagnosis of the structure. There are various artificial intelligence techniques, such as neural networks, fuzzy logic, deep learning, pattern recognition, machine learning. Among data driven techniques, machine learning has shown great potential to increase efficiency of SHM systems. This AI branch deals with the design of algorithms that can learn about the structural behavior from data and make predictions from learned data[3]. In the supervised learning approach, the model is built using samples that represent classes, and future inputs will be classified in one of them. Otherwise, in an unsupervised learning model, the objective is to cluster samples from the dataset that exhibits a high level of proximity. There is no labels for samples from the dataset. SVM is a suitable supervised machine learning technique to classify data. Gangsar and Tiwari[4] developed a methodology to classify ten different fault conditions of induction motors using SVM.

This paper proposes an effective methodology based on Lamb waves and support vector machine algorithm to assess the integrity of a composite plate. The inspection is performed by means of an arrangement of piezoelectric transducers forming a circular array of eight sensors with a centered actuator, dividing the monitored area into eight regions. Discrete wavelet and Hilbert transform are applied to the raw signals in order to minimize noise and dispersion effects as well as to improve the peak amplitude estimation. Damage indexes obtained from the acquired data are used as input to an eight-dimension SVM algorithm based on a grid search function to determine the best kernel and optimum kernel's parameters.

2 STRUCTURAL ASSESSMENT

Lamb waves have been widely used on non-destructive evaluation techniques to assess the structural integrity on SHM systems [5]. Piezoelectric transducers attached to the structure under inspection, generate and measure these waves. Information about the presence of damage, its location and its severity

are obtained by analysing the parameters of the reflected and transmitted waves resulting from the interaction between the incident wave and the damage. There are two methods for using Lamb waves to detect damage, known as pitch-catch and pulse-echo [6]. The simplest pitch-catch approach uses at least two transducers to inspect the region between them, as illustrated in Figure 1. It is seen in this figure an actuator and a sensor, both piezoelectric patch, where the actuator generates a burst signal captured by the sensor, which incorporates the medium characteristics. Damage onset on this region causes scattering of the waves, which modifies some measured signal parameters. Comparison between a known signature of the healthy structure and an recently measured signal may conduct to detection and identification of damage. Figure 2 shows how the signal may be affected by damage localized between the sensor and actuator. In this case, signal amplitudes measured by the sensor decreases due to attenuation of incoming wave on the damage. A different change of parameters may also occur if the damage is not in the direct line between the transducers.

Figure 1: Positioning of transducers to the pitch-catch approach

Figure 2: Acquired signals using the pitch-catch approach for damage and undamaged cases

Signals from the measuring system need to be processed by specific algorithms to separate information from noise, regular reflections and other interferences in the system. The wavelet transform is a signal processing technique used to represent signal features in time and frequency domains simultaneously. It has the ability to detect aperiodic short-time events, unlike the Fourier transform which is particularly useful for the analysis of periodic signals. These transient events are detected through the similarity between its shape in time domain and a waveform known as mother wavelet. This approach fits well to analyze non-stationary signals, because its spectral components vary along time. The propagation of Lamb waves is an example of signal with punctual occurrences. Mallat [7] presented an efficient method to implement the wavelet transform in discrete time, through multi-resolution analysis and digital

filter banks. This theory relates the Discrete Wavelet Transform (DWT) with a filter bank composed by high and low pass quadrature mirrored filters, through which the signal is decomposed into details and approximations. The approximation is obtained as the output of the low pass filter and is related to the smoothed signal. The output of the high pass filter provides the details of the signal, related to transient events contained in the signal. Figure 3(a) shows the layout of the filter bank, composed by high pass filter (H1) and low pass filter (H0), for two levels of resolution.

The symbol $\downarrow 2$ represents a down-sampling or decimation of the filtered signal. Each decomposition level separates the spectral components at frequency bands, which depends of the sampling frequency (f_s) of the signal acquired. Figure 3(b) shows the frequency response of high and low pass ideal filters for two level decomposition DWT.

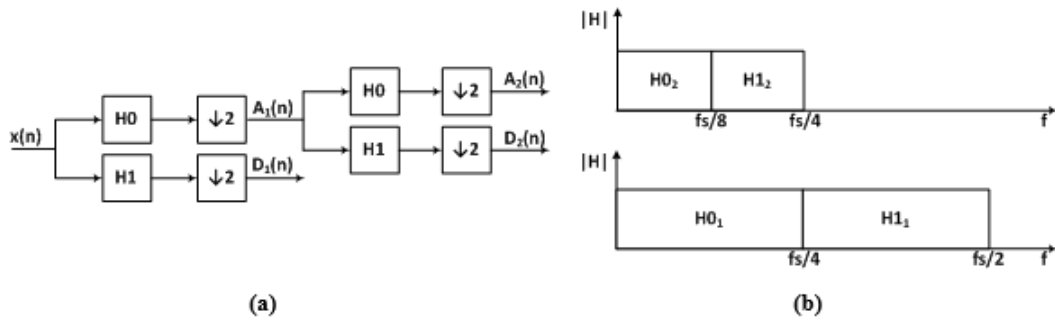

Figure 3: Two level analysis filter bank for DWT and frequency range of high and low pass filters

Higher frequency signal components are located at lower level details. Analysing the decomposed signal into several details provides information that could be hidden in the original signal, probably masked by noise from the measurement system. Considering a tone burst containing five cycles of a 40 kHz sine wave multiplied by a Hanning window applied to the actuator to excite Lamb waves at structure, the main component of the signal measured by sensors with a sample rate of 1,21MHz corresponds to the fourth level detail coefficients of DWT.

Hilbert transform can be used to highlight some specific points of the processed signal, for example, the amplitude and the instants that peaks occurs. This signal processing technique creates an analytical signal from a real signal[8]. The absolute value of the analytical signal corresponds to signal envelop.

In order to illustrate the effect of applying these signal processing techniques, Figure 4 shows the raw signal measured by a sensor, the detail coefficients of fourth level of its DWT with the mother wavelet Daubechies 40 and its envelop. It clearly minimizes the noise and eliminates the continuous voltage level present in the measurement system, enhancing the desired signal attributes. The peak amplitude and the instant they occur are much more evident on the signal envelop. These parameters can be used to monitor the integrity of the structure.

As shown in Figure 5, the onset of damage changes envelop peak amplitudes of signal measured by the sensor. Thus, a damage index (DI) could be defined by the percentage difference between peak amplitudes of the processed signals obtained from the healthy structure (A_h) and the damaged structure (A_d), given by:

$$DI\% = \frac{A_h - A_d}{A_h} * 100 \quad (1)$$

According to Equation (1), a decrease on the signal amplitude results in a positive DI. On the other hand, a negative DI indicates an increase on the signal amplitude.

3 SUPPORT VECTOR MACHINE

3.1 The optimal hyperplane (linear SVM)

This section describes basic SVM concepts that can be found in [9], [10] and [11].

Having in hands a training set of instance-label pairs $(x_i, y_i), i = 1, 2, \dots, m$ where $x_i \in R^n$ and $y_i = +1, -1$, for the linearly separable case, a correct data points classification is given by:

$$\langle w \cdot x_i \rangle + b \geq +1 \quad \text{for } y_i = +1 \quad (2)$$

$$\langle w \cdot x_i \rangle + b \leq -1 \quad \text{for } y_i = -1 \quad (3)$$

One set of inequalities can be achieved combining Equations (2) and (3) .

$$y_i(\langle w \cdot x_i \rangle + b) \geq 1 \quad \forall i = 1, \dots, m \quad (4)$$

Solving the following optimization problem leads to the hyperplane with the maximum margin:

$$\text{Min}_{(w, b)} \frac{1}{2} w^T w \quad \text{subject to : } y_i(\langle w \cdot x_i \rangle + b) \geq 1 \quad (5)$$

To solve this problem one must find the saddle point of the Lagrange function:

$$L_p(w, b, a) = \frac{1}{2}w^T \cdot - \sum_{i=1}^m (\alpha_i y_i (\langle w, x_i \rangle + b) - 1) \quad (6)$$

On Equation (6) α_i represents the Lagrange multipliers, hence $\alpha_i \geq 0$. An optimal saddle point is needed because the L_p must be minimized with respect to the primal variables w and b and maximized with respect to the non-negative dual variable α_i . By differentiating L_p with respect to w and b :

$$\frac{\partial}{\partial b} = 0, w = \sum_{i=1}^m \alpha_i y_i \quad (7)$$

$$\frac{\partial}{\partial b} = 0, \sum_{i=1}^m \alpha_i y_i = 0 \quad (8)$$

The Karush KuhnTucker (KKT) conditions for the optimum constrained function are necessary and sufficient for a maximum of Equation (6). The corresponding KKT complementarity conditions are:

$$\alpha_i [y_i (\langle w, x_i \rangle + b) - 1] = 0 \quad \forall i \quad (9)$$

Substituting Equations (7) and (8) into (6), then L_p is transformed to the dual Lagrangian $L_D(\alpha)$:

$$\text{Min}_{\alpha} L_D(\alpha) = \sum_{i=1}^m (\alpha_i \alpha_j y_i y_j \langle x_i, x_j \rangle) \text{ Subject to : } \alpha_i \geq 0 \quad i = 1, \dots, m \text{ and } \sum_{i=1}^m (\alpha_i y_i) \quad (10)$$

The $L_D(\alpha)$ must be maximized with respect to non-negative α_i to find the optimal hyperplane. In order to determinate the dual optimization problem parameters w^* and b^* of the optimal hyperplane, one must find the solution α_i . Finally, we obtain an optimal decision hyperplane $f(x, \alpha^*, b^*)$ Equation (11) and an indicator decision function $\text{sign} [f(x, \alpha^*, b^*)]$.

$$f(x, \alpha^*, b^*) = \sum_{i=1}^m [(\alpha_i^* y_i (\langle x_i, x \rangle + b^*)) = \sum_{(i \in sv)}^m \alpha_i^* y_i (\langle x_i, x \rangle + b^*) \quad (11)$$

Only small subsets of the Lagrange multipliers α_i usually tend to be greater than zero in a typical classification task. These vectors are the closest to the optimal hyperplane, regarding geometrically aspects. The support vectors are the respective training vectors having nonzero α_i , given that the optimal decision hyperplane $f(x, \alpha^*, b^*)$ depends on them exclusively.

3.2 Non-linear SVM

For a higher dimensional problem, the nonlinear SVM maps the training samples via a mapping function, which are also called kernel function. In the dual Lagrange (Equation (10)), the kernel function (Equation (12)) replaces the inner products, and the non-linear SVM dual Lagrangian $L_D(\alpha)$ (Equation (13)) is similar with that in the linear generalized case.

$$(\Phi(x_i) \cdot \Phi(x_j)) = k(x_i, x_j) \quad (12)$$

$$L_D(\alpha) = \sum_{i=1}^m \alpha_i - \frac{1}{2} \sum_{i=1}^m \alpha_i \alpha_j y_i y_j (x_i, x_j) \quad (13)$$

Subject to: $0 \leq \alpha_i \leq C$, $i = 1, \dots, m$ and $\sum_{i=1}^m \alpha_i y_i = 0$

Using the method for solving the optimization in the separable case, one can solve this optimization model. Thus, the optimal hyperplane takes the form Equation (15). Including the bias term within the kernel function, the nonlinear SV classifier can be shown as Equation (16).

$$f(x, \alpha^*, b^*) = \sum_{i=1}^m y_i \alpha_i^* \langle \Phi(x_i), \Phi(x) \rangle + b^* \quad (14)$$

$$f(x, \alpha^*, b^*) = \sum_{i=1}^m y_i \alpha_i^* k(x_i, x) + b^* \quad (15)$$

$$f(x, \alpha^*, b^*) = \sum_{i=1}^m y_i \alpha_i^* \langle \Phi(x_i), \Phi(x) \rangle = \sum_{i=1}^m y_i \alpha_i^* k(x_i, x) \quad (16)$$

Some kernel functions include polynomial, radial basis function (RBF) and sigmoid kernel [12], which are represented by the functions Equations (17), (18), and (19). In order to improve the accuracy of the classification, these kernel parameters in the kernel functions should be properly set.

$$\text{Polynomial kernel: } k(x_i, x_j) = (1 + x_i \cdot x_j)^d \text{ where: } d = \text{polynomial degree} \quad (17)$$

$$\text{Radial Basis Function (RBF): } k(x_i, x_j) = \exp(-\gamma \|x_i - x_j\|^2) \quad (18)$$

$$\text{Sigmoid function: } k(x_i, x_j) = \tanh(k \cdot x_i \cdot x_j - \delta) \quad (19)$$

4 EXPERIMENTAL PROCEDURE

The experiments were conducted on a carbon fiber square plate of 300 mm x 300 mm x 1 mm to experimentally assess structural integrity. The experimental setup, shown in Figure 6 consists of nine circular buzzers of 20 mm diameter forming a circular arrangement with a centered actuator with 100mm radius. A Labview[®] instrumentation system were developed to apply a tone burst containing five cycles of a 40 kHz sine wave, multiplied by a Hanning window, to the central actuator. This system was also used to acquire the signals measured by the eight sensors, with a sample frequency of 1.2 MHz. Raw data were processed and analyzed using MatLab[®]. Mother wavelet Daubechies 10 was adopted in the DWT for all signals and the detail coefficients of fourth level corresponds to the Lamb wave propagation. A pair of magnetic cubes with 5x5x5 mm were used to obtain a punctual mass change on the plate, which may represent damage. This artificial damage was placed randomly within a monitored region to demonstrate the ability to isolate the damaged region inside the circular area, with each region tested separately.

Damage indexes extracted from the processed signals were used as input for a nine-dimension SVM algorithm implemented in Python using *sklearn* package [13]. The algorithm parameters were chosen using a technique called grid search. It tests the algorithm implementation with different values for the function parameters. The parameters tested were:

- Kernel Trick: RBF, Polynomial and Sigmoid;
- C-Parameter: a range from 1e-3 to 1e3;
- Gamma-Parameter: a range from 1e-7 to 1e3.

In this set up, several experiments were made using different combinations of parameters and, with every test made, the closer it was getting from the optimum combination.

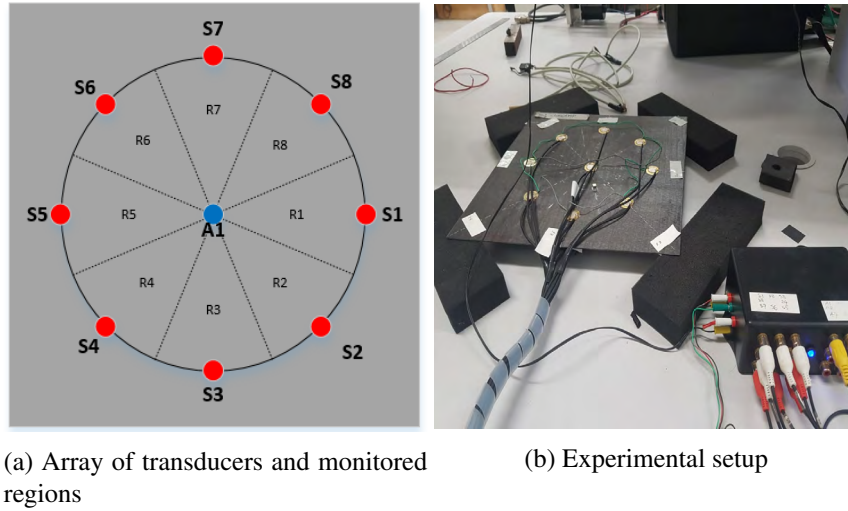

Figure 6: Plate's disposition of transducers and experimental setup

To reduce the variance problem, it was also used the K fold cross validation technique, with K equal to 5. In this technique, the data is divided in K-folds. Out of K folds, K-1 sets are used for training while the last set is used for testing. The algorithm is trained and tested K times and, with every loop, a new set is used as testing set while the others are used as training. The results obtained by the K fold cross validation technique is the average of the results obtained by each set.

For better understanding, Figure 7 shows a block diagram that visually explains the technique.

Figure 7: First instance of the 5-fold cross validation technique

The dataset was divided into 5 sets. The algorithm is trained and tested 5 times. In the first instance, SET A to SET D were used as training sets and SET E was used as testing set. The second instance used SET A as testing set while the remaining sets were used as training. The process continues until every set is used as testing set and as training set at least once.

Finally, the best results were optimized utilizing the RBF kernel, C-parameter value of 127 and gamma-parameter value of $3e-3$.

The experimentally gathered dataset was compounded by 900 measurements divided equally by all the 9 SVM algorithm classes, being R1 to R8 for damaged regions and R0 for the healthy structure

class. The test-train split was made utilizing 80% of the total data for training and the remaining 20% for testing.

5 RESULTS AND DISCUSSION

The algorithm had an accuracy of 70.5% , and its confusion matrix is shown in Table 1. Also, the bar chart presented on Figure 8 shows, in percentage, the accuracy of the classifier per class. Observing Table 1, one can see that, regarding the presence or absence of damage, out of 180 tests, the algorithm had a performance of no false positives and 0.3% (6 cases) of false negatives.

Table 1: SVM algorithm's confusion matrix

	R0	R1	R2	R3	R4	R5	R6	R7	R8
R0	20	0	0	0	0	0	0	0	0
R1	0	12	2	0	3	1	0	0	2
R2	0	1	16	1	2	0	0	0	0
R3	2	0	2	11	2	1	0	0	2
R4	1	0	0	0	18	0	0	0	1
R5	0	0	1	1	3	12	2	1	0
R6	1	0	0	0	1	1	13	4	0
R7	1	0	0	0	0	0	3	12	4
R8	1	3	0	1	0	0	1	1	13

Figure 8: Algorithm's accuracy per class

A visual analysis of the classifiers behaviour can be a challenge as the algorithm works with an eight-dimension input. Even though one cannot clearly see the hyperplane that divides all the SVM classes, some patterns can still be identified observing the set of polar plots presented on Figure 9.

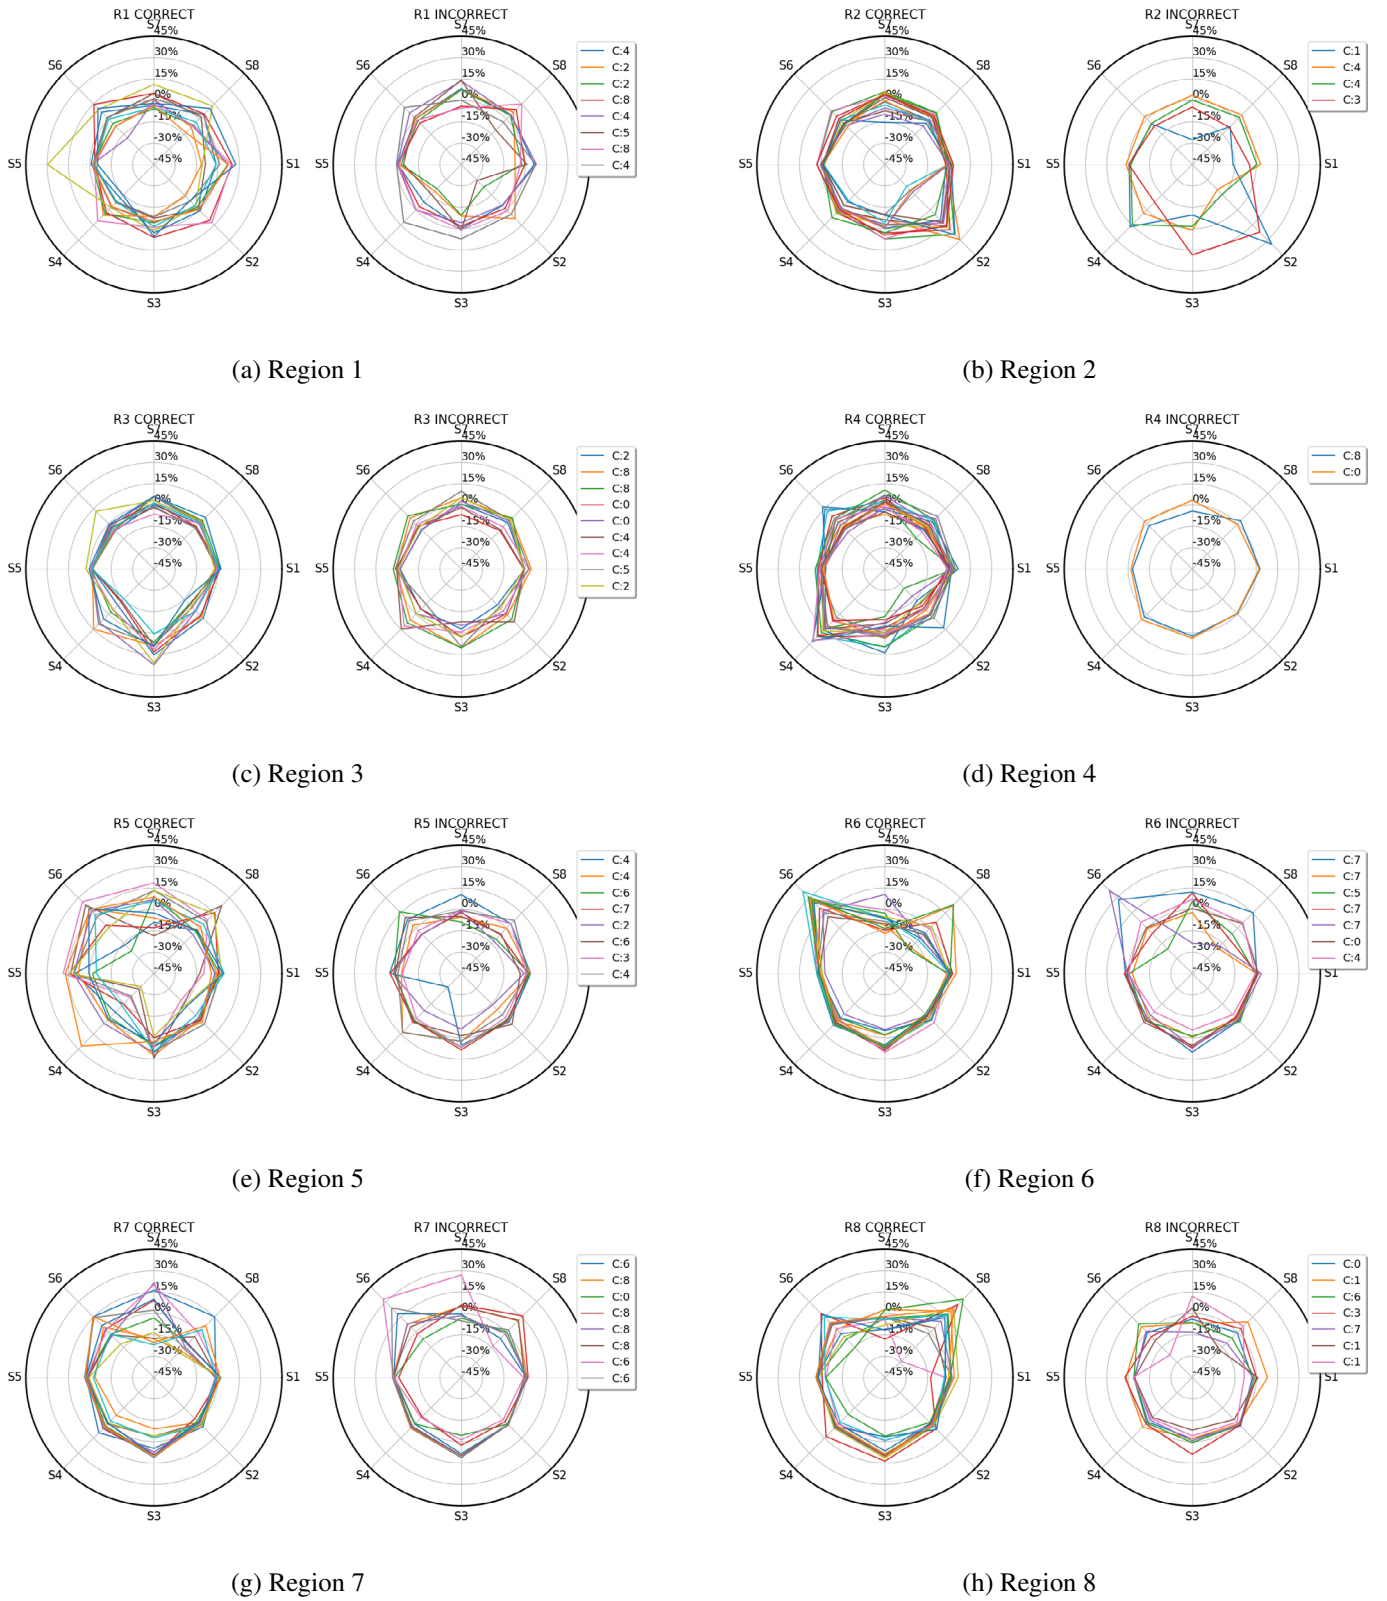

Figure 9: Damage indexes for correct and incorrect test predictions

The plots show the behaviour of the tests regarding the damage indexes (Equation (1)) of all the eight sensors, which were the input of the classifier. The radial axis corresponds to the DI while angular coordinates to its respective sensor. For an easier comprehension, the angular coordinate of each sensor were placed according with its real disposition on the plate, already showed on Figure 6.

The polar graphics to the left of each damaged region shows the behaviour presented by the correctly classified tests while the graphs to the right shows the incorrectly ones. The legend box next to the incorrect cases lists the true damaged region in each test.

It is worth mentioning that in most of the incorrect prediction cases, the classifier predicted damage in the neighbour region. For instance, for the eight wrong predictions of region 7, three indicated damage in region 6 and four indicated damage in region 8. Thus, despite giving a wrong classification, in a real situation it would at least give the user informations of damage presence and a direction of in which region it might be.

Another important aspect that can be mentioned is that, even though the DI of most regions present an expected behaviour, like the ones observed by Souza and Nobrega[14], they differ from the expected outcome in some regions, forming patterns that have not been yet identified. These changes in the expected behaviour could be attributed to the materials anisotropy. Despite these unexpected behaviours, the classifier still works its ways to automatically identify a pattern and predict the plates damaged region in most cases.

6 CONCLUSION

In this paper, the use of statistical indicators and machine learning methods were used as a strategy to detect structural changes in a composite material plate. The proposed approach used a SVM algorithm to identify the presence of damage and, if damage indeed exists, classify it in 8 pre defined regions.

In general, the method obtained good results even with the additional difficulty generated by the material's anisotropy, achieving a classification rate greater than 70%.

In practice, the main advantage of the proposed approach is to develop an continuous monitoring system that automatically identify and locates damage.

Even though statistical parameters do not show meaningful visual variation in some cases, they are still able to point out subtle differences among the vibration signals. These differences allow artificial intelligence methods to detect structural alterations caused by the presence of damage.

The good results achieved by the classifier emphasizes the effectiveness of the presented approach and motivates the continuous work on the development of the computer aided statistical analysis for SHM. In spite of the good results, the method using SVM, as in all methods based on supervised learning, has some limitations such as the large amount of data to train the models and the need of prior knowledge of the structural behaviour.

Future work will keep on investigating and developing supervised and unsupervised learning approaches as means to continuously increase their effectiveness and introduce new attributes such as automatically identify new target regions that were not pre defined.

Key words: Structural Health Monitoring, Damage imaging, Damage quantification, Aeronautic composite structures, Ultrasonic Lamb waves

Abstract. Thanks to their high strength to mass ratio, composite materials are now widespread in the aerospace industry. Nevertheless, this type of material is subject to various internal damages and it is mandatory to monitor in real time their structural integrity. Structural Health Monitoring (SHM) is a process based on embedded sensors whose aim is to detect, locate, classify and quantify potential damages appearing in a structure in order to avoid structures catastrophic failures and to estimate their residual life. The most widely used technique to perform SHM of aeronautical structures made up of composite materials is based on the use of ultrasonic Lamb waves. However, even if robust and precise SHM algorithms exist for damage detection and localization, there is still a huge need for reliable algorithms for damage quantification. In this paper, a damage quantification strategy based on a post-processing step of the results of damage imaging method is presented. Such a method allows for damage size assessment of a delaminated area by post-processing the images produced by damage localization algorithms. Localization methods take raw signals from sensor as input and return a map of index representing the likelihood of presence of a damage over the surface of the structure under study. From this spatial probability map, region of high localization index can be identified around the estimated damage location and the area this region can be computed. A data-driven model representing the mathematical relationship between the computed area and the actual size of the damage is then inferred. The proposed method is successfully validated on numerical simulation data carried out on CFRP plate samples equipped with a stiffener and of a piezoelectric sensor-actuator network with several configurations of damage size.

1 INTRODUCTION

Maintenance is a great cost for airlines since structure checks require to ground an aircraft for several days [1]. These inspections are fixed-interval with a rate provided by the constructor. Nevertheless, as the current state of the structure is unknown, this rate is not condition-based. That is why real time monitoring of structures is of high interest in the industry and in particular in aeronautics. This research field is known as Structural Health Monitoring or SHM.

Various techniques are used to monitor possible damage apparition in a structure. The most used is the emission and reception of ultrasonic Lamb waves [2, 3]. Such waves are easy to generate at high frequencies using ultrasonic transducers (such as piezoelectric elements called PZT) making them able to interact even with small damages [4]. Moreover, Lamb waves can propagate in large structures with

low dissipation thanks to their small attenuation ratio. Structures are usually equipped with a network of PZT components acting both as actuators and sensors [5]. A classical SHM process can be decomposed in four distinctive steps [6]:

- **Detection:** evaluation of presence of a damage in the structure under study;
- **Localization:** estimation of the position of damage;
- **Classification:** identification of the damage type (crack, delamination, etc.);
- **Quantification:** assessment of the damage's size.

However, even if robust and precise SHM algorithms exist for damage detection and localization, there is still a huge need for reliable algorithms for damage quantification. Several methods dedicated to this issue have already been proposed in the literature. One method consists in computing a relevant damage index that varies with the size of the damage [7]. Another approach is to train an Artificial Neural Network (ANN) on simulated data. The size of a damage is then estimated using experimental data as an input of this ANN [8]. Statistical methods have also been investigated. Bayesian updating techniques have been applied to crack size assessment [9] and delamination [10]. Multi-class classification for damage quantification with a support vector machine have been successfully validated on a beam [11]. These methods are interesting but do not take into account spatial information available at the end of the localization step of the SHM process that may be relevant also for quantification purposes.

Localization methods are on the basis of the damage quantification approach proposed here. These methods have been extensively studied in the literature. Time-of-arrival (TOA) [12] method is a triangulation algorithm used for localization. The idea is to compute the time of flight of the wave between the actuator and the sensor and to compare this time to the one taken by the wave scattered by the damage. It gives a locus of possible positions of the damage under the form of an ellipse. This process is used with at least 3 PZTs in order to get a unique damage localization estimate. Difference time-of-arrival (DTOA) [12] are based on the same principle. In this approach difference of time of arrival of the wave scattered by the damage are computed at two sensors. This gives a hyperbola of possible positions. As in the TOA algorithm, 3 PZTs or more are necessary to assess a unique position of the estimated damage location. In the delay-and-sum method (DAS) [13] for each point of the structure under interest and each actuator-sensor path, time of arrival of the Lamb wave are computed as if there was a damage at this position. Then, the residual of the signal is computed (*i.e.* the difference of magnitude between the reference signal and the one that is tested). For each tested point, the resulting damage index map is averaged over each actuator-sensor path. This method showed great results on an aluminum plate [14] and on a composite plate [15, 16]. RAPID (Reconstruction Algorithm for the Probabilistic Inspection of Damage) [17] algorithm consists in computing the probability of a defect occurrence using the relative amplitude of the signal change on each actuator-sensor path. This probability is computed using the signal difference coefficient and a ratio representing how far is the point from the direct path. The defect distribution probability within the sensor network is then expressed as a linear summation of all the signal change effects of every pair. For each point the signal is averaged between all path. This method has been successfully tested on aluminum plates [15].

Some attempts to post-process the results of the damage imaging methods mentioned above for damage size quantification purposes have already been tried in the literature. TOA algorithm has been used to quantify the size of an impact damage on a composite panel [18, 19]. This method has been validated on experimental and numerical data. Damage imaging methods results have also been applied to assess the position of crack tips. The size of the crack is then estimated from the area computed between the

tips position [20, 21]. However, none of these methods addressed the case of a delamination type damage which is crucial in composite structures.

In this paper, an alternate damage quantification strategy based on a post-processing step of the results of damage imaging method and focusing on delamination-type damage is presented. Such a method allows for damage size assessment of a delaminated area by post-processing the images produced by damage localization algorithms. Localization methods take raw signals from sensor as input and return a map of index representing the likelihood of presence of a damage over the surface of the structure under study. From this spatial probability map, region of high localization index is identified around the estimated damage location and the area of this region is computed. A data-driven model representing the mathematical relationship between the computed area and the actual size of the damage is then inferred. As more and more aeronautic structures are made of composite [22], SHM processes have to be tested on this type of material. That is why the proposed method is validated on numerical simulation data carried out on CFRP plate samples. These samples are equipped with a stiffener and of a piezoelectric sensor-actuator network with several configurations of damage size. The proposed method is detailed in Sec. 2 and validated on numerical data coming from simulation of a composite plate equipped with a stiffener described in Sec. 3. Results are shown and discussed in Sec. 4.

2 METHOD

The workflow of the damage size quantification algorithm based on the post processing of damage imaging algorithms is divided in two steps. The first one is the learning step. It consists in building a data-based model from numerical or experimental data. These data are raw signals from actuator and sensor placed on the structure under study for multiple sizes of damages. In the second step, the size of an unknown damage is predicted with the model previously built. The overview of the method is depicted in Figure 1. N_{sens} stands for the number of sensors, N_{rep} corresponds to the number of repetitions of the measure, N_{dam} represents the number of damage cases and N_{conf} stand for the number of PZTs configurations. A PZTs configuration is a subset of all the transducers glued to the structure. For example in a case where a sample is equipped with 3 PZTs, measures can be done with 4 different PZTs configurations: [1,2], [2,3], [1,3] and [1,2,3].

2.1 LEARNING STEP

For any localization algorithm, raw signals are first denoised, filtered and time-aligned for each damage case (*i.e.* for each different size of damage available in the data base used for learning). The group velocity of the ultrasonic Lamb waves is then computed to be used in the localization method picked by the user: TOA, DTOA, RAPID or DAS. Once the localization process is done, a damage localization index (DLI) map is obtained for each damage case. Next, the resulting DLI maps are post-processed for all damage cases. A threshold function is applied to the image to extract a binary map. Then an image segmentation algorithm is used to partition the binary DLI map in several regions of interest and to select the one surrounding the estimated damage position. This region is called “*high DLI region*” and its area is computed. At this point, the area of the “*high DLI region*” has been computed for multiple sizes of damage. The idea is now to learn the mathematical relationship existing between the “*high DLI region*” areas and the actual damage sizes. A regression is then performed on these data in order to infer the damage size quantification model.

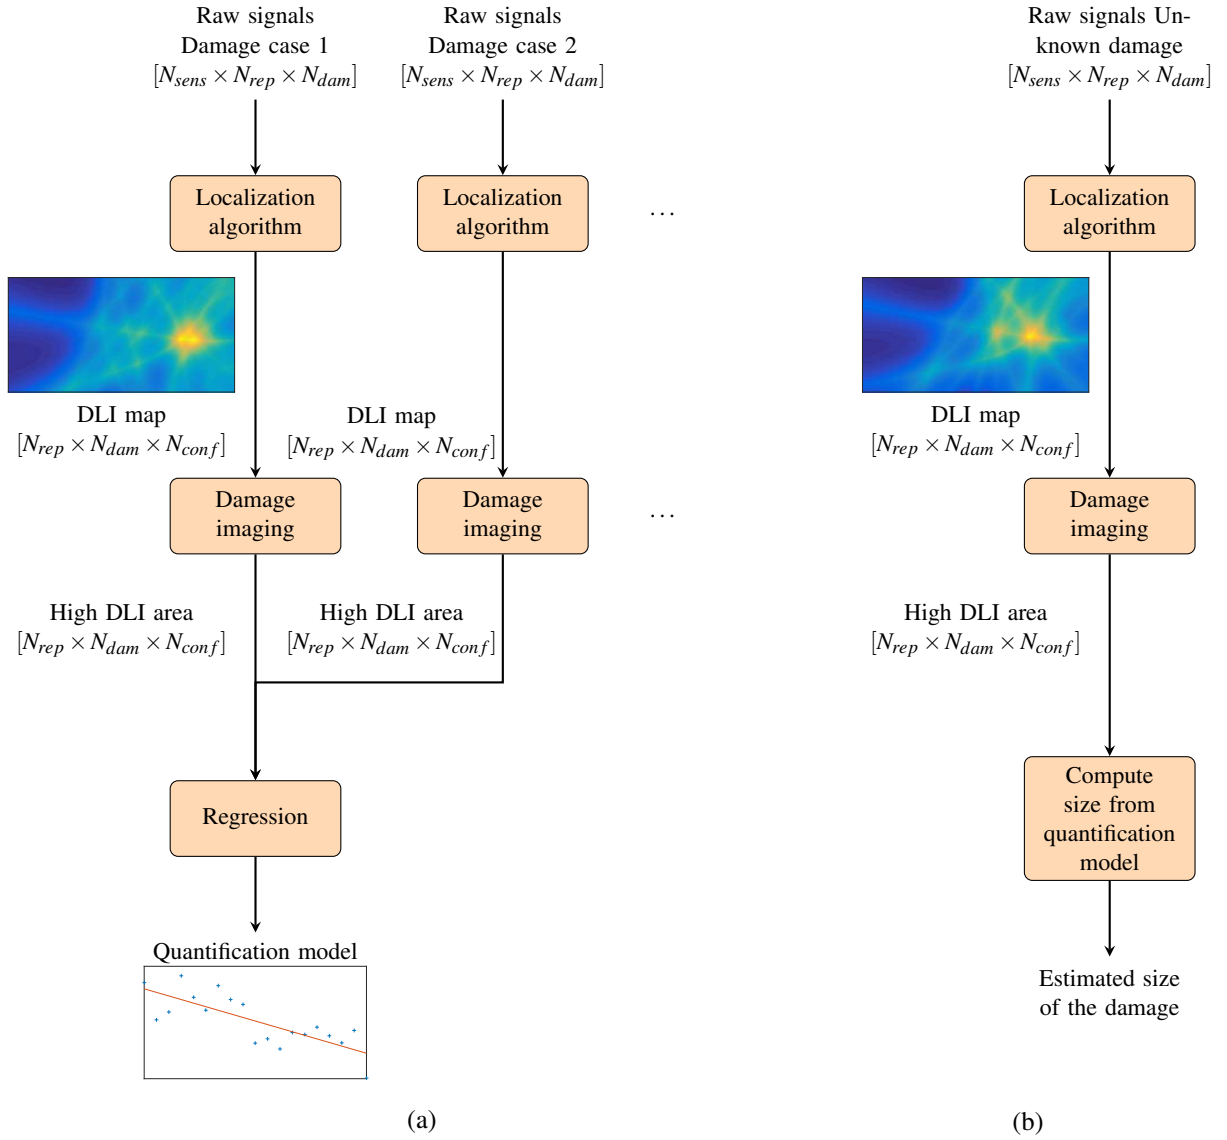

Figure 1: Overview of the damage size quantification algorithm based on the post processing of damage imaging algorithms. Description of the learning step (a) and the prediction step (b).

Figure 2: FEM model of the stiffened panel used for simulation

2.2 PREDICTION STEP

Now that a quantification model has been built, it can be used to estimate the size of an unknown damage. In this prediction process, raw signals coming from the structure in an unknown damaged state are denoised, filtered and time-aligned. Then the same localization algorithm and damage imaging process used for the learning step are applied. Finally the estimated size of the unknown damage is computed from the quantification model using the high DLI area computed.

3 STRUCTURE UNDER STUDY

The method described in this paper is validated using numerical data. The structure under consideration is a stiffened composite panel. The structure is made of graphite-epoxy plies with the stacking sequence $[45^\circ/0^\circ/45^\circ/90^\circ/-45^\circ/0^\circ]$ in the skin. The properties of one ply are given in Table 1.

Table 1: Material properties

	Density [g/cm^3]	$E(0^\circ)$ [GPa]	$E(90^\circ)$ [GPa]
Unidirectional	1.57	163	10
Woven	1.56	85	79

The structure is equipped with five PZTs components that can be used both as sensor and actuator. The FEM model with the PZT and damage position is shown in Figure 2. Coordinates of these piezoelectric elements and of the simulated damage can be found in Table 2.

Table 2: Coordinates of PZT elements and damage center

	PZT1	PZT2	PZT3	PZT4	PZT5	Damage
x(mm)	50	25	275	275	200	150
y(mm)	25	98.8	140	66.3	82.5	66.25

Damages have circular shape with a radius varying between 1mm and 10mm by step of 0.5mm leading to 19 damage cases. The damage is represented by a decrease of the Young modulus of 90% in the

Figure 3: Sensitivity of the RAPID method to β parameter (a) and threshold (b).

damaged area. A healthy case *i.e.* without damage is used as reference for comparing the signals. Simulation have been conducted using the *Matlab* toolbox SDTools [23]. Signal used is a 5-cycles tone burst of 160 kHz central frequency with random noise in order to introduce variability in the data. The signal to noise ratio, as defined in Eq. (1), is 70dB.

$$SNR = 10 \log_{10} \left(\frac{P_{signal}}{P_{noise}} \right) \quad (1)$$

where P_{signal} and P_{noise} are signal and noise power respectively. For each damage case 10 repetitions have been performed. The sampling frequency is 2 MHz. Localization algorithm can be performed in two running mode. The first one is called “*test*”. It means that only the first repetition of the healthy state and the first repetition of the damage case will be compared. In the other mode called “*full*” each repetition is compared of the healthy state is compared with each repetition of the damage case in order to take the take the variability of the measure into account.

4 RESULTS AND DISCUSSION

4.1 PARAMETERS

The damage quantification method proposed in this paper has been tested with several localization algorithms: TOA, DTOA, RAPID and DAS. Each of these algorithms depend on a parameter. In the TOA and DTOA algorithms, a decay rate of an exponential windowed function applied is introduced to reduce secondary reflections [12]. DAS depends on the number of samples over which time integration is performed [13]. In the RAPID approach the user can set a parameter called β corresponding to the the spread of the ellipses around each path [15]. Moreover, the damage quantification method itself also has one parameter which is the threshold level. To show the influence of the parameters tuning, sensitivity of the RAPID algorithm to β parameter and threshold is depicted Figure 3.

Thus, for each localization method the best set of parameters has to be found in order to get the damage size regression with the minimum error. Computations were performed for a range of parameters in order to find the best set of parameters in this range. These computations were run in “*test*” mode. Table 3 provides the best sets of parameters that have been found. One can notice that the best threshold

value hardly varies between each method. For TOA and DTOA the ellipse or hyperbola shape of the high DLI region implies changeability of the high DLI area computed, leading to irregular variation of the goodness of fit over the decay parameter. Thus, finding a value of this parameter that minimize the error of the regression for any threshold value cannot be achieved efficiently. On the opposite, DAS method shows no influence of its specific parameter in the regression. RAPID algorithm gave better regression results with a β parameter slightly greater than 1 as noticed in [15].

Table 3: Parameters and best set of parameters for each localization method

	Localization parameter	Best localization parameter	Best threshold value
TOA	Decay rate of an exponential windowed function applied to reduce secondary reflections.	$6.0 \cdot 10^{-6}$	0.22
DTOA	Decay rate of an exponential windowed function applied to reduce secondary reflections.	$7.0 \cdot 10^{-6}$	0.22
DAS	Number of samples over which time integration is performed.	11	0.46
RAPID	Parameter set to adjust the spread of the ellipses around each path.	1.125	0.22

Once these best parameters have been selected, results are shown in Fig. 4. It appears that DAS and RAPID show a clear correlation between high DLI area computed and the actual size of the damage. However, results obtained with TOA and DTOA demonstrated poor regression quality.

Once these parameters have been found, the method was run in *full* mode. The quantification model was inferred using the first 14 damage cases *i.e.* from 1mm to 7.5mm. Next, the size of the damage for greater sizes are estimated as depicted in the Figure 1a. In an industrial context it corresponds to building a model from small size of a damage and use this model to estimate future size of the damage.

The estimated sizes are compared with the actual size of the damages in the Table 4. From this table it appears that quantification model built with DAS or RAPID methods give accurate results whereas model inferred with TOA or DTOA show poor precision when the size of the testing damage move away from the learning range. It could be explained by the difference between these two types of method. In one hand, TOA and DTOA only deal with time of arrival of the signal which is not influenced by the size of the damage. On the other hand, DAS and RAPID take amplitude of the signals into account which make the results more influenced by the size of the damage. Another reason of this difference could also be the shape of the high DLI region which has great influence on the quality of the regression. In the TOA and DTOA, high DLI region is made up of ellipse or hyperbola which area does not clearly vary with the damage size as discussed in the previous subsection. On the contrary high DLI region in the DAS and RAPID methods is circular and the high DLI variation is monotonic over the size of the damage which lead to a more accurate model. Another point is that in DAS and RAPID method high DLI computed is equal to zero for damage size under 4mm. It means that can only be build with damage greater than this value. Nevertheless this limitation is not an issue since in aeronautical applications only damages of 20mm of radius or more are sought. Finally, DAS method results is constant for each predicted damage size.

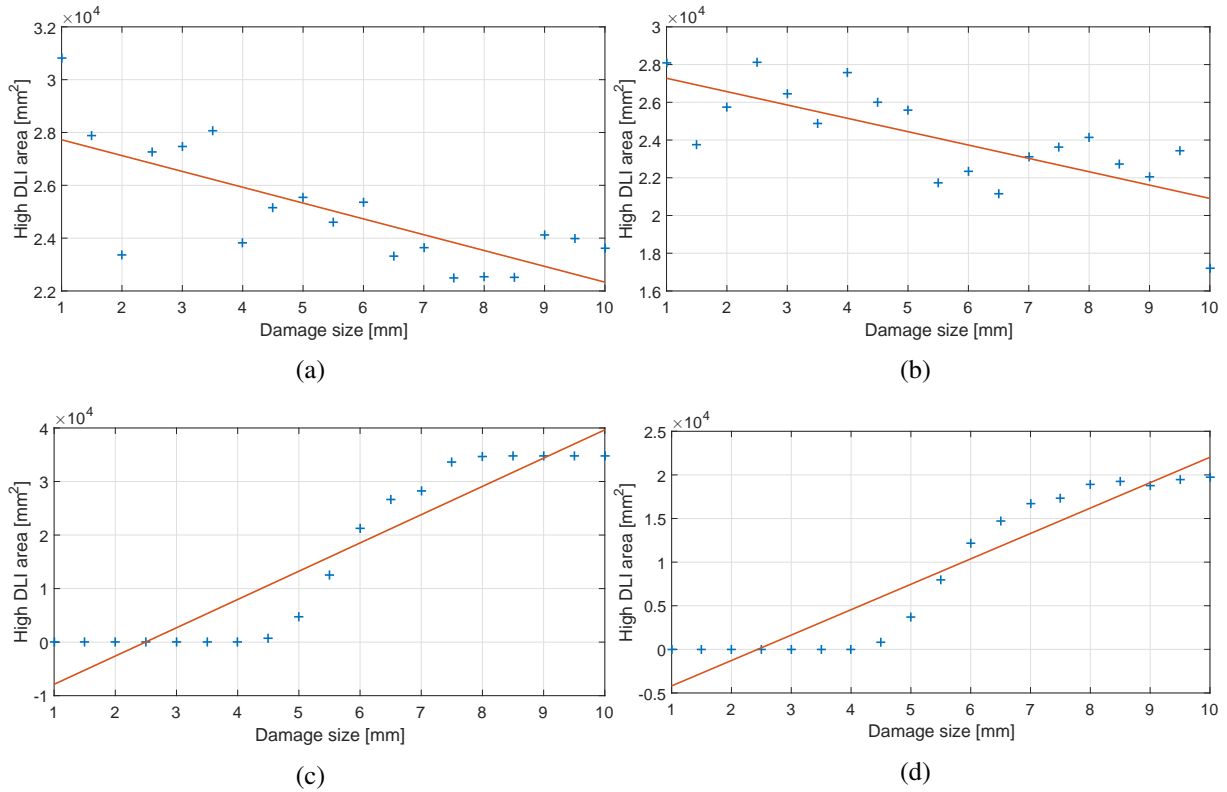

Figure 4: Results with best set of parameters for TOA (a), DTOA (b), DAS (c) and RAPID (d) methods. The line is the linear regression relation between high DLI area and damage size.

5 CONCLUSION

In this paper, a damage quantification strategy based on a post-processing step of the results of damage imaging method has been presented. Such a method allows for damage size assessment of a delaminated area by post-processing the images produced by damage localization algorithms such as TOA, DTOA, DAS and RAPID. From these images, region of high localization index can be identified around the estimated damage location and the area of this region can be computed. A data-driven model representing the mathematical relationship between the computed area and the actual size of the damage is then inferred. The proposed method has been successfully validated on numerical simulation data carried out on CFRP plate samples equipped with a stiffener and of a piezoelectric sensor-actuator network with several configurations of damage size. Results using RAPID method showed particularly promising results.

Future work will be focus on the validation of this method using experimental data.

Key words: AR Models, Multiple Models, Extrapolated Model, Quantification, Prognosis

Abstract. A simple data-driven AutoRegressive (AR) model may be used to assess a model to describe and to predict the time-series outputs of the PZT sensors receiving Lamb waves for different operating conditions in composite structures. Thus, this paper presents the potentiality of the use of a set of AR models to detect, locate, and, mainly, to extrapolate a damage sensitive index based on changes in one-step-ahead prediction errors. To illustrate this proposal, an aeronautical composite panel with bonded piezoelectric elements, that act both as sensors and actuators, is used to study the relationship between the variation of the parameters of the identified model and the presence of various simulated damage. A damage progression evaluation by extrapolating the AR parameters is also suggested and examined based on cubic spline functions to verify the future state and to observe how the damage could evolve, based on some simplified assumptions. This step could help to make a decision about a possible required repair without adopting a complicated and costly physical model.

1 INTRODUCTION

The structural health monitoring (SHM) approaches seem to be in a mature stage in the steps of detecting and localization of possible damages in structures with several powerful methods proposed and validated in the last decades. One way to address this issue may be using data-driven model identification based on guided wave propagation or random inputs. For example, Nardi et al. [1] using an autoregressive (AR) model were able to detect delamination in a carbon-fiber-reinforced-plastic laminate plate excited by random input using a couple of piezoelectric patches as actuator and sensors. Kim et al. [2] also showed a possible data-driven system identification through a state-space model to capture the wave motion in metallic structures. da Silva [3] applied autoregressive with exogenous input (ARX) model to perform predictions and a waveform generator in a 10 layers carbon-epoxy plate excited by

guided waves assuming different central frequencies and environmental conditions¹ and noted some benefits and disadvantages of the possible performance of this strategy for SHM.

However, to reach a high level in an SHM's hierarchy² numerous drawbacks need to be overcome yet. One of them is that it is essential to have an adequate mathematical model if the user wants to predict a future state based on previous past data to interrogate about the existence and evolution of damage propagation. So, these models demand to incorporate information about the damage behavior in its dynamics to gain a comprehensive physical insight of the monitored structure; consequently, this model should be most physical possible. However, to construct numerical models, for example, using finite element models with damages in an initial stage, require much time and may have a high cost for a real-time monitoring system in the industrial field, even modeling in its healthy state. Another limitation is that the behavior of damage evolution usually is much complicated to be modeled in a real-world application because complex types of damage can appear coincidentally with several confounding effects, like noise, uncertainties, temperature changes, operational variability, etc..

An identified data-driven model, as suggested by Nardi et al. [1] or da Silva [3], could be attractive to be adopted to extrapolate or to quantify a damage progression as a surrogate model to reach a subsequent application of higher forms of SHM's hierarchy. Thus, this paper is a first effort of the authors in this direction seeking to extrapolate AR polynomials through spline functions to extend how damage-sensitive index could evolve based on simplified assumptions. The proposed procedure has two steps to be implemented. First, damage detection and location using an index extracted by predictions errors filtered with a reference AR model is performed. To classify the structural states an analysis of variance is utilized [4]. Next, when damage is detected a new set of models, named by *initial damaged models*, is captured to extrapolate a projected state. A carbon-epoxy laminated plate with controlled progressive structural change similar to a real damage is used to exemplify the method. Next sections describe these steps and final remarks.

2 DAMAGE DETECTION USING PREDICTION ERRORS

Assuming a discrete time-series $y(k)$ measured by a PZT sensor in a healthy state, a normalization is conducted to remove offset and have mean 0 and scaled to have standard deviation 1:

$$\hat{y}(k) = \frac{y - \bar{y}}{\sigma(y)} \quad (1)$$

where $\hat{y}(k)$ is the normalized signal, \bar{y} is the mean and $\sigma(y)$ is the standard deviation. For simplicity, hereafter y is used to denote \hat{y} . Now, a simple AR model can be described by a compact difference equation [5]:

$$A(q)y(k) = e_{ref}(k) \quad (2)$$

where $e_{ref}(k)$ is the one-step-ahead error prediction in a healthy condition assumed to be a white noise and $A(q) = \sum_{i=0}^{n_a} a_i q^{-i}$ is the healthy AR polynomial³ with the coefficients a_i with a lag-order n_a , e. g., $y(k)a_i q^{-i} = a_i y(k-i)$, where q^{-i} is a lag operator and k is the time sample. The order can be estimated using Akaike information criterion (AIC) and the polynomial $A(q)$ may be identified through a least squares or Yule-Walker approach, fully available in Matlab or Octave software. When a new normalized

¹temperatures changes.

²for example, quantification and prognosis.

³Usually the coefficients a_i are normalized such that $a_0 = 1$.

data, $x(k)$, in an unknown state is measured, one can try to predict using the corresponding reference model:

$$A(q)x(k) = e_{unk}(k) \quad (3)$$

where $e_{unk}(k)$ is the unknown error prediction to be classified in a healthy or damaged state. Various papers have been using a simple damage-sensitive index \mathcal{DI} based on a comparison of the variance $\sigma^2(\cdot)$ of prediction errors [6]:

$$\mathcal{DI} = \frac{\sigma^2(e_{unk})}{\sigma^2(e_{ref})} \quad (4)$$

If \mathcal{DI} belongs a \mathcal{F} -distribution⁴ there is no damage and the unknown condition is associated to healthy state (null hypothesis \mathcal{H}_0 is true). On another hand, if the structure presents a damaged state, the probability distribution of the unknown error changes and the alternative hypothesis \mathcal{H}_1 is true [7, 6].

To classify the cluster of damages states, a one-way analysis of variance (ANOVA) can be also used to test the hypothesis that the samples in the running tests \mathcal{DI} belong to a population with the same means (null hypothesis \mathcal{H}_0), i.e., the systems is classified as healthy state, against the alternative hypothesis \mathcal{H}_1 that the population means are not all the same, i. e., damaged state [8, 4]. A Tukey's multiple comparison test to decide whether the results of ANOVA are statistically significant is also performed to enable us visible to distinguish the clusters correlated with different damages.

3 EXTRAPOLATION OF AR COEFFICIENTS

After clustering using ANOVA⁵, a new set of AR models for each initial damage recognized is estimated since the reference model given by Eq. (2) is not anymore accurate. This initial damaged model is described to predict the current state output $x_j(k)$ by:

$$\mathcal{A}_j(q)x_j(k) = e_{d_j}(k) \quad (5)$$

where $\mathcal{A}_j(q) = \sum_{i=0}^{n_a} \mathcal{A}_{ji}q^{-i}$ is the AR polynomial with coefficients \mathcal{A}_{ji} and $e_{d_j}(k)$ is the prediction error (white noise) in the damaged state $j = 1, \dots, n_d$ classified by ANOVA, where n_d is the number of initial damaged states. An important simplifying assumption is considered here: *this classified initial damage is an early state and do not change abruptly comparing with reference (healthy state)*. Consequently, the same regressive order n_a and framework (AR model) may be employed and the change is smooth between the coefficients, i.e., $A(q) \approx \mathcal{A}_j(q)$, once $|a_i - \mathcal{A}_{ji}| < \delta$ for all i and δ is a small value. It is essential to observe that the damage index given by eq. 4 is sensitive to the changes to detect damage, but the specific changes in the coefficients are in general smooths when this structural variation is in the initial states.

Rearranging the coefficients of reference model $A(q)$ and damaged $\mathcal{A}_j(q)$ as:

$$\mathbf{A} = \begin{bmatrix} a_0 & a_1 & \cdots & a_{n_a} \\ \mathcal{A}_{10} & \mathcal{A}_{11} & \cdots & \mathcal{A}_{1n_a} \\ \mathcal{A}_{20} & \mathcal{A}_{21} & \cdots & \mathcal{A}_{2n_a} \\ \vdots & \vdots & \ddots & \vdots \\ \mathcal{A}_{n_d0} & \mathcal{A}_{n_d1} & \cdots & \mathcal{A}_{n_dn_a} \end{bmatrix} \quad (6)$$

⁴i.e., e_{unk} and e_{ref} have a normal distribution

⁵Different classifiers can provide adequate results; the requirement here is to have the initial damage well classified to estimate a model for extrapolating.

where the first line of the matrix $\mathbf{A} \in \mathbb{R}^{n_d+1 \times n_a}$ is formed by the reference coefficients and the next one by the initial damage states. To enable to perform adequate extrapolations of the AR coefficients in the reference and damaged conditions, the number of states needs to be $n_d \geq 3$; otherwise, only linear extrapolation is plausible. So, it was assumed $n_d = 3$ structural states in damage clusters to permit to use cubic splines. This piecewise polynomials can be used to extend each polynomial coefficient λ_i associated to a future state through [9]:

$$\lambda_i(z) = f_i(z) + \xi_i, \quad i = 0, 1, \dots, n_a \quad (7)$$

where $z_0 < \dots < z_{n_a}$ are defined intervals associated with the order n_a , $f_i(z)$ a smoothing spline estimate by some minimizer of a penalized criterion, and ξ_i is an independent random error. More details to find the spline f_i can be seen in [10].

The important issue here is to recognize that now it is possible to have a future model to predict the data $x_j(k)$, when $j = n_d + 1$ represents a future state. This model is given by:

$$\Lambda(q)x_j(k) = \varepsilon_j(k) \quad (8)$$

where $\Lambda(q) = \sum_{i=0}^{n_a} \lambda_i q^{-i}$ is the extrapolated AR model in a future damage condition. The basic premise is that the damage progression occurs as previously captured by evolution in the lines of matrix \mathbf{A} . Thus, a new index and hypothesis tests can also be estimated to evaluate the progression and the changes of distribution of the extrapolated prediction error $\varepsilon_j(k)$ and in the damage index \mathcal{DI} .

4 EXPERIMENTAL EXAMPLE

Figure 1 shows a carbon-epoxy laminated with layup containing 10 plies unidirectionally oriented along 0° with four PZTs SMART Layers from Accelent Technologies, with 6.35 mm in diameter and 0.25 mm in thickness with a free-free boundary condition. PZT 1 is used as an actuator with a five-cycle tone burst input signal applied with 35 V of amplitude and center frequency of 250 kHz. The outputs are collected in PZT 2, PZT 3 and PZT 4 with a sampling rate of 5 MHz and timespan of 200 μ s. Data acquisition was controlled by Labview using a NI USB 6353 from National Instrument (NIDaq) and an oscilloscope DSO7034B Keysight assuming a controlled temperature of 30°C with all tests conducted inside a thermal chamber.

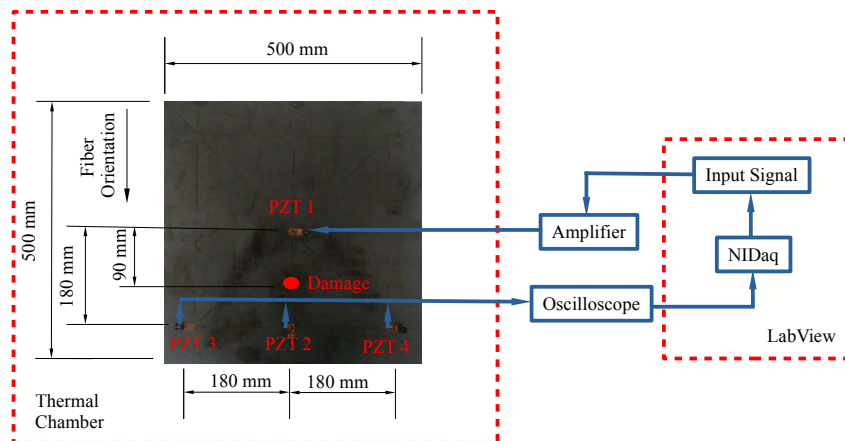

Figure 1: Illustration of the experimental setup with details about the geometry and instrumentation utilized.

Figure 2: Healthy output time-series when PZT 1 acts as an actuator with a central frequency of 250 kHz.

Figure 2 illustrates the output time-series measured by PZTs in a healthy state normalized by Eq. 1. An industrial adhesive putty was glued on the plate surface to simulate gradual damage by an additional mass increasing progressively the coverage area in the path between PZT 1 and PZT 2. This change modifies local material properties with a similar effect to the real damages in composites structures as performed by Lee et al. [11]. In each structural state, 100 tests were repeated for an adequate statistical characterization of the proposed damage detection.

4.1 AR model identification

The AIC order selection with a focus of prediction indicates that order of $n_a = 40$ is sufficient to give an adequate validation for all paths of propagation, as seen in fig. 3. A raffle is performed to sort within 100 realizations randomly the signals in the PZT 2, PZT 3 and PZT 4 to be used as a reference and a specific healthy model $A(q)$ is identified in each path using the least square method. This is executed to reduce computational processing time. Other realizations were filtered using this reference model by Eq. 2 to estimate the prediction error in the healthy state.

Figure 4(a) shows the comparison between the measured versus predicted assuming one validation data. The analysis of the autocorrelation function of residuals also indicates that the prediction errors are white noises, i. e., the model has identified adequately, as observed in the fig. 4(b).

4.2 Damage detection

Once a reference model, named by H , is correctly identified, it is used to detect some possible structural change. Only half of the data in the healthy state is utilized, and the next 50 is applied to evaluate the presence of false positive using the hypothesis test. A set of blind tests using three different structural states associated with damage is performed, named by D1, D2 and D3 with progressive damage severity associated with area covered given by 490 mm^2 (0.19%), 707 mm^2 (0.28%) and, 962 mm^2 (0.38%), respectively. Each structural condition was also measured by 100 realizations in each path. It is worth noting that the algorithm admits that all these data are assumed in unknown condition to be classified initially in two groups: healthy or damage. The prediction errors of these unknown conditions are computed using Eq. 3 and then the damage index \mathcal{DI} is estimated by each test using the Eq. 4. The Lilliefors test is used to warranty that the variance of the prediction errors $\sigma^2(\cdot)$ in healthy states have normal

Figure 3: AIC order selection with focus in prediction.

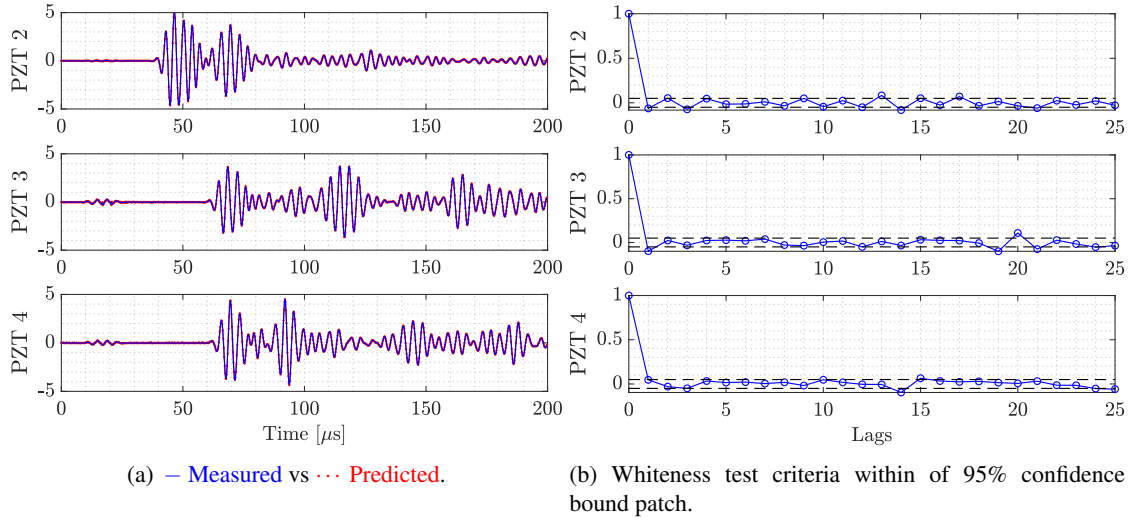

Figure 4: Healthy output predicted by healthy model AR(40).

distributions, i. e., the \mathcal{DI} trends to have a \mathcal{F} – distribution in the reference condition [6].

Figure 5(a) illustrates the index \mathcal{DI} , where is possible to observe, as presumed, that the sensor PZT 2 is sensible to the presence of damage while other PZTs the distinction between the different situations is not possible. Figure 5(b) displays the evolution of the indices with the increase of the damage using a box-and-whisker plot assuming known each damage state. A superposition in the upper quartile of the indices computed in the healthy state and the lowest quartile (even the median value) of damage states are also observed in PZT 3 and PZT 4.

Figure 6 illustrates the receiver operating characteristics (ROC) curve to detect damage against reference condition considering all PZTs sensors. The line (0,1) designates the correct classification that is achieved by PZT 2, that is the path where the damage is located. Additionally, the ANOVA procedure is computed to classify if the means are different or not, combined with a Tukey multiple comparisons to see whereby statistically significant the clusters are.

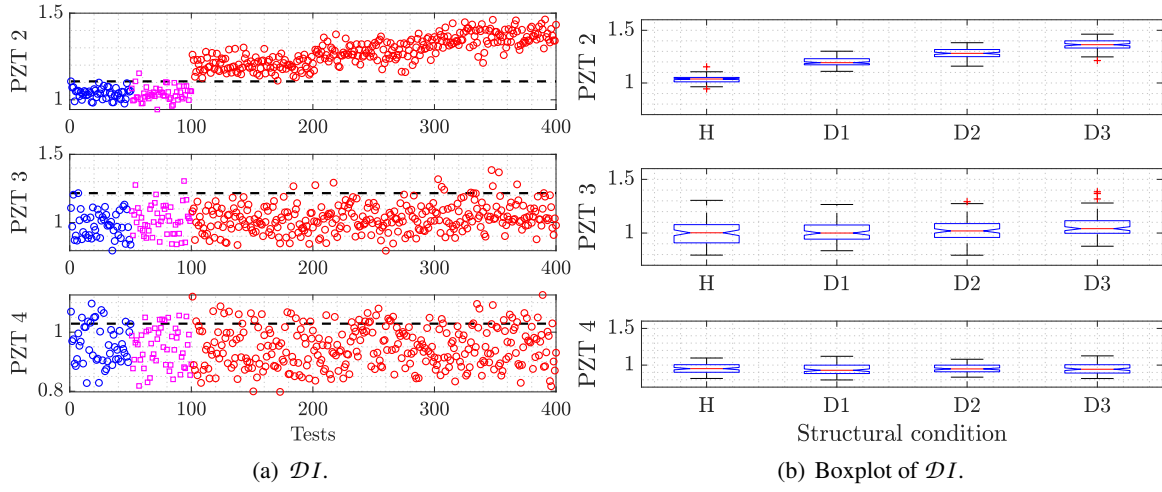

Figure 5: Damage index DI . (a) Damage index DI : Healthy - training data (o), Healthy - test data (□) and Damaged (o). — is the threshold line assuming a significance level of 5%. (b) Box plots to observe the median, quartiles and outliers in the index distribution.

Figure 6: Receiver Operating Characteristics (ROC) curve: □ PZT 2, o PZT 3, and * is PZT 4.

Figure 7 presents this plot for PZT 2, where the circle is the mean value of the cluster with a 95% confidence interval. Three groups, $n_d = 3$, are distinctly separated and correlated with three possible structural states. After clustering, a new set of AR models in each damage group for PZT 2 is identified for monitoring the structural state and to implement the extrapolation explained in the next section. Other PZTs are not used here to identify new models because none variations are observed permitting the identification of a new polynomial $\mathcal{A}_j(q)$ in Eq. 5.

4.3 Prevision of future AR damaged model

Three damaged models are estimated using one of the conditions presents in the clusters in fig. 7 after detecting and clustering. Combined with the reference model, a matrix given by Eq. 6 is formed with $n_d = 3$ and $n_a = 20$ to help the extrapolation. A cubic spline polynomial created with the data in matrix

Figure 7: Classification of the clusters of different damage states using ANOVA of DI . 3 groups (in red) have means significantly different from healthy H .

\mathbf{A} permits to estimate an extrapolated model $\Lambda(q)$ to use Eq. 8 to predict future states.

More eight future damage conditions are simulated by increasing the covered area to prove the benefits of the extrapolated model. First, a damage $D4$ with a surface area covered of 0.5% is used to predict the future state. Figure 8(a) presents the comparison between the measured and predicted by the extrapolated model in damage condition $D4$. Figure 8(b) shows the residual analysis by the autocorrelation function to confirm an adequate prediction.

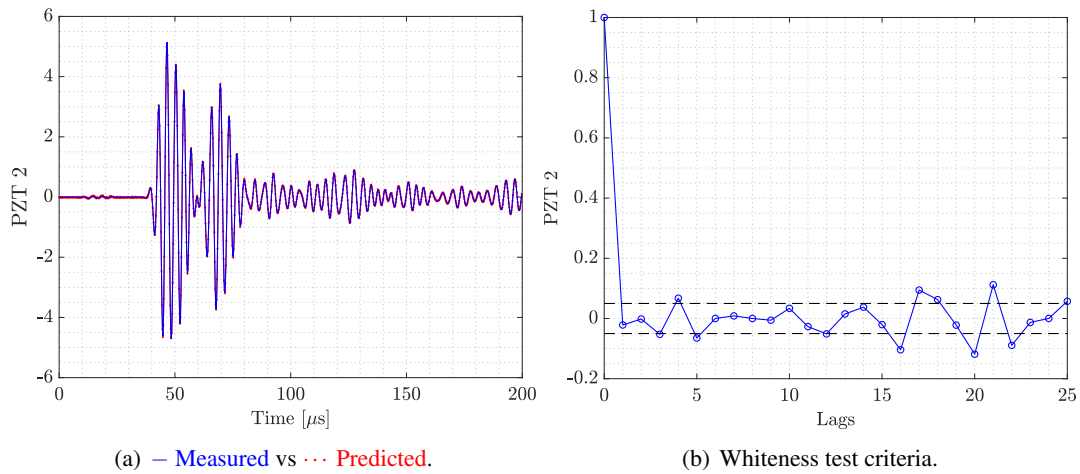

Figure 8: Output predicted by the extrapolated model AR(40) for damage condition $D4$.

When the damage condition is measured a model can be identified, and one can compare the DI obtained by model identified by extrapolation and when the damage happens, now assuming the new reference as $D4$. The box-plot is also presented in fig. 9(a) for the other damage conditions to observe its similarity comparing the real data measured and extrapolated. It is possible to observe a similarity, where the DI using the prediction errors filtered by extrapolated model presents a more significant dispersion. Figure 9(b) illustrates the predictions obtained by the filtered model using the real data (measured) and

extrapolated model. It is found a more significant dispersion to a broad horizon when the damage (surface area covered by the adhesive) is supposed severe and the model is not validated for this situation. This choice here of the validated horizon of prediction is correlated with the level of severity of the damage, once the extrapolation is done considering does not modify the framework and order of the AR model. Additionally, it is fundamental to observe that usually when damage is alerted in a monitored system, a repair or visual inspection can be performed to evaluate the structural safety. Thus, assuming a short horizon with initial damage, this extrapolated model has a nice feature almost equal to a real model identified when the damage increases and is helpful to make decisions.

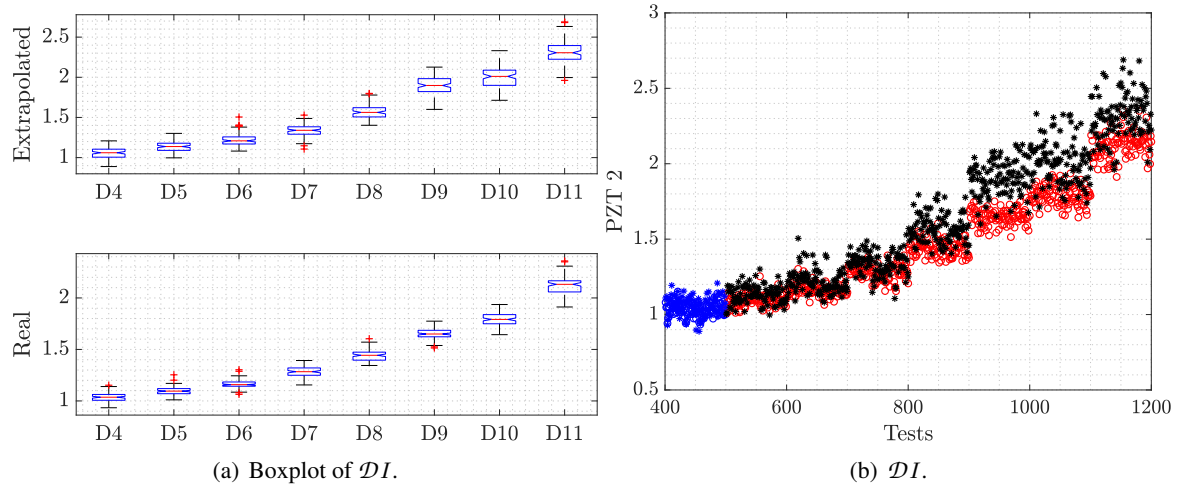

Figure 9: Damage index DI for PZT 2: (a) Box plots of the damage index DI in extrapolated condition D4 to observe the median, quartiles and outliers in the index distribution assuming the extrapolated model and damaged model. (b) \circ real damage D4 represents the new reference, $*$ extrapolated damaged D4 (extrapolated new reference), $*$ extrapolated damage, and \circ real Damaged (red) is the future damaged condition.

Figure 10 shows the ROC curve comparing the similar performance between the extrapolated and the real model to detect all future damage conditions. The extrapolated model in structural state D4 also allows dividing the clusters associated with the other damages using ANOVA, as seen in fig.11.

5 CONCLUSIONS

This paper demonstrated that multiple AR identified models in the healthy and in the initial damaged conditions could be helpful to perform an extrapolation to a future state if the damages progress in a similar way. This kind of technique combined with a Bayesian approach for extrapolating, seeking to reach high levels of SHM's hierarchy, may provide a significant physical insight if we compare with the trend curves computed by damage-sensitive index with some machine learning approach. First, a model is identified associated with parameters that can predict future states or conditions before the occurrence. Of course, the basic premise is that the evolution of the initial damage is not abrupt and does not happen in different points. Investigations regarding these issues are necessary because in a real-world scenario the behavior of a damage evolution is complex.

To identify with other input signals, for example, random input, and with different temperatures and operational conditions is required to be able to conduct tests with a focus in a simulation and not the only prediction. Other models can also be employed, in particular, Gaussian Process (GP) combined with AutoRegressive models because of the ability of these models to predict with band confidence and admit

Figure 10: Receiver Operating Characteristics (ROC) curve: □ Extrapolated, and ○ Real.

Figure 11: Classification of the clusters of different damage' states using ANOVA of DI assuming extrapolated model. 3 groups (in red) have means significantly different from healthy H .

a priori probability identified to extrapolate a future state. Numerical simulation using finite element models are further beneficial to correlate more intense and complicated damage progression with an extrapolated data-driven model, and some studies are started in this direction.

Abstract: One of the most important issues in engineering is the monitoring and the early detection of structural damages to prevent catastrophic failures. This process is referred to as Structural Health Monitoring and is expected to provide considerable improvements with respect to safety and maintenance costs. More particularly, the focus is here put on composite structure representative of aeronautic applications and the damages to be monitored are of “delamination” type. Nonlinear features generated by Lamb wave/damage interaction were employed for the detection of the delamination damage. Experiments are conducted on composite plates made of carbon fiber reinforced polymer equipped with two piezoelectric transducers. One plate is calibrated with a delamination damage at the center using laser shock wave technique. Nonlinear features of Lamb waves are observed in the experimental results. Finite element method is here used for investigating the nonlinear wave properties as well as the wave/damage interaction. Two damage models are studied and implemented at delamination area: a spring model and a contact model. An undamaged plate is also presented as reference in both finite element simulations and experiments. Results show that higher harmonics can be used as identification of the existence of delamination damage in a composite structure. A contact interaction model can represent the mechanical behavior of delamination damage and can be used for a real delamination modelling.

Key words: Structural Health Monitoring (SHM), Lamb wave, delamination, Finite Element method

1. INTRODUCTION

One of the most important issues in engineering is the monitoring and the early detection of structural damages to prevent catastrophic failures. This process is referred to as Structural Health Monitoring (SHM) and is expected to provide considerable improvements with respect to safety and maintenance costs [1]. In SHM, the first stage and the most important part is damage detection.

In the past decades, various techniques for damage detection have been investigated. Among them the wave propagation-based method has become the most commonly used method for its

convenience and low costs. Specifically, Lamb waves are widely used in beam- and plate-like structures due to the high sensitivity to multiple defects with high precision of identification, the ability to cover entire cross-sectional area, convenience for usage, cost-effectiveness and low energy consumption [2], [3]. With a high susceptibility to interference on a propagation path, e.g. damage or a boundary, Lamb waves can travel over a long distance even in materials with a high attenuation ratio, such as carbon fiber-reinforced composites, and thus a broad area can be quickly examined [4].

So far, most of the existing Lamb wave damage detection methods are based on linear wave propagation properties, such as time of flight, reflected waves, transmitted waves and mode conversion information at the excitation frequency [5]–[8]. However, these methods are only sensitive to large defects such as an open crack, but for tiny damages nonlinear techniques are required [9]. Compared to linear techniques, nonlinear Lamb waves are more sensitive to smaller, even barely visible damages such as delaminations in composite structures or cracks. Generally, the nonlinear phenomena are induced mainly due to two types of physical mechanisms. One mechanism is related to the nonlinear relationship between strain and stress of materials in structures and components [10], [11]. The other mechanism is the so-called non-classical nonlinearity, which is often due to other mechanisms such as, for example, a contact acoustic nonlinearity (CAN) [10]. Here in this paper, a delamination type damage is focused, where nonlinearities are induced due to the second mechanism, that is, the contact between the interfaces of the delamination in composite structures.

Generally, when the incident wave passes through the damage, the damage interfaces tend to move towards each other under compressive pressure, and opposite each other under tensile pressure [10]. This may lead to the interaction between damage interfaces. In this case, when Lamb wave interacts with contact-type of damage, such as delamination damage, higher harmonics can be generated due to the contact between damage interfaces [11]–[13].

Several studies focused on the higher harmonics generated by CAN in plate-like structures. Finite element (FE) simulations and experiments were conducted to investigate the nonlinear Lamb wave/damage interaction as well as the wave propagation. Yang *et al* [11] carried out a three-dimensional (3D) simulation and also experiments on an aluminum plate to investigate the second harmonic generation due to a fatigue crack. The investigations were conducted using S0 and A0 Lamb waves generated by eight piezoceramic discs. Delrue *et al* [14] built a 3D model for a composite rectangular plate containing a circular delamination for the investigation of its nonlinear behavior. The excitation was applied by out-of-plane nodal displacement. Ramadas *et al* [15] the mode conversion of Lamb waves due to the presence of delamination. The delamination was modelled by de-merging the nodes at delamination region. The excitation was modelled by giving out-of-plane displacements on the surface of the composite plate. Hong *et al* [16] developed a solid model for simulating the generation of the nonlinearities when ultrasonic waves traverse a fatigued medium. The excitation was applied by piezoelectric wafers on an aluminum plate. Soleimanpour *et al* [12] studied the potential of a baseline-free structural health monitoring techniques based on higher harmonics resulting from the interaction of guided wave with a delamination. They employed a 3D FE model to simulate the delamination damage behavior in a composite beam, with a displacement excitation.

From the above stated studies, it can be observed that in FE simulation study, a common way to generate Lamb waves is to apply an out-of-plane displacement excitation on plate structures. This is only a simplification of the excitation by piezoelectric transducers, which are

commonly used in experiments. However, the electro-mechanical behavior of piezoelectric transducer excitations and directly displacement excitations can be quite different, and thus the wave/damage interaction may be also different from experiments. Some scholars used piezoelectric wafers to induce Lamb waves in simulation, but mostly on aluminum plates. In this study, piezoelectric elements are employed to generate Lamb waves in composite plates.

In order to test and verify the nonlinear Lamb wave/damage interaction theories and the proposed finite element models, experimental investigations are necessary, and particularly, physical supports are firstly needed. Generally, Teflon inserts [12], [17], [18], attaching industrial putties [19] and convention impacts [20][21] are the major existing techniques used for delamination generation. The main weakness with these techniques is that they do not allow for an effective control of the induced damage. For example, the calibration of delamination using impacts may induce other types of damage. As for Teflon insert technique, the problem is that it remains far from a realistic delamination damage.

As an alternative to conventional damage generation techniques, a new method named Laser Shock Wave Technique (LSWT) [22] is used to calibrate delamination damages in composites. In this paper, studies are conducted using the composite specimens with delaminations generated by laser shock. Two damage models are presented to investigate the interaction between Lamb wave and a well-controlled real delamination damage. An undamaged model is used as baseline.

This paper is organized as follows. First, the experimental configuration and results are presented in section 2. Then the FE model of a composite plate and the delamination region as well as the simulation results are illustrated in section 3. In section 3, the comparison between FE simulation and experiments are also presented. Finally, the paper is concluded in section 4.

2. EXPERIMENTAL STUDY

In this section, experiments are performed for the detection of delamination damage in composite plates.

2.1 Experimental system

The experiments are conducted using a SHM system developed by author's team. The experimental setup is shown in Figure 1(a). The specimen is suspended to the workbench in nearly free boundary conditions in order to prevent the specimen from interacting with other supports (e.g. test bench). Two composite plates made of carbon-fiber reinforced polymer (CFRP) are employed for testing: a damaged plate and an undamaged plate. The plates are in the size of $315 \times 100 \times 2.24 \text{ mm}^3$, constituting of 16 plies with a stacking sequence of $[0^\circ/90^\circ]_8$. The material properties of this plate are listed in Table 1.

Each composite plate is equipped with two PZT disks (diameter 25 mm, thickness 0.5 mm) produced by Noliac, as shown in Figure 1(b). One PZT is used as transmitter for signal generation and the other is used as signal receiver. The excitation signals are transmitted from the signal generator through the amplifier to PZT1 to generate elastic waves inside the plate. The waves propagate inside the plate and arrive at PZT2. Then PZT2 transforms the elastic waves to electrical signals, and the signals are collected by the data acquisition system. The input signal is a sine wave signal at the frequency of 109kHz with its amplitude of 10V after amplification. The sampling frequency of data acquisition is 10^6 Hz .

The damaged plate contains a circular delamination damage at the center. Damage was introduced into samples in a calibrated way using laser shock wave technique. The specimen was subjected to a symmetrical laser impact of two laser beams. This resulted in a 7 mm diameter nearly circular delamination at midplane of the composite plate [23].

2.2 Experimental results

Figure 2 shows the experimental signals received by the PZT2 from both healthy and damaged plates. The results in Figure 2(a) are calculated by converting the time signal into the frequency domain using a fast Fourier transform (FFT) which includes the incident waves and the reflected waves from the plate edges and the delamination. From the signal amplitudes obtained from the undamaged plate, only one peak can be observed at 109kHz, which corresponds to the fundamental frequency. In contrast, the signal amplitudes obtained from the delaminated plate show the existence of second and third order harmonics in frequency domain. In addition, the subharmonics at 0.5 and 1.5 times of the fundamental frequency also appear. Figure 2(b) shows the short time Fourier transform of the received signal from the damaged plate. In this diagram, the subharmonics and superharmonics are also apparent. This is evidence that a delamination damage generated by laser shock induces nonlinear features of Lamb waves, and this phenomenon can be used as identification for real delamination damages in composite structures.

Table 1: Materials properties used in FE model (1 ply)

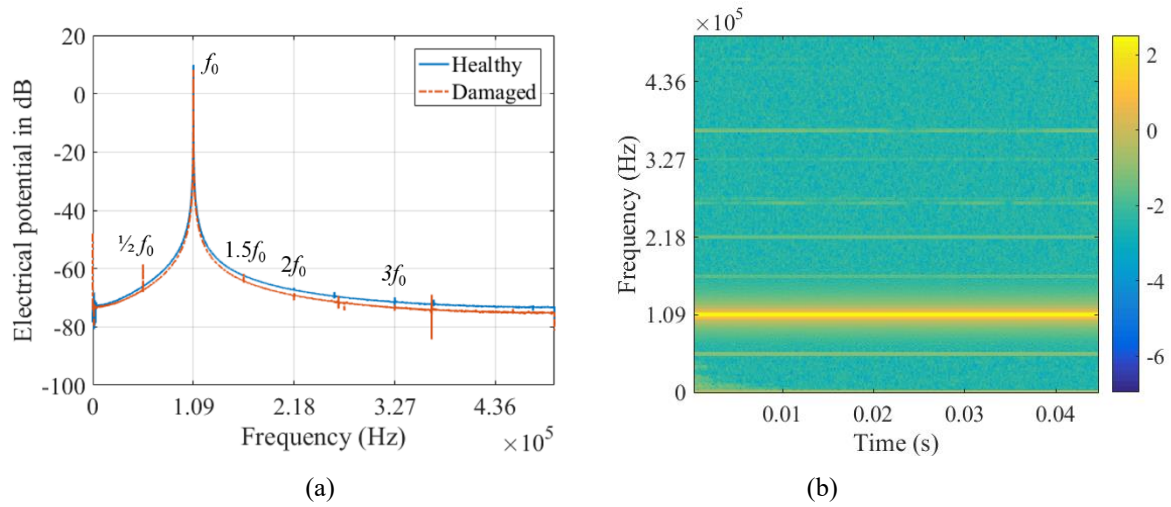

Figure 2: Experimental results: (a) comparison of the responses in frequency domain for the undamaged plate and the damaged plate. f_0 is the fundamental frequency. (b) Time-frequency distribution of the experimental signal received from the damaged plate

3. FINITE ELEMENT SIMULATION

In order to investigate the nonlinear phenomena appearing in the experiments, FE simulations are conducted. Two damage models are employed and compared, representing different interaction mechanisms between delamination interfaces.

3.1 Model of composite plate

In this section, the FE method is used to simulate the propagation of Lamb waves in a cross-ply laminated composite plate. Figure 3 shows the FE model built in the commercial software ABAQUS. In this model, the composite plate is modeled by bonding two shell layers using “tie” interaction except the delamination region. Each layer contains 8 plies. Eight-node shell elements (S8R) are used to avoid a high aspect ratio between length in the in-plane direction and thickness in through-thickness direction of the solid elements.

Two piezoelectric transducers (PZT) are bonded to the surface of the plate for transmitting and receiving electrical signals. The PZTs are modelled using quadratic solid piezoelectric elements (C3D20E). The meshes at the contact surfaces of piezoelectric elements and the plate are identical, which assures the coupling between PZT and the plate. The electrical potential of the bottom surfaces of the PZT elements are set to be 0. The input signal is exerted on the top surface of PZT1, and the electrical potential on the top surface of PZT2 is measured. A sinusoidal wave at the frequency of 109kHz is used as the excitation signal.

3.2 Element size and time step

It was shown previously [24] that in simulation of wave propagation temporal and spatial resolution should be small enough to satisfy the convergence requirements. In general, the time increment required for a dynamic analysis is

$$\Delta t < \frac{1}{10f_{max}}$$

where Δt is the time increment in the analysis procedure, and f_{max} is the highest frequency of interest. In this study, the higher harmonics in the received signals are of interest, which reflect the existence of delamination damage. Therefore, the highest frequency to be detected is the frequency of the third harmonics, i.e. $3 \times 109\text{kHz} = 327\text{kHz}$. Then the time increment can be expressed as $\Delta t < 3 \times 10^{-7}\text{s}$. In order to achieve better accuracy, the time step is set as $0.2\mu\text{s}$.

In a wave propagation study, the element size is usually associated with the investigated minimum wave length λ_{min} . It is generally recommended that more than 10 nodes per wave length should be used, and this criterion can be expressed as [24]

$$l_e < \frac{\lambda_{min}}{10}$$

where l_e is the element length.

Since the number of nodes in a single wavelength can influence the accuracy of wave propagation simulation, a convergence study for element size is conducted. The model used here is the same plate model illustrated previously but with a smaller size ($300\text{mm} \times 30\text{mm}$). The excitation is a 5-circle tone-burst displacement excitation applied as a boundary condition to the left edge of the plate. Two types of excitation are considered here: the out-of-plane displacement excitation for approximation of A0 wave and the in-plane displacement excitation for approximation of S0 wave [25]. Five cases of different element sizes are studied: 5mm, 2.5mm, 2mm, 1mm and 0.5mm. The time of flight (ToF) of the amplitude is measured in the convergence study.

The effects of element sizes on ToF for both in-plane displacement excitation and out-of-plane displacement excitation are depicted in Figure 4. A straight line parallel to x-axis is shown in Figure 4(a), indicating that the ToF curve may converge at element size larger than 5mm. Thus, 5mm is accurate enough for simulating S0 wave. Meanwhile, Figure 4(b) shows a monotonic increase in ToF by decreasing the element size. The ToF first increases drastically when element size decreases from 5mm to 2.5mm, and then it shows a slight increase with element size decreasing from 2.5mm to 0.5mm. The ToF converges to 0.1803ms at element size of 1mm. However, the ToF at 2mm is 0.1801ms, showing only 0.1% difference with respect to the convergent value. Therefore, in this study, the global element size is set to be 2mm along the in-plane direction to achieve a trade-off between the simulation accuracy and computational costs. In the delamination region the local element size is set to be 0.4mm.

Figure 3. FE model of the composite plate using quadratic shell elements

3.3 Damage model

In this section, two damage models are presented: the spring model and the contact model. In the spring model, delamination is modelled by adding a set of linear spring elements. These spring elements connect the nodes distributed on the delamination interfaces, as shown in Figure 5. The relative movement between delamination interfaces are controlled by the spring stiffness, which is defined along the axial direction of the spring elements, that is, the through thickness direction of the plate.

In reality, no penetration will happen between contact surfaces; however, in finite element analysis, hypothetical penetration is possible. If the spring stiffness is too small, penetration may happen between the delamination interfaces, while with a spring stiffness far too large, there won't be any interaction between the interfaces. Therefore, an appropriate spring stiffness is needed. A sensitive analysis of spring stiffness was conducted. Several spring stiffnesses were investigated, and results show that the sensitive zone happens between $10^3 \text{N/m} \sim 10^6 \text{N/m}$, as shown in Figure 6. Therefore, in this study, the spring stiffness is $5 \times 10^4 \text{N/m}$.

The contact damage model is implemented by applying a surface-to-surface contact to the delaminated region. Figure 7 shows two types of relationship between contact pressure and overclosure (interpenetration) between the surfaces: "hard" contact interaction and the free boundary condition at contact surfaces. When the contact interfaces are separated, no pressure is exerted onto the surfaces, and if contact interfaces are in contact, the penetration is 0. This avoids the hypothetical penetration in FE simulation, at the cost of longer computational time.

The delamination is a circular area located in the mid-plane of the plate, i.e. between the 8th and 9th ply. The diameter of the delamination region is 7mm. The centroid of the delamination is located at the center of the plate. An undamaged plate is also investigated for reference.

Figure 4: Effect of element size on ToF when the FE model subject to a displacement excitation at the left edge: (a) in-plane displacement excitation, (b) out-of-plane displacement excitation.

Figure 7: Schematic of the contact pressure-overclosure relationship in the surface-to-surface contact model at delamination region [26]

Figure 8: Simulation results: comparison of the models' responses in frequency domain for the undamaged plate model (healthy), damaged plate model with contact interaction (contact) and damaged plate model with spring elements (spring) at delamination region. f_0 is the fundamental frequency.

3.4 Simulation results

A comparison of the amplitudes of the received signals in frequency domain is shown in Figure 8 for the undamaged model, the spring model and contact model respectively. The signals are obtained by measuring the electrical potential at the receiving PZT and transforming into frequency domain. As shown in Figure 8, besides the fundamental frequency, the higher harmonics can be observed clearly from the contact model, including second, third, fourth and fifth order harmonics. However, in the healthy model and spring model, the peak amplitudes only appear at fundamental frequency. It can be concluded that a contact interaction model can be used to characterize the nonlinear features of Lamb wave/damage interaction, while a linear spring model is not appropriate for the representation.

3.5 Comparison between finite element simulation and experiments

Comparisons of the amplitudes of the received signals in frequency domain from experiments and FE simulations are shown in Figure 9. The results are obtained after baseline subtraction, i.e. subtract the signals from the healthy plate. Significant difference is observed in Figure 9(a), between experimental results and FE results from the spring model. From the FE results, no super-harmonics or subharmonics can be observed in the signal amplitudes, leading to a disagreement between experiments and FE results.

In contrast, it is possible to observe from Figure 9(b) that results from contact model show good agreement with the experimental results. Both show the second and third harmonics in the amplitudes. However, in case of FE simulation data many higher harmonics are observed. On the other hand, in case of experimental data second and third harmonics as well as subharmonic at half of the fundamental frequency are distinctly alongside the other harmonics. This discrepancy between FE simulation and experimental observations may be due to the effect of the experimental system and the presence of environmental noise. From the above discussion, it can be concluded that results from the contact model shows better agreement with those from experiments, compared to the linear spring model.

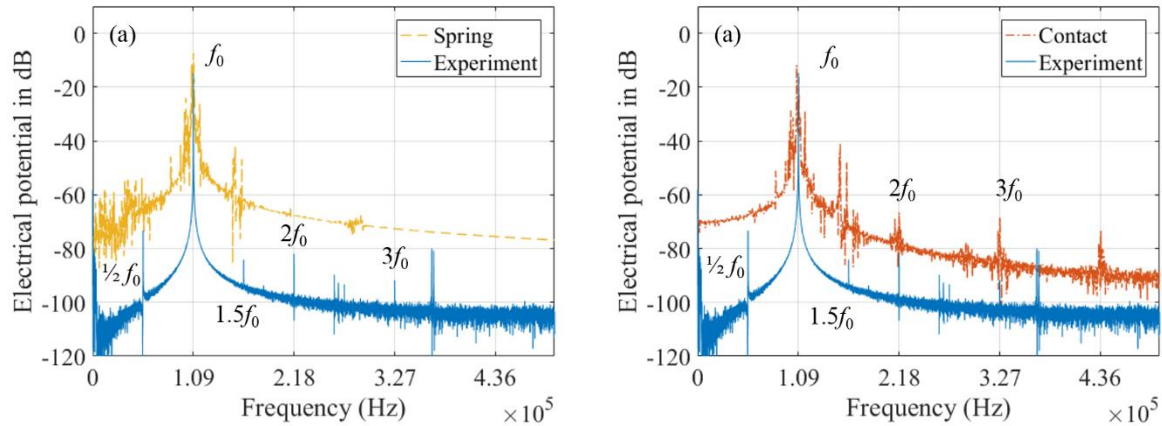

Figure 9: Comparison of amplitudes of receiving signals from experiments and FE simulations in frequency domain after baseline subtraction: (a) experiments and nonlinear damaged model (with contact interaction), (b) experiments and linear damaged model (with linear spring elements). f_0 is the fundamental frequency.

4. CONCLUSION

Nonlinear phenomena induced by delamination damage in composite structures are investigated in this paper. Experiments are conducted on a healthy plate and a plate with delamination damage generated by the laser shock technique. Fourier transform is used to transform the time signals into frequency domain. Experimental results from the damaged plate show superharmonics and subharmonics, while only fundamental frequency component appears in the healthy case. An analysis of the interaction between Lamb waves and delamination damage is performed using FE simulation method. Two damage models, the spring model and the contact model, are employed and calculated. The simulation results show that super-harmonics can be observed from the contact model, while only fundamental frequency exists in the spring model and healthy model. A comparison was conducted between experiments and FE simulations, showing that results from the contact model achieved good agreement with experimental results. It can be concluded that a contact interaction model is appropriate for characterizing the interaction between Lamb wave and a real delamination damage, and that it can be used to simulate nonlinear interaction between delamination interfaces.

Key words: Structural health monitoring, Lamb wave, attenuation prediction, composite materials, viscoelastic damping.

Abstract. The inspection and detection of damage in composite materials using Lamb waves are particularly effective because Lamb wave can propagate over relatively large distance and hence can cover a large area with few testing time and equipment. However, comparing to the dispersion features that have been investigated systematically in the literature, predicting simply and reliably the spatial attenuation, which is the decrease of the amplitude of the propagating wave with distance, is still a challenge especially for structures large enough to industrial scale. In this paper, a simple model able to predict Lamb wave attenuation for different frequencies, which takes three damping models, Hysteretic, Kelvin-Voigt and Biot models into account, is derived directly from dispersion equations. Experiments on a practical aeronautical component, a Fan Cowl Structure, are carried out to validate the developed model. The merits of the proposed method lie in the fact that it is derived directly from dispersion equations instead of relying on complex finite element models and are thus simple to compute. Despite its simplicity, it is still effective when predicting attenuation coefficient for geometrically complex structures such as the Fan Cowl Structure.

1 INTRODUCTION

One of the most important issues in engineering concerns the monitoring and the early detection and localization of structural damages in order to prevent catastrophic failures. This process is referred to as Structural Health Monitoring (SHM) and is expected to provide considerable improvements with respect to safety and maintenance costs. Over half a century, modern SHM techniques have attained maturity in engineering practice, playing a significant role in evaluating the integrity and durability of engineered structures and assets [1]. With efficient, continuous and automated SHM techniques it is possible to identify structural damage at an early stage so as to prevent further failure occurring, producing huge economic and human benefit [2]. A SHM system generally focuses on three aspects: i) identifying the existence, location and classification of damage, ii) evaluating the severity of damage and iii) predicting the residual service life of structure.

Monitoring the health and integrity of complex aeronautical structures at the operation condition is mandatory. Among all kinds of SHM techniques, ultrasonic wave strategy based on Lamb waves is particularly effective in accomplishing this task because Lamb waves are able to propagate over relatively large distances and thus can cover a large with short testing time and few sensors. This benefit results in reduced labor and time to perform a test, and

makes long range inspection possible [3].

The dispersion and attenuation property of Lamb wave are two essential factors that need to be considered carefully when inspecting a structure by means of Lamb waves. Contrasting with dispersion which is the velocity change with frequency and that has already received sound exploration over the past decades, understanding and modeling the attenuation of Lamb wave in composite materials is still an open challenge. Existing efforts are limited to simulation and small-scale experiments. Recently, the damping effect on dispersion curves in plates was investigated theoretically [4]. The theoretical model to calculate the attenuation coefficient in viscoelastic anisotropic lamina was established based on linear 3D elasticity [5]. Two alternatives for this purpose were achieved via semi-analytical finite element method [6] and spectral collocation method [7]. The Rayleigh damping model was adopted to investigate the attenuated Lamb wave propagation in composite structures [8,9]. This model was also adopted to investigate damage detection of composite structures [10].

However, the investigation of Lamb wave attenuation in practical aeronautical structures caused by viscoelastic damping has been scarcely studied after the authors made an overall literature survey. This is owing to the complicated service conditions of aeronautical structures, including complex geometry and boundary of the structure itself, varying environment temperature and noise contamination etc. However, knowledge of in situ attenuation of Lamb waves for these structures is very desirable to deploy SHM strategies to monitor them. To solve this issue, this paper establishes a predictive model of Lamb wave attenuation for practical aeronautical structures and the experiment on a large-scale structure has been conducted to validate the model. Being able to predict spatial attenuation in such complex aeronautic structures paves the way for potential applications such as transducer network design optimization and amplitude-based damage localization algorithms development.

2 PREDICTIVE MODEL OF LAMB WAVE ATTENUATION

2.1 Attenuation representation of Lamb wave

When a Lamb wave mode is excited and propagates in a thin plate with infinite width, the displacement formula of the plate along the propagation direction can be expressed as follows [1].

$$u_x(x, t) = Ae^{j(kx - \omega t)} \quad (1)$$

where, A is the amplitude of wave at the origin point in temporal and spatial domain; k and ω are wavenumber and circular frequency respectively; x and t are the sensing distance and wave propagation time respectively; $j = \sqrt{-1}$.

It is supposed that as long as damping is considered the wavenumber is complex-valued,

$$k^* = k_r + jk_i \quad (2)$$

where, both k_r and k_i are real positive number. The superscript “*” denotes that the term correlated belongs to complex numbers space in this paper.

Substituting Eq. (2) into Eq. (1) can result in the following formula.

$$u_x(x, t) = Ae^{-k_i x} e^{j(k_r x - \omega t)} \quad (3)$$

Comparing Eq. (3) to Eq. (1), if the wavenumber is a complex number, the magnitude decays exponentially over the propagation distance, and this phenomenon is the so called

attenuation behavior of Lamb wave. Thus, k_i is defined as the attenuation coefficient in unit Np/m. Lamb wave attenuation is mainly caused by viscoelastic damping [6]. Hence, the damping models should be expounded firstly.

2.2 Damping effects on Lamb wave attenuation

There are generally two classical damping models to describe the viscoelasticity: Hysteretic (HR) model and Kelvin-Voigt (KV) model [11]. For both models, the Young modulus becomes a complex number E^* presented in Eqs. (4) and (5) respectively, in which the real part is defined as the storage modulus E representing the storage of energy and the imaginary part reflects the loss of energy. Besides the two models, a less common damping model named Biot (BT) model is used to investigate the damping effect on Lamb wave attenuation as presented in Eq. (6). This model is mainly applied to highly damped aerospace structures [12].

$$E^* = E(1 - j\gamma_{HR}) \quad \text{for Hysteretic model} \quad (4)$$

$$E^* = E \left(1 - j\gamma_{KV} \frac{f}{f_0} \right) \quad \text{for Kelvin - Voigt model} \quad (5)$$

$$E^* = E \left[1 + \frac{2}{\pi} \gamma_{BT} \ln \sqrt{1 + \left(\frac{2\pi f}{\epsilon} \right)^2} - j \frac{2}{\pi} \gamma_{BT} \arctan \left(\frac{2\pi f}{\epsilon} \right) \right] \quad \text{for Biot model} \quad (6)$$

where, γ_{HR} , γ_{KV} and γ_{BT} are the damping ratio for HR, KV and BT model respectively; ϵ is the scaling factor for BT model; f_0 is the reference frequency of KV model and it is set arbitrarily to be 250kHz in this paper. As this parameter is just a normalization parameter, setting arbitrarily its value is not an issue. If $\gamma_{KV} = \gamma_{HR}$ and $f = f_0$, KV model is equivalent to HR model at the frequency f_0 [11].

In light of the complex Young modulus, no matter which damping model being used, the classical dispersion equations become complex equations:

$$\begin{cases} \frac{\tan(\alpha_T^* h)}{\tan(\alpha_L^* h)} = -\frac{4k^2 \alpha_L^* \alpha_T^*}{(\alpha_T^{*2} - k^2)^2} & \text{for symmetric modes} \\ \frac{\tan(\alpha_T^* h)}{\tan(\alpha_L^* h)} = -\frac{(\alpha_T^{*2} - k^2)^2}{4k^2 \alpha_L^* \alpha_T^*} & \text{for anti - symmetric modes} \end{cases} \quad (7)$$

where, h is the half thickness of plate. $\alpha_L^* = \sqrt{\frac{\omega^2}{c_L^{*2}} - k^2}$ and $\alpha_T^* = \sqrt{\frac{\omega^2}{c_T^{*2}} - k^2}$; $c_L^* = \sqrt{\frac{\lambda^* + 2\mu^*}{\rho}}$

and $c_T^* = \sqrt{\frac{\mu^*}{\rho}}$ are the velocity of longitudinal and transverse mode respectively. $\lambda^* = \frac{E^* \nu}{(1+\nu)(1-2\nu)}$ and $\mu^* = \frac{E^*}{2(1+\nu)}$ are the Lamé constants. ν and ρ are the Poisson ratio and density respectively.

The phase velocity c_p is the quotient between circular frequency and real wavenumber. The group velocity c_g is the partial derivative of circular frequency to real wavenumber.

$$c_p = \frac{\omega}{k_r} \quad (8)$$

$$c_g = \frac{\partial \omega}{\partial k_r} = \frac{c_p^2}{c_p - \omega \frac{dc_p}{d\omega}} \quad (9)$$

2.3 Numerical algorithm of predicting Lamb wave attenuation

The solution of the real-valued dispersion equation forms the dispersion curve, which is usually expressed as two pairs (ω, c_p) and (ω, k) . However, the task of solving the complex dispersion equation is more complicated in the damped case because for the solution pair (ω, k^*) there are actually three real variables (ω, k_r, k_i) given that $k^* = k_r + jk_i$.

In order to overcome this issue, a two-step approach is proposed to work out the solution of the complex dispersion equation. In step 1, the solution pair (ω, k) for the real-valued equation $f(\omega, k) = 0$ is obtained, which can be easily achieved via many mature algorithms [13]. In step 2, the first three points of (ω, k^*) are acquired by directly solving the complex-valued equation $f^*(\omega, k^*) = 0$, during which the first three points of (ω, k) are taken as the initial guess because the real and complex solutions in (ω, k_r) plane mutually overlap at the initial stage of the dispersion curve. This is true since the effect of damping is relative low, such that $|k_i| \ll |k_r|$ and the strategy of searching the solutions of complex case in the neighborhood of the real case is working. For subsequent solutions, a curve tracing technique should be used in order to avoid branch crossing of different modes and thus guarantee a stable solution [13]. Specifically, the initial guess for the current solution is quadratically extrapolated from the previous three accurate solutions firstly, and then the current solution is obtained by directly solving the complex-valued dispersion equation. The presented two-step procedures form the numerical algorithm of predicting attenuation coefficient as summarized in Figure 1.

It should be noted that a strong complex equation solver is necessary for this algorithm. The authors hence employ the Levenberg–Marquardt based approach which is generally more efficient than Gauss-Newton method for solving a highly nonlinear equation to iteratively find the root of a complex equation from an initial guess [14].

3 DATA-DRIVEN BASED STRUCTURAL PARAMETERS ESTIMATION METHOD

It is evident from Figure 1 that in order to run the algorithm, the nine parameters should be provided in the first place. Normally, the thickness d , density ρ and reference frequency f_0 can be obtained easily. The other six parameters should be estimated from the collected Lamb wave signals, by which the group velocity and attenuation coefficient can be identified easily. Thus, the approach to identify the two parameters is described firstly.

3.1 Linear regression to identify group velocity and attenuation coefficient

3.1.1 Identification of group velocity

Under a specified frequency, a certain Lamb wave mode propagates in an isotropic plate or in an anisotropic plate but along a fixed direction with constant group velocity. Thus, the time-of-arrival (ToA) of Lamb wave is proportional to the sensing distance.

$$t_a = \frac{x}{c_g} + t_0 \quad (10)$$

where, t_a is the ToA; t_0 is the initial time of wave excited from actuator; x is the sensing distance; c_g is the group velocity for the propagating mode.

A series of t_a versus propagation distance x can be extracted from collected signals by indicating the time moment at the peak of the specified wave packet. If the scatter diagram

$(x_i, t_{a,i})$ is plotted, these scatter points should align with a straight line. Thus, linearly regressing these scatter points can be used to identify group velocity that is the inverse of the slope of the regressed line according to Eq. (10).

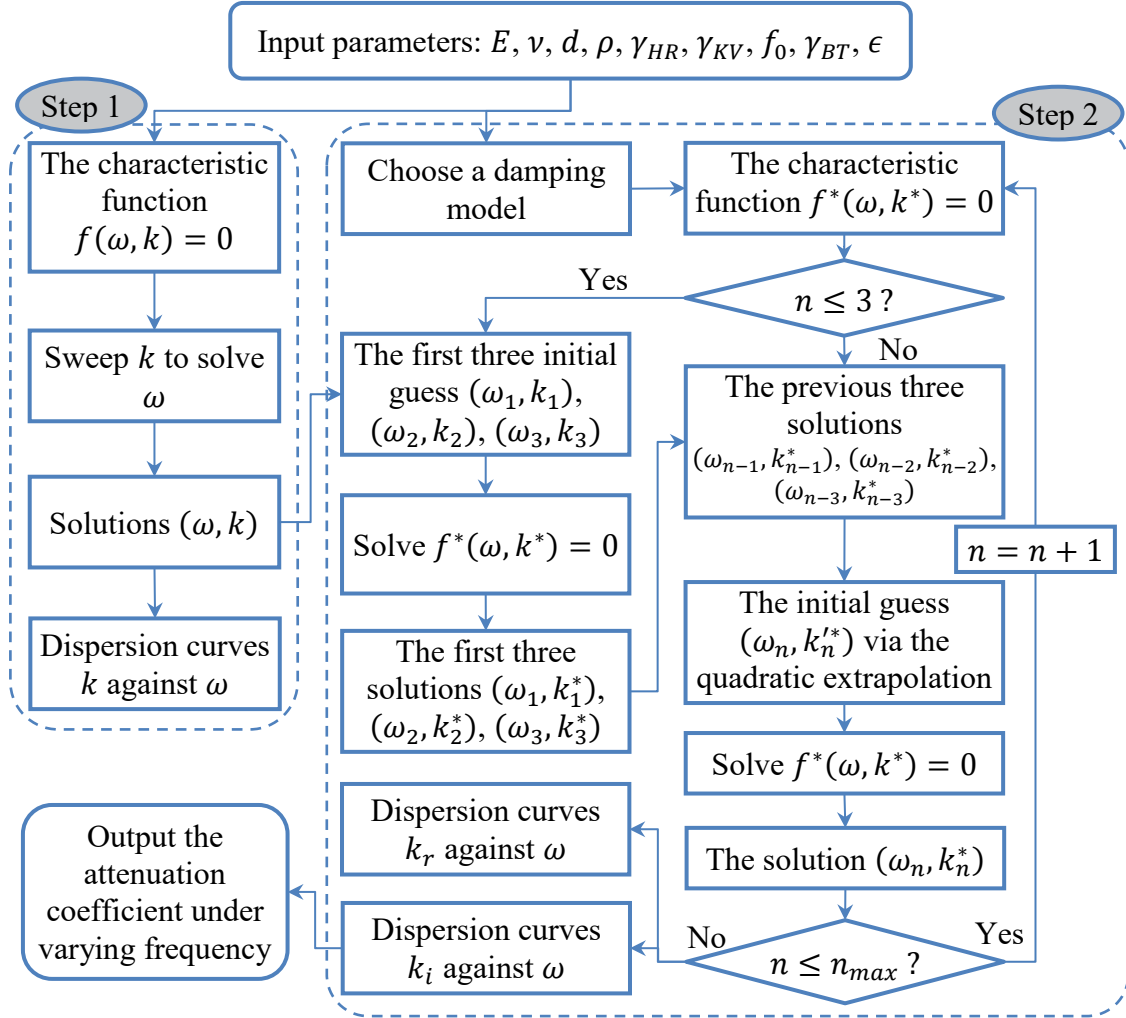

Figure 1: The flowchart of the numerical algorithm for predicting the attenuation coefficient

3.1.2 Identification of attenuation coefficient

Based on Eq. (3), the amplitude of wave exponentially decreasing over propagation distance is stated as following.

$$u_m = Ae^{-k_i x} \quad (11)$$

Making logarithm operation at two sides of Eq. (11) results in the linear formulation.

$$\ln u_m = -k_i x + \ln A \quad (12)$$

This equation manifests that the attenuation coefficient k_i can be identified from recorded signal by linearly regressing logarithmic amplitude of wave versus propagation distance, in which the attenuation coefficient is the negative of the slope of the regressed line.

3.2 The least square formulation for estimating material properties

The identified group velocity and attenuation coefficient can be used to estimate structural material properties.

3.2.1 Estimation of storage modulus and Poisson ratio

The theoretical group velocity that can be calculated from classical dispersion equations is expressed as the function with respect to storage modulus E and Poisson ratio ν if the frequency f is given.

$$c_g = G(E, \nu; f) \quad (13)$$

Once a series of group velocities under various frequencies are obtained from experiment, denoted as $(f_l, \tilde{c}_{g,l})$ ($l = 1, 2, \dots, m$), the least square formulation can be used to estimate storage modulus and Poisson ratio.

$$\arg \min_{E, \nu} \sum_{l=1}^m [G(E, \nu; f_l) - \tilde{c}_{g,l}]^2 \quad (14)$$

where the symbol “ \sim ” means that the variable it applies is extracted from experimental data. m is the number of excitation frequency during experiment.

3.2.2 Estimation of damping parameters

The theoretical attenuation coefficient k_i is expressed as the function with respect to a general damping parameter γ if the frequency f is given.

$$k_i = K(\gamma; f) \quad (15)$$

where, γ is γ_{HR} , γ_{KV} and γ_{BT} , ϵ for HR, KV and BT model respectively.

Therefore, if a series of attenuation coefficients under diverse frequencies are available from experiment, denoted as $(f_l, \tilde{k}_{i,l})$ ($l = 1, 2, \dots, m$), the least square method can be also used to estimate the damping parameter respectively for the three damping models.

$$\arg \min_{\gamma} \sum_{l=1}^m [K(\gamma; f_l) - \tilde{k}_{i,l}]^2 \quad (16)$$

It should be noted that during performing the least square model of estimating damping parameters, the storage modulus and Poisson ratio estimated through Eq. (14) should be used. When all the required parameters are available, they can be inputted into the algorithm stated in Figure 1 to predict attenuation coefficient.

4 EXPERIMENTAL INVESTIGATION FOR A PRACTICAL AND GEOMETRICALLY COMPLEX AERONAUTICAL STRUCTURE

4.1 Experimental setup and signal presentation

A practical aeronautical structure, namely a fan cowl structure (FCS), is employed to validate the proposed Lamb wave attenuation coefficient prediction algorithm. The structure is made up of composite materials. Its thickness and density are 2.24mm and 1554kg/m³ respectively. The geometry and transducers layout are shown in Figure 2. There are in total 13 piezoelectric lead zirconate titanate (PZT) transducers surface installed on the plate, among which PZT 1-6 and PZT 7-13 respectively align with an approximated straight line and are thus denoted as Group 2 and Group 3. Naturally, Group 1 includes all the PZTs. Since this

structure is large enough and a typical structure in aeronautical engineering, it is suitable for study the Lamb wave attenuation in composite plates.

During testing, input signal is chosen as a five-cycle sinusoid burst signal modulated by Hanning window. The central frequency varies from 50kHz to 250kHz with 5kHz increment. The signal from the function generator is passed through an amplifier for enlarging the voltage in order to produce Lamb wave signals powerful enough. In this experiment, the peak value of the excitation signal is $\pm 50V$. The actuator yields diverse Lamb wave modes and other sensors receive the signal. The data acquisition system (DAS) is adopted to collect signal and then stored in laptop for latter usage.

The sampling frequency is set to be 1MHz given that this value is the maximum capability of the DAS. In order to reduce noise, 10 repetition measurements are performed for each actuator excitation and then the 10 signals are processed with time averaging and wavelet denoising techniques. Figure 3 shows the typical Lamb wave signal in Group 2 in which PZT 1 serves as the actuator and its signal is normalized to the same magnitude of order than the receivers. It is evident that the signal amplitude decreases with the increasing of propagation distance.

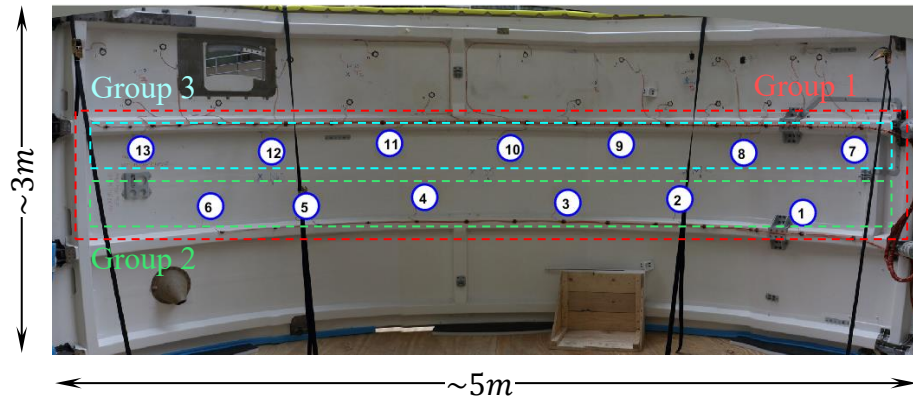

Figure 2: The FCS structure

Figure 3: Typical Lamb wave signal (100kHz)

4.2 Dispersion curve identification for group velocity and attenuation coefficient

4.2.1 Group velocity and attenuation coefficient identification

The linear regression model described in section 3.1.1 is used to identify the group velocity at a given frequency. Taking the S0 mode of 100kHz as example, the experimentally measured scatter points between ToA and sensing distance are presented in Figure 4(a). The regressed lines for the three groups are also plotted based on these scatter points, for which the parameter $\alpha = 0.05$ is given to provide the confidence level (95%). In Table 1, the results including group velocity, the lower and upper bound of group velocity and the correlation coefficient of the three groups extracted from regression are listed. Combining Figure 4(a) and Table 1, it can be seen that the three kinds of sensor configuration produce pretty close group velocity identification result and meanwhile keep a very high correlation coefficient 0.99.

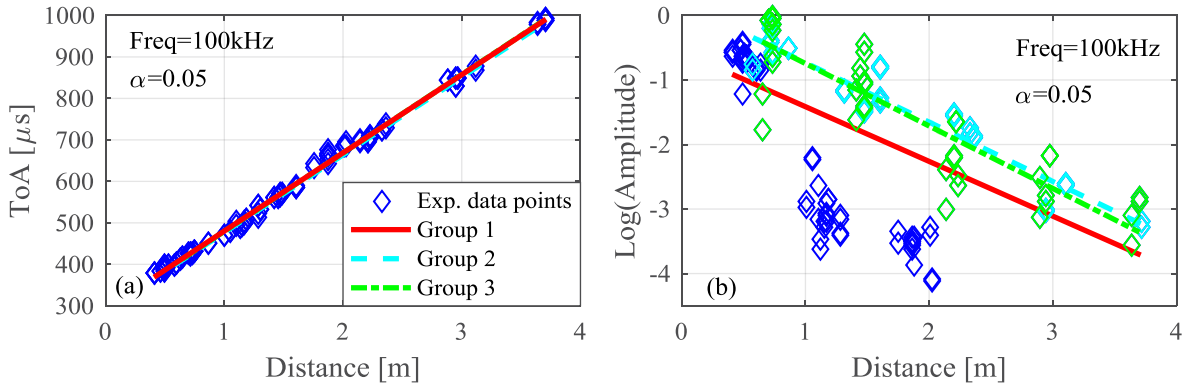

Figure 4: Example of (a) group velocity identification and (b) attenuation coefficient identification via linear regression method. In this figure, α is used to give the confidence level with $100(1 - \alpha)\%$.

The same strategy is designed to identify attenuation coefficient in section 3.1.2. Like Figure 4(a), the linear regression process is illustrated in Figure 4(b) under the same frequency 100kHz. The results extracted from Figure 4(b) are presented in Table 2, from which the dispersed scatter points can be observed. This is due to the difficulty to exactly extract the peak value of S0 mode wave packet given the low sampling frequency (1MHz) and noise contamination. Moreover, the lower correlation coefficient of Group 1 (smaller than 0.6) manifests that the anisotropy of composite materials has an essential impact on attenuation since all propagation directions in Group 1 are mixed together whereas in Group 2 and 3, there exists only one main direction. Thus, Group 2 and 3 are employed to identify the attenuation coefficient dispersion curves in subsequent section.

Table 1: Regression results for group velocity identification (corresponding to Figure 4(a))

Group 1			Group 2			Group 3		
c_g (m/s)	c_g bound (m/s)	R^2	c_g (m/s)	c_g bound (m/s)	R^2	c_g (m/s)	c_g bound (m/s)	R^2
5308	[5258,5359]	0.99	5340	[5279,5402]	0.99	5291	[5257,5325]	0.99

Table 2: The regression results for attenuation coefficient identification (corresponding to Figure 4(b))

Group 1			Group 2			Group 3		
k_i (Np/m)	k_i bound (Np/m)	R^2	k_i (Np/m)	k_i bound (Np/m)	R^2	k_i (Np/m)	k_i bound (Np/m)	R^2
0.85	[0.66,1.04]	0.39	0.92	[0.81,1.03]	0.92	0.97	[0.80,1.13]	0.79

4.2.2 Identified dispersion curves of group velocity and attenuation coefficient

The group velocity and attenuation coefficient at each frequency can be identified by using the method shown in Figure 4(a) and (b) respectively. After that, the group velocity dispersion curves can be formed as shown in Figure 5(a), in which only the result of Group 1 is presented given that the three groups generate pretty close group velocity dispersion curves, and the attenuation coefficient dispersion curves are shown in Figure 5(b). Additionally, Figure 5(c) presents the respective correlation coefficients for group velocity and attenuation. There is no doubt that for group velocity identification all correlation coefficients are greater than 0.95. Hence the identified S0 mode group velocity dispersion curve is reliable.

From the attenuation coefficient dispersion curves (Figure 5(b)) and its corresponding correlation coefficients (Figure 5(c)), the following findings are observed. Firstly, both groups' curves present the same trend, i.e., attenuation increasing with frequency firstly and then decreasing. Secondly, the correlation coefficients of both groups at the initial several points (50-60kHz) are smaller than 0.6. This may be explained by tuning effect of Lamb wave, for which at the lower frequency range, the amplitude of S0 mode is too small to be easily extracted from experimental signals [15]. Finally, the correlation coefficient starts to diminish after 150kHz for both groups, which could be explained by the low sampling frequency and high frequency noise contamination. In later damping parameters estimation, only the identified attenuation coefficients of Group 3 in frequency range from 70kHz to 150kHz are used to be the training data when implementing Eq. (16).

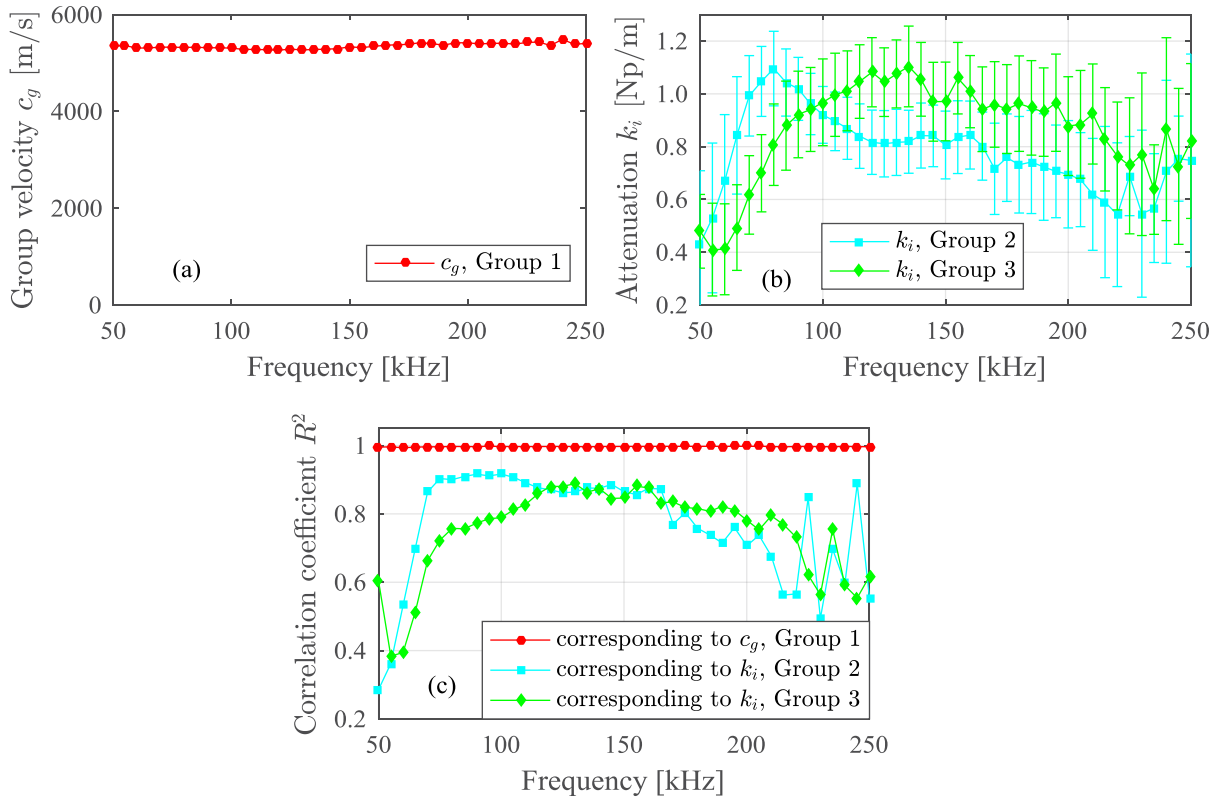

Figure 5: (a) the group velocity dispersion curve, (b) the attenuation coefficient dispersion curve and (c) correlation coefficient

4.3 Estimation of material properties

The experimentally identified dispersion curves of group velocity and attenuation coefficient are further employed to estimate the material properties via the least square method presented in section 3.2. Thus, the group velocity dispersion curve shown in Figure 5(a) is firstly adopted to estimate the storage modulus and Poisson ratio. The initial and optimal values of both parameters are listed in Table 3.

The calculated group velocity dispersion curves for S0 and A0 mode using the optimal value and the experimentally identified data points are depicted in Figure 6. It can be seen that the calculated S0 mode group velocity dispersion curve agrees well with the experiment. Besides, the calculated S0 mode phase velocity dispersion curve is provided as well in this figure which totally overlaps with the calculated group velocity dispersion curve in the frequency range. Comparing the calculated S0 and A0 mode group velocity dispersion curves, it is easy to infer that A0 mode Lamb wave propagates at approximately the half speed of S0 mode in the evaluated frequency range. Thus there is no any A0 mode group velocity can be identified from the experiment because of the abundant S0 mode wave reflections.

Figure 6: Comparison between the calculated and identified dispersion curve of group velocity

The experimentally identified attenuation coefficients are subsequently employed to estimate the damping parameters of the three damping models based on Eq. (16). The initial and optimal values are listed in Table 3, in which the optimal term γ_{KV} and ϵ do not change from its initial value, which is caused by accident.

Table 3: The estimated parameters of FCS

	E	ν	γ_{HR}	γ_{KV}	γ_{BT}	ϵ
Initial value	50GPa	0.2	0.03	0.03	0.03	10
Optimal value	44.4GPa	0.05	0.014	0.03	0.017	10

4.4 Attenuation coefficient prediction for a wide frequency range

All the required parameters are provided as inputs to the developed algorithm presented in Figure 1 and the attenuation coefficient for a wide frequency range is predicted as shown in Figure 7(a). The experimentally identified attenuation coefficient of Group 2 and 3 in the frequency range from 70kHz to 150kHz is provided as well for comparison. It can be seen that the predicted curves for HR and BT model agree well with the experimentally identified points with strictly linear trend. However, the curve of KV model presents the concave trend. Thanks to this reason, it is only suitable for predicting attenuation coefficient in a narrow frequency band for the current composite structure.

The developed numerical algorithm in Figure 1 is further used to predict the wavenumber which is extracted from the real part k_r of the complex solution as depicted in Figure 7(b). The identified wavenumber calculated via $k = \frac{\omega}{c_p}$ is also provided for comparison, in which c_p is replaced by c_g given that the approximated relation ($c_p \approx c_g$) from Figure 6. It can be seen that the theoretically calculated wavenumber dispersion curves for HR and KV model are consistent with the experimentally identified data points. But BT model predicts a minor smaller wavenumber in the evaluated frequency range than HR and KV model. The high coincidence between the predicted and identified wavenumber or group velocity reveals that the group velocity, phase velocity and wavenumber can be obtained more reliable from experiment or theoretical prediction than the attenuation coefficient.

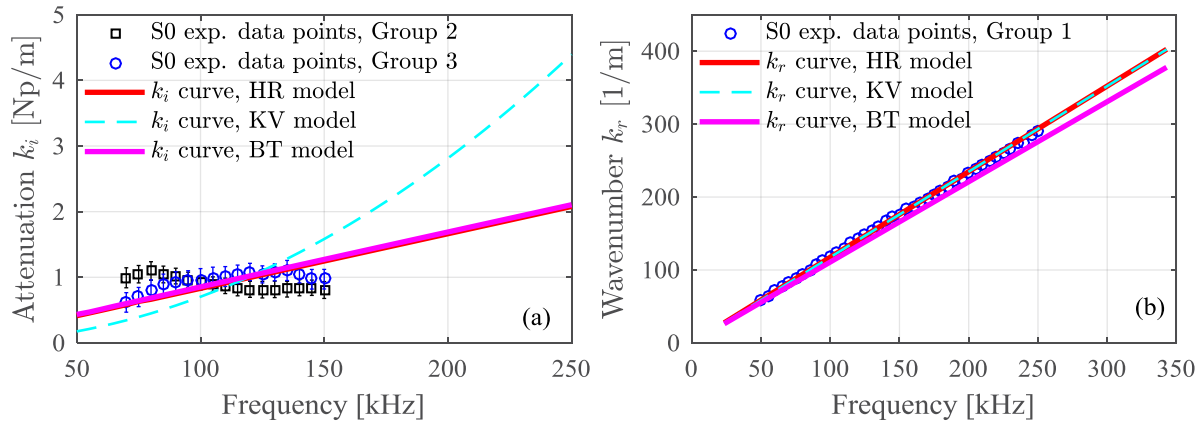

Figure 7: Prediction of (a) attenuation coefficient and (b) wavenumber at a wide frequency range

5 CONCLUSIONS

- In this article, a numerical algorithm to predict Lamb wave attenuation coefficient is proposed firstly. This algorithm is derived directly from dispersion equations by considering three damping models, HR, KV and BT model. The curve tracing technique is adopted to enhance the reliability of solving the complex equation.
- The linear regression method is used to identify group velocity and attenuation coefficient from experimentally measured Lamb wave signals. The least square formulation is designed for estimating the storage modulus and Poisson ratio of material as well as damping parameters of the three damping models.
- A comprehensive case study on a practical aeronautical structure validated that the

proposed attenuation coefficient prediction algorithm is feasible and effective. Comparing to group velocity, accurately identifying and predicting attenuation of Lamb wave in complex composite structures is more difficult and urgent. The presented outcomes in this article are an useful attempt.

Key words: Parametric finite element model, Composite stiffened panel, Structural health monitoring, Fiber Bragg gratings, Non-linear buckling analysis.

Abstract. A common defect of composite stiffened panel structures is the disbond at the interface between the two constituents (skin/stringer), as a result of inefficient manufacturing process or foreign object impacts in service. Generally, discontinuities within the volume of an elastic solid media subjected to mechanical load, cause anomalies on the strain field in the near vicinity of the discontinuity. Utilizing this observation, the current work investigates the effect of artificially induced disbonds between skin/stiffener at a co-cured CFRP/epoxy single-stiffener generic element. A structural health monitoring methodology is developed, leveraging on numerically simulated strains along the stringer foot which aims to assess the health state of the sensorized structure as compared with a pristine baseline. The study is implemented with a parametric finite element model generating various disbonded cases. Longitudinal strain values are acquired at the exact points where in reality actual Fiber Bragg Grating sensors will be located.

1 INTRODUCTION

Primary airframe structures made of composites tend to increasingly replace more conventional materials. Their advantages correlate to the high specific mechanical properties over metallic materials. Nevertheless, these materials suffer from hidden damages, such as delaminations/disbonds which arise major concerns if not identified at an early stage. In this direction, researchers utilize Structural Health Monitoring technologies to identify and assess damage. Fiber optic sensors (FOS) technology has gained increasing popularity as an alternative method of real-time strain measurements during structural service with minimum additive weight. A popular category of FOS are fiber Bragg grating sensors (FBGs) [1]. Quite a few researchers developed health monitoring methodologies like Li et al. [2], who proposed an automated algorithm based on static strain FBG readings on naval composite T-joints. A baseline of the pristine specimen was developed through which disbond cases were qualitatively

detected. A new method to identify strain modification along disbonds, exploiting Artificial Neural Networks (ANNs), was proposed by Kesavan and co-authors on the aforementioned specimens [3]. Takeda et al. [4] investigated interlaminar damage occurred by low-velocity impacts on CFRP stiffened panels. They used embedded FBGs to monitor the reflection spectra using the central wavelength of the sensors. A framework utilizing FBG strain readings was proposed by Airolidi et al. [5]. The authors developed an integrated Health and Usage Monitoring System (HUMS) of composite spars belong to wing-box, aiming to monitor both load and damage. A study based on static strains obtained by closely placed optical fibers with FBGs, was implemented in [6]. In this case, the differential strain of closely attached sensors placed away from damage, maintained a linear relation with respect to a reference strain, while sensors closest to damage showed a non-linear behavior. Sbarufatti et al. [7] followed a model-based methodology leveraging on a global-local finite element model of a helicopter tail boom in order to evaluate real fatigue crack propagation events. Damage detection was enabled by utilizing the Mahalanobis distance, considering a damage index calculated at each sensor. The methodology was validated experimentally using permanently placed FBGs to record strain data. Finally, a parametric numerical model was created by Zarouchas and Alderliesten [8] to evaluate the damage tolerance capabilities of aluminum stiffened panels. A non-linear buckling analysis was applied, and critical stability aspects of the panel regarding the disbond characteristics, i.e. position and size were highlighted.

The objective of the present paper is to study the effect of disbonds in the strain-field developed on the feet of single-stiffener panels (SSPs) and propose strain-based Health Indicators (HIs) capable of identifying and monitoring structural damage and specifically skin/stringer disbonding. Parametric numerical modeling is implemented to this direction.

2 NUMERICAL ANALYSIS

The numerical modeling procedure is presented in the following. First, the SSP specimen is introduced and its geometrical characteristics are detailed. The test article is consisting of two individual parts, a thin composite flat plate, the skin, and a composite T-section stiffening beam, called i.e. the stringer. The present study investigates the distribution of longitudinal static strains on the outer surface of each stringer foot in health and defected scenarios. The main objective of this work is to utilize the baseline and the strain alterations caused by skin/stiffener disbond and propose suitable HIs to assess/monitor the health state of the structure. The interrogation points are selected in a manner to simulate permanently installed optical fiber sensors, with Bragg gratings in pre-selected locations. Initially, strains from the pristine (healthy) SSP are obtained. Then, a parametric finite element model is created, simulating several disbond cases, in order to assist the objective of this study. Further details regarding the parameterized way of modeling are given below.

2.1 Single-Stiffener Panel configuration

The geometrical dimensions of the SSP, expressed in *mm* are provided in Figure 1, accompanied by the stacking sequences of each member. The material used in this study is an IM7/8552 carbon/epoxy unidirectional continuum fiber-reinforced prepreg, with nominal cured

ply thickness 0.131 mm [9] and mechanical properties [10] as detailed in Table 1. From a numerical analysis point of view, the final geometry of the two members is modelled considering a co-bonding manufacturing technique, without adhesive film in the interfacial region.

Figure 1: Dimensions of SSP specimen, a) perspective and b) cross-sectional view

Table 1: Engineering and interlaminar properties of IM7/8552 [10]

E_{11} (GPa)	E_{22} (GPa)	G_{12} (GPa)	ν_{12}	G_{Ic} (N/mm)	G_{IIc} (N/mm)	η (-)
150	9.08	5.29	0.32	0.277	0.788	1.6

2.2 Finite Element Model

The numerical model created, simulates the quasi-static compression of the pre-defined SSP. The SSP is loaded under displacement control, in an attempt to simulate the real test procedure. Cast-tab pots are used as load/support members to uniformly transmit the load to the specimen. Hence, two 30 mm exterior regions on the longitudinal direction bind to the pots. A schematic illustration of the test article is showed in Figure 2, indicating also the two SMARTapes[®] accommodating the optical fibers with FBGs (provided by SMARTEC-Switzerland) and the respective sensor spacing. These tapes are made of GFRP/epoxy and protect the accommodating optical fibers from harsh environmental conditions. The global coordinate system (XYZ) of the model is located at the symmetry plane of the top loading tab. Also, a local system (xyz) is defined at the start of each SMARTape[®] (one illustrated in Figure 2). Results regarding disbonds underneath this region will be expressed at the local coordinate system, as shown in Chapter 3.

The numerical study was implemented using the commercial finite element code Abaqus/Standard[®] [11]. Both members are modelled as one discrete layer of 4-node quadrilateral shell elements with reduced integration (S4R) and three integration points along the thickness. Every layer of composite laminates was modelled as a transverse isotropic material, according to the properties presented at Table 1, with thickness equal to the cured ply thickness the material provider suggests i.e. 0.131 mm. Earlier experimental works highlighted that degradation of the material properties is negligible in the early post-buckling region [12]. Thus, for the numerical modeling tasks associated with the present study, progressive

introduced in the imminent non-linear analysis, following the pattern of the considering buckling modes

- A constant, low amplitude force acting along the buckling direction

The second method can alter the strain field in the adjacent region of the actuation point, while the second represents a more sensible way to model the buckling behavior. In the present study, the first way of introducing imperfections is chosen, especially due to the need to obtain as much as possible reliable strain estimations. These imperfections in general are defined by superimposing multiple eigenmodes, and have the following amplitude form with respect to the global coordinate system:

$$\Delta x_i = \sum_{i=1}^n w_i \varphi_i \quad (1)$$

where w_i is the scale factor correlated with the i -th mode shape φ_i . Only the 1st buckling mode was introduced as the lowest modes are frequently more critical, and a scale factor equal to 10% of the stiffener thickness was used. A static Newton-Raphson (N-R) solver, incorporating non-linear geometry formulation was utilized to solve the equilibrium of the non-linear problem. A maximum displacement equal to 0.25 mm was set for loading BC, as deep post-buckling analysis was not relevant with the current study. Due to such excitation, buckling occurred and characterized by the non-linear relation between the reaction force and displacement of the panel. Also, the maximum lateral deflection of skin midplane reached 4.7 mm. So, as buckling load considered the limit load where the linear load-displacement relation is maintained. A mesh convergence study was implemented, regarding the buckling load as this was obtained from both linear and non-linear analysis.

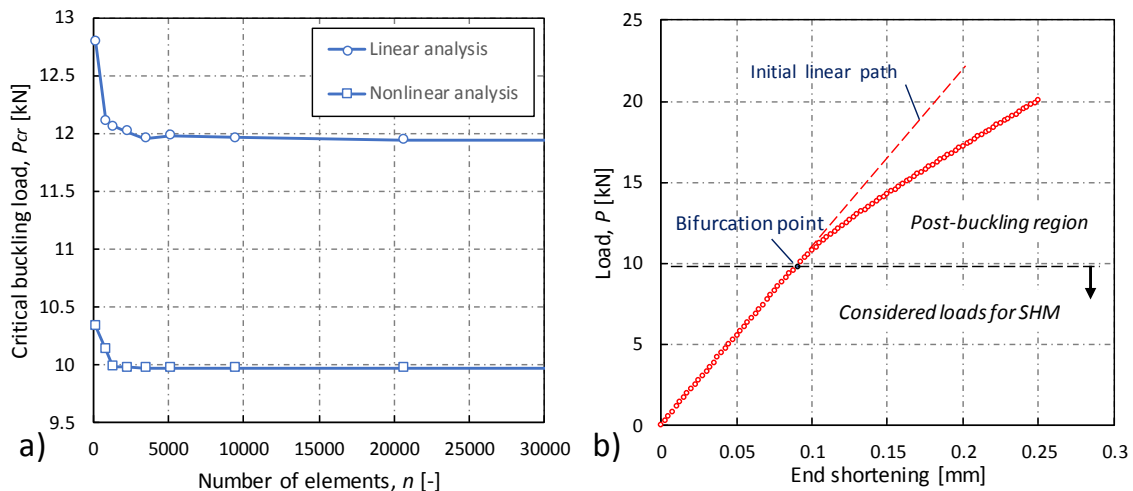

Figure 3: a) Mesh convergence and b) load-displacement curve for considered mesh density

The relevant results are depicted in Figure 3 and the load-displacement curve of the chosen mesh density is illustrated in Figure 3. Convergence was achieved in much lower number of elements, but in order to increase the fidelity of the model, an approximate element size of 2.00

mm was selected producing a total discretization of 20550 elements, as shown in Figure 4. Implementation of the Virtual Crack Closure Technique (VCCT) [13] also requires refined (global) mesh configurations or local refinement.

2.3 Parametric Analysis

The next task deals with the development of a parametric finite element model of the SSP with an artificially induced skin/stiffener, rectangle disbond. The parameterization concerns the position and the size of the disbond assuming a constant width along the right foot, as shown in Figure 4. In order to generate repetitive disbond scenarios at the skin/stiffener interface, a script written in Python® [14] was elaborated. The advantage of this method was the easy applicability, while the script was executed directly via the interface of Abaqus®. Most importantly, all manual tasks regarding the modeling using Graphical User Interface (GUI) of Abaqus® could be expressed in Python® language using proper libraries of the program. So, the script was created on the basis of iteratively generate the geometry, including the parametric position and size of the disbond, while it entailed all of the rest of the model attributes, as these have been previously described (material properties, mesh, BCs, etc.).

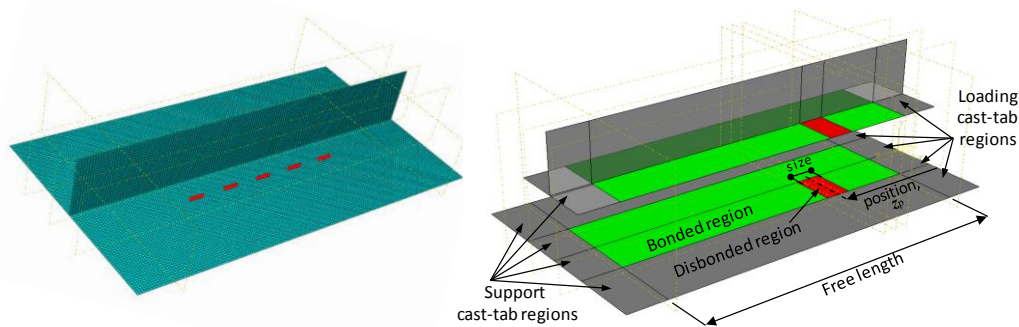

Figure 4: a) Discretized SSP, highlighting the right-foot FBG set, b) partitions of SSP

As we described previously, tie constraints were introduced at the interface region between the skin and the stiffener. Modeling the disbond was achieved by erasing that interaction and allow each of the individual regions of the disbond to freely move, without any kinematic constraint imposed by the other. The specimen was divided in partitions, in a manner of ensuring that coincident nodes at the interface of the two parts were generated. This approach prevented excessive distortion of the elements at the interface while it also allowed the correct implementation of the VCCT, in interfacial disbond propagation case studies. In current analysis, the VCCT was also used in order to assess if the disbonded regions do propagate under the defined loading condition. The interlaminar fracture properties of the IM7/8552 were used according to Table 1. Note that the VCCT is implemented by replacing the tie constraints with a contact interaction. This technique numerically calculates in every step the strain energy-release rate in a pre-defined crack/disbond front. For given critical strain energy-release rates of the material, the B-K criterion [15] controls the fracture initiation and allows the front

elements to separate if the criterion is satisfied. Also, the VCCT implementation requires to explicitly determine the unbonded region nodes in order to evaluate the strain energy release rate along the formed disbond fronts. This was also taken into consideration in the written script, so we can indicate the node sets that were created per iteration as:

- one node set, representing the bonded region, unique for every pair of disbond position and size
- ten node sets, representing the FBGs along each foot, unique for all pairs of disbond position and size

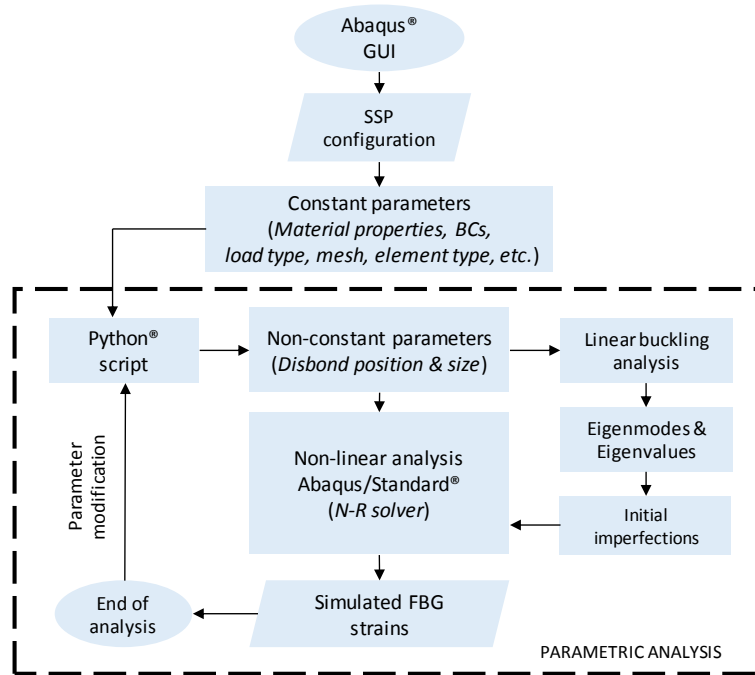

Figure 5: Explanation flow chart of the parametric analysis

None of the considered analyses showed propagation of the associated disbond. Generally, if it is ensured that fracture procedures are not involved, simple tie constraints can be utilized at the bonded region of the two members over the VCCT. A detailed flow chart describing the parametric implementation of the present work, is shown in Figure 5. After completion of every iteration, the disbond characteristics were updated, regarding either the position or the size.

3. DAMAGE ASSESSMENT OF SKIN-TO-STIFFENER DISBOND

In the current section, the effectiveness of two Health Indicators (HIs) on the detection of numerically simulated skin/stiffener disbonds will be investigated. The strain data obtained from the pristine specimen are considered as the baseline. Next, a SHM methodology based on the results obtained by the parametric analyses of skin-to-stiffener disbonds was evaluated. As mentioned before, the parametric analysis generates models with disbond in the interface of skin/stiffener, beneath the right foot. The assessment of disbond cases, within the assumed sensor topology, initiated by introducing a health indicator to estimate the sensitivity of the

FBGs to the disbond position. Finally, the behavior of a second health indicator was investigated versus the disbond size.

3.1 Baseline SHM Methodology

The static strains obtained from the pristine specimen after the non-linear analysis, establish the healthy-baseline which is utilized to reveal the presence of disbonds. Only strains prior to buckling, that belong to the linear portion of load-displacement curve are considered. Furthermore, regarding the disbond cases, similar data are gathered and stored, for each individual disbond scenario. The strains of every FBG are simulated for several load values as different displacements are imposed. Small discrepancies between the strains at the two feet are observed, mainly for the two FBGs closest to the loading tab. The presence of an interfacial disbond region, affects the strain distribution along the foot. An arbitrary case of disbond at position $z_p = 60 \text{ mm}$, and three different sizes, is depicted in Figure 6, under a constant static compressive load of 6.0 kN. The strain perturbation induced by the disbond can be clearly noticed in the vicinity of its edges. The gradient in those regions abruptly increases and the deviation from the pristine (dashed line) distribution is highlighted. The left (fully-bonded) foot shows no deviation from the baseline. Also, the marked points that illustrate FBG readings are highlighted along the curves. Generally, the difference between the strain reading of each FBG for disbonded case and the baseline i.e. the differential strain, shows an increasing trend proportional to the load. The most affected FBG shows higher discrepancies and is linearly increasing up to buckling load, as shown in Figure 6. Hence, a notable remark is extracted as the rest of the FBGs show almost negligible deviation from the baseline up to the buckling load. As the disbond changes position along the foot, a similar pattern of the strain discrepancy was obtained following the disbond position (not shown here). Moreover, the gradient and the amplitude of the discontinuity is not maintained constant and exhibits dependency both on position and load.

In order to estimate the impact of the disbond position to strain modification, a Health Indicator (HI) will be utilized based on the relative strain differences of each FBG in an arbitrary condition with the baseline. The HI is a metric of the strain change, under the same load amplitudes and is calculated as shown in eq. (2).

$$HI_i^1 = \left(\frac{|\varepsilon_{11}^{pristine} - \varepsilon_{11}^{disb}|}{\varepsilon_{11}^{pristine}} \right)_i, i = 1, 2, \dots, 10 \quad (2)$$

where i corresponds to the FBG number. To see the effect of changing external load, an average value of the HI with changing load can be simply calculated, considering n total load cases:

$$\overline{HI} = \frac{1}{n} \sum_{i=1}^n HI_i^1, i = 1, 2, \dots, 10 \quad (3)$$

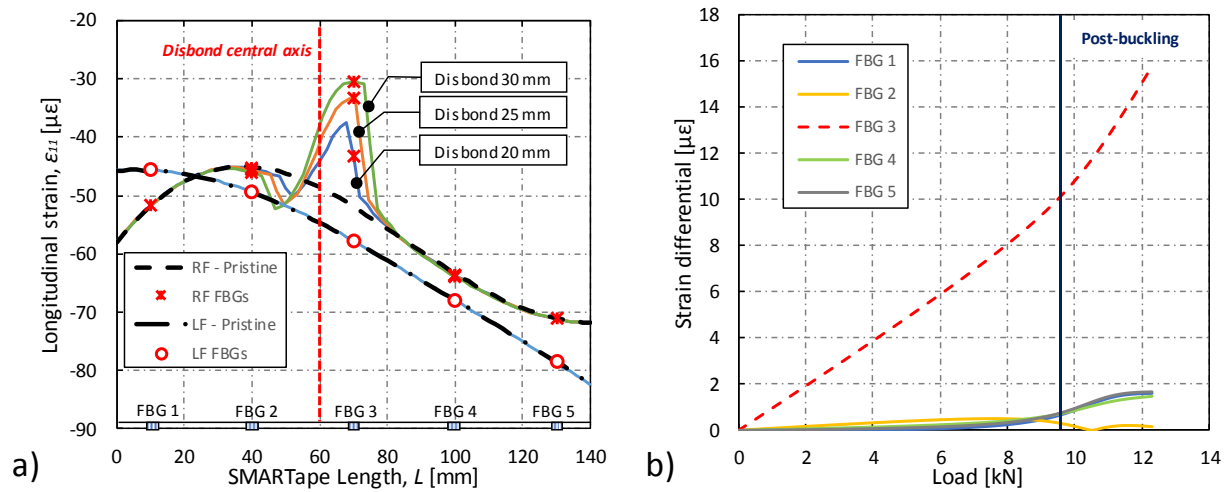

Figure 6: a) Simulated strain distributions along left (LF) and right (RF) foot, associated with disbond cases and b) differential strain over load on RF for 20mm disbond case

Assuming a constant disbond size of 20 mm, the HI indices of the FBGs located at the right foot ($i = 1, 2, 3, 4, 5$) are calculated. Through the parametric numerical model, disbands in several positions in a range 10-130 mm regarding the local coordinate system (xyz) are created. The disbond position is incrementally increasing by 5 mm. The average HI is calculated for every FBG, and the results versus the disbond position are depicted in Figure 7. HI values above 2% are obtained by the current sensor topology, to almost every position of the disbond along the foot. It can be noticed that lower discrepancies occur when a sensor is placed at central position along the disbond against the cases that a sensor is above the disbond front. This estimation can be evaluated by noticing the strain discontinuity profile as it is shown in Figure 6.

Figure 7: Health indicator predicted by each FBG versus the disbond position along RF

Next, we introduce a second HI fit for Structural Health Monitoring, while the disbond is increasing. This HI combines the strain readings from all sensors. In fact, it represents the percentage each FBG sensor holds of the cumulative strain among the five FBG sensors, and is defined as:

$$HI_i^2 = \varepsilon_i^N = \frac{\varepsilon_{11}^i}{\sum_i \varepsilon_{11}^i}, \text{ for RF: } i = 1, \dots, 5 \text{ and for LF: } i = 6, \dots, 10 \quad (4)$$

where again i corresponds to FBG numbering. This HI is inspired by the observation that the strain of the unaffected sensors shows minor deviation from the healthy condition. In Figure 8a the average values of the HI for every FBG are presented, indicating first the pristine values accompanied by several disbond size cases. The central axis of the growing disbond is at $z_p = 60 \text{ mm}$, as mentioned before and the disbond is assumed to grow by the same length from each side. Finally, in Figure 8b the HI is presented for every FBG under increasing size of disbond. The 3rd sensor on the RF is the most affected by the disbond front and this fact is illustrated with a monotonical drop on its index of about 8% regarding the intact specimen value. The rest FBG sensors show a slight increase of their HI values, no more than 2%. Only the 2nd sensor shows an increase higher than 2% in the case of 50 mm disbond as the disbond front reaches this sensor too.

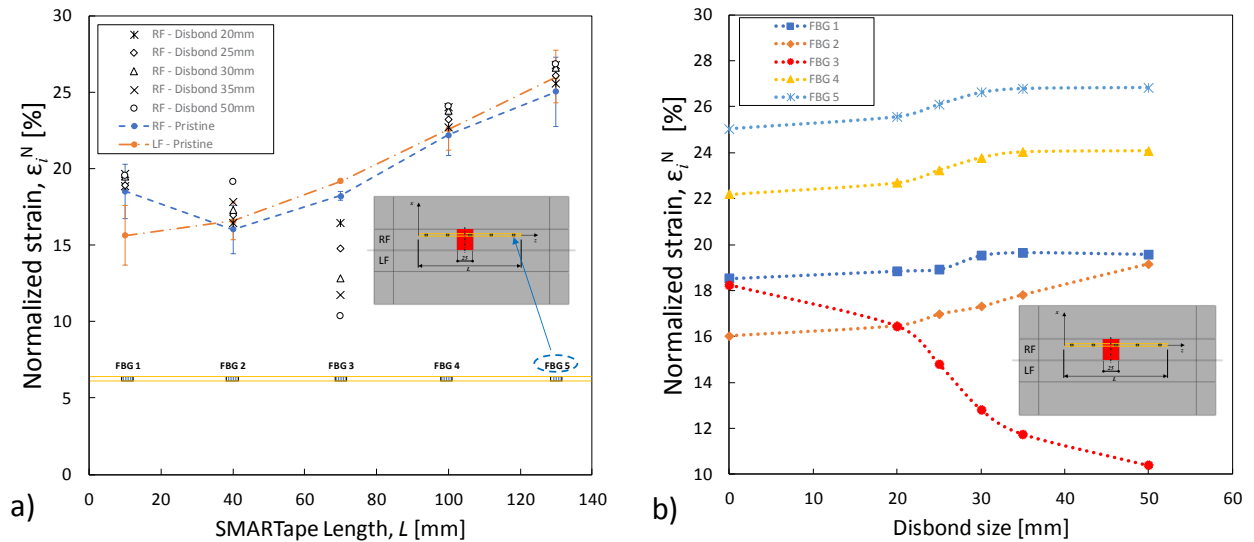

Figure 8: a) Normalized strain indices of FBGs on pristine and various disbonded specimens and b) gradual change of indices versus an increasing disbond size

4 CONCLUSIONS

In the current study, a model-based methodology for damage assessment on generic single-stiffener composite panels was approached. Towards that end, a finite element analysis was conducted in order to simulate the composite panel subjected to uniaxial compressive

loading. Longitudinal strains were computed at predefined regions where permanent FBG sensors will be attached. Initially, a non-linear buckling analysis was executed deriving the investigated strains on pristine (healthy) structure. Furthermore, numerous skin-to-stiffener disbonds were introduced via a parametric numerical model using Python[®] scripting.

First, by a strain differential methodology, the impact of the disbond positioning to the strain distribution was evaluated. For that purpose, a health indicator was used comparing longitudinal strains of the pristine baseline with the disbonded cases. Then, another indicator representing a strain normalization scheme of every sensor was calculated. The aforementioned index was illustrated for several disbond sizes and indicated a monotonic drop on the sensor that was more affected by the disbond. Conclusively, the first health indicator utilizes strains from the pristine baseline and those out of disbonded cases. It can be characterized as baseline-dependent. A drawback of this indicator lies on its load dependency, whilst a very interesting outcome is the small scatter that the indicator showed in the whole load range they were examined. On the other hand, the second indicator does not rely on baseline data. From that perspective and from the monotonic behavior it exhibits for increasing disbond size, it constitutes a promising choice for SHM.

Key words: structural state awareness, acoustic emission, lamb waves

Abstract. This study aims to demonstrate the effectiveness of blending passive and active acoustic-based health monitoring methods to impact damage diagnostics of composite structures. The structural state awareness is introduced as a term to characterize the health condition that a structure is and how this condition can be quantified by blending health monitoring techniques. To this aim, a Carbon Fiber Reinforced Polymer (CFRP) composite plate was fabricated and subjected to a simulated low-velocity impact by performing repeated quasi-static indentation tests where a loading-unloading-reloading test profile was adopted. Two Acoustic Emission (AE) broadband sensors and a network of eight piezoelectric (PZT) sensors were attached on the composite plate surface. AE (passive method) was employed during the loading and reloading phases of the indentation tests to in-situ monitor the damage initiation and progression, while scanning of the plate with Lamb waves (active method) was done to localize the damage when the structure was unloaded. The obtained results showed that the proposed blended passive and active acoustic-based method has the potential to provide useful information about the impact-induced damage in composite structures.

1 INTRODUCTION

Structural state awareness implies that existence, location, type and size of damage should be known at any given time of a structure's life, enabling the engineering team to assess the structural integrity and make proper decisions about the structure's maintenance and repair plan. Sensing equipment should be embedded or permanently attached at the structure in order to provide in real time and continuously health monitoring data. It is well known that one technique cannot solely perform all the measurements required to describe the state awareness of a composite structure and a combination and synergy of at least two techniques is needed. Among several techniques, i.e. ultrasonic C-scan [1,2], active thermography [3,4] vibration and modal analyses [5,6], acoustic based methods such as Lamb waves and Acoustic Emission (AE) [7-12] have a great potential to be employed as Structural Health Monitoring

(SHM) techniques where they can be permanently installed at the structure and monitor its health state during operation.

This study aims to demonstrate the effectiveness of blending passive and active acoustic-based health monitoring methods. A composite plate was subjected to a low velocity impact by performing quasi-static indentation tests where a loading-unloading-reloading test profile was adopted. AE (passive method) was used to determine if damage occurred and its type, while lamb waves (active method) were used to locate the damage. Two acoustic emission broadband sensors and a network of 8 PZT sensors each were attached at the surface of the plate. AE was employed during the loading and reloading phases of the indentation tests while scanning of the plate with the lamb waves took place when the structure was unloaded. Multiple actuator-receiver paths were selected and each PZT emitted a five-cycle hanning window signal of several frequencies.

Results showed that AE successfully provided information, whether and at which load damage occurred, indicating its severity. It was found that results about location, provided by lamb waves, were sensitive on the selected excitation frequency. Section 2 presents the material and the equipment used as well it introduces the experimental campaign and the experimental set-up. Section 3 provides details about the damage image reconstruction algorithm (DIRMA) and the principal equations to calculate the damage index (DI). Section 4 presents the experimental results, analyses the observations and discusses the effectiveness of the blended process towards the establishment of the structural state awareness. Finally, in section 5, conclusions are drawn.

2 MATERIAL AND EXPERIMENTAL CAMPAIGN

One composite panel with dimensions of 500 mm×500 mm×2 mm were manufactured using CFRP prepregs with a layup [(0/90)/45/90/-45/0]_s and cured according to the manufacturer recommended cure cycle.

Selecting the optimal PZT sensor is not straightforward and besides the features of the PZT sensor, it depends on parameters such as the geometry of the structure, its material, the sensors network and the experiment type. In order to generate uniform guided waves in all directions, circular disk PZT sensors supplied by PI Ceramic GmbH were used. The specifications of the PZT disks are reported in Table 1.

Table 1. The specifications of the PZT sensors

Specifications	Value	Unit
Commercial Name	PI Ceramic 000053020 with silver wrap-around electrodes	-
Material	PIC255	-

Shape	Circular disk	-
Diameter	6.50	[mm]
Thickness	0.25	[mm]
Resonance frequency	308	[kHz]

An AMSY-6 Vallen, 8-channel AE system with 4 parametric input channels and maximum sampling rate of 10 MHz was used to perform the AE measurements. In order to record the AE activity during the out-of-plane loading of the composite plates, two broadband, resonant-type, and single-crystal piezoelectric transducers from Vallen Systeme GmbH, AE1045S-VS900M with operating frequency of [100-900 kHz], with two external 34 dB pre-amplifiers were utilized. The recording threshold and sampling rate were set 40 dB and 2 MHz, respectively. Sonotech Ultrasonic Couplant was applied between the sensor and specimen surfaces to get an appropriate acoustical coupling. The functionality of the AE sensors and the data acquisition system was checked by proceeding a pencil lead break test according to ASTM E976 standard [13].

The utilized equipment for baseline test is shown in Figure 1. The function generator Agilent 33500B Series was employed to generate Hanning-windowed sinusoidal tone burst excitation signals with a sampling frequency of 250 MHz and a 10V peak-to-peak amplitude. In addition, the effect of excitation frequency on the DIMRA results was investigated by repeating the baseline tests for four different excited signals with the central frequencies ranging from 150 to 450 kHz in steps of 100 kHz. In order to eliminate the effect of clamping fixture on the wave measurement, both of baseline and current state measurements were done on the clamped panels Fig. 1.b.

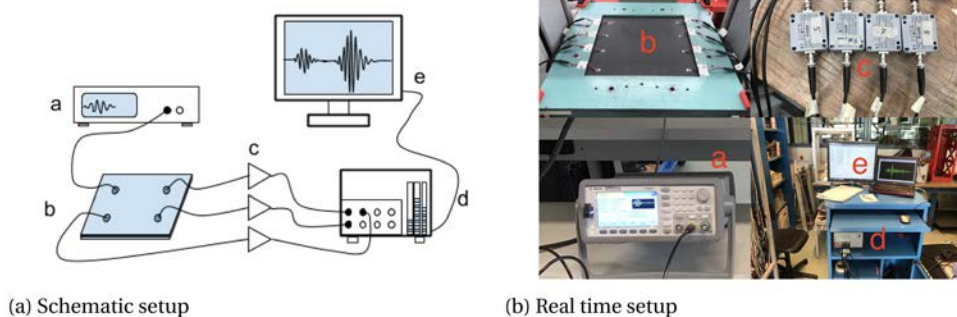

Figure 1. a) The schematic, and b) the real view of the experimental setup for baseline tests (test apparatus description: (a) Agilent 33500B Series waveform generator, (b) panel with attached sensors, (c) preamplifiers with a gain of 34 dB, (d) Vallen AMSY-6 acoustic signal processor, and (e) Laptop with Vallen Acquisition and Vallen Visual TM software).

The initiation and evolution of Barely Visible Impact Damage (BVID) in the scoping panel were studied using five designed sequential indentation tests where a step-by-step increasing load (saw tooth shape) was applied to the specimens. The indentation load was applied to the

specimen by pushing a semi-spherical indenter with diameter of 37 mm by a Zwick 20 kN tensile/compression machine. The indentation load was applied under displacement control condition with the loading rate of 2 mm/min at the position of X= 28 mm and Y= 32 mm from the upper right specimen's corner. The AE system was utilized to monitor the damage state during the loading stage and active PZT sensors were employed to explore the BVID location when the panel was unloaded (between two consecutive load cycles). In the loading and reloading stages, the panel was loaded up to the moment that a load drop in the force-displacement curve occurred. Then, the panel was unloaded. The maximum displacement and load for these five load cycles are presented in Table 3.

Table 2. Maximum displacement and load for different load cycles.

Load cycle	Maximum displacement [mm]	Maximum load [kN]
LC1	8.4	2.31
LC2	9.1	2.86
LC3	9.7	3.36
LC4	12.3	5.67
LC5	13.4	6.99

3 DAMAGE IMAGE RECONSTRUCTION ALGORITHM

The proposed DIMRA localizes BVID zone in the impacted panel by calculating the similarity of the recorded Lamb waves for the current state with the baseline state. DIMRA consists of the following four steps:

1. Each PZT functions as an actuator while all other PZTs act as the receiver. This process is iterated for all network PZT disks in the baseline and current states.
2. DI is calculated based on the similarity between the Lamb waves of the current state and baseline.
3. The Pixel Influence Weight (PIW) is calculated for each actuator-receiver pair.
4. The obtained results for different actuator-receiver pairs are combined to create a damage probability contour over the inspected area.

3.1 Damage Index

DI is based on Pearson Correlation Coefficient (PCC) and it is defined for each path of the PZTs network and shows the effect of damage on the desired path. The PCC shows the linear similarity between two signals by a real value between -1 and +1, which PCC of -1 shows completely opposite behavior of two signals and PCC of +1 illustrates that two signals have completely the same trend and finally PCC of 0 shows that there is no correlation between two signals. PCC (ρ) is calculated by Equation (1) [14]:

$$\rho = \frac{C_{BD}}{\sigma_B \sigma_D} \quad (1)$$

$$C_{BD} = \sum_{l=1}^L (X_B(l) - \mu_B)^2 \cdot (X_D(l) - \mu_D)^2$$

$$\sigma_B = \sqrt{\sum_{l=1}^L (X_B(l) - \mu_B)^2}$$

$$\sigma_D = \sqrt{\sum_{l=1}^L (X_D(l) - \mu_D)^2}$$

where subscripts B and D denote baseline and damaged states (current state), respectively. C_{BD} is the covariance between two the signals, σ is the standard deviation of signal, μ is the signal mean value, X is the signal samples, and L is samples number. The DI based on PCC is calculated as follows:

$$DI_{pearson} = 1 - |\rho| \quad (2)$$

$DI_{pearson}$ is varying from 0 to 1, which 0 indicates no damage state and 1 shows the highest damage probability.

3.2 Pixel influence weight

The PIW assumes that the probability of the damage for a specific path decreases with increasing the distance from the path. In order to apply this assumption a probability ellipse is created, by creating a mesh over the area of interest for inspection. Then, the probability distribution forms an ellipse that the two PZT sensors act as the focal points. The effect of the damage located outside the ellipse's boundaries on the sensing path is considered zero. To create the probability distribution inside the ellipse, a shape factor, β , is defined so that on a straight line between the sensors, the PIW is maximum, 1, and it linearly decreases to 0 on the ellipse's boundaries.

The probability ellipse is calculated using Equation (3). For every pixel on the grid, first the R value is created. R indicates the ratio of the length of the major axis, a , over the distance between the two focal points, $|AR|$. (X_A, Y_A) and (X_R, Y_R) are the coordinates of the actuator and receiver, while (x, y) indicates the location of the pixel and $S(x, y)$ represents the PIW [14, 15].

$$R(x, y) = \frac{\sqrt{(X_A - x)^2 + (Y_A - y)^2} + \sqrt{(X_R - x)^2 + (Y_R - y)^2}}{\sqrt{(X_R - X_A)^2 + (Y_R - Y_A)^2}} \quad (3)$$

$$S(x, y) = \frac{\beta - R(x, y)}{\beta - 1} ; \text{ for } \beta > R(x, y)$$

$$S(x, y) = 0; \text{ for } \beta \leq R(x, y)$$

The boundaries of the ellipse are controlled by shape factor β (Equation (4)), which is usually considered a value between 1.02 and 1.6 [16, 17]. The shape factor of 1.05 is considered for the present study.

$$a = \beta \cdot |AR|; \text{ Major axis} \quad (4)$$

$$b = |AR| \cdot \sqrt{\beta^2 - 1}; \text{ Minor axis}$$

3.3 Data fusion

For all the paths, the corresponding DI_{a-r} value is first multiplied to the corresponding $PIW_{a-r}(x, y)$ for all the pixels and then the pixel intensity ($P_{int}(x, y)$) is determined by taking the sum over all paths [15]. Figure 6 shows the data fusion for two paths.

$$P_{int}(x, y) = \sum_{a=1}^m \sum_{r=1}^n PIW_{a-r}(x, y) \cdot DI_{a-r} \quad (6)$$

Figure 2. The data fusion of two paths in DIMRA.

4 RESULTS

4.1 Damage severity analysis using AE

The specimens were subjected to the five sequential indentation loads according to section and AE was used for in-situ monitoring of the induced damages in the specimens during the loading stage and Lamb wave technique was employed to localize the damaged zone in the specimen when it was unloaded between two consecutive load cycles. Figure 3 shows AE counts, AE energy, and load versus time curves for the five load cycles. The maximum load of the each loading cycle and the corresponded time are illustrated on the vertical and horizontal axes. The AE activities of load cycles LC1 and LC2 are initiated at the high load levels while some AE activities with the low values of energy and count are seen from the initial stage of loading at load cycles LC3 and LC4 which are probably related to matrix

cracks. The high energy and count AE activities in load cycles LC3 and LC4 are initiated after the maximum load level of the previous loading cycles that shows there is not a critical damage in the structure yet. However, during the loading cycle LC 5, initiation of high energy and count AE activities at a load level lower than the maximum load of the previous loading cycle in load cycle (LC4) illustrates the presence of critical damage with an unstable growth behavior in the structure.

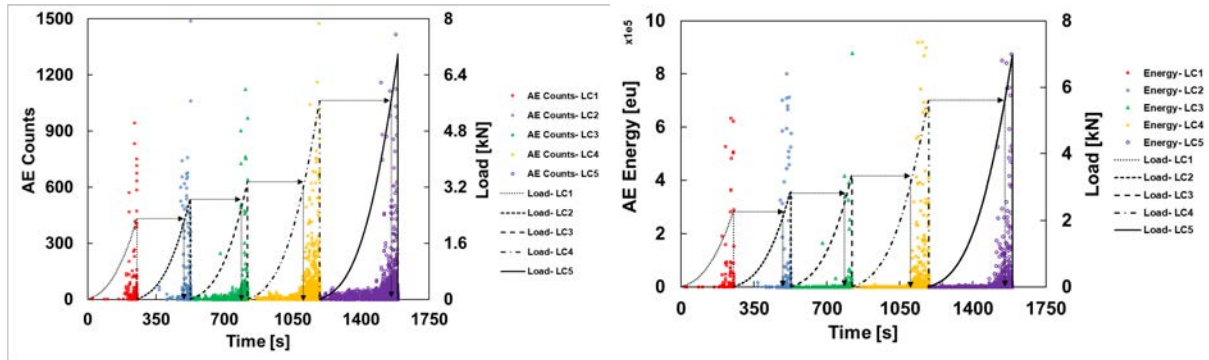

Figure 3. a) AE counts and load versus time, and b) AE energy and load versus time curves for the 5 load cycles.

In order to accurately detect the critical damage and also specify the severity of damage, Kaiser and Felicity effects are employed. Kaiser effect states that the considerable AE activities during the reloading cycle for an intact structure should initiate in the proximity of the maximum load of the previous loading cycle. While Felicity effect states that observing the considerable AE activities at the load level less than the maximum load of the previous load cycle is a sign of the presence of the critical damage in the structure [18]. In order to quantify damage severity, Felicity Ratio (FR) index is defined as follows:

$$FR = \frac{P_{AE}}{P_{max}} \quad (7)$$

where P_{AE} is the corresponding load to the initiation of the considerable AE activities in the current load cycle and P_{max} is the maximum load of the previous load cycle. FR values equal or greater than 1 showcase the Kaiser effect and FR values less than 1 proves the Felicity effect. Figure 4a, shows the cumulative AE energy versus load curve for the five load cycles. Kaiser effect can be easily seen for load cycles LC2 to LC4, while Felicity effect is obviously seen for load cycle LC5. The FR indices for load cycles LC2 to LC5 are presented in Figure 4b. As can be seen, the FR indices of load cycles LC2 to LC4 are larger than 1, validating the Kaiser effect and confirm that the damage induced to the structure is not critical while FR index of load cycle LC5 is considerably less than 1 that illustrates Felicity effect and that the structure is severely damaged.

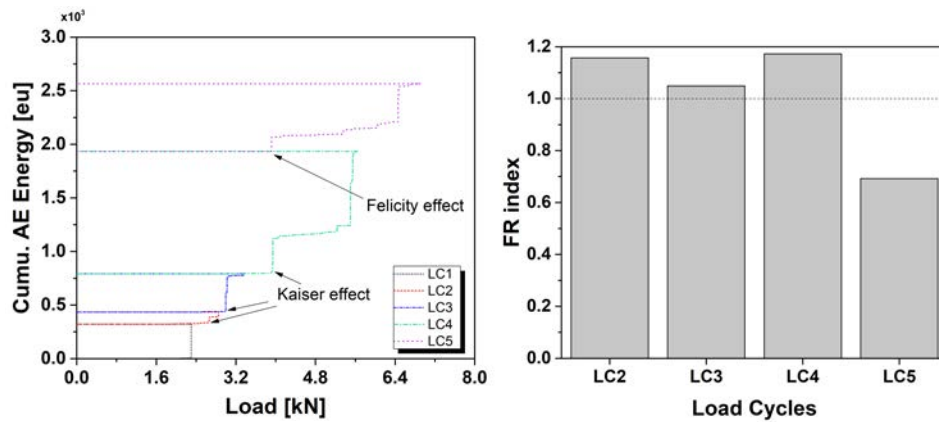

Figure 4. Cumulative AE energy versus load curve for the five load cycles.

4.2 Damage Localization using Lamb wave technique

Lamb wave technique was employed between each two consecutive load cycles to localize the damaged zone in the composite plate. In order to accurately localize the damaged zone, the best excitation frequency of the PZT actuator should be selected. To this aim, the PZT actuator was excited by four different frequencies. Figure 5 shows the predicted damage location by the IMRA for these excitation frequencies at load cycle LC4. The real location of the impact event is shown by a circle on the images. The pixel with the highest intensity shows the predicted location of damage in each image. As can be seen, by increasing the excitation frequency the localization error is increased. This is due to the fact that the increase of the excitation frequency decreases the Lamb wave's wavelength which causes the wave to become more sensitive to smaller damage types such as intralaminar matrix cracks that subsequently leads to higher values of DI. Moreover, due to the bias induced by the algorithm during data fusion, an increase in DI leads to relatively higher pixel intensities at the center of the sensors network where the most paths will overlap. Therefore, the excitation frequency of 150 kHz was finally selected for the damage localization in load cycles LC1 to LC5.

Figure 5. Image reconstruction at load cycle LC4 for different excitation frequencies.

The damage localization results for load cycles LC1 to LC5 are shown in Figure 6. As can be seen, by increasing the applied load from load cycle LC1 to load cycle LC5, the pixel intensity rises considerably that shows the severity of damage in the structure is continuously

increasing. The DI_{Pearson} using an excitation frequency of 150 kHz manages to localize the critical damage at load cycle LC5 with an error of 0.9 cm.

Figure 6. Image reconstruction for the five load cycles

5. CONCLUSIONS

This study proposed a blended passive and active acoustic-based health monitoring method for impact damage diagnostic in composite structures. A CFRP composite plate was fabricated and subjected to a sequential increasing indentation load. AE was used to in-situ detect the critical damage in the specimen during the loading stage. To this aim, FR index was utilized to identify the critical damage level. Due to the occurring of non-critical matrix cracks from the start of reloading stage, using the number of AE events to create FR index, leads to very conservative results while using the parameters of AE energy to calculate FR index could correctly detect the critical damage state which is corresponded to unstable delamination growth in the structure. Lamb wave technique was then employed to localize the damaged zone in the composite plate when the plate was unloaded between two consecutive load cycles. The proposed DIMRA located the damaged zone by comparing the current state Lamb wave with the baseline Lamb wave and introducing one damage index, DI_{Pearson} . The results illustrated that DI performance depends on the selected frequency of the Lamb wave signals; a high excitation frequency, i.e. 450 kHz, misleads the localization with an error up to 11cm, due to the sensitivity of short wavelengths towards interlaminar matrix cracks. In contrast, a Lamb wave with excitation frequency of 150 kHz is more sensitive to larger damage areas, such as delamination, which are present at loading case 5 and where the error between the actual and predicted damage location drops significantly to 0.9 cm.

Keywords: magneto-rheological damper; skyhook controller with GAG; speed bump, time-frequency analysis method.

Abstract. Speed bumps are widely used in roads to reduce the traffic accidents. However, the transient impact caused by the speed bumps may increase the health risk of drivers and passengers and damage of vehicle. In this paper, the traditional skyhook controller and skyhook controller with adaptive genetic algorithm (GAG) is designed to attenuate the unwanted vibration. For verifying the effectiveness of the skyhook controller with GAG, the road test of the B segment car installed with four MR dampers is undertaken. The time domain and time-frequency methods are both used to analysis the vibration, and the results demonstrate that the reduction of peak value of vertical acceleration of skyhook controller with GAG is better than that of skyhook controller, comparing with the uncontrolled system.

1. Introduction

In recent years, vehicle is widely used in people's life, meanwhile the number of traffic accidents were increasing. The excessive speed is often thought to be a major cause of traffic accident, hence speed limits will reduce the mean speed of traffic by at least one quarter [1]. In order to reduce the number and severity of traffic accidents and improve the local environment for people who live, work or visit any area, the speed bumps are widely mounted in all sorts of avenues and roads. Hence, many researchers studied the relation between the number, dimension, geometry and position of the speed bumps and the ride and handling of vehicle [2-7]. Several tests have been done with different speed bumps by D. Garcia-Pozuelo [6-7]. To keep comfort loss to a minimum, the speed limit of 30km/h would be adequate for the speed bump 5x60 [6]. Meanwhile, the vertical acceleration in the center of gravity is increasing with the width of speed bump but not increasing with vehicle speed [7]. Back pain is a disease that often appears on the bus driver, due to repeated exposure of mechanical shocks when frequently riding over traffic speed bumps [8], and the health risk increases with increased number of bumps per day. J. Sandover [9] shown clearly that transient vibrations with multiple shocks are more hazardous than stationary vibration. Z. Michaelvan [10] studied the impact damage to fruit during the passage of a truck over a speed bump, and the

largest amount of damage generally occurs at a driving speed close to 30 km/h. Hence, it is necessary to reduce the vibration of the vehicle body when it passing through the speed bumps at low velocities.

The vehicle suspension is used to absorb and buffer the vibration and impact of which from road to vehicle body. Generally, the suspension is divided into three types: passive, semi-active and active. Compared to the others, the semi-active suspension, this has characteristics of reliable, flexible, low-power, and fast response, is usually used to reduce the vibration of vehicle, especially the semi-active suspension with MR damper. The control of semi-active suspension with MR damper is always designed to reduce the vibration of vehicle body in various random roads [11-14]. X.M. Dong and M. Yu et al [9] applied the five representative control algorithms including the skyhook control, the hybrid controller, the LQG controller, the sliding mode controller and the fuzzy logic controller to the mini passenger car. The random road and various speeds (40 km/h, 60 km/h and 80 km/h) are chosen for the test, the results indicated the control performance of skyhook and sliding mode controllers are better than the others. The research is beneficial to select the control strategy in real-time vehicle suspension system control. T. R. M. Rao et al [15] studied the performance of an omnibus passing over a speed bump. The three-degree-of freedom quarter car semi-active suspension system is modelled, and to overcome the problem of integral of acceleration in the skyhook control, the semi-active constraints is modified by the product of the derivative of sprung mass acceleration and the relative velocity of between the sprung and unsprung mass. The simulation results shown the sprung mass acceleration can be reduced by 32%, when the car velocity is 40 km/h. S.B. Choi et al [16] studied performance characteristics of a real semi-active ER (electro-rheological) suspension system, and the result of bump test shown ride comfort of vehicle can be improved by employing four independent skyhook controllers. So far, the skyhook controller has approved to be effective in suspension control. Traditional skyhook controller will take a lot of time to adjust the four skyhook gains by using trial-and-error method, due to the complexity and nonlinearity of vehicle. To improve the control performance and efficiency, the adaptive genetic algorithm (AGA) was adopted in this study to optimize the four independent skyhook gains.

In this paper, the traditional skyhook controller and skyhook controller with GAG are adopted to control the vibration of a vehicle semi-active suspension with MR damper passing through speed bump with different velocities, respectively. In section 2, the traditional skyhook control and skyhook control with GAG are designed for the semi-active suspension system with MR damper. In section 3, the experimental apparatus was established and the results are analyzed. At last, some concluding remarks are given in Section 4.

2. Skyhook control with adaptive genetic algorithm design

2.1 Skyhook controller

The skyhook control, which is proposed by D. Karnopp [17], is widely used in the vehicle semi-active suspension system [18-20]. As a state feedback control with the vertical velocity of the sprung mass, the skyhook control aims to reduce the vertical acceleration of the sprung mass, by inserting a virtual damper between the sprung mass and an imaginary sky. However, it is impossible to implement in the real vehicle suspension system due to the limited space of the suspension. In the practice suspension system, the controlled damper (MR damper) is amounted between the sprung mass (frame) and unsprung mass (wheel). The controlled

damping force was generated to follow the virtual damper, and then the semi-active skyhook control law is expressed by,

$$f_i = \begin{cases} f_{i\max} & \dot{x}_{si}(\dot{x}_{si} - \dot{x}_{ui}) \geq 0, \text{ and } |-c_{si}\dot{x}_{si}| > |f_{i\max}| \\ -c_{si}\dot{x}_{si} & \dot{x}_{si}(\dot{x}_{si} - \dot{x}_{ui}) \geq 0, \text{ and } |-c_{si}\dot{x}_{si}| \leq |f_{i\max}| \\ f_{i\min} & \text{else} \end{cases} \quad (1)$$

Where $i=1,2,3,4$ represent four suspension units, f_i is the actual MR damping force, $f_{i\min}$ is the MR damping force in the absence of magnetic field, $f_{i\max}$ is the maximum of the MR damping force, and c_{si} is the skyhook gain.

The four independent semi-active skyhook controllers are adopted in the whole vibration control of a vehicle passing through speed bump, and the four skyhook gains are determined by using trial-and-error method.

2.2 Skyhook controller with Adaptive Genetic Algorithm

Genetic algorithms (GA) are the most promising optimization algorithm with powerful global search ability based on natural evolution rule. The traditional GA has the drawback of premature, low efficiency and local optimum. To overcome the drawback, the adaptive genetic algorithm (AGA) was used to obtain optimal skyhook gain coefficient. The schematic diagram of the AGA is shown in Figure 1.

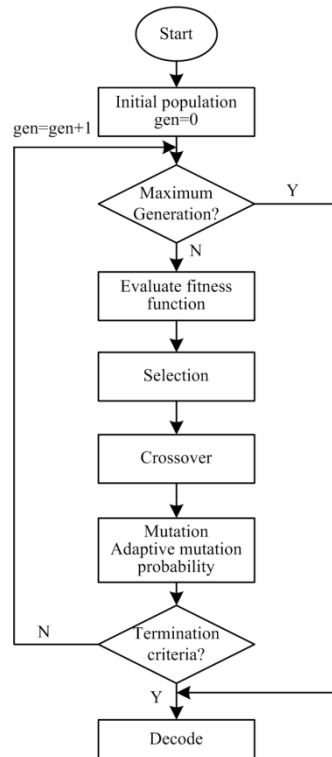

Figure 1. Schematic diagram of the AGA.

It is a key issue to encode the optimal parameters before AGA. There are three encode

algorithms are usually used, bit string encode, gray encode, real number encode. The bit string encode is adopted in this study because of its simplicity. The solution spaces (Γ_i) of four skyhook gains are given and the dimension of gene will be determined by equation (2). As a result, a chromosome will contain 4 genes, and its dimension is 56.

$$\left\{ \Gamma_i \mid \Gamma_i \in [0, 10000] \right\} \quad i = 1, 2, 3, 4 \quad (2)$$

$$2^{13} < (10000 - 0) < 2^{14}$$

Initial population. The initial population is generated randomly in the solution space. To improve the algorithm efficiency, the uniform random was used to ensure the individuals is uniform distributed in the solution space.

Fitness function. In this study, the goal is to improve the ride comfort of the driver when vehicle passing through speed bump. In other words, the object is to minimize the VDV's of vertical acceleration at driver's position. Therefore, the fitness function is given as follows,

$$f_i = \frac{1}{\left[\int_0^T a_d^4(t) dt \right]^{\frac{1}{4}}} \quad i = 1, 2, \dots, m \quad (3)$$

Where m is the size of population and $a_d(t)$ is the weighted acceleration of the driver.

Selection. The selection operator is based on pattern theory, since it will ensure the optimal solution of GA can increased exponentially. The individual will be chosen as parent population, if the individual's fitness higher than the population average fitness.

Crossover. The one-point crossover operator is used. Set a uniform random number between 0 and 1, if the random number less than the crossover probability P_c , then the adjacent individuals will cross, otherwise it will not.

Mutation. The simple mutation operator is used. Set a uniform random number between 0 and 1, if the random number less than the mutation probability P_m , then bit inverse the mutation point. In order to avoid destroying the good individual, the dynamic mutation probability is adopted. The mutation probability is big when the fitness of individual is small, and vice versa.

$$P_{mi} = 0.01 - \text{Index}_i \frac{0.01}{m} \quad i = 1, 2, \dots, m \quad (4)$$

Where Index_i is the index value of the i th individual.

Decode. The bit strings are always used in GA processing. To obtain the optimal skyhook gains, the optimal chromosome should be decoded. The decode equation as follows,

$$c_{si} = (\text{bitstring})_{dec} \frac{10000}{2^{14} - 1} \quad (5)$$

In this study, the crossover probability, maximum mutation probability, population size and maximal generation number are 0.8, 0.01, 50 and 50, respectively.

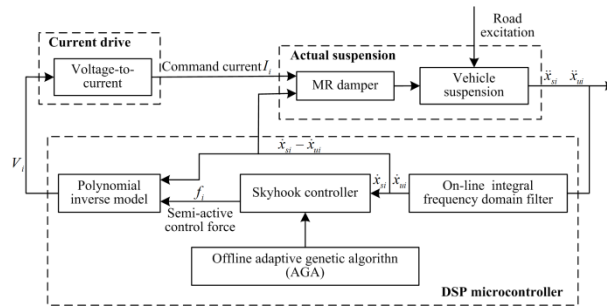

3. Road test and Result analysis

In order to experimentally validate the designed controller, a segment B vehicle has been

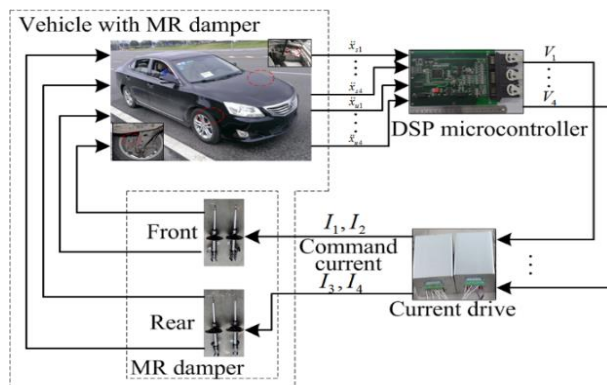

used, which is shown in Figure 2. The schematic of MR damper-based semi-active suspension system with controller is shown in Figure 3. In Figure 3, four acceleration sensors (Model ADXL335, ADI) are used to measure sprung acceleration of the front left suspension, front right suspension, rear left suspension and rear right suspension, respectively. And the another four acceleration sensors (Model MMA7361, Freescale) are used to measure unsprung acceleration of four corners of suspension, respectively. The eight acceleration signals are collected by DSP microcontroller (TMS320F28335, TI), and then the applied voltages are calculated by the DSP microcontroller with the control algorithm. Subsequently, the current drive converts the voltages to current which input to the dampers. The vibration of driver, as the evaluation index of ride comfort, is measured by acceleration (Model 356B40, PCB), which acquired by using Moveable Data Recorder (MDR05, Beijing AREODATA CO.LTD). The test road is asphalt road, and the rubber speed bump of 50mm height and 380mm width, which approximate trapezoidal shape, is shown in Figure 2.

Figure 2. Test vehicle

(a)

(b)
Figure 3. MR damper-based semi-active suspension system with controller (a) Schematic diagram
(b) photograph

The vehicle speeds are chosen as 10km/h, 20km/h and 30km/h, and the road test have been done on the basis of the method of running test-Automotive ride comfort (ISO 2631-1:1997(E)). The skyhook and skyhook with GAG algorithms (skyhook-GAG) are programming to the DSP microcontroller, respectively. The vertical acceleration responses at driver's position under different control strategies and vehicle speeds are shown in Figure 4, Figure 5 and Figure 6. It becomes obvious that the performance of the skyhook-GAG controller is better than the other two. Not only the bump response peak but also the random response had a great attenuation. Hence, this is directly indicates the improvement of the ride comfort of the skyhook-GAG controller. The peak values of acceleration response which the front wheel and rear wheel pass through the bump are shown in Table 1, Table 2 and Table 3. The peak values of vertical acceleration increased with the increase of vehicle speed, and the peak values of vertical acceleration with skyhook-GAG controller are less than that of vertical acceleration with passive and skyhook controllers. Compared to the passive controller, the peak values of vertical acceleration with skyhook-GAG controller for different vehicle speeds can be reduced by 26.23%, 31.59% and 15.34%, respectively. While the reduction of peak values of vertical acceleration with skyhook algorithm for different vehicle speeds are 15.94%, 9.96% and 10.04%, respectively. The VDVs for passive, skyhook controller and skyhook-GAG controller under different vehicle speeds are shown in Table 4. The VDVs of skyhook-GAG controller are less than the other two, which is in accordance with the peak values of vertical acceleration response. The experimental results presented evidently verify the effectiveness of the skyhook-GAG control scheme in terms of improved ride comfort, when vehicle pass through speed bump.

	(m/s^2)	(m/s^2)	(m/s^2)
Front	8.865	7.975	7.5048
Rear	8.025	7.288	7.1568

Table 4 VDV for different vehicle velocities and controllers

Speed	Uncontrolled ($m/s^{1.75}$)	Skyhook ($m/s^{1.75}$)	Skyhook-AGA ($m/s^{1.75}$)
10km/h	9.568	7.874	6.482
20km/h	11.241	10.662	9.722
30km/h	13.435	12.643	11.998

In addition, joint time-frequency analysis method is also used to analysis the human's vibration, since the vibration of bump is actually a time variable nonstationary signal. As shown in Figure 7 to 9, the vibration energy with skyhook-AGA controller is lower than that with passive and skyhook controller. Meanwhile, the vertical acceleration response frequency at driver's position increases with the increase of speed. when the speed is equal to 30km/h, the main response frequency of vertical acceleration at driver's position is 10 to 15 Hz, which is close to the second resonance peak. Hence, once the speed is greater than 30km/h, the skyhook control algorithm is no longer suitable for the control of body vibration, since the skyhook will reduce the first resonance peak while increase the second resonance peak.

4. Conclusion

In this study, the vibration control of a vehicle semi-active suspension with MR damper passing through speed bump under low velocity is investigated. The traditional skyhook controller and skyhook controller with GAG (skyhook-GAG) was designed to reduce the vibration from the road surface to the driver. Meanwhile, in order to verify the effectiveness of the designed control, a road test of the B segment car installed with four MR dampers is undertaken. The traditional skyhook and skyhook-GAG controller are programmed to the DSP microcontroller, respectively. The results indicated that compared to the uncontrolled system, the performance of skyhook-GAG controller is better than that of skyhook controller, and the reduction of peak value of vertical acceleration with skyhook-GAG controller can up to 31.59%. Meanwhile, the result with time-frequency analysis method shown that the vertical acceleration response frequency at driver's position increases with the increase of speed, and the skyhook control algorithm is no longer suitable for the control of body vibration when the speed is greater than 30km/h.

Key words: MRE isolator, FC, FNNC, Sinusoidal excitation.

Abstract. This paper presents the design method of a fuzzy-neural network controller (FNNC) for a MRE vibration control system with sinusoidal excitations to improve the vibration attenuation. A semi-active FC is designed to obtain the controlled force based on the feedback signals of the relative displacement and absolute displacement of the isolation structure, then the BP neural network with good learning capability is employed to emulate the dynamic behaviours of output force of fuzzy controller (FC), excitation displacement, velocity and controlled current applied to the coil in MRE isolator. The acceleration responses of the system with FNNC are evaluated by physical experiments, the results indicate that the FNNC could maintain satisfying control effect in the presence sinusoidal excitations and is also more optimal than conventional FC, the reason is that the neural network controller can approximate the nonlinear function relationship among the controlled force, excitation displacement, velocity and controlled current, but the function relationship is only considered as the linear function in conventional FC.

1 INTRODUCTION

Recently, magnetorheological elastomer (MRE) vibration control method, with the advantages of low power consumption, good stability and adjusting parameters under the applied magnetic fields, has attracted more and more attention in engineering fields [1-4], such as civil structures, precision manufacturing and vehicle suspension. Control strategies play an important role in MRE vibration control system with fixed system structure [2-5]. There are ON-OFF control, a clipped-optimal control, Lyapunov-based control, sub-optimal H_∞ control and fuzzy control. Due to the independence of system model and strong robust, fuzzy control has been paid more concern. However, FC designed in MRE vibration control system usually estimated the relationship of the feedback signals and controlled force, and was not describe the nonlinear function of controlled force and coil current (the inverse model of MRE isolator) accurately in real time control system, which made the limited vibration attenuation.

The inverse model of MRE isolator is critical element for real time control application. In general, there are two approaches to obtain the inverse models of systems. One is inverting the derived forward model. Some papers on the forward MRE isolator modelling are reported in [6-8] which are all focused on parametric models. Due to the highly nonlinearity of MRE isolator, there are too parameters to be identified. Moreover, if the inverse models are to be derived from these forward parametric models, the invertibility and zero dynamics of these models must be investigated first. Therefore, it is difficult to obtain the corresponding inverse dynamic model by inverting the derived forward parameters model. The other named non-parameter model is directly identifying the inverse model from the input and output data set without relying on a precise mathematical model.

Neural network is a kind of non-parametric modelling method to approximate any nonlinear mapping relationship between input and output, which is not able to be solved by a mathematical model. BP neural network has the simple structure and less computation, which is suitable to establish the inverse model of MRE isolator online [9]. The genetic algorithm (GA) [10-13] is a kind of optimization algorithm based on the mechanism of natural selection and evolution. It encodes the parameters to be solved and do some basic genetic operations on these codes, such as reproduction, crossover and mutation. Since the ability of GA to make a robust search for a global optimum in complex space, it has been applied in many applications. It has been shown that GA is quite well in identifying the BP network model for a wide class of non-linear systems [14, 15]. Therefore, GA is employed in this paper to optimize the structure of BP network for MRE isolation system.

The main contribution of this work is to propose a FNNC for sinusoidal excitations excitation to improve attenuation of the acceleration. The control force associated with the FC is generated by adopting the MRE isolator, and the BP neural network is employed to approximate the nonlinear function between controlled force, excitation displacement and velocity and controlled current. FNNC, consists of fuzzy controller, BP neural network based MRE isolator inverse model, is designed in Section 2. In section 3, control experiments are carried out to verify the effectiveness of the proposed FNNC. Finally, the conclusions are summarized in Section 4.

2. FNNC DESIGN

2.1 The dynamic model of MRE isolation system

The MRE vibration isolation system is shown in Figure 1. Base on the Newton's motion law, the dynamic equation of the isolation system are derived as

$$m\ddot{x}_2(t) = k_0(x_1(t) - x_2(t)) + c_0(\dot{x}_1(t) - \dot{x}_2(t)) + \Delta k(x_1(t) - x_2(t)) + \Delta c(\dot{x}_1(t) - \dot{x}_2(t)). \quad (2)$$

The output force generated by MRE isolator $F_{MRE}(t)$ is described by

$$F_{MRE}(t) = \Delta k(x_1(t) - x_2(t)) + \Delta c(\dot{x}_1(t) - \dot{x}_2(t)). \quad (3)$$

Where m represents the mass of the isolation structure. k_0 and Δk are the isolator stiffness without magnetic field application and the increment stiffness under the

electromagnetic field, respectively. c_0 and Δc are the damping coefficient with zero magnetic field and increased damping coefficient under the electromagnetic field. $x_1(t)$ and $x_2(t)$ are the displacement of the base and isolation structure, respectively.

Figure 1. Dynamic model of MRE isolation system

The semi-active control law is described as [4]

$$F_{MRE}(t) = \begin{cases} F_{\max} & x_2(t)x_r(t) \geq 0, F_c(t) \geq F_{\max} \\ F_c(t) & x_2(t)x_r(t) \geq 0, F_c(t) < F_{\max} \\ 0 & x_2(t)x_r(t) < 0 \end{cases} \quad (4)$$

where F_{\max} is the maximum output force of the MRE isolator, $F_c(t)$ is the desired force computed by the designed FC in the following section, and $x_r(t) = x_2(t) - x_1(t)$ is the relative displacement between the isolation structure and base.

The scheme of MRE vibration isolation control system with FNNC is shown in Figure 2. The control system consists of MRE isolator, isolation structure, sensors and FNNC(FC and BP neural network controller). The FC and BP neural network controller will be designed in the following section.

Figure 2 The scheme of MRE vibration isolation control system with FNNC

2.2 Fuzzy controller design

The input variables of the developed FC are selected as relative displacement $x_r(t)$ between the isolation structure and base, and the isolation structure displacement $x_2(t)$, while

the output is chosen as the force $F_{MRE}(t)$ generated by MRE isolator. There are seven input and output linguistic variables, such as negative big (NB), negative medium (NM), negative small (NS), zero (ZO), positive small (PS), positive medium (PM), and positive big (PB). The discourse domain of the variables is $[-7, 7]$. D , RD and U are the isolation structure's displacement, the relative displacement and the output force in the fuzzy set, respectively. The fuzzy rules, membership function and fuzzy inference are complete same with that in [4].

2.2 BP neural network based inverse model of MRE isolator

The BP neural network is employed to describe the functional relationship between applied current, displacement, velocity and output force in the paper. The network with the structure of input layer, output layer and hidden layer is shown in Figure 3.

Figure 3 The structure of BP neural network for MRE isolator inverse model

How to determine the optimal structure of BP neural network is the first thing to be done. In this paper, the GA is used to optimize the structural parameters of BP neural network. Genetic algorithm is a global optimization algorithm based on natural selection and evolution mechanism, which is suitable for dealing with complex nonlinear problems that are difficult to solve by traditional search methods.

Let the number of neurons in each hidden layer be the same. The real number coding method is used to encode the number of hidden layers m and hidden layer neurons n in the BP network. Considering the complexity of the network structure, the values of the parameters to be optimized in the genetic algorithm are respectively set to: $m \in [1, 3]$, $n \in [1, 30]$ are positive integers. The network is trained by the weights generated by random initialization, and the mean square error value of the training samples under each network structure is calculated. The reciprocal of the mean square error value is used as the fitness function of the genetic algorithm. The optimization indicators and constraints are as follows:

$$\begin{aligned} \max \quad & F_{in} = 1 / \text{MSE}(e) \\ \text{s.t.} \quad & \begin{cases} m \in [1, 3] \\ n \in [1, 30] \end{cases} \end{aligned}$$

where e is the mean square error between the experimental current value and predicted current values with BP neural network.

The GA is used to optimize the above problems, and the individuals with the greatest fitness are selected to inherit to the next generation, and the evolutionary groups are genetically manipulated through crossover and mutation to generate a new generation of populations. The initial values of each parameter selected in the genetic algorithm are shown in Table 1. The BP network structure parameters obtained by real-coded genetic algorithm are shown in Table 2. The network is a four-layer structure network consisting of three input neurons, two hidden layers and one output layer, in each hidden layer. The number of neurons is 15. Therefore, the optimal structure of BP neural network is 7-15-15-1.

Table 1 Initiation and update of GA parameters

Initialization parametrs	Value
Maximum number of iterations	30
Number of populations	40
Mutation probability	0.01
Crossover probability	0.8

Table 2 Optimized values of BP neural network

Parameter to be optimized	Value
Implicit number of layers	2
Number of neurons in the hidden layer	15

According to the structure of BP neural network optimized by GA, the BP neural network based inverse model of MRE isolator is built. The input of the network is relative displacement, relative velocity, current force, and output variable is current. The experimental data obtained by the test is divided into a training data set and a test data set for training a BP network whose structure is determined by a genetic algorithm. Taking the same frequency sinusoidal excitation with excitation displacement amplitudes of 0.045mm, 0.09mm, 0.135mm, frequency of 40Hz, 60Hz, 80Hz and current of 0-1.5A, the mean square error (MSE) between predicted current and actual current is 0.0025. The experimental current and predicted current are shown in Figure 3(a). The error distribution is shown in Figure 3 (b), the range is small [-0.5046, 0.9854], and the regression coefficient shown in Figure 3(c) is 0.99427.

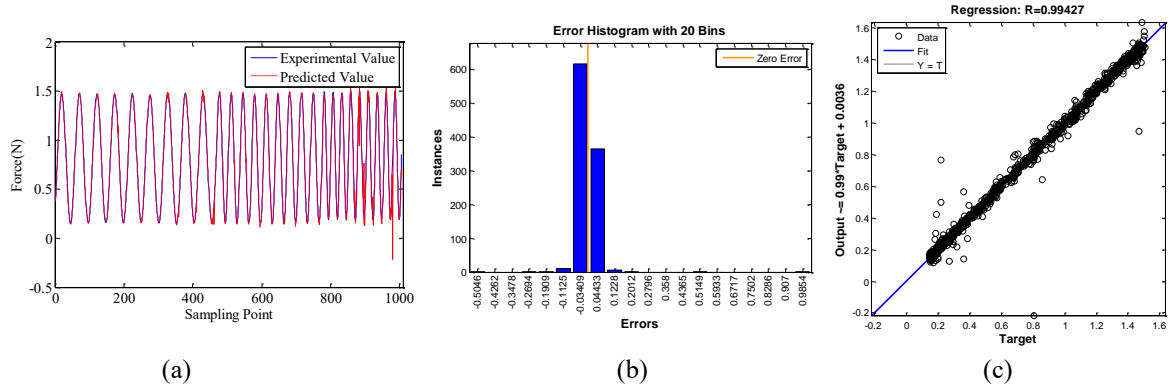

Figure 4 The training results with BP neural network for MRE isolator inverse model (a) force (b) error distribution (c) regression

The generalization ability of the BP neural network is verified by the test data set different from the training data set. The generalization result is shown in Figure 5, and the mean square error is 0.004. The error distribution range is $[-0.2594, 0.7572]$, the error is mainly concentrated near the zero value. The regression coefficient is 0.99059.

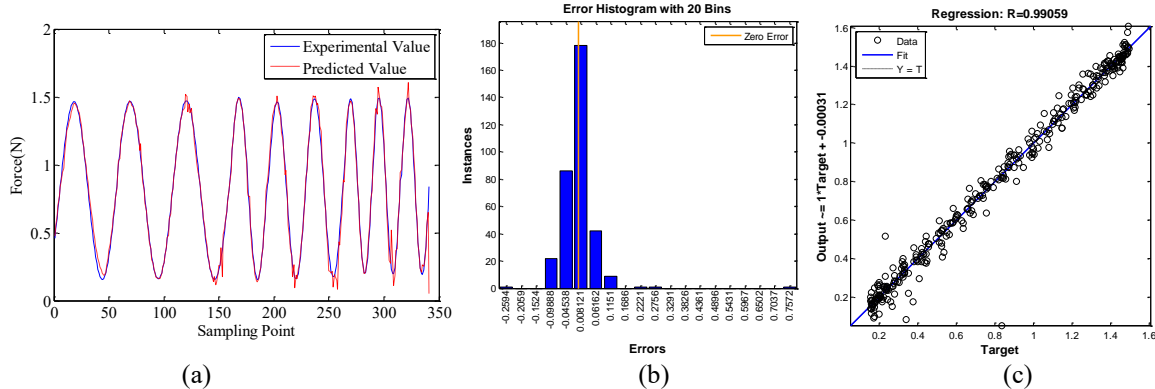

Figure 5 The generalization results with BP neural network for MRE isolator inverse model (a) force (b)error distribution (c) regression

From the inverse model generalization results, we can see that MSE value of BP network is 0.004 and the regression coefficient is 0.99059, which is close to 1. Therefore, the BP neural network performs a better estimated capacity for the inverse model of MRE isolator.

3. EXPERIMENTAL VERIFICATION AND ANALYSIS

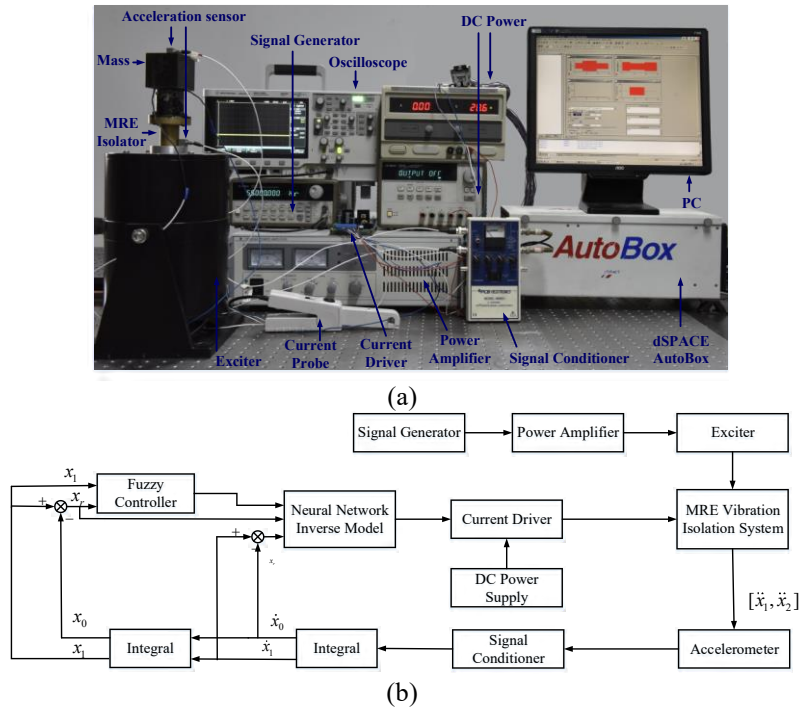

Figure 6 MRE vibration isolation Fuzzy-Neural Network control experimental system: (a) physical map; (b) system structure

The fuzzy-neural control experimental system for MRE vibration isolation system is shown in Figure 6. The MRE isolator is mounted on the surface of an electromagnetic exciter (JZK-50, Lianneng Electronics, China), and the load is connected to the top of the isolator by a screw. The sinusoidal excitation signal is generated by a signal generator (Model 33120A, Agilent, USA), which is amplified by a power amplifier (YE5874 type, Nerneng Electronics, China) to drive the exciter to generate vibration. Two piezoelectric accelerometers (Model 333B52, Piezotronics, USA) are mounted on the exciter table and the load to measure the base excitation acceleration signal and the load response acceleration signal, respectively. The signal measured by the sensor is a charge signal, which is converted into a voltage signal by a signal conditioner (Model 480B211, Piezotronics, USA), then acquired by dSPACE Autobox (DS1005, dSPACE, Germany), and fuzzy-neural network controller in Matlab/Simulink is downloaded to the dSPACE Autobox hardware-in-the-loop simulation system. The control current output from the controller is applied to the MRE isolators through the current driver. Two DC power supplies (model E3631A, Agilent, USA) supply the current driver.

3.1 Experimental results and analysis

The sinusoidal excitation is applied to MRE isolator with an amplitude of 0.2 g at a frequency of 30 Hz to 60 Hz and a step size of 10 Hz. The variation of the response acceleration amplitude of the FNNC and the traditional FC is shown in Figure 7-10. The

attenuation at different frequencies and the response RMS of the passive and controlled conditions of the controlled object are shown in Table 3. The attenuation ratio of the FNNC and the traditional FC is shown in Figure 11. It can be seen from figures and table that the acceleration RMS attenuation rate with FNNC is always more than that with FC, and the maximum value with former method reaches 42.12%, but the latter is only 34.26% when the excitation frequency is 50Hz.

Figure 7 Results of FNNC and traditional FC with excitation amplitude of 0.2g and frequency of 30Hz (a) acceleration (b) Control current

Figure 11 Comparison of attenuation rates of different controllers with different excitation amplitudes of 0.2g

4 CONCLUSIONS

This paper studies the FNNC design for a MRE vibration isolation system with sinusoidal excitations. The MRE isolation system's passive model is obtained from acceleration sweep experiment. An AFC is devised based on the working principle of the MRE isolator and fuzzy theory, the adaptive mechanism (factor adjustment) of which is constructed on passive system model and peak observer, which is implication of excitation frequency. Experimental results show that the decrease of the isolation structure acceleration under the FNNC is 42.12% higher at most than the one of the conventional FC. And the FC could maintain consistent performance in the presence of varying excitation parameters (amplitude from 2.0 m/s² frequency from 30Hz to 60 Hz).

Key words: Magnetorheological Fluids, smart MR-based sealing, capillary pressure

Abstract. In previous contributions an MR-sealing was developed to increase the energy-efficiency in idle-mode in combination with the MR-fluid movement control. While the maximum capable pressure of the sealing is based on the yield stress depending on the magnetic characteristics of the particle chain structure in this contribution the interaction between the carrier liquid and the particle structure will be in the focus of interest. The proposed investigation is based on a theoretical analysis considering the capillary pressure and the maximum intruding length. Along with the determination of significant material parameters an experimental study is performed on a novel test-setup to determine the mentioned interaction between the chain structure and the carrier liquid.

1 INTRODUCTION

Sealing approaches based on ferrofluids are already well investigated and applied in many different applications for example in hard drive discs, X-ray tubes, hermetic robots or loud speakers [1]. A low intrinsic friction in the absence of wear is the key feature of ferrofluids. Furthermore, the tightness can be maintained even at high eccentricities [2]. Unlike ferrofluids (FF), magnetorheological fluids (MRF) consist of iron particles with the diameter in a range of 4 to 12 μm , fairly normal distributed. The bigger particle size results in a significant higher magnetic moment \mathbf{m} as given in Eq.1.:

$$\mathbf{m}_{ma} = \int_V \mathbf{M} dV, \quad (1)$$

where \mathbf{M} is the magnetization of a object with the volume V . Consequently, higher magnetically induced forces can be observed resulting in higher yield stress. Thus, the field of application of MRF takes advantage of the higher yield stress which are utilized for the realization of dampers, brakes and clutches [3]. MR-based sealings offer higher pressure loads compared to FF, but suffering from the drag torque in rotating applications [4, 5].

The particles of the MRF form a chain structure under the impact of a magnetic field, therefore, increasing the yield stress significantly, while the carrier liquid remains within the space between the particles. The FF approach is classified as a stable dispersion due to the small particle size. However, Brownian motion superimposes all external effects and a separation into two individual phases (particles and carrier liquid) is not possible. This study deals with a detailed investigation of the interacting forces between

the iron particles and the carrier liquid of magnetorheological fluids for a better understanding for the design of MR-based sealings. The first MR-based sealing for the utilization in a MRF-based actuator was designed and successfully applied in [6] resisting a pressure load of about 2350 Pa. Lately, we presented an optimized design, which shows a significant increase in the compactness and energy-efficiency [7]. Both designs were developed by considering the maximum pressure load which can be compensated by the yield stress of the MRF due to the particle chains formed by the magnetic field. In this study a second effect is observed on the tightness of MR-based sealing, which is most likely related to the carrier liquid within the void between the chain structures. Thus, the pressure load is acting simultaneously on the particle structure and the carrier liquid. Thereby, the counter force of the liquid is based on the interaction between the particles and the liquid.

In the first section an overview of the developed MR-based sealing for MRF-actuators is presented. In the second section a theoretical analysis, based on a capillary pressure to describe and understand the phenomena is given. Along with the last section an experimental study is introduced to determine and prove the interaction between the particle chain structure and the carrier liquid.

2 APPLICATION OF MR-FLUID SEALINGS

In this section the application of MR-fluid sealings in energy-efficient MRF-based coupling elements is presented. Usually, for the separation of rotating parts in MRF-based coupling elements radial shaft sealings are required. But on the effective radius of the shear gap a conventional dynamic sealing needs huge space on the one hand. On the other hand it will occur friction-based losses. Thus a MRF-based coupling element was equipped with the smart MR-sealing in combination with the MR-fluid movement control [7]. The design is depicted in figure 1 a) showing also the distribution of the MRF for characteristic states of operation of the conditional stable MR-fluid movement control. The according distribution of the magnetic flux density is illustrated in figure 1 b). Each upper shear gap shows the loss-less idle mode. This state is achieved by the impact of radial accelerations due to rotational speed resulting in a separation of the two rotors. By this, drag torques caused by viscous friction can be completely prevented

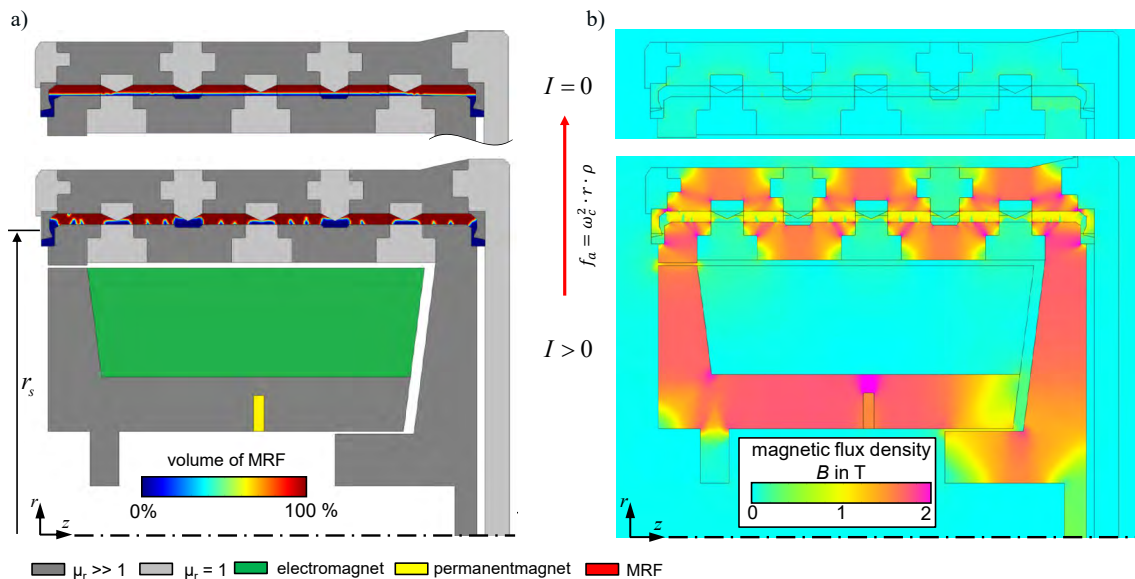

Figure 1: Magnetic circuit of an MRF-based coupling element with partially filled shear gaps operating with the conditional stable MR-fluid movement control a) and the according distribution of the magnetic flux density b).

above certain rotational speeds n . In the fully illustrated magnetic circuit the torque transmission mode is depicted. By the magnetic field of the electromagnet the MRF is moved by magnetically induced volume force densities, resp. Kelvin forces, to engage both rotors and transmit torque by the MR-effect. The movement of the MRF is simulated with the software Comsol Multiphysics. The more detailed design of the applied MR-fluid sealing for the MRF-based clutch equipped with a conditional stable MR-fluid movement control, as proposed in figure 1, is shown in figure 2 a-c). In figure 2 a) the clutch is shown in standstill and the MRF moves towards the smart sealing due to the impact of gravity. Due to the magnetic field of the permanent magnet (PM), positioned within the inner magnetic circuit below the center of the electromagnet (compare figure 1), the yield stress of the MRF is slightly increased in the area of the radial sealing gap and in the shear gap. Therefore, leakage at the sealing and sedimentation in the shear gap is avoided. Under the impact of higher rotational speeds (figure 2 b)), the MRF will be moved out of the sealing gap and placed at the outer rotor by radial acceleration f_a . Similar to the conditional MR-fluid movement control drag torque can be completely eliminated [7]. Activating the electromagnet (EM) in figure 2 c)) results in a movement of the MRF from the outer rotor towards the inner rotor to engage the clutch according to the MR-fluid movement control. Consequently, the MRF is utilized to transmit torque on the one hand and to realize a sealing on the other hand ensuring an energy-efficient operation. In figure 2 d) a novel measurements are shown focusing on the impact of certain degrees

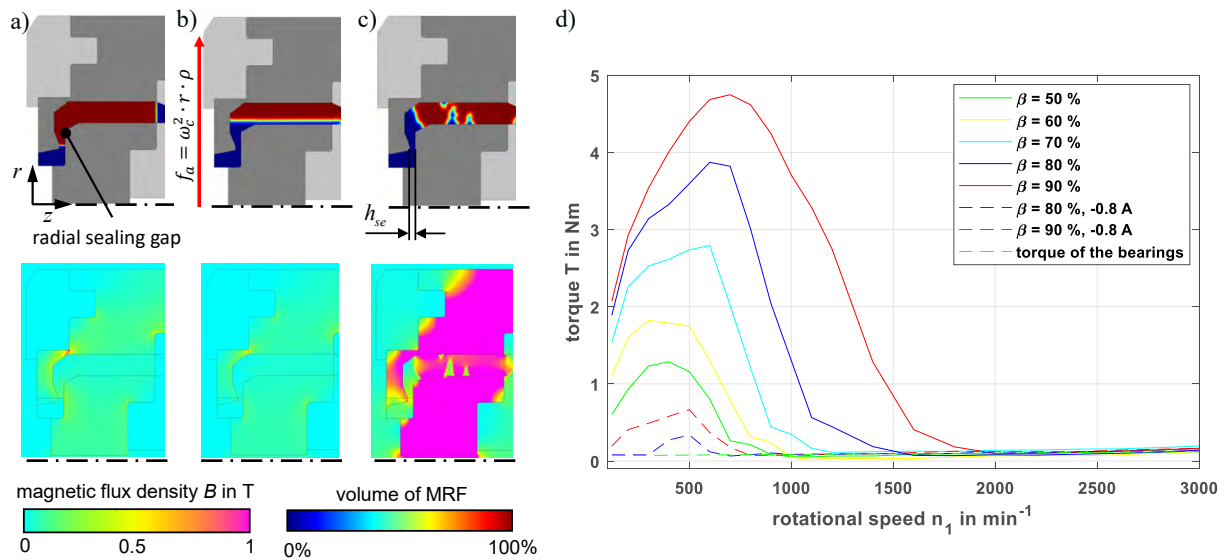

Figure 2: Schematically design of the smart MR-based sealing and distribution of the MRF during standstill (a), at rotational speed (b) and during torque transmission (c). Experimentally measured behavior of the idle torque at a rising rotational speed n_1 and a constant rotational speed of the inner rotor $n_2 = 100 \text{ min}^{-1}$ for certain degrees of filling β d).

of filling β on the critical rotational speed ω_c of the outer rotor. The degree of filling has a significant impact on the torque capacity of MR-actuators. A higher degree of filling results in a much higher torque capacity on the one hand. But, with rising volume of MRF in the shear gap it becomes also harder to separate the shear surfaces on the other hand. The changed drag torque behavior can be comprehended by figure 2. An increasing degree of filling β results in a much higher magnitude of the drag torque and also in an enhanced critical rotational speed ω_c . For example, a degree of filling of $\beta = 90\%$ results in the critical rotational speed of $\omega_c = 2000 \text{ min}^{-1}$. However, the compensation of the magnetic field of

the permanent magnet in the shear gap by the electromagnet can be used to significantly reduce the drag torque and the critical rotational speed ω_c during the operation. Due to the compensation the drag torque can be completely eliminated in the range of $n_1 > 750 \text{ min}^{-1}$ except the drag of the bearings for the maximum degree of filling of $\beta = 90\%$. The required electrical power for the compensating current I is $P_{el} < 1 \text{ W}$. Thus, an energy efficient operation can be provided also at high degrees of filling.

A separation of the particle and carrier liquid was not investigated so far. In literature no contribution is known dealing with the interaction between the carrier liquid and the particle chain structure of the MRF. Consequently, a first investigation of this interaction behavior will be presented in the next sections.

3 EXPECTED INTERACTION FORCES

As mentioned before, the arrangement of particles fixed by a magnetic field is assumed as particle chains. The structure can be also compared to porous media as illustrated in figure 3 a). Considering the carrier liquid within the chain structure the interaction between this porous media and the laminar homogeneous flow of the liquid is usually described by Darcy's law [8]. Darcys law is based on a special solution of the Navier-Stokes-Equation considering the permeability of the porous material and the friction of the liquid by the dynamic viscosity η as flow resistance. However, in a defined volume of MRF exposed to a magnetic field no flow of the carrier liquid was detected and therefore the Darcy's law is not applicable. At zero or very small velocities the impact of the surface tension become more important instead [9]. Hence, a model based approach focusing on the capillary pressure is applied in this section.

3.1 Analytical approach

The capillary pressure of fluids causes a rising behavior of fluids within the porous media. The model representation is based on capillary tubes, which capillary radius r_c correlates with the investigation of the proposed material. The time-dependent behavior of a liquid in a capillary can be described by the Hagen-Poiseuille-Equation [10]:

$$\frac{dh}{dt} = \frac{r^2 \cdot \Delta p}{8\eta \cdot h(t)}. \quad (2)$$

Therein, h represents the height of the capillary tube, η the dynamic viscosity and the pressure difference Δp . Especially the pressure difference determines the achievable rising height h which is ascribed to the hydrodynamic pressure p_p and the capillary pressure p_c expressed by the Young-Laplace-Equation:

$$\Delta p = p_c - p_p = \frac{2\lambda \cos \theta}{r_c} - \rho \cdot g \cdot h. \quad (3)$$

The Young-Laplace-Equation [11] describes the relationship between the surface tension λ and the curvature of the fluid surface resulting in the inner pressure. Since, no transient behavior is expected (respectively leakage would have been observed in previous works) the finite height h_{fin} can be used to describe the interaction forces. Therefore, Eq.3 is inserted in Eq. 2, also known as Washburn-Equation [12]. At steady state dh/dt vanishes by which the final length h_{fin} is calculated by:

$$h_{fin} = \frac{2\lambda \cdot \cos \theta}{r_c \cdot g \cdot \rho}. \quad (4)$$

The utilized parameters can be comprehend by figure 3 b). Hence, the capillaries in the porous medium are not comparable to the assumed tube geometry different approaches were developed to consider irregular capillaries. For example in [13] the porous media is assumed as an array out of particles resulting

in a periodical sinusoidally capillary size. Under consideration of the periodical contour only the average maximum radius $r_{c,max}$ of the capillary is required for the calculation of the stationary maximum height h_{fin} . The average maximum radius $r_{c,max}$ of the capillaries within the MRF particle chain structure can be calculated with respect to the particle volume fraction of $c_v = 0.47$ and the assumption of an homogeneous particle distribution, compare figure 3 c):

$$V_Q \cdot c_v = V_P \Rightarrow x_Q^2 \cdot 2r \cdot c_v = \frac{8}{3}\pi r^3. \quad (5)$$

Therein, x_Q is the edge length of the representative cuboid volume and r is the mean radius of an iron particle.

Figure 3: MRF-particles fixed by a magnetic field B a) showing the plane for the illustration of important modeling parameters in b). Representative cubit volume for the calculation of the capillary radius $r_{c,max}$. in c)

3.2 Determination of material parameters

The remaining surface tension λ and the angle of the surface curvature θ have to be determined by experimental investigation. Therefore, a setup based on two different capillary tubes was used [14]. Due to the capillary pressure the carrier liquid rises in the capillaries and by the height difference of Δh the surface tension can be determined, as illustrated in figure 4 a):

$$\lambda = \frac{\Delta h \cdot r_2 \cdot r_1 \cdot \rho \cdot g}{2 \cdot \cos(\theta) \cdot (r_2 - r_1)}. \quad (6)$$

The angle of the surface curvature on a glas surface was determined as $\theta = 8^\circ$, see figure 4 b). The measurement on the pure particle material was not applicable due to the absorption of the carrier liquid. However, the small surface curvature, which can be expected for oil, results in an almost neglectable impact in this approach. Applying Eq. 6 under consideration of the density of $\rho = 754 \text{ kg/m}^3$ the surface tension of the carrier liquid can be determined as $\lambda = 24.9 \text{ mJ/m}^2$. Thus, the final height of the carrier liquid within the particle structure can be calculated with equation 4 to $h_{fin} = 2.89 \text{ m}$ resulting in a capillary pressure of $p_p = 21.44 \text{ kPa}$. Hence, a test-setup with a length of 2.89 meter MRF exposed to a magnetic field is not feasible and not appropriate for the representation of the MRF in the shear or sealing gap a smaller gap is chosen for the test-setup in the next section. The remaining height h_{fin} is considered by an additional pressure load.

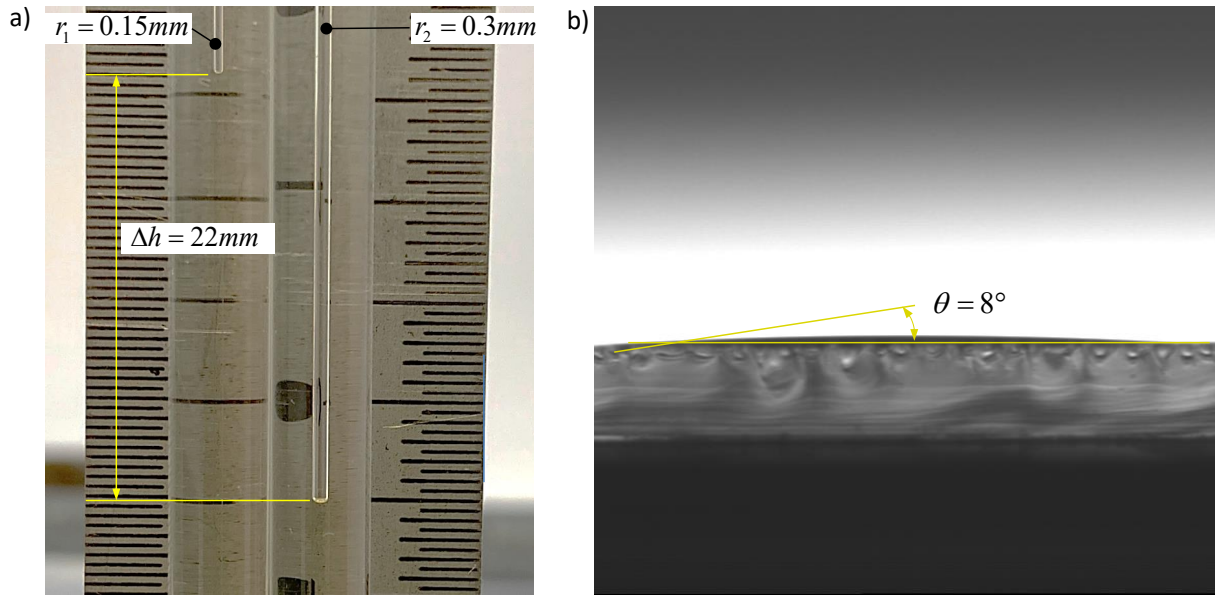

Figure 4: Experimental investigation of the surface tension λ with the double capillary method a) and determination of the angle of the surface curvature θ b).

4 EXPERIMENTAL INVESTIGATION OF THE CAPILLARY PRESSURE

As mentioned before the capillary pressure of the carrier liquid within the particle structure is in the focus of this investigation. The objective is the determination of the equilibrium between the capillary pressure and a defined pressure load.

4.1 Setup

Based on a magnetic circuit the MRF is exposed to a magnetic field in a small gap with the height h_g and the length l_g . An enclosing pressure chamber provides a well defined impact of the pressure load p_1 on the shear gap in z-direction. The whole test-setup is exposed to the ambient pressure p_0 as illustrated in figure 5 a). The pressure load p_1 will be controlled by the shown U-tube pressure gauge partially filled with water and air. Since the height of the gap is very small the impact of the hydrodynamic pressure of the carrier liquid in the probe is neglected. Hence, only the interaction force between the particle chain structure and the carrier liquid is in the focus of interest the yield stress of the MRF will be adjusted to resist at least a 5 times higher pressure load than the calculated capillary pressure. Thus a stable and homogeneous particle chain structure can be sustained. The required yield stress can be simply estimated by [3]:

$$\tau(|B|) = \Delta p \cdot \frac{h_g}{l_g \cdot 3}. \quad (7)$$

Therein describes $\tau(|B|)$ the yield stress depending on the magnetic flux density B . According to the characteristics of the utilized MRF Basonetic 5030 a magnetic flux density of approx. $B = 0.52\text{ T}$ is sufficient. Based on this requirements the magnetic circuit, illustrated in figure 5 b), was designed to affect on the MRF as proposed.

Figure 6: Photography of the test-setup for the experimental investigation showing the measurement at a pressure load of approx. $p_1 = 215$ kPa.

interaction between the particle structure and the carrier liquid. Consequently, a separation during the off-state in the sealing or shear gap due to gravity effects can be excluded. Moreover, it was observed that MR-fluid sealings are not feasible for a 100% leakage proof against gas at certain pressure loads. Compared to FF the void within the particle structure is the limiting factor of the MR-based sealing if a hermetic seal is required. In case of the sealing applied in energy-efficient MRF-based coupling elements with partially filled shear gaps this restraint is not relevant, since no significant pressure load occurs during operation.

5 CONCLUSIONS

Within this contribution the interaction between the particle chain structure and the carrier liquid of MRF are investigated to gain more information about the feasibility of MR-based sealings and the MR-fluid movement control. In an analytical approach based on the capillary pressure sufficient binding forces are determined, which are generally proved by an experimental investigation. Consequently, the interaction within a relevant continuum of MRF exposed to a magnetic field withstand the impact of gravity. The investigation revealed a very slight leakage flow of air (gas) through the voids of the particle structure, which demonstrates a disadvantage compared to sealings based on ferrofluids. Nevertheless, the proof of applicability in MRF-based coupling elements in combination with the MR-fluid movement control was found.

Key words: Multi-Axis, Vibration Isolation, Magnetorheological, Seat Suspension.

Abstract. This study presents the multi-axis vibration isolation performance of a full-scale magnetorheological (MR) fluid-based seat suspension for both individual and simultaneous three-axis directional inputs via experiment. To this end, a semi-active MR seat damper was designed and fabricated to cope with all three-axis directional excitation. The damping capability of the multi-axis MR seat damper was experimentally evaluated for both axial and lateral directions in terms of dynamic stiffness and loss factor by an servo-hydraulic testing machine. Before building a full-scale MR seat suspension, we constructed a 1/3rd scale MR seat suspension to check if the fabricated MR seat damper is capable of sufficiently reducing the seat vibration under practical excitation input levels. In addition, to efficiently suppress the seat vibration, a narrow-band frequency shaped semi-active control (NFSSC) algorithm was formulated. Finally, we constructed a full-scale MR seat suspension with a 50th percentile male dummy and conducted the three-axis vibration isolation testing by using a hydraulic multi-axis simulation table (MAST) for both individual (in this case, excitation input was swept over wider frequency range up to 200 Hz) and simultaneous three-axis directional inputs. The feasibility of the full-scale MR seat suspension effective for the seat vibration reduction was experimentally evaluated.

1 INTRODUCTION

Excessive vibration of aerial vehicles affects occupants with short-term effects such as discomfort, loss of situational awareness and fatigue. Occupants exposed to long-term whole-body vibration have chronic health issues such as back pain, cervical and spine injuries. Vibration spectra ranging up to 80 Hz effect various human body parts, e.g., the resonant frequency of the cervical and lumbar regions is from 2.5 to 5.5 Hz, and head and shoulder regions is from 20 to 30 Hz. Thus, prolonged vibration produces chronic musculoskeletal stress and may cause permanent damage. For these reasons, seat suspensions are a key vibration mitigation strategy for aerospace vehicles.

Most published research on MR seat suspensions has focused on vibration suppression in only the vertical direction because this vibration is dominant for most cases and most MR seat dampers can only produce a single-axis controllable damper force. But, in practical situations, occupants will be exposed to three-axis excitation inputs. In addition, the testing of vibration isolation performance in MR seat suspensions has been conducted primarily for a relatively low frequency range below 30 Hz, because most experimental setup have been constructed as a single degree-of-freedom (DOF) seat suspension system having one relatively low resonant frequency below 10 Hz. Moreover, most researches has been conducted to measure vibration attenuation on scaled-down MR seat suspensions. Therefore, a key research goal of this study was to test and evaluate multi-axis vibration isolation performance of a full-scale MR seat suspension for both individual (in this case, excitation input was swept over wider frequency range up to 200 Hz) and simultaneous three-axis directional inputs.

2 MULTI-AXIS MR SEAT DAMPERS FOR SEAT SUSPENSIONS

Figure 1 presents the schematic diagram of the multi-axis MR fluid-based seat damper. The electromagnetic coil is configured around the bobbin and the outer cylinder acts as the magnetic flux return. The bobbin is attached to the top elastomer through a connecting screw. When current is applied to the electromagnetic coil, the magnetic densities are concentrated on the bottom and radial sides of the bobbin. As a result, this MR seat damper can produce the resisting MR yield forces in both axial (i.e., vertical) and lateral (i.e., radial) directions. More detailed working principles of this MR seat damper can be found in reference [1].

Figure 1: The multi-axis magnetorheological (MR) fluid-based seat damper. (a) schematic diagram. (b) fabricated seat damper.

Figure 2 presents the axial dynamic stiffness and loss angle of the multi-axis MR seat damper. In these tests, the MR seat damper was initially compressed in axial direction by 2 mm for emulating the static deflection due to the occupant's mass. As seen in this figure, the dynamic stiffness and loss angle increased as the frequency increased. But, in response to the applied current input, both the dynamic stiffness and loss angle significantly increased. Compared to zero-field (i.e., 0 A) input case, 3 A current input case shows about 4 times greater dynamic stiffness and loss angle. This implies that when current is applied, the stiffness of the MR seat damper becomes much greater and its damping also increases. Generally speaking, higher stiffness and high damping are good for the vibration reduction of

a system at an axial resonant frequency. On the other hand, similar to the axial excitation case, the lateral dynamic stiffness and loss angle also increased (see Figure 3), as the frequency increased. But, compared to the axial excitation case, the increments of the lateral dynamic stiffness and loss angle for the applied current input were smaller. But, the MR seat damper still shows at least 2 times larger dynamic stiffness and loss angle than zero-field input case for lateral direction.

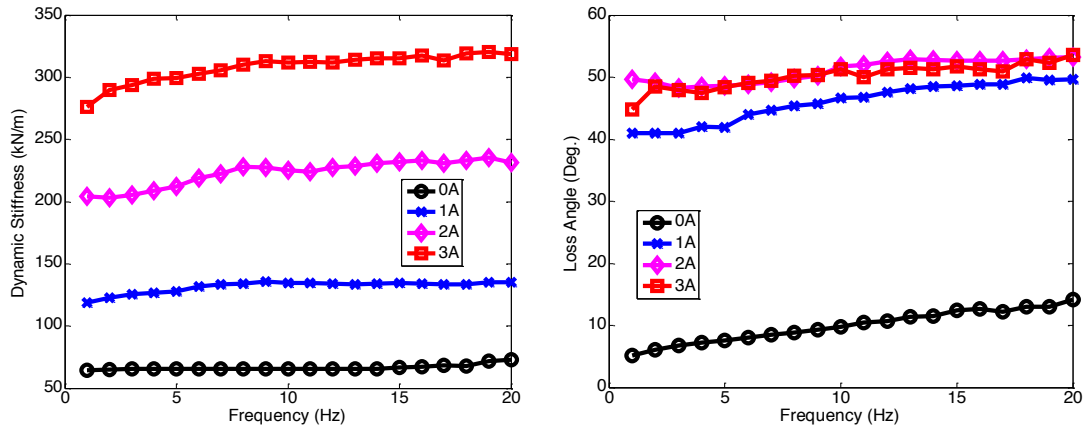

Figure 2: Axial dynamic stiffness and loss angle of the multi-axis MR seat damper under ± 1.0 mm excitation displacement.

Figure 3: Lateral dynamic stiffness and loss angle of the multi-axis MR seat damper under ± 1.0 mm excitation displacement.

3 SCALED-DOWN SEAT SUSPENSION USING AN MR SEAT DAMPER

3.1 Testing setup

Figure 4 presents the photograph of the single DOF testing stand for the $1/3^{\text{rd}}$ scale-down MR seat suspension for the axial direction. The MR seat damper is placed between the mass and the hydraulic excitation actuator and the mass linearly moves along with the guiding rails. The mass is chosen to be equal to $1/3^{\text{rd}}$ of the full-scale system mass because the full-scale MR seat suspension has three MR seat dampers. In this study, two different masses of 65 and 95 lbs were chosen for the vibration isolation testing. The hydraulic excitation actuator

provides the excitation input displacement or acceleration. For applying a control current input to the MR seat damper, an in-house controller box was used. The in-house controller box has a digital signal processor (DSP) chip to program and has own computing power to execute a vibration control algorithm without any other laptop. In addition, the controller box has three-axis acceleration measurement capability and can be operated by a 28 V battery for portable purpose. Thus, without using other sensors and current amplifiers, the in-house controller box can determine a control current input from the acceleration measured by its own accelerometer.

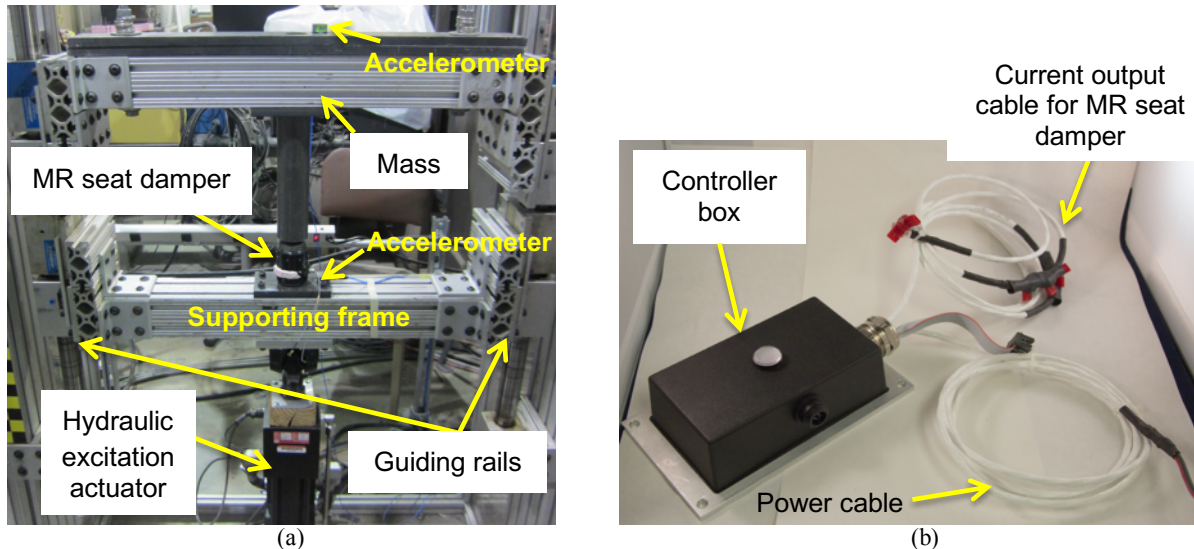

Figure 4: Photograph of the single degree-of-freedom (DOF) testing stand for the 1/3rd scale-down MR seat suspension for the axial (i.e., vertical) direction. (a) testing stand. (b) controller box.

3.2 Vibration control algorithm

In order to efficiently reduce the vibration of the MR seat suspension, we used the narrow-band frequency shaped semi-active control (NFSSC) algorithm [2]. Different from classical semi-active control algorithms, this NFSSC algorithm can be designed without resorting to an active vibration control algorithm superposed by the energy dissipation constraint (called “clipping control”). In addition, the NFSSC algorithm requires neither an accurate damper model nor system identification of damper model parameters. Thus, the NFSSC algorithm can be simply implemented by using fewer sensors.

The NFSSC algorithm will apply a larger current input to the MR seat damper when the dominant frequency of the excitation input is close to the resonant frequency of the MR seat suspension for achieving high damping. But, in frequencies other than the resonant frequency area, a minimized current input will be applied. The desired frequency shaping of the control input can be exactly matched to the frequency response behavior of the dynamics of a single DOF vibration isolation system as follows:

$$\left| \frac{z_{nout}(\omega)}{z(\omega)} \right| = \sqrt{\frac{1 + 4\zeta_{na}^2 \frac{\omega^2}{\omega_{na}^2}}{\left[\left(1 - \frac{\omega^2}{\omega_{na}^2}\right)^2 + 4\zeta_{na}^2 \frac{\omega^2}{\omega_{na}^2} \right]}} \quad (1)$$

Here, ω_{na} and ζ_{na} are the resonant frequency and damping ratio of the single DOF vibration isolation system, respectively. Also, z_{nout} is the output displacement of the single DOF vibration isolation system under the excitation displacement input, z . Note that the resonant frequency, ω_{na} of the single DOF vibration isolation system will be intentionally set to be close to the resonant frequency, ω_n of the MR seat suspension. Corresponding governing equation of the single DOF vibration isolation system given in Eq. (1) is obtained as follows:

$$\ddot{z}_{nout}(t) = -\omega_{na}^2 [z_{nout}(t) - z(t)] - 2\zeta_{na} \omega_{na} [\dot{z}_{nout}(t) - \dot{z}(t)] \quad (2)$$

The output displacement, z_{nout} , will increase around the resonant frequency, ω_n of the MR seat suspension. If the control current input is determined to be proportional to the amplitude given in Eq. (1), a larger current input will be obtained only in narrow-band frequency range where it corresponds to the resonant frequency area of the single DOF vibration isolation system given in Eq. (1). Finally, the control current input of the NFSSC algorithm is

$$i = \begin{cases} k_n \left| \frac{\ddot{z}_{nout}(t)}{\ddot{z}(t)} \right| & \text{if } i \leq i_{\max} \\ i_{\max} & \text{if } i > i_{\max} \end{cases} \quad (3)$$

Here, k_n is the control gain of the NFSSC algorithm. Note that the control current input given in Eq. (3) can be also implemented by using the ratio of the output displacement to the excitation displacement input. But, in this study, the acceleration was used in Eq. (3) because the acceleration could be measured more easily than the displacements for this MR seat suspension application.

To calculate the control input given in Eq. (3) in real-time, we need to solve Eq. (2) in real-time. For a simple implementation, Eq. (3) was discretized using the Euler method as follows:

$$\begin{aligned} z_{nout}(n) = & [2 - 2\zeta_{na} \omega_{na} h] z_{nout}(n-1) + [-1 - \omega_{na}^2 h^2 + 2\zeta_{na} \omega_{na} h] z_{nout}(n-2) \\ & + 2\zeta_{na} \omega_{na} h z(n-1) + [\omega_{na}^2 h^2 - 2\zeta_{na} \omega_{na} h] z(n-2) \end{aligned} \quad (4)$$

Here, n is the sampling number and h is the time step of the calculation. In this study, the time step was chosen to be $h=0.5$ ms. Using Eq. (4), the final control current input, $i(n)$ of the NFSSC is given by

$$i(n) = \begin{cases} k_n \left| \frac{z_{nout}(n) - 2z_{nout}(n-1) + z_{nout}(n-2)}{z(n) + \alpha} \right| & \text{if } i \leq i_{\max} \\ i_{\max} & \text{if } i > i_{\max} \end{cases} \quad (5)$$

Here, α is a constant used to prevent the denominator of Eq. (5) from becoming zero when $z(n)$ is zero.

3.3 Experimental testing results

Figure 5 presents the transmissibility of the 1/3rd scale-down MR seat suspension for the axial direction. In this case, the sinusoidal excitation input was swept from 1 to 30 Hz with the constant acceleration levels of ± 0.05 g and ± 0.1 g. Note that these vibration acceleration levels were chosen because these acceleration input values are practically available for seat suspensions in military propeller aircraft [3]. The maximum control current input was limited to 2 A by the consideration of the current output capability of the in-house controller box because three MR seat dampers will be used for a full-scale MR seat suspension and they should be activated by one controller box (maximum current output capability was 6 A). In order to improve the vibration isolation performance in the high frequency range, the measured acceleration input fed into Eq. (5) was filtered by a low-pass filter with the cutoff frequency of 15 Hz, and then, the current input below 0.3 A was made to be zero. In this figure, the thin solid line stands for no control case (i.e., 0 A case) and the thick solid line implies the results controlled by the NFSSC algorithm. The MR seat damper using the NFSSC algorithm can effectively reduce the vibration of the MR seat suspension under

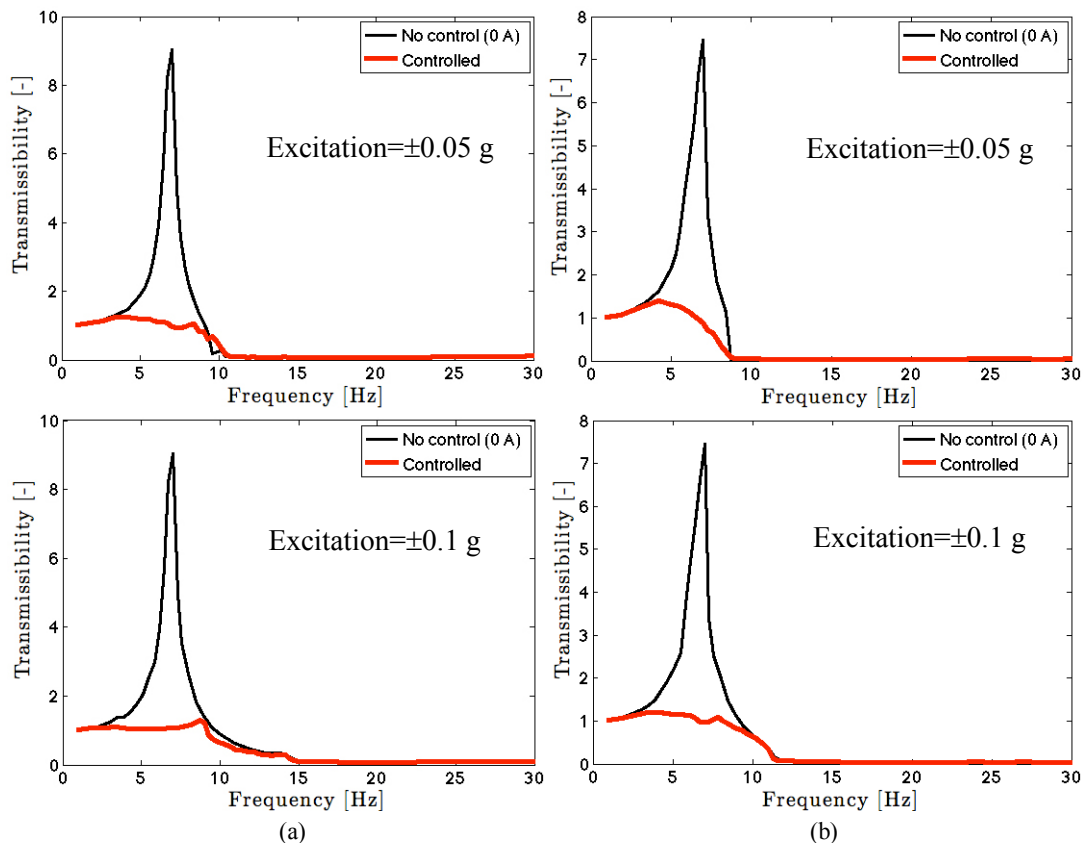

Figure 5: Transmissibility of the 1/3rd scale-down MR seat suspension for the axial direction. (a) 95 lbs of the mass. (b) 65 lbs of the mass.

practical excitation vibration input levels. In addition, for the variations of the masses and the excitation input levels, the MR seat damper under the NFSSC algorithm can still show good seat vibration suppress performances.

4 FULL-SCALE SEAT SUSPENSION USING MULTI-AXIS MR SEAT DAMPERS

Figure 6 presents the experimental testing configuration of a full-scale MR seat suspension. The seat base was rigidly attached to the floor. The dummy was installed upon the top part of the seat, and was tightly fasten by the seat belt to minimize unwanted dynamic impacts between the dummy and the seat. The seat pad (i.e., the cushion on the seat pan) was placed between the dummy and the seat pan to emulate practical seat condition. In this case, 50th percentile male dummy was chosen and its total mass including the backpack and the top part of the seat was 215 lbs. Three MR seat dampers were configured below the seat pan. These three MR seat dampers were electronically connected to the single controller box in serial. The seat can accommodate three (X, Y, Z axes) translational motions. Here, X-axis (i.e., fore-and-aft direction) is set by the normal direction to the face of the dummy pointing outward.

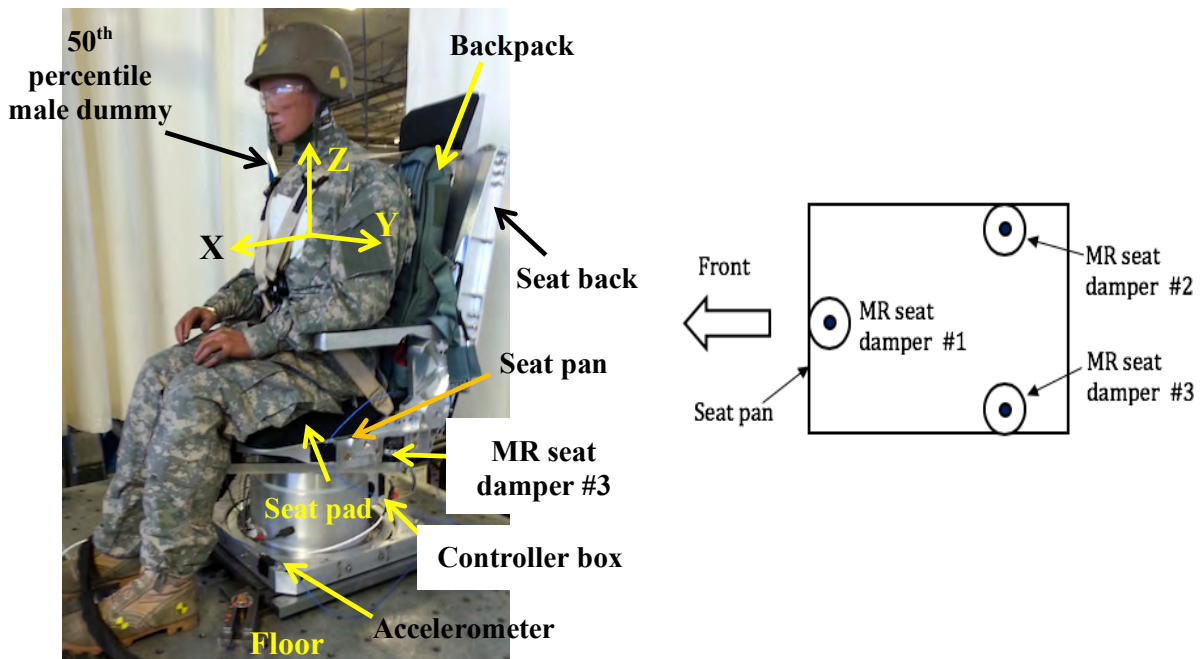

Figure. 6: Experimental testing configuration of a full-scale MR seat suspension on the hydraulic multi-axis simulation table (MAST).

Here, the Y-axis is the lateral direction and Z-axis is the vertical direction. For three-axis acceleration measurements, three-axis accelerometers were mounted on the floor, the seat pan, the seat pad, and the seat back. Note that these acceleration measurements were used only for the vibration isolation evaluation purpose, not for the vibration control purpose. For vibration isolation testing, the MR seat suspension was mounted on a hydraulic MAST and the floor was vibrated in three-axis direction either individually or simultaneously. In this study, two different excitation inputs were used: first is the sinusoidal input with a constant

acceleration level of ± 0.1 g and second is representative seat transient input. The controller box was installed at the backside of the seat base and determined a control current input based on the three-axis excitation inputs measured by its own three-axis accelerometer.

The control current inputs (i_x , i_y , and i_z) in each direction are given as follows:

$$i_d(n) = \begin{cases} k_{n,d} \left| \frac{y_{out,d}(n) - 2y_{out,d}(n-1) + y_{out,d}(n-2)}{y_d(n) + \alpha_d} \right| & \text{if } i_d \leq i_{max} \\ 0 & \text{if } i_d \leq 0.3A \\ i_{max} & \text{if } i_d \leq i_{max} \end{cases} \quad (6)$$

Here, the subscript, d is the indication of the axis direction like $d = x, y$ and z . Finally, the control input of the NFSSC algorithm for the vibration control of the three-axis full-scale MR seat suspension was given as follows:

$$i(n) = i_x(n) + i_y(n) + i_z(n) \quad (7)$$

4.1 Testing results under sinusoidal excitation input

Figure 7 presents three-axis transmissibility at the seat pan of the full-scale MR seat suspension under the NFSSC algorithm for each directional excitation input. In this figure, the solid line stands for the controlled MR damper case and the dashed line stands for rigid damper case. Note that, in the rigid damper case, three MR seat dampers were replaced by three rigid aluminum blocks. In this study, the rigid damper case was used as baseline performance because such rigid structured seat suspension with a seat pad has been used in military propeller aircraft. On the other hand, the subscript of “ o ” implies the output and the subscript of “ i ” implies the excitation input. In this testing, single excitation acceleration input for three-axis direction was individually applied to the full-scale MR seat suspension and the transmissibility was determined by using the input and output accelerations. Even though the excitation input was a single harmonic, the output is a three-axis acceleration. Thus, different from the SDOF testing case shown in Fig. 5, a total of nine different transmissibilities were obtained for the full-scale testing case. As seen in Fig. 7, when the excitation input’s direction is the same as the output accelerations’ direction (for example, $|\ddot{x}_o / \ddot{x}_i|$, $|\ddot{y}_o / \ddot{y}_i|$, and $|\ddot{z}_o / \ddot{z}_i|$), the transmissibility values at lower frequency range (i.e., below 20 Hz) become relatively larger. On the other hand, the rigid damper case shows low transmissibility value in lower frequency range, but much higher transmissibility values in higher frequency range (i.e., after 30 Hz). Such high transmissibility (greater than 1) in higher frequency range may come from high frequency resonant modes of the dummy and the seat. The controlled MR seat damper shows fairly low transmissibility value at relative lower frequency range that is close to the performance of the rigid damper case. In addition, in higher frequency range, the controlled MR seat damper achieved significant vibration isolation performance compared to the rigid damper case. Such a good vibration isolation performance of the full-scale MR seat suspension implies that the NFSSC algorithm could provide high damping (i.e., high current input) at only the low frequency resonant frequency area of the seat suspension as explained earlier.

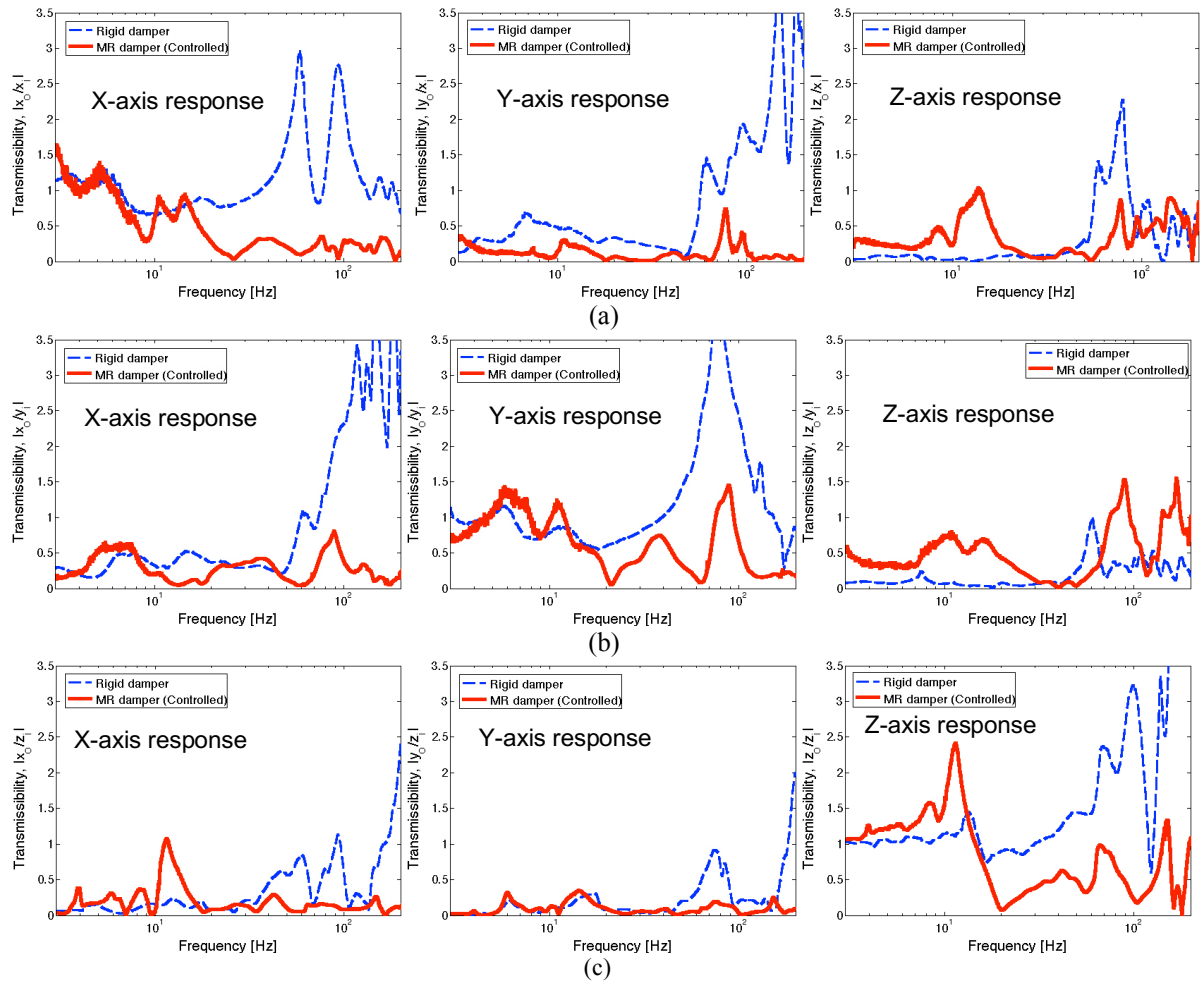

Figure 7: Three-axis transmissibility at the seat pan of the full-scale MR seat suspension under the NFSSC algorithm for each directional excitation input (excitation level: ± 0.1 g). (a) for X-axis excitation input. (b) for Y-axis excitation input. (c) for Z-axis excitation input.

For quantitative comparison on the transmissibility, we used the root mean square (RMS) transmissibility, T_{rms} , defined by

$$T_{rms} = \sqrt{\frac{1}{\omega_2 - \omega_1} \int_{\omega_1}^{\omega_2} T(\omega)^2 d\omega} \quad (8)$$

Here, $T(\omega)$ is the transmissibility in the frequency domain, ω_1 is the starting frequency, and ω_2 is the ending frequency. Smaller RMS transmissibility value implies better vibration isolation performance over the calculated frequency range. Figure 8 presents the RMS transmissibility of the full-scale MR seat suspension under the NFSSC algorithm for each directional excitation input. In the figure, the circle symbol stands for the rigid damper case and the rectangle symbol stands for the controlled MR seat damper case. In addition, the direction of “yx” in this figure implies Y-axis output to X-axis excitation input. The same notational rule can be applied to the other directional symbols like “zx”, “xy”, and “yz”, etc.

In this case, we divided the frequency domain into two regions: one is the relatively low frequency range of 3-20 Hz and the other is the higher frequency range of 20-200 Hz. As seen in this figure, for the relatively low frequency range, the controlled MR seat damper case shows good vibration isolation performance at the seat pan almost similar to the rigid damper case. Similar vibration isolation performance was also observed at the positions of the seat pad and the seat back. But, for the higher frequency range, the controlled MR seat damper case shows much better vibration isolation performance than the rigid damper case for most of different directional inputs. On the other hand, at the positions of the seat pan and the seat pad, the largest RMS transmissibility occurs in the direction of “zz”. But, at the position of the seat back, the largest RMS transmissibility occurs in the direction of “xx”. The reason is that the X-axis output at the seat back contains the front-and-back rocking motion also. Another interesting observation is that the seat pad could not effectively reduce the relatively low frequency dominant vibrations, but showed a little bit improved vibration isolation performance for the high frequency dominant vibrations. In addition, for the controlled MR seat damper case, the effect of the seat pad on the vibration suppression performance is insignificant.

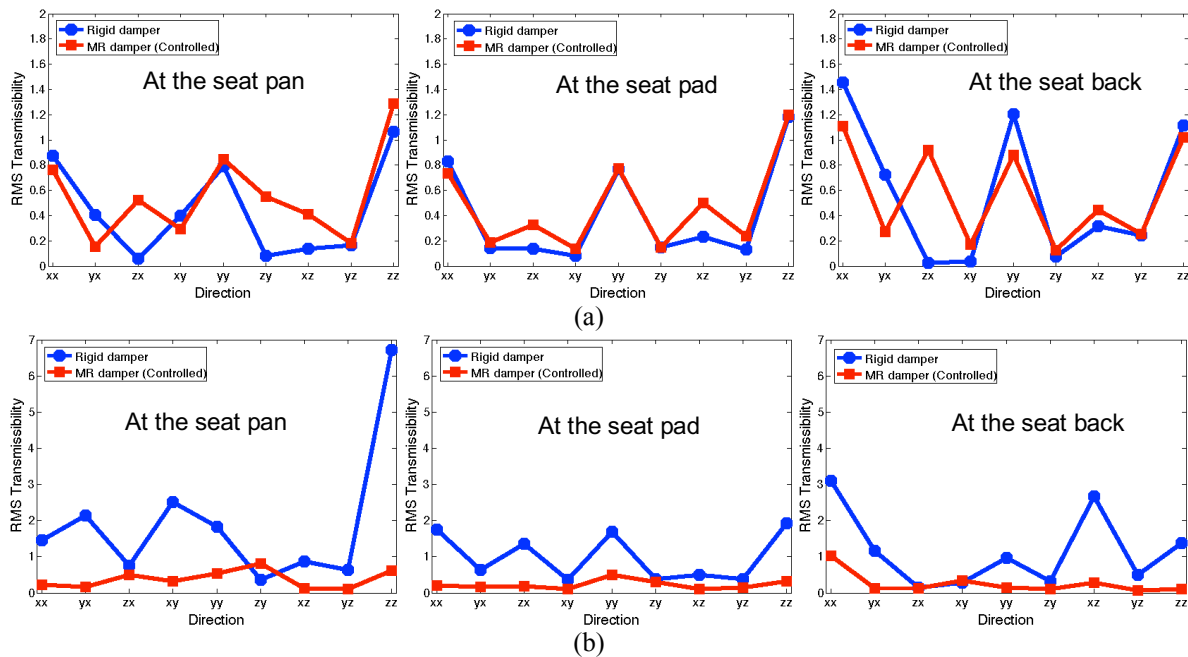

Figure 8: RMS transmissibility of the full-scale MR seat suspension under the NFSSC algorithm for each directional excitation input. (a) for the relative low frequency range (3-20 Hz). (b) for the higher frequency range (20-200 Hz).

4.2 Testing results representative seat transient inputs

Figure 9 presents the measured time responses at the seat pan of the full-scale MR seat suspension under the NFSSC algorithm for each directional representative transient excitation input [3]. In this figure, the dashed line stands for the rigid damper case and the solid line stands for the controlled MR seat damper case. As seen in this figure, X-axis excitation input case shows most severe transient acceleration outputs than other axes excitation input cases.

In addition, for X-axis transient input case, Z-axis acceleration output is larger than X-axis acceleration output. As seen in this figure, the controlled MR seat damper case shows much better vibration isolation performance than the rigid damper case for each directional representative transient input.

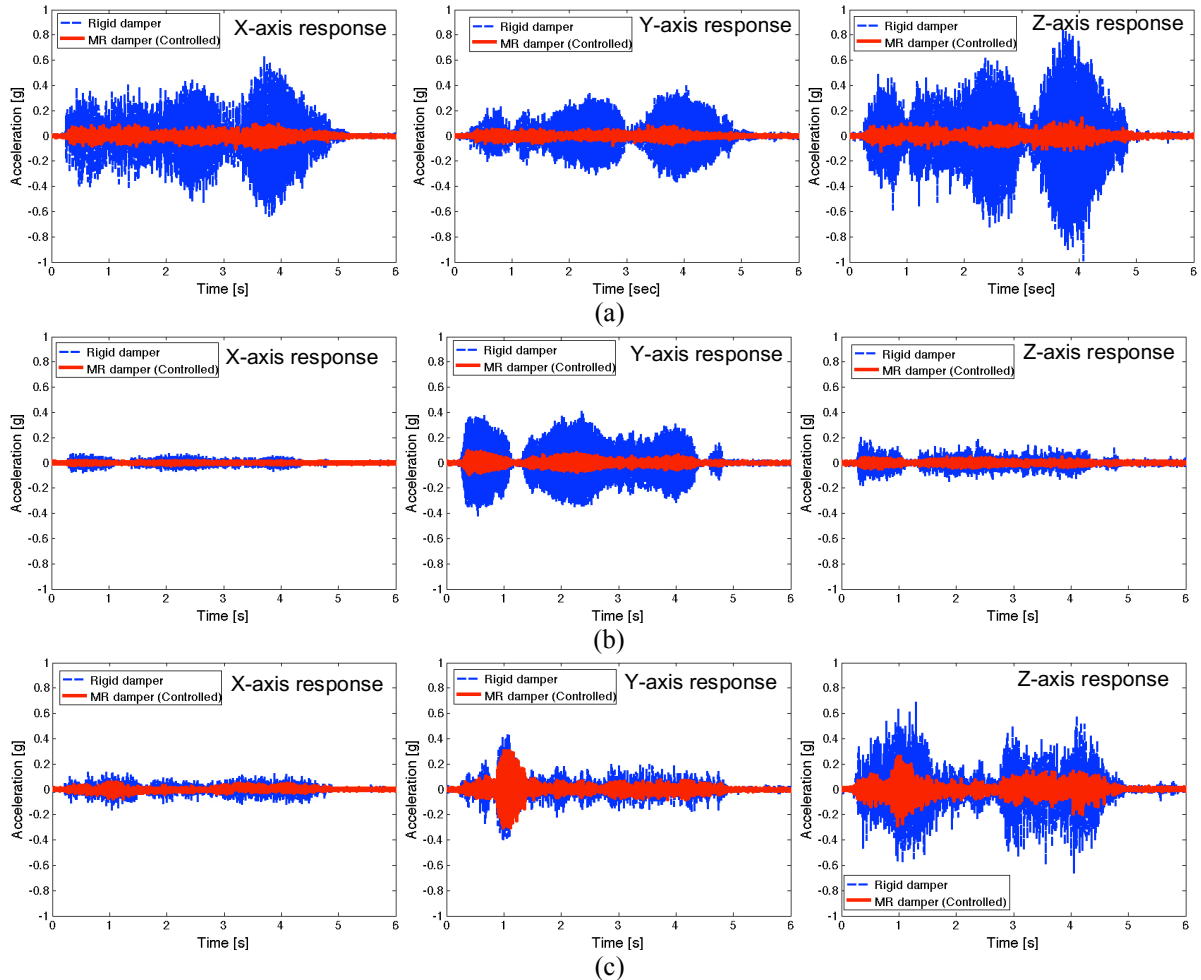

Figure 9: Measured time responses at the seat pan for the full-scale MR seat suspension under the NFSSC algorithm for each directional representative transient excitation input. (a) for X-axis excitation input. (b) for Y-axis excitation input. (c) for Z-axis excitation input.

Figure 10 presents the RMS accelerations of the full-scale MR seat suspension under the NFSSC algorithm. In Fig. 10a, the directional symbols like “xx”, “yx”, and “zx”, etc can be interpreted similar to the symbols in Fig. 8. As seen in Fig. 10a, the controlled MR seat damper case shows good vibration isolation performance at all measured positions for each directional excitation input. For observing the vibration isolation performance under simultaneous three-axis (i.e., X-, Y-, and Z-axis) excitation inputs, Fig. 10b was presented. Because of simultaneous three-axis excitation inputs, the output RMS acceleration levels in Fig. 10b were increased than the individual input case shown in Fig. 10a. But, for the controlled MR seat damper case, the increment of the RMS acceleration levels is much less than the rigid damper case. As observed in Fig. 10b, the controlled MR damper case still

showed good vibration isolation performance at the seat pan, seat pad, and seat back for simultaneous three-axis excitation inputs.

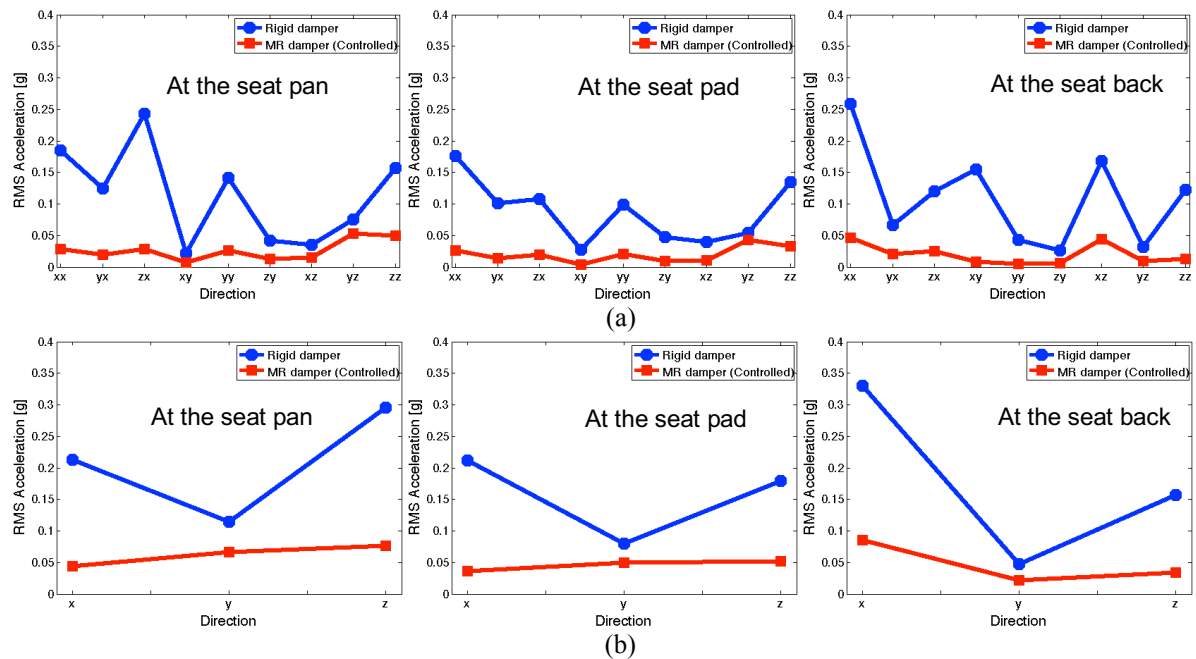

Figure 10: RMS accelerations of the full-scale MR seat suspension under the NFSSC algorithm. (a) for each directional transient excitation input. (b) for simultaneous three-axis transient excitation inputs.

5 CONCLUSIONS

In this study, the multi-axis vibration isolation performance of a full-scale magnetorheological (MR) seat suspension under a narrow-band frequency domain semi-active (NFSSC) algorithm was experimentally investigated for both individual (in this case, excitation input was swept over wider frequency range up to 200 Hz) and simultaneous three-axis directional inputs. From the results presented in this study, it was experimentally confirmed that the NFSSC algorithm could effectively suppress the multi-axis seat vibrations by using fewer sensors.

Abstract. Magnetorheological (MR) fluids are composed of magnetizable particles, usually carbonyl iron particles (CIPs), suspended in a carrier fluid and change their viscosity with the application of a magnetic field. In the current study we investigate the effect of mesocarbon microbeads (MCMBs) with graphitization as an alternative particle substitute to increase the yield force of MR fluids. The MCMBs are defined as passive in response to a magnetic field when compared to the CIPs. This study presents the results of three different MR fluid compositions tested in a rheometer and in an MR damper with a 1 Hz sinusoidal displacement input. The yield stresses and yield forces are determined for a sweep of currents using the Bingham plastic model. Finally, the durability of each fluid is tested by cycling the MR damper at 2 Hz for 25,000 cycles.

1 INTRODUCTION

Magnetorheological (MR) fluids have variable viscosity and are composed, in their most basic form, of magnetizable particles, usually carbonyl iron particles (CIPs), suspended in a carrier fluid (e.g. hydrocarbon oil). The viscosity of an MR fluid changes with the introduction of a magnetic field. This is particularly useful for applications in hydraulic devices where a variable yield force is desirable. For example, MR fluids have seen applications in the aerospace [1-2] and biomedical [3] industries.

Although the observed MR effect is primarily due to the CIPs, several research studies have investigated the introduction of other particles to enhance the effect. In particular, several studies have characterized MR fluids employing nonmagnetizable particles [4-7]. An increase in either yield stress or yield force in these MR fluids has been shown in both experimental studies [4-5,7] and simulations [4,6-7]. The majority of studies investigating the effect of nonmagnetizable particles on MR fluids have focused on hollow glass spheres [4-5,7] with one study showing an increase in yield stress at magnetic saturation [4] and another study revealing a doubling of the yield force [5]. However, in the study including endurance testing, the yield force dropped back down to baseline levels as the glass beads were crushed during prolonged damper cycling at higher frequencies [5]. This study employs mesocarbon microbeads (MCMBs) in an effort to achieve yield force enhancement without the observed degradation over thousands of cycles. The MCMBs were chosen as the passive particles, in relation to the CIPs, because they are solid and are thus expected to be more durable than the hollow glass beads used in previous studies.

The increase in yield stress due to the substitution of nonmagnetizable particles in MR fluids has been attributed to a particle jamming-like mechanism [6]. In simulations, repulsive-force clusters form and increase the yield stress when nongmagnetizable particles of the same average diameter as the magnetizable particles are used in an MR fluid. Based on our previous study [5] and the study by Wilson et al. [6], the combination of the MCMBs and CIPs, will result in a fluid synergistically combining the magnetorheological effect and particle jamming.

2 METHODOLOGY

2.1 Fluid Formulation

This study utilizes MIL-PRF-83282D (AeroShell Fluid 31; Shell), a synthetic hydrocarbon hydraulic fluid with a kinematic viscosity of 14.0 mm²/s at 40 °C. MIL-PRF-83282D is commonly used for aircraft applications and is thus a viable carrier fluid with practical applications. A 35 volume percent (vol%) bidisperse mixture of carbonyl iron particles (1:1 ratio of 1.8-2.3 μm average diameter and 7-9.5 μm average diameter; BASF) and the appropriate vol% of MCMBs after graphitization (10-13 μm average diameter; Bonding Chemical) were mixed into the carrier fluid. The fluid compositions tested are listed in Table 1.

Table 1: MR Fluid Compositions

Sample Name	MIL-PRF-83282D, vol%	CIPs, vol%	MCMBs, vol%
MR-Fe35-C0	65	35	0
MR-Fe35-C5	60	35	5
MR-Fe35-C10	55	35	10

2.2 Rheometer Testing

All fluids were tested in an Anton Paar MCR 300 parallel plate rheometer with the shear rate ranging from 0.1 – 1000 Hz. Tests were conducted with the current ranging from 0-5 A.

2.3 Damper Testing

The MR fluids were also tested in flow mode with a LORD RD-8041-1 long stroke MR damper (LORD Corporation). The damper was pressurized to 2000 kPa and tested using a Material Test System (MTS) 810 machine (Figure 1). Each test applied a ± 12.7 mm sinusoidal displacement excitation to the damper's piston which was pre-compressed by 19.05 mm. The resulting force vs. displacement data was obtained for applied currents of 0-1 A with 0.2 A increments.

2.4 Endurance Testing

For one fluid composition, MR-Fe35-C10, the damper was cycled at 2 Hz and data was collected periodically using the procedure in § 2.3.

Figure 1: MR damper mounted on MTS machine

3 RESULTS

The effect of the MCMBs is characterized for Fe particle volume fraction, $\phi_{Fe} = 0.35$, and increasing MCMB volume fraction, ϕ_{MCMB} .

3.1 Rheometer Testing

The field off rheometer tests show an increase in viscosity (μ , defined as the slope of the shear stress, τ , vs. shear rate, $\dot{\gamma}$, curves) with increasing particle content (Figure 2a). The Bingham plastic model for shear stress is fit to the shear stress vs. shear rate data from $\dot{\gamma} = 300 - 1000 \text{ s}^{-1}$ to obtain the yield stress, τ_y :

$$\tau = \tau_y + \mu\dot{\gamma} \quad (1)$$

where τ_y is the intercept with the shear stress axis. Yield stress as a function of current is shown for each fluid in Figure 2b. The result of increasing ϕ_{MCMB} is inconclusive with respect to yield stress.

3.2 Damper Testing

The inconclusive rheometer tests necessitate the MR damper tests, thereby switching from shear mode to flow mode. An example force vs. displacement plot for MR-Fe35-C5 is shown in Figure 3a. This data is replotted as force vs. velocity (Figure 3b) and fitted with the Bingham plastic model to obtain the yield force, f_y :

$$F(t) = f_y \text{sgn}(\dot{x}) + C_{po}\dot{x} \quad (2)$$

where \dot{x} is the velocity, C_{po} is the post-yield damping, and f_y is the intercept with the force axis.

Yield force as a function of current is shown for each fluid in Figure 4. f_y increases as ϕ_{MCMB} increases. The increase is higher when ϕ_{MCMB} is increased from 0.05 to 0.10 than when it is increased from 0 to 0.05, indicating that the MCMBs have a nonlinear effect on the yield force when $\phi_{Fe} = 0.35$.

Figure 2: (a) Shear stress (τ) as a function of shear rate ($\dot{\gamma}$) with the field off for each fluid (b) Yield stress as a function of current for each fluid

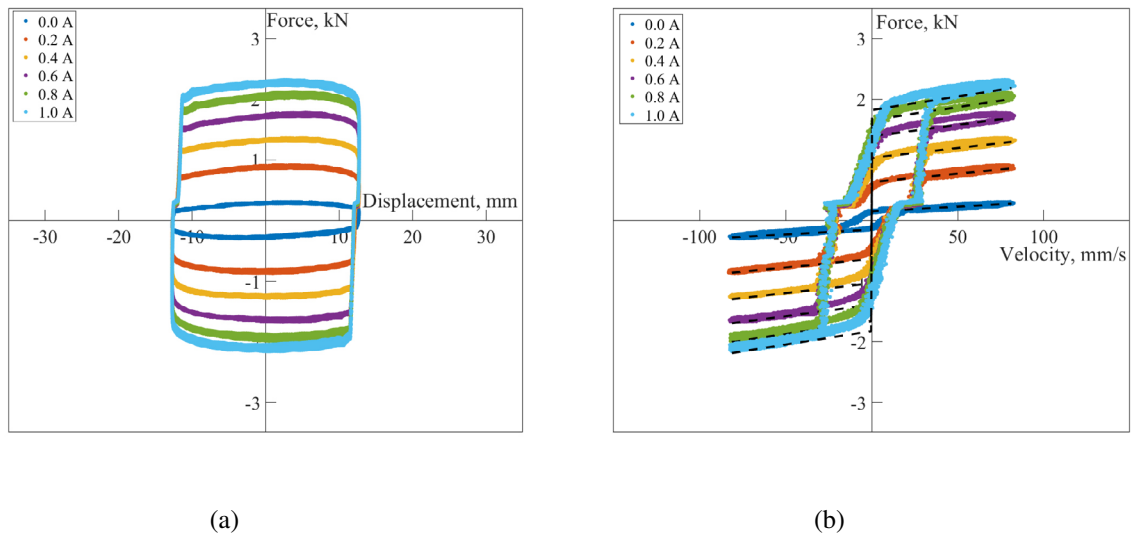

Figure 3: Representative plots of an MR damper filled with MR-Fe35-C5 (a) force vs. displacement data (b) force vs. velocity data fitted with the Bingham plastic model

4 Endurance Testing

The results of the endurance tests are shown in Figure 5. There is no clear reduction in yield force over 25,000 cycles.

Figure 4: Yield force for MR fluids with $\phi_{Fe} = 0.35$ and $\phi_{MCMC} = 0, 0.05$, and 0.10

Figure 5: Endurance testing for Fe-35-C10 over 25,000 cycles

5 DISCUSSION

The field off rheometer tests exhibited darker circles of fluid in the middle of the sample post-testing while the field on tests exhibited darker circles surrounding the spindle plate post-testing. This suggests

a migration of carbon particles, which are darker in color than the Fe particles, due to centripetal acceleration. The migration of the particles off the platen during field on tests potentially contributes to the inconclusiveness of those reported results. However, because MR fluids are generally used in flow mode devices such as dampers and shock absorbers [1-3], it is the damper results that are of the greatest interest. The MR damper was cycled prior to each set of dynamic tests to promote fluid uniformity. The small volume of fluid expelled during the sealing of the damper may have resulted in slightly higher solids loading due to separation of the fluid from the particles near the top of the fluid reservoir. This can lead to a slight increase in the reported MCMB and Fe concentrations. Finally, the simulations run by Wilson et. al were done for magnetic and passive particles of the same average diameter [6], while the average diameter of the MCMBs in this study was slightly larger than that of the iron particles. The particle jamming-like effects observed in this study may thus follow a slightly different trend than those simulated by Wilson et al. [6].

6 CONCLUSIONS

Shear mode tests conducted with the rheometer yielded inconclusive results with respect to increasing carbon particle content in MR fluids with $\phi_{Fe} = 0.35$. However, flow mode tests using an MR damper revealed a nonlinear increase in yield force with increasing ϕ_C . Higher total particle content leads to greater enhancement of the yield force. If this effect is due to the particle jamming-like mechanism described in [6], the results suggest increased total particle content amplifies the effects of the mechanism. Furthermore, the yield force did not decrease over 25,000 cycles at 2 Hz. Future work would include endurance testing of a fluid with MCMBs over a greater number of cycles, to better characterize durability.

Key words: Robocasting, Acoustic energy focusing, Frequency band gaps

Abstract. In this contribution, acoustic phenomena taking place in MHz frequency range in robocast ceramic scaffolds are presented. The acoustic properties of several scaffold geometries were studied both experimentally and numerically. The elastic responses were calculated by finite element method (FEM) where computational unit cells were designed to represent the periodic geometry of the sintered scaffolds. It is shown that tetragonal scaffolds, where the rods in the neighboring layers are perpendicular, focus acoustic energy along the principal directions of the ceramic rods. On the other hands, a hexagonal structure, which has the periodicity of 3 layers with the orientation angle of 60° between the neighboring rods, is in-plane isotropic in the low-frequency limit. The FEM study was also performed up to higher frequencies and it was found there are several frequency band gaps for the longitudinal waves.

1 INTRODUCTION

With the rise of additive manufacturing (AM) methods, various structures with complex geometries can be easily produced [1]. Therefore, the AM methods can be utilized for manufacturing of phononic crystals with periodic arrangements with the dimensions of several millimeters, where such structures can experience frequency band gaps in kHz to MHz ranges [2, 3, 4, 5]. Robocasting is an AM direct-ink writing method for the fabrication of scaffolds consisting of a layered structure of thin ceramic rods [6, 7]. At first, a ceramic powder is mixed with deionized water and organic additives to form a colloidal suspension with highly shear-thinning behavior. This suspension is subsequently extruded through a thin nozzle following a layer-by-layer 3D printing route to produce a ceramic green body. The organic additives are then burnt out, and the scaffolds are consolidated by spark plasma sintering. Usually, each layer consists of mutually parallel thin rods and the neighboring layers are oriented at a different angle. As the rods in the neighboring layers partially intersect and the scaffolds are typically made of tens of layers, the scaffolds have a periodic structure with phononic-crystal behavior [8].

2 MATERIALS AND METHODS

Elastic and acoustic properties of several types of scaffolds were studied by finite element method (FEM) using COMSOL Multiphysics software. These properties are strongly affected by the scaffolds geometry which lead to different types of macroscopic symmetry; in this work, the scaffolds with tetragonal, orthorhombic or hexagonal symmetry are studied.

For the tetragonal scaffolds, the rods of neighboring layers are mutually perpendicular with the constant in-plane spacing between the rods in the same layer, as shown in Figs. 1 and 2. These two tetragonal scaffolds differ mainly in the in-plane spacing of the rods l , which is equal to $650\text{ }\mu\text{m}$ for the LT sample (LT means "*large tetragonal*" due to the larger spacing between the rods) vs. $308\text{ }\mu\text{m}$ for the ST ("*small tetragonal*") sample, while the rods diameters d ($210\text{ }\mu\text{m}$ vs. $218\text{ }\mu\text{m}$) and the out-of-plane spacing h between the layers of the same rods orientation ($275\text{ }\mu\text{m}$ vs. $261\text{ }\mu\text{m}$) are almost identical. Also, due to the much higher in-plane spacing, the LT scaffold occupy relative space of 36.3% with the effective density of $1.212\text{ g}\cdot\text{cm}^{-3}$, and the ST scaffold occupy relative space of 76.5% with the effective density of $2.555\text{ g}\cdot\text{cm}^{-3}$.

In addition, another scaffold with the perpendicular orientation of the rods in the neighboring layers was studied; this scaffold, entitled RO as "*rectangular orthorhombic*", has two different in-plane spacings, $309\text{ }\mu\text{m}$ between the rods oriented in the x_1 axis and $591\text{ }\mu\text{m}$ between the rods in the x_2 direction, as shown in Fig. 3, and thus it exhibits orthorhombic symmetry. The rods have diameters of $238\text{ }\mu\text{m}$ and the out-of-plane spacing is $297\text{ }\mu\text{m}$, which gives an effective density of $2.165\text{ g}\cdot\text{cm}^{-3}$, when occupying a relative space of 64.8% .

Another scaffold with different geometry, named AO as "*angular orthorhombic*", also exhibit orthorhombic symmetry. This scaffold, shown in Fig. 4, consists of rods with diameter of $186\text{ }\mu\text{m}$ and in-plane spacing of $462\text{ }\mu\text{m}$, and the angle between the direction of rods in the neighboring layers is 46° . The scaffold has the periodicity of 2 layers and the out-of-plane spacing between the rods of same orientation is $250\text{ }\mu\text{m}$, with an effective density of $1.458\text{ g}\cdot\text{cm}^{-3}$.

Finally, elastic coefficients of a hexagonal scaffold, shown in Fig. 5, were determined. In this scaffold, the neighboring layers are rotated at 60° angle such that the scaffold geometry is periodical after 3 layers. The out-of-plane spacing between these 3 layers is $385\text{ }\mu\text{m}$, the rods have diameter of $215\text{ }\mu\text{m}$ and the in-plane spacing of the rods is $l = 576\text{ }\mu\text{m}$, where the distance between crossing points along the single rod is $a = 2l/\sqrt{3} = 665\text{ }\mu\text{m}$. Thus, the scaffold occupies the relative space of 44.4% with the effective density of $1.483\text{ g}\cdot\text{cm}^{-3}$.

The geometrical parameters of the additive-manufactured robocast scaffolds were used as templates for designing computational unit cells and the material parameters of SiC were utilized (density of $3.34\text{ g}\cdot\text{cm}^{-3}$, Young's modulus of 305 GPa and Poisson ratio of 0.19). Elastic coefficients C_{ijkl} of the studied scaffolds were obtained by the FEM calculation by applying tensile or shear straining modes. From the calculated elastic tensors C_{ijkl} , distributions of Young's moduli and group velocity were then plotted to illustrate the anisotropic properties of the scaffolds [10, 11]. In this paper, the resulting group velocity data is plotted as discrete points in order to show the acoustic energy focusing in the scaffolds; each point corresponds to the different direction of propagation, where the initial angles are equidistantly distributed within the studied plane. Therefore, when the density of the plotted points is higher in a certain direction, the acoustic energy is focused along such directions.

In addition, longitudinal frequency band gaps of the LT scaffold and the hexagonal scaffold were also obtained by the FEM analysis. The computational unit cells were utilized to calculate dispersion curves along the principal directions of the rods by Bloch wave solution, as described in [8]. The resulting

eigenmodes were then analyzed in order to find out at which frequency ranges there is no eigenmode with dominant longitudinal displacements, which thus correspond to longitudinal frequency band gaps.

3 RESULTS AND DISCUSSION

The elastic coefficients of the LT scaffold calculated by the FEM are:

$$c_{ij(LT)} = \begin{pmatrix} 63.62 & 3.01 & 5.15 & 0 & 0 & 0 \\ 3.01 & 63.62 & 5.15 & 0 & 0 & 0 \\ 5.15 & 5.15 & 33.58 & 0 & 0 & 0 \\ 0 & 0 & 0 & 5.78 & 0 & 0 \\ 0 & 0 & 0 & 0 & 5.78 & 0 \\ 0 & 0 & 0 & 0 & 0 & 2.64 \end{pmatrix} \text{ GPa.} \quad (1)$$

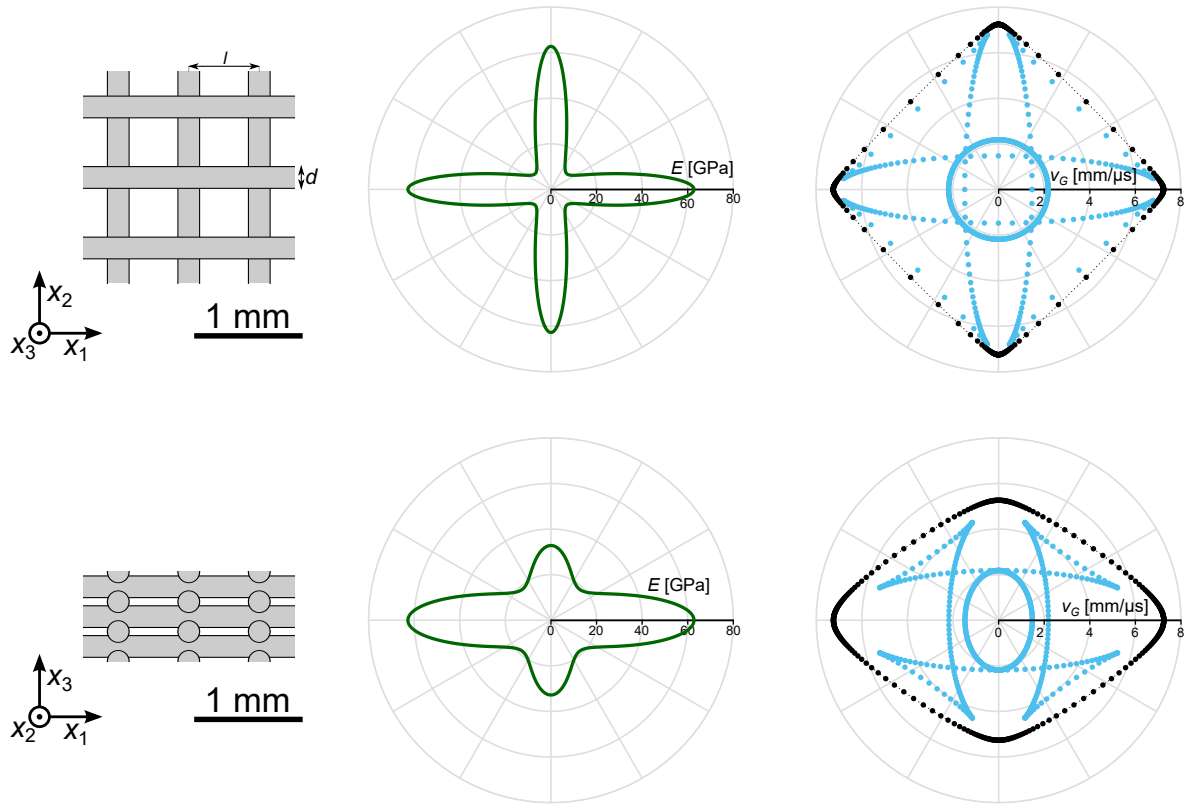

Figure 1: Young's modulus E and group velocity v_G distributions in the principal planes of the LT scaffold

The elastic coefficients of the LT scaffold suggest that this scaffold is strongly anisotropic, which is also clearly evident in the Young's modulus plots in Fig. 1. In the x_1x_2 plane, the Young's modulus in the direction of the rods is $E_1 = E_2 = 62.75$ GPa, while the minimum value in the direction between the rods is $E_{min,45^\circ} = 9.77$ GPa, i.e. more than 6 times lower than the maximum $E_1 = E_2$ value. This anisotropy is given by the scaffold geometry, as the perpendicular rods of neighboring layers intersect in very low overall area compared to the dimensions of the scaffolds. Therefore, the elastic coefficients of

c_{12} and c_{66} corresponding to the shearing modes in the x_1x_2 plane are significantly lower than the other c_{ij} coefficients, which results in the highly anisotropic Young's moduli distribution given in Fig. 1.

This anisotropy, given by the LT scaffold geometry, has also a strong effect on the group velocity properties, as shown in the right-hand section of Fig. 1. For the quasi-longitudinal waves (outer black-colored points in the group velocity plots) in the LT scaffold, the maximum value of $v_{G1} = v_{G2} = 7245 \text{ m}\cdot\text{s}^{-1}$ correspond to the wave propagation in the direction of the rods in the scaffold structure, and the minimum value in the x_1x_2 plane, $v_{G,min,45^\circ} = 5445 \text{ m}\cdot\text{s}^{-1}$, lies in the diagonal direction between the rods, similarly to the Young's modulus distribution in this plane. Moreover, the $v_{G,min,45^\circ}$ value is only slightly higher than the $v_{G1}/\sqrt{2}$ value ($5123 \text{ m}\cdot\text{s}^{-1}$) which suggests that the quasi-longitudinal waves propagates almost independently in the perpendicular ceramic rods. As a result, the acoustic energy of quasi-longitudinal waves propagating through the scaffold becomes strongly focused along the principal direction of the rods in the scaffold structure. Similar behavior of the acoustic focusing along the rods is also observed for one the quasi-transverse waves (blue-colored in the group velocity plot) with the polarization within the x_1x_2 , while the other quasi-transverse waves with the polarization vector lying close to the x_3 propagate with much smaller, but directionally independent velocity.

Figure 2: Young's modulus E and group velocity v_G distributions in the x_1x_2 plane of the ST scaffold

The elastic coefficients of the ST scaffold are:

$$c_{ij(ST)} = \begin{pmatrix} 173.56 & 23.80 & 32.43 & 0 & 0 & 0 \\ 23.80 & 173.56 & 32.43 & 0 & 0 & 0 \\ 32.43 & 32.43 & 181.65 & 0 & 0 & 0 \\ 0 & 0 & 0 & 57.94 & 0 & 0 \\ 0 & 0 & 0 & 0 & 57.94 & 0 \\ 0 & 0 & 0 & 0 & 0 & 37.99 \end{pmatrix} \text{ GPa}, \quad (2)$$

and the Young's modulus and group velocity distribution in the x_1x_2 plane are given in Fig. 2. This scaffold also exhibit elastic and acoustic anisotropy; nevertheless, due to much higher in-plane spacing between the rods and thus much higher relative density, the elastic anisotropy is significantly weaker than for the LT scaffold. The maximum values of the Young's modulus in the x_1x_2 plane are $E_1 = E_2 = 165.83 \text{ GPa}$, while the minimum value lies in the diagonal direction $E_{min,45^\circ} = 107.85 \text{ GPa}$. Similarly, the maximum value of the group velocity in the x_1x_2 plane is $v_{G1} = v_{G2} = 8242 \text{ m}\cdot\text{s}^{-1}$ and the minimum value is $v_{G,min,45^\circ} = 7314 \text{ m}\cdot\text{s}^{-1}$, which is much lower difference than for the LT scaffold.

The results for the tetragonal LT and ST scaffolds show that only by changing the scaffold geometry, the level of elastic anisotropy and the acoustic energy focusing can be significantly changed. In these

tetragonal scaffolds, the direction x_1 and x_2 are macroscopically equivalent as the in-plane spacing are the same through the whole scaffold, unlike for the RO scaffold, which has two different in-plane spacings in the x_1 vs. x_2 direction. The obtained elastic coefficients for this RO scaffold are:

$$c_{ij(RO)} = \begin{pmatrix} 163.78 & 11.84 & 17.86 & 0 & 0 & 0 \\ 11.84 & 93.63 & 17.69 & 0 & 0 & 0 \\ 17.86 & 17.69 & 105.87 & 0 & 0 & 0 \\ 0 & 0 & 0 & 33.56 & 0 & 0 \\ 0 & 0 & 0 & 0 & 23.26 & 0 \\ 0 & 0 & 0 & 0 & 0 & 15.43 \end{pmatrix} \text{ GPa.} \quad (3)$$

As expected, the highest Young's modulus and group velocity values, $E_1 = 159.90$ GPa and $v_{G1} = 8698 \text{ m}\cdot\text{s}^{-1}$, lie along the direction of more dense rods arrangement in the x_1 direction when compared to the x_2 direction, $E_2 = 90.19$ GPa and $v_{G2} = 6576 \text{ m}\cdot\text{s}^{-1}$. The minimum value of the Young's modulus in the x_1x_2 plane, $E_{min,48^\circ} = 49.19$ GPa, lies in the direction with 48° angle to the x_1 axis, i.e. slightly closer to the direction of less dense arrangement of the rods.

Figure 3: Young's modulus E and group velocity v_G distributions in the x_1x_2 plane of the RO scaffold

The elastic coefficients of the AO scaffold are:

$$c_{ij(AO)} = \begin{pmatrix} 107.12 & 40.22 & 10.30 & 0 & 0 & 0 \\ 40.22 & 51.07 & 24.84 & 0 & 0 & 0 \\ 10.30 & 24.84 & 49.68 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2.93 & 0 & 0 \\ 0 & 0 & 0 & 0 & 14.77 & 0 \\ 0 & 0 & 0 & 0 & 0 & 22.42 \end{pmatrix} \text{ GPa.} \quad (4)$$

As shown in Fig. 4, the axes of x_1 and x_2 are chosen such that they intersect the angles between the rods in halves and thus they correspond to the symmetry axes within the x_1x_2 plane. The minimum value of the Young's modulus in this plane is $E_2 = 26.93$ GPa, and the maximum value $E_{max,21^\circ} = 75.70$ GPa lies close to the direction of the rods and it is slightly higher than the Young's modulus in the x_1 direction, $E_1 = 73.17$ GPa. For the group velocity, the minimum value in the x_1x_2 plane lies along the x_2 axis, $v_{G2} = 5918 \text{ m}\cdot\text{s}^{-1}$, while the maximum value lies along the x_1 axis, $v_{G1} = 8572 \text{ m}\cdot\text{s}^{-1}$. Moreover, in Fig. 4, it can be clearly seen that the density of the plotted group velocity data is much higher near the x_1 direction than near the x_2 direction, suggesting that in this type of scaffold geometry, the acoustic energy

Figure 4: Young's modulus E and group velocity v_G distributions in the x_1x_2 plane of the AO scaffold

is focused not only along the rods but also along the directions which lie between the lower angle of 46° between the rods when compared to the perpendicular x_2 axis.

For the hexagonal scaffold, the computed elastic coefficients are:

$$c_{ij} = \begin{pmatrix} 66.05 & 19.45 & 8.80 & 0 & 0 & 0 \\ 12.96 & 66.05 & 8.80 & 0 & 0 & 0 \\ 8.80 & 8.80 & 44.32 & 0 & 0 & 0 \\ 0 & 0 & 0 & 9.30 & 0 & 0 \\ 0 & 0 & 0 & 0 & 9.30 & 0 \\ 0 & 0 & 0 & 0 & 0 & 23.30 \end{pmatrix} \text{ GPa.} \quad (5)$$

Figure 5: Young's modulus E and group velocity v_G distributions in the x_1x_2 plane of the LH scaffold

As this scaffold exhibit hexagonal symmetry, all the directions within the x_1x_2 plane are macroscopically equivalent and thus, Young's modulus of $E_1 = E_2 = 59.43$ GPa, and group velocities of qL waves, $v_{G1} = v_{G2} = 6674 \text{ m}\cdot\text{s}^{-1}$, and also qT waves are constant in this plane, as shown in Fig. 5. Nevertheless, all these calculations correspond to the quasi-static loading of tensile/shear straining modes, but when the dynamic loading is assumed, where the frequency of the acoustic waves is such high that the wavelengths become comparable to the in-plane spacing between the rods in one layer, acoustic energy can be focused along the principal directions of the rods even in the hexagonal scaffolds [9].

Figure 6: Calculated longitudinal band gaps (shaded areas) of tetragonal and hexagonal scaffolds up to 12 MHz, where the thick lines correspond to dispersion curves with dominant longitudinal displacements. The arrow above the 3rd band gap for the LT scaffold denotes that this band gap also continues up to higher frequencies.

The calculated longitudinal frequency band gaps up to 12 MHz for the LT scaffold and for the hexagonal scaffold are shown in Fig. 6, where the thick lines correspond to dispersion curves with dominant longitudinal displacement component. For the LT scaffold, there are three distinct dispersion curves with longitudinal character, which lead to frequency band gaps at ~ 3.2 – 4.5 MHz, ~ 6.9 – 7.8 MHz and another band gap beginning at ~ 11.6 MHz which continues up to higher frequencies above 12 MHz. For the hexagonal scaffold, there are two band gaps at ~ 3.8 – 5.4 MHz and ~ 6.2 – 7.8 MHz. Above 7.8 MHz, there are few dispersion curves which do not have strictly longitudinal or shear character, and thus some acoustic energy at these frequencies can be absorbed while another fraction of acoustic energy can still be transferred through the hexagonal scaffold when the longitudinal waves propagate along the direction of the rods.

Moreover, as the dispersion curves in Fig. 6 are linear in the low-frequency limit for both scaffolds, corresponding phase and group velocities are equal when the wavelengths are significantly higher than the in-plane spacings between the rods, i.e. when the wave number k is close to zero. Also, in Fig. 6, it can be seen that the velocity of qL waves in the LT scaffold is much higher than the velocities of qT waves, which is consistent with the group velocity values along the x_1 axis shown in Fig. 1. Similarly for the hexagonal scaffolds, dispersion curves for the qT waves have different slopes near $k = 0$ which correspond to different velocities for the qT waves, as shown in Fig. 5.

4 CONCLUSIONS

Elastic and acoustic properties of several types of scaffold structures were studied by FEM analysis. It is shown that these scaffolds can be strongly anisotropic depending on their geometry. For the scaffolds of perpendicular orientation of the rods in the neighboring layers, Young's moduli are higher in the principal direction along the rods than in the direction between the rods, which results in acoustic energy focusing along the rods directions. The level of elastic anisotropy and the acoustic energy focusing also depends on the in-plane spacings between the rods in each layer; the scaffolds with higher in-plane spacing have generally lower Young's moduli, but also the acoustic energy is much strongly focused along the rods in such structures. On the other hand, the scaffold with macroscopic hexagonal symmetry is in-plane isotropic at least in the low-frequency limit. The FEM analysis was also utilized for the determining longitudinal frequency band gaps. It is shown that one of the tetragonal scaffolds and the hexagonal scaffolds both experience several frequency band gaps with the first longitudinal band gap at ~ 4 MHz.

Key words: Vibration Energy Harvesting, Piezoelectric Materials, Finite Element Method

Abstract. In the last few years, piezoelectric materials have been widely used for vibration energy harvesting due to its efficiency for converting mechanical energy into electrical one. In the literature, various approaches have been devoted for modeling the piezoelectric harvesters in order to predict its electromechanical coupling responses. In this paper, we present a finite element modeling of a bimorph piezoelectric harvester as typical cantilever beam which is composed of an elastic substrate covered by two piezoceramic layers. The generated electricity is due to the vibration of the host structure. The main purpose of this work is to develop a reduced order model able to predict the responses of the harvester and to improve simulation efficiency with a low computation cost. In order to reach this goal, the electromechanical problem is projected on a truncated eigenvectors basis with short-circuited boundary conditions. Furthermore, a numerical example of a bimorph harvester as case study is presented and analyzed. Through this example, the effect of the basis truncation on the electromechanical outputs is discussed in term of computation error and time. Results show that for an optimal truncated basis, the reduced order model gives good results in comparison to the direct methods with lower cost of calculation.

1 INTRODUCTION

Piezoelectric has received a considerable attention for vibration energy scavenging over the last years. This material has been extensively used in vast engineering areas due to its specific characteristics. In fact, piezoelectric material enables the transformation of mechanical strain into electricity and vice-versa. These two conversion ways allow direct connection to electronic components and yield well to two applications: (1) the sensing using the direct effect piezoelectric (e.g. vibration energy harvesting) and (2) the actuating using the inverse effect piezoelectric (e.g. structural vibration reduction). This work focus on the energy harvesting using piezoelectric elements attached to an elastic structure and excited by the base motion.

Recently, various techniques have been appeared in the literature to investigate the electromechanical coupling of a composite cantilevered beam with piezoelectric elements, which is used often as a vibration energy harvester. An analytical solution based on a single degree of freedom model, considers that the composite cantilever beam is similar to a mass-spring-damper system. In this approach, the piezoelectric composite beam is modeled by a second order differential equation of the tip displacement of the harvester as variable [1]. Lately, Erturk and Inman [1, 2, 3] introduced an analytical distributed parameter solutions for bimorph and unimorph piezoelectric energy harvesters with closed-form expressions and showed that for sinusoidal base excitation, the model might yield highly agreement with physical experiments. Whereas, several studies used the finite element method as an alternative sophisticated technique to solve approximately the most complicated electromechanical problem. Bendary [4] developed a finite element model for sensors and actuators based on the classical laminate theory. Results show that as expected for thin plates, the classical theory gives acceptable accuracy with minimal computational effort. De Marqui [5] investigated an electromechanical coupled finite element plate to estimate the electrical output responses of unimorph and bimorph piezoelectric plate harvester devices. This model was derived based on the classic Kirchhoff plate theory, which neglects shear deformation. Amini [6] presented a finite element modeling for functionally graded piezoelectric harvesters based-on the Euler Bernoulli beam theory. The model is validated by comparison to the analytical solution of a similar bimorph piezoelectric energy harvester.

Reduced order modeling of mechatronic systems has become an interesting issue for improving simulation efficiency. For instance, many optimization algorithms require a high number of model evaluations which cause a high computational cost, hence the necessity for such reduced order model. In recent published research, H.-J. Xiang [7] introduced a reduced order model of piezoelectric energy harvesters using a Krylov subspace-based scheme. An implementation of this model with nonlinear energy harvesting circuits is made in a system level. This approach is validated with various harmonic response and transient response analysis. M. Kudryavtsev et al. [8] introduced a novel reduced order model techniques for a large-scale multiport model of a micro electromechanical system based piezoelectric energy harvester. Results show an excellent concordance between the full-scale and the reduced order models of the harvester for harmonic simulation.

This paper proposed an efficient finite element reduced order model of piezoelectric energy harvester able to predict its electrical outputs recovered in an efficient way. A bimorph cantilever beam is chosen as an energy harvester case study due to its widespread usage. A gait is proposed to determinate the reduced order model: (1) an electromechanical finite element formulation for the dynamic analysis of a general piezoelectric structure is first proposed, (2) the development of an appropriate reduced order model of the coupled electromechanical problem is then presented. The proposed methodology based on a normal mode expansion which requires the computation of the eigenmodes of the structure in short circuit condition. Despite its reduced size, this model is proven to be very efficient for simulations of harmonic vibration analyses of the harvester. In the last part of this research, a numerical example of a piezoelectric bimorph cantilever beam, is presented and analyzed.

2 FINITE ELEMENT REDUCED ORDER MODEL OF ELECTROMECHANICAL PROBLEM

The finite element formulation of elastic structure with piezoelectric elements proposed in [9, 10] is used. This formulation uses a standard discretization of the mechanical degrees of freedom and provides less restrictive assumptions for the electrical state which is fully described by very few global discrete unknowns: (i) the electric charge contained in the electrodes and (ii) the voltage between the electrodes. It is well adapted to practical applications since realistic electrical boundary conditions, such that equipotentiality on the electrodes and prescribed global electric charges, naturally appear [12]. Therefore, the governing undamped electromechanical problem of piezoelectric structure is thus obtained:

$$\mathbf{M}_m \ddot{\mathbf{U}}(t) + \mathbf{K}_m \mathbf{U}(t) + \mathbf{K}_c \mathbf{V}(t) = \mathbf{F}(t) \quad (1)$$

$$\mathbf{K}_e \mathbf{V}(t) + \mathbf{Q}(t) - \mathbf{K}_c^T \mathbf{U}(t) = \mathbf{0} \quad (2)$$

where \mathbf{M}_m is the global $(N \times N)$ mass matrix, \mathbf{K}_m is the global $(N \times N)$ stiffness matrix and \mathbf{K}_c is the global $(N \times P)$ electromechanical coupling matrix, \mathbf{K}_e is the diagonal global $(P \times P)$ capacitance matrix, $\mathbf{F}(t)$ is the global $(N \times 1)$ vector of mechanical forces, $\mathbf{Q}(t)$ is the global $(P \times 1)$ vector of electric charge outputs, $\mathbf{U}(t)$ is the global $(N \times 1)$ vector of mechanical coordinates and $\mathbf{V}(t)$ is the global $(P \times 1)$ vector of output voltages across the piezoelectric elements. Here, N and P respectively, are the number of mechanical degrees of freedom and the number of piezoelectric elements.

The Equation (1) corresponds to the mechanical equation of motion including the force induced by electromechanical coupling. Whereas, the Equation (2) corresponds to the electrical circuit equation with mechanical coupling.

The global mechanical damping matrix \mathbf{C}_m is often taken to be a linear combination of the mass and stiffness matrices as follow (Rayleigh damping):

$$\mathbf{C}_m = \alpha \mathbf{M}_m + \beta \mathbf{K}_m \quad (3)$$

where α and β are the constant of proportionality which are determined in physical experiments.

The charge-voltage global variables are also intrinsically adapted to include any external electrical circuit into the electromechanical problem. For the purpose to simulate the piezoelectric energy harvesting, the structure is dissipated through a resistive load. Using Ohm's law, we obtains the following additional equations:

$$\mathbf{V}(t) = R \dot{\mathbf{Q}}(t) \quad (4)$$

2.1 Normal modes of short-circuit condition

The system short-circuit normal modes present the solutions of Equation (1) with $\mathbf{V} = \mathbf{0}$ and $\mathbf{F} = \mathbf{0}$. In addition, these modes depend only on the mechanical properties of the system, thus:

$$[\mathbf{M}_m - \omega_i^2 \mathbf{K}_m] \Phi_i = \mathbf{0} \quad (5)$$

where ω_i is the natural frequency and Φ_i is the $(N \times 1)$ mode shape vector.

For orthogonality properties, these modes verify the following conditions:

$$\Phi_i^T \mathbf{M}_m \Phi_j = \delta_{ij} \quad \text{and} \quad \Phi_i^T \mathbf{K}_m \Phi_j = \omega_i^2 \delta_{ij} \quad (6)$$

where δ_{ij} is the Kronecker symbol.

2.2 Projection on the short-circuited basis

Equations (1) and (2) describe the electromechanical behavior of the piezoelectric structure with the dimension of matrices are usually very large, which requires a considerable computational effort. The aim of this section is to construct a reduced system with much smaller dimension [7] by introducing the modal matrix $\Phi = [\Phi_1, \Phi_2, \dots, \Phi_N]$ of size $(N \times N)$, N is the total number of degrees of freedom in the finite elements model associated to the structure. In fact, the displacement vector is sought as [11]:

$$\mathbf{U}(t) = \Phi \mathbf{q}(t) \quad (7)$$

where the vector $\mathbf{q} = [q_1 \ q_2 \ \dots \ q_N]^T$ is the unknown modal amplitudes.

By applying the Ritz-Galerkin projection method, which consists in inserting the above equation in Equations (1) and (2) including the damping term, and multiplying the first obtained equation by Φ^T and using the orthogonality properties of Equations (6), the problem writes including the damping term, for all $i \in \{1, \dots, N\}$ and $p \in \{1, \dots, P\}$ is:

$$\ddot{q}_i(t) + 2\zeta_i \omega_i \dot{q}_i(t) + \omega_i^2 q_i(t) + \sum_{p=1}^P \chi_i^{(p)} V^{(p)}(t) = F_i(t) \quad (8)$$

$$C^{(p)} V^{(p)}(t) + Q^{(p)}(t) - \sum_{k=1}^N \chi_k^{(p)} q_k(t) = 0 \quad (9)$$

where ζ_i is the modal damping coefficient defined as follows:

$$\zeta_i = \frac{\alpha}{2\omega_i} + \frac{\beta\omega_i}{2} \quad (10)$$

$\chi_i^{(p)}$ is the modal coupling coefficient of the p^{th} piezoelectric element, which is defined for all $i \in \{1, \dots, N\}$ by:

$$\chi_i = \Phi_i^T \mathbf{K}_c = (\chi_i^{(1)} \chi_i^{(2)} \dots \chi_i^{(p)}) \quad (11)$$

and $F_i(t) = \Phi_i^T \mathbf{F}(t)$ is the forcing term of the i^{th} mode.

For harmonic responses in the frequency domain and taking into account the connected resistive load introduced in Equation (4), the voltage of the p^{th} piezoelectric element is written as follows:

$$V^{(p)} = \frac{j\omega \sum_{i=1}^N \chi_i^{(p)} q_i}{\left(\frac{1}{R} + j\omega C^{(p)}\right)} \quad (12)$$

Substituting the expression of the voltage in Equation (12), N mechanical oscillators are given as follows:

$$-\omega^2 q_i + 2j\omega \zeta_i \omega_i q_i + \omega_i^2 q_i + j\omega \sum_{p=1}^P \frac{\left(\chi_i^{(p)}\right)^2}{\left(\frac{1}{R} + j\omega C^{(p)}\right)} q_i + j\omega \sum_{p=1}^P \sum_{\substack{k=1 \\ k \neq i}}^N \frac{\chi_i^{(p)} \chi_k^{(p)} q_k}{\left(\frac{1}{R} + j\omega C^{(p)}\right)} = F_i \quad (13)$$

The idea behind the reduced order modeling is the projection of the general electromechanical problem on a truncated short-circuited basis $\Phi^{trun} = [\Phi_1, \Phi_2, \dots, \Phi_{N_s}]$; where $N_s \in \{1, \dots, N\}$ is

the number of the projection modes and $N_s \ll N$. Consequently, the matrix system represents a reduced-order model using the short-circuited basis. If only few modes are kept for the projection, the size of this reduced-order model is $(N_s + P)$ which is much smaller than the full system $(N + P)$.

The major interest of choosing the short-circuit eigenmodes as the expansion basis is that its can be computed with a classical elastic mechanical problem. This operation can thus be done by any standard finite elements code.

3 APPLICATION TO A BIMORPH PIEZOELECTRIC ENERGY HARVESTER

In this section, the previous formulation is used for a bimorph piezoelectric vibration energy harvester excited by a harmonic base motion. The harvester consists in an Euler Bernoulli beam composed of two layers of piezoceramic and an elastic substrate which are assumed to be perfectly bonded to each other as shown in Figure 1. Thus, the total number of layers is equal to 3 and the number of piezoelectric elements is equal to 2 ($P = 2$). The piezoceramic layers (which are poled in the thickness direction) are covered by continuous electrodes (which are assumed to be perfectly conductive) of negligible thickness. A resistive electrical load is mounted in series with the two piezoceramic layers. The electrical voltage and the mechanical vibration of the harvester are presented by its Frequency Response Functions (FRFs) which are defined here as the response outputs of the harvester per base acceleration $a_b(t)$ (in terms of the gravitational acceleration $g = 9.81m.s^{-2}$) given in [5, 13].

The geometrical and physical parameters (adapted by Erturk and Inman [2]) used in this study are given in Table 1. The ratio of the overhang length to the total thickness is about 85.7, which makes it reasonable to neglect the shear deformation and the rotary inertia effects of the harvester for the first few vibration modes. For the purpose of simulation, one takes $\xi_1 = 0.010$ and $\xi_2 = 0.012$ as the mechanical damping ratios of the first two modes. The discretization provides $N = 90$ mechanical degrees of freedom using linear elements.

Figure 1: A Clamped free bimorph piezoelectric energy harvester under base excitation with a load resistance mounted in series

The analysis given here considers the frequency range from $f_s = 1 \text{ Hz}$ to $f_f = 4500 \text{ Hz}$. In this range three natural frequencies are appeared. The multi-mode and the single-mode of tip displacement and voltage FRFs are normalized with respect to the base acceleration g , and are computed from Equations (12) and (13). They are plotted in modulus (appointed H_D and H_V respectively for the modulus of the tip displacement FRF and the modulus of the voltage FRF)

Table 1: Material and electromechanical properties of the harvester shown in Fig.2

Parameters	Descriptions	Units	PZT-5A	Aluminum
L	Beam length	mm	30	30
b	Beam width	mm	5	5
h_p, h_s	Layers thickness	mm	0.15	0.05
E_p, E_s	Young's modulus	GPa	61	70
ρ_p, ρ_s	Mass density	kg/m^3	7750	2700
e_{31}	Piezoelectric constant	C/m^2	-10.4	—
ϵ_{33}	Permittivity constant	nF/m	13.3	—

for a set of resistance load.

In the following, the simulations of these single-mode expressions are compared to those of the multi-mode (obtained by direct method) for the first three vibration modes with a load resistance mounted in series with piezoelectric layers. Figure 2 shows the single-mode of voltage FRFs for $i = 1$, $i = 2$, and $i = 3$ along with the multi-mode for a load resistance equal to $R = 100 \Omega$. As can be seen in this figure, the single-mode solutions agree with the multi-mode solution only at the vicinity of the resonance frequency of the respective mode of interest.

**Figure 2:** Comparison of the multi-mode (direct approach) and the single-mode (modal projection) of voltage FRFs with $R = 100 \Omega$

The frequency response predictions of the single-mode tip displacement FRFs for $i = 1$, $i = 2$, and $i = 3$ are shown in Figure 3 along with the multi-mode tip displacement FRFs. Again, the single-mode FRFs exhibit agreement with the multi-mode FRFs around the modes of interest. The slight overestimation of the resonance frequencies due to ignoring the neighboring vibration modes is the case here too, and the error in the single-mode resonance frequencies is less than 0.1% for these vibration modes (compared to the resonance frequencies of the multi-mode) for excitations at the fundamental short- and open-circuit resonance frequencies. Note that the

Figure 3: Comparison of the multi-mode (direct approach) and the single-mode (modal projection) of Tip displacement FRF $R = 100 \Omega$

slightly overestimated open-circuit resonance frequency is used in the single-mode simulations. The predictions of the single-mode FRFs for this most important vibration mode are very accurate. Therefore, it can comfortably be used as a first approximation in the modeling of a piezoelectric energy harvester beam for modal excitations.

To study the reduced order harvester model efficiency, we choose truncated basis contain a number of eignmodes which is a multiple of the number of the natural frequencies in the studied frequency range ($N_s = \{3, 6, 9, 69\}$) comparing with the full system projection ($N_s = N$).

Figures 4 and 5 show that the FRFs of the harvester are agree at the vicinity of the resonance frequencies for all basis of projection with the finite element direct method resolution but is not the case for the other excitation frequencies.

Two criteria are opted in this study: (1) the sum of the least square between the projected responses on the truncated basis and the direct method given in the following Equations (14) and (15) respectively for the tip displacement FRF and voltage FRF, which can give information about the accuracy of the reduced model simulation.

$$Obj^D = \sum_{f=f_s}^{f_f} \left(H_D^D(f) - H_D^{N_s}(f) \right)^2 \quad (14)$$

$$Obj^V = \sum_{f=f_s}^{f_f} \left(H_V^D(f) - H_V^{N_s}(f) \right)^2 \quad (15)$$

where H_D^D and H_V^D are respectively the modulus of tip displacement and voltage FRFs computed by the direct method and $H_D^{N_s}$ and $H_V^{N_s}$ are respectively the modulus of the tip displacement and voltage FRFs calculated by modal projection on a short-circuit truncated basis. (2) the second criteria is the time required for only one simulation.

Table 2 lists the two criteria for the harvester responses. Figure 6 shows the two criteria of

N_s	Tip displacement		Voltage	
	$Obj^D (\mu m/g)^2$	Time (s)	$Obj^V (\mu m/g)^2$	Time (s)
3	2.00 E-02	38.248	2.51 E-07	38.949
6	2.77 E-05	39.638	1.20 E-09	39.944
9	2.48 E-06	41.031	2.35 E-10	41.199
69	9.10 E-11	81.409	7.73 E-13	81.685
N	5.32 E-11	94.852	5.15 E-13	95.302

comparison for the harvester responses ((a) tip displacement FRF and (b) voltage FRF) versus the short-circuit basis size. Results show that for a small basis size, reduced order model simulation give responses with low precision (high Obj value) in a short computation time. Furthermore, the accuracy of the responses increase monotonically (Obj decreases) with the increase of the projection basis size, whereas the time of computation increase also. Indeed, high accuracy of simulation causes high numerical computation cost. For our case study, $N_s = 6$ is recommended for this frequency range.

4 CONCLUSIONS

In this research, the general finite element governing equations of the general electromechanical problem is firstly presented. Model reduction technique has been developed which consists in a modal projection of the system equations on a truncated basis of eigenvectors in order to reduce its matrices size. This basis is obtained with short circuit boundary conditions. The main goal is to predict the output responses of the harvester with high accuracy and low computational cost. Although an example of a bimorph piezoelectric energy harvesting, results show that the computational cost and the responses accuracy of the full-scale model have been reduced

Figure 5: Comparison of the multi-mode voltage FRF for different basis size with direct method, $R = 10^2 \Omega$

monotonically with the reduction of the model scale. Moreover, the responses accuracy of the reduced order model is affected by errors introduced by the process of mode truncation that can be controlled or minimized by a modal truncation augmentation method [14]. In this method, the effects of the truncated modes are considered by their static effect only.

Abstract. This paper presents the fragment of investigation related to modification of the original elastic structure in order to provide damping of the specified vibration modes in a structure with the imposed constraints on its mass and dimensions. It is proposed to supplement the initial structure with viscoelastic layer and attach a piezoelectric element, which is shunted by external electric circuit. Studies related to the selection of mechanical and geometric properties of viscoelastic layer, mutual disposition of viscoelastic and piezoelectric elements are presented. The investigation was carried out in the framework of the problem of natural vibrations for piecewise-homogeneous electro-viscoelastic bodies. The method was illustrated numerically by solving the natural vibration problem for a cantilevered plate.

1 INTRODUCTION

The processes of the design and operation of structures may give rise to situations, which require their modification associated with a change of their dynamic properties, for example, dissipative ones. Conventionally, the improvement of structure characteristics is based on the techniques, in which the original structure is fitted with the elements made of viscoelastic materials.

However, this approach has restrictions associated with the acceptable thickness of viscoelastic layer (the mass added to the original object), with the characteristics of the used material and with the possible area of coverage of the surface of a structure. Due to the development of smart-technologies, an increasing interest of researchers is focused by another approach, which is based on fitting viscoelastic structures with the elements made of piezoelectric materials connected to the external electric circuits. The presence of such elements provides additional energy dissipation, increasing thereby the dissipative properties of structures in a wide frequency range. Herewith the different mechanisms of energy dissipation complement each other in some frequency ranges and perform main work in other frequency ranges [1, 2]. In this regard, the approach based on the use of smart-technologies with piezoelectric materials connected to external electric circuits can offer considerable

promise for providing additional damping of vibrations when there are strict constraints on mass and dimensional parameters of structures, which are relevant for products in airspace, aircraft and automotive industries. In the literature, this approach depending on the strategy of structural dynamic behavior control is named either active constrained layer damping (ACLD) or passive constrained layer damping (PCLD).

The paper [3] should be mentioned as one of the first papers where such an approach is considered. The great interest of researchers in this method and the state of the art in this field demonstrated in the review papers [1, 2]. Despite the abundance of papers devoted to the problem there are still unsolved questions due to the complexity and versatility of the problem. Thus, the investigation of the possibility of using the piezoelectric and viscoelastic elements simultaneously to provide robust and efficient damping of structural vibrations at specified frequencies is rather relevant, especially with regard to existing structural restrictions.

The application of this technique bring up the following questions: what material should be used for viscoelastic layer, which area of a structure should be covered with it, what will be a response from the damping factors, how the system with the viscoelastic coating will respond to the attachment the piezoelectric element, how piezoelectric element should be located on a the structure and with respect to viscoelastic element, what values should take the parameters of external electric circuit for damping the specified modes of vibrations of the modified electro-viscoelastic structure, etc.

The present paper is a part of a series of studies devoted to estimation of viscoelastic and piezoelectric elements embedded into the original elastic structure on damping factors. These investigations were carried out on the basis of the solution to the problem of natural vibrations of electro-viscoelastic structures.

2 MATHEMATICAL STATEMENT OF THE PROBLEM

The problem of natural vibrations for piecewise-homogeneous electro-viscoelastic bodies in the complete coupled mathematical formulation is considered in paper [4]. This problem is described by the following variational equation:

$$\int_{V_1} (\sigma_{ij} \delta \varepsilon_{ij} + \rho \ddot{u}_i \delta u_i) dV + \int_{V_2} (\sigma_{ij} \delta \varepsilon_{ij} - D_i \delta E_i + \rho \ddot{u}_i \delta u_i) dV = 0 \quad (1)$$

Here, the volume V_1 is related to a viscoelastic part of the structure; the volume V_2 is related to a piezoelectric part; D_i, E_i are the components of the vectors of electric flux density and electric field intensity, respectively; σ_{ij} are the components of the symmetric Cauchy stress tensor; ε_{ij} are the components of the linear strain tensor; u_i are the components of the displacement vector. The constitutive relations for the piezoelectric part of volume V_2 are written as follows:

$$\left. \begin{aligned} \sigma_{ij} &= C_{ijkl} \varepsilon_{kl} - \beta_{ijk} E_k \\ D_k &= \beta_{ijk} \varepsilon_{ij} + \varepsilon_{ki} E_i \end{aligned} \right\} \quad (2)$$

where C_{ijkl} are the components of the tensor of elastic constants; β_{ijk} and ε_{ki} are the components of the tensors of piezoelectric coefficients and dielectric coefficients, respectively

($i, j, k, l = 1, 2, 3$). Within the framework of this paper, we use the assumption that the behavior of viscoelastic material is described in terms of the complex dynamic moduli, as it was made in [5]. The model of linear hereditary viscoelasticity describes the dissipative mechanisms operating in the body of volume V_1 . The constitutive relations of this model can be written as

$$\begin{aligned}\sigma_{ij} - \sigma\delta_{ij} &= 2\tilde{G}\left(\varepsilon_{ij} - \frac{1}{3}\vartheta\delta_{ij}\right) = 2(G_{\text{Re}} + iG_{\text{Im}})\left(\varepsilon_{ij} - \frac{1}{3}\vartheta\delta_{ij}\right), \\ \sigma &= \tilde{B}\vartheta = (B_{\text{Re}} + iB_{\text{Im}})\vartheta\end{aligned}\quad (3)$$

where $\tilde{G} = G_{\text{Re}} + iG_{\text{Im}} = G_{\text{Re}}\left(1 - i\frac{G_{\text{Im}}}{G_{\text{Re}}}\right) = G_{\text{Re}}(1 - i\delta_g)$, $\tilde{B} = B_{\text{Re}} + iB_{\text{Im}} = B_{\text{Re}}\left(1 - i\frac{B_{\text{Im}}}{B_{\text{Re}}}\right) = B_{\text{Re}}(1 - i\delta_b)$ are the complex dynamic shear and bulk moduli; σ is the mean stress; ϑ is the volumetric strain;; δ_g, δ_b are the mechanical loss tangents for the shear and bulk moduli, respectively; s_{ij}, e_{ij} are the components of deviatoric parts of the stress and strain tensors.

Let us consider the case, in which damping characteristics of the structure specified by the viscoelastic properties of the material it is made of are independent on the frequency, i.e. the shear and bulk moduli $G_{\text{Re}}, B_{\text{Re}}$ and the mechanical loss tangents δ_g, δ_b are constants. The solution to the problem of natural vibrations is sought in the form of $u(x, t) = u(x)e^{j\omega t}$, where $u(x) = \{u_1(x_1, x_2, x_3), u_2(x_1, x_2, x_3), u_3(x_1, x_2, x_3), \varphi(x_1, x_2, x_3)\}$ is the generalized state vector containing the components of mechanical displacements u_1, u_2, u_3 and electric potential φ ; $\omega = \omega_{\text{Re}} \pm i\omega_{\text{Im}}$ is the complex natural vibration frequency where ω_{Re} denotes the angular natural frequency of vibrations and ω_{Im} is the damping index characterizing the damping rate of vibrations. Damping factors of a vibrating structure (viscoelastic or electro-viscoelastic) ξ are defined using the following formula [6]:

$$\xi_j = (\omega_{\text{Im}})_j / (\omega_{\text{Re}})_j \quad (4)$$

Here ω_{Im} is the imaginary part of complex natural vibration frequency (damping index), ω_{Re} is the angular natural frequency of vibrations of an original elastic structure, $j = 1, \dots, M$ and M is the number of natural vibration frequencies being considered. The solution to the formulated problem of natural vibrations of electro-viscoelastic structures is sought using the method presented in [7].

3 FORMATION OF THE VISCOELASTIC STRUCTURE

Consider a cantilever plate made of isotropic material (figure 1) fully or partially covered with viscoelastic layer. The objective is to increase the level of damping of the first two flexural vibration modes of this plate. Let us specify some restrictions (for example, on the added mass and layer thickness) in compliance with the requirements for operation characteristics of the structure. The added mass should be less than 5% of the mass of the plate, and the thickness of the viscoelastic layer t should not exceed the thickness of the plate t_p , i.e. $t \leq t_p$. Changes in the dynamic properties of the structure induced by attaching the viscoelastic layer should be minimal. These limitations are of demonstrative and arbitrary nature. All further calculations is carried out based on these set of restrictions.

Figure 1: Computational scheme for the plate with viscoelastic layer.

The plate (fig.1) has the following dimensions $l_p = 210$ mm, $b_p = 26$ mm, $h_p = 0.6$ mm and made of elastic material with the following properties: Young's modulus $E = 2 \cdot 10^{11}$ Pa, Poisson's ratio $\nu = 0.49$, mass density $\rho = 7800$ kg/m³. The first two natural vibration frequencies are equal to 11.24 Hz and 70.39 Hz respectively.

Now, it is necessary to determine with account of the above mentioned operational restrictions what characteristics the viscoelastic material should have in order that the damping coefficient should reach the maximal values for the first two vibration modes. For this purpose physical and mechanical properties of viscoelastic materials are changed in the following ranges: Young's modulus $E = 2 \cdot 10^5 \div 2 \cdot 10^9$ Pa, Poisson's ratio $\nu = 0.3 \div 0.49$, mass density $\rho = 1000 \div 2000$ kg/m³, tangents of mechanical losses $\delta_g = 10^{-5} \div 0.2$, $\delta_b = 10^{-5} \div 0.2$. These properties correspond to different kinds of rubber, silicone and polyurethane [5]. The ranges of changing the shear modulus and bulk modulus are $G_{Re} = 7.4 \cdot 10^4 \div 7.5 \cdot 10^8$ Pa, $B_{Re} = 1.96 \cdot 10^5 \div 3.33 \cdot 10^{10}$ Pa, which are defined by relations (5)

$$G_{Re} = E / [2(1 + \nu)], \quad B_{Re} = E / [3(1 - 2\nu)] \quad (5)$$

When studying the influence of geometric factors (thickness and coverage area of the plate surface with viscoelastic layer) on the damping coefficients, the following characteristics were considered: shear modulus $G_{Re} = 0.177$ MPa, bulk modulus $B_{Re} = 8.8$ MPa, mechanical loss tangents $\delta_g = \delta_b = 0.2$, mass density $\rho = 1200$ kg/m³, that correspond to the class of viscoelastic materials under study.

Here, we restrict our consideration to the frequency-independent properties of the viscoelastic material such as shear modulus G_{Re} , bulk modulus B_{Re} and mechanical loss tangents δ_g, δ_b .

3.1. Determination of the viscoelastic layer thickness

First let's consider the worst option from the viewpoint of changes introduced into original structure: we assume that the surface area of the viscoelastic layer is equal to the surface area of the plate $l_v = l_p$, $b_v = b_p$, $h_v = h_p$.

Figure 2: The vibration damping factors (solid line) and changes in the natural vibration frequencies (dashed line) versus the thickness of viscoelastic layer.

Figure 2 shows the plots of the coincident damping factors $\xi_1 = \xi_2 = \xi$ and the corresponding changes of natural vibration frequencies $\Delta\omega$ as a function of the thickness t of the viscoelastic layer. The shaded area corresponds to the constraint put on the mass of the structure after adding a viscoelastic layer (should not exceed 5%). This constraint leads to the maximal acceptable thickness is equal to 0.2 mm. Herewith the change in natural vibration frequencies values does not exceed 2%. For the further calculations, the thickness of the viscoelastic layer is set equal to 0.2 mm.

3.2. Determination of the coverage area of a structure with the viscoelastic layer

We impose that the dimensions of piezoelectric element limit minimal size of the viscoelastic layer because piezoelectric element will be attached in future to the structure, i.e. $l_v = 50$ mm, $b_v = 20$ mm, $h_v = 0.36$ mm. Next the dimensions of the viscoelastic layer are uniformly increased up to full coverage of the surface area of the structure $l_v = l_p$, $b_v = b_p$, $h_v = h_p$. First, using the approach presented in [8], we determine the location of piezoelectric element on the original plate, such that will allow damping of the vibrations at the first vibration mode. Then, we do the same for the second mode of vibrations.

In the first case the coordinates of the center of piezoelectric element mass should be $x = 37$ mm, $y = 0$ mm (the first option), and for the second case the coordinates are $x = 105$ mm, $y = 0$ mm (the second option). A viscoelastic layer of the size equal to the dimensions of the piezoelectric element is arranged correspondingly: at first, its arrangement corresponds to the first option and then - to the second option.

Figure 3 represents the plots of the damping factors for the first (ξ_1) and the second (ξ_2) vibration modes and changes of natural vibration frequencies $\Delta\omega_i$ ($i = 1, 2$) versus the covered

area of the palte surface S at the initial location of the viscoelastic layer according to the first option (fig.3a) and to the second option (fig.3b).

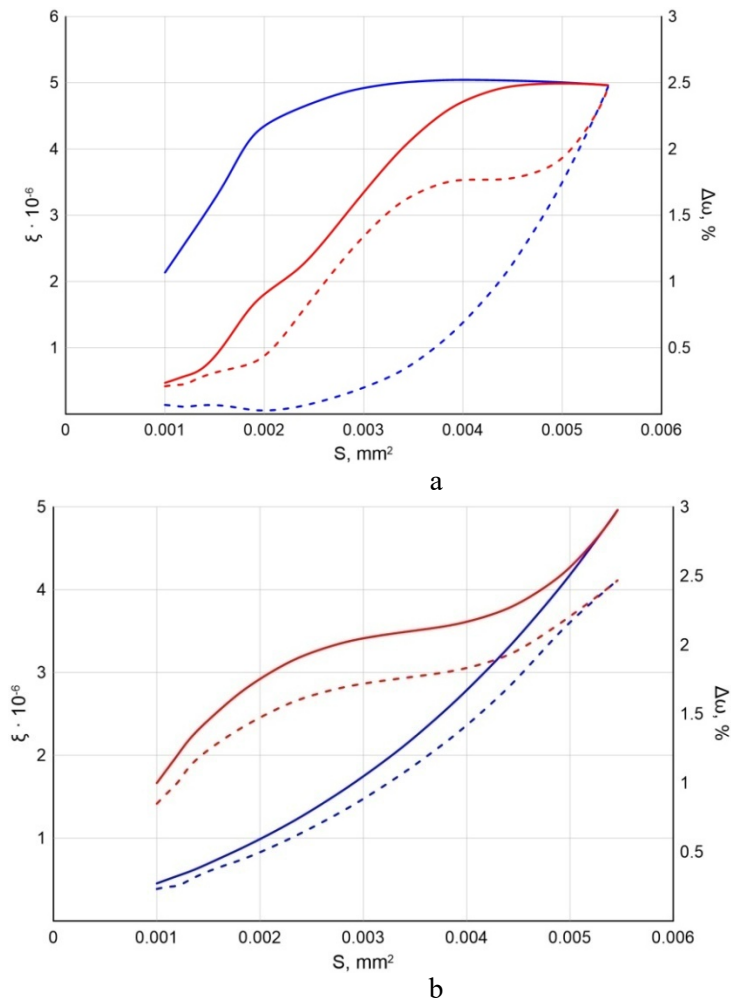

Figure 3: Relations of damping factors for damping the first (ξ_1 , blue solid line) and the second (ξ_2 , red solid line) vibration modes and changes of natural vibration frequencies (blue dashed line for the first one and red dashed line for the second one) depending on the area of the viscoelastic layer arranged according to the first (a) and the second (b) options.

The obtained results show that in order to reach the highest possible damping factor $\xi_1^{(1)}$ it is sufficient to cover 60% of the structure surface area, provided that the viscoelastic element is located according to the first option. Herewith the change in the value of the first natural vibration frequency is 0.3% and corresponding change for the second natural vibration frequency is 1.6%. In order to reach maximal achievable damping factor for the second frequency it is necessary to cover at least 80% of the structure surface area. In this case, the values of the corresponding natural vibration frequencies change by less than 2%.

If the viscoelastic layer covers, 80% of the plate surface area and is arranged on the plate surface according to the second option (in the middle), we obtain the following result:

$\xi_1^{(2)} / \xi_1^{(1)} = 53.6 \%$, $\xi_1^{(2)} / \xi_1^{(1)} = 72.2 \%$. If a viscoelastic layer, c extending length-wise from the clamped end of the plate, covers the same 80% of the plate surface, then the damping factors for both vibration modes are equal and maximal, herewith the change limitations in the structure are not violated.

3.3. Determination of the viscoelastic layer mechanical properties

First, we define the values of tangents of mechanical losses of complex shear and bulk moduli, which provide the highest values of coefficients of vibration damping with mentioned above limitations on modifying the structure. Earlier it was showed that for reaching the maximal damping of vibration modes in the considered frequency range from 0 to 100 Hz it is sufficient to cover with viscoelastic layer 80% of the plate length starting from the rigid clamp. Consider this coverage area with a margin and let the plate be covered by the viscoelastic layer by 90% starting from the clamp and across the full width. This made in order to expand the influence of the viscoelastic layer on other modes of vibrations.

The investigations results of influence of mechanical losses tangents values for shear modulus δ_g (for this case, $\delta_b = 0$) and bulk modulus δ_b (for this case, $\delta_g = 0.2$) on coefficients of vibration damping are presented in figure 4. Here $\xi_1 = \xi_2 = \xi$. This plot shows that quantities of δ_b and δ_g do not affect the damping factors until reaching some certain value. However, damping factors start dramatically increasing when δ_g reaches this certain value. For the further studies we set that $\delta_g = 0.2$ and $\delta_b = 0$.

Further, let us determine the magnitudes of instantaneous shear and bulk moduli that provide the highest values of coefficients of vibration damping for the specified conditions. For obtaining that the value of the one modulus (shear modulus, for example) was fixed and the values of the other modulus (bulk modulus) were varied, and vice versa. The obtained results depending on the values of Poisson's ratio are presented in figure 5. This figure also represents the plots of changing shear modulus and bulk modulus. The results presented in figure 5 shows that shear modulus substantially influence the magnitude of the vibration damping factor. Herewith bulk modulus has almost no influence on values of damping factor.

Figure 4: Damping factors $\xi_1 = \xi_2 = \xi$ depending on values of loss tangents of shear modulus (blue line) and bulk modulus (red line).

Investigations related to determination of properties of the viscoelastic coating of the original structure allow to conclude that the number of parameters have a significant impact on damping factor of the system. These parameters are: all geometrical parameters of viscoelastic layer (thickness, area); the layout of the viscoelastic layer, especially if the possibility of damping of several vibration modes within some specified frequency range is considered; shear modulus and tangent of mechanical losses corresponding to it. These factors must be taken into account when modifying the structure with viscoelastic layer.

Figure 5: Damping factors depending on G_{Re} when $B_{Re} = const$ (blue solid line); depending on B_{Re} when $G_0 = const$ (red solid line); instantaneous shear modulus G_{Re} (blue dashed line) and bulk modulus B_{Re} (red dashed line) depending on values of Poisson's ratio.

Based on the performed investigations we can state that for reaching maximal damping factors for the first two vibration modes of the structure under limitations of acceptable changes in the properties of a structure it is necessary to cover by the viscoelastic layer the 80% of structure surface, starting from the clamp with 0.2 mm thickness. The most suitable for this purpose material should have the following physical and mechanical properties: Young's modulus $E = 2 \cdot 10^3$ MPa, Poisson's ratio $\nu = 0.49$ ($G_{Re} = 750$ MPa, $B_{Re} = 3.33 \cdot 10^4$ MPa), mass density $\rho = 1200$ kg/m³ and tangents of mechanical losses $\delta_g = 0.2$, $\delta_b = 0$. These properties correspond to the reinforced polyurethane of the Elastollan [5].

4 FORMATION OF THE ELECTRO-VISCOELASTIC STRUCTURE

Consider a cantilever piecewise-homogeneous isotropic viscoelastic plate (figure 1) which is formed by coating the original elastic structure with viscoelastic layer. In the section 3 of the present article it was showed that by appropriate choice of viscoelastic material the highest value of damping factor can be provided for two vibration modes in frequency range from 0 up to 100 Hz, $\xi = 0.012$.

In paper [9] it was demonstrated that coefficient of vibration damping of the initial structure can be increased by attaching piezoelectric element shunted with external electric circuit. Let us study how damping factors for the first two vibration modes changes if piezoelectric element with the dimensions 50x20x0.36 mm is attached to the piecewise-homogeneous viscoelastic structure.

Physical and mechanical properties of the plate: Young's modulus $E = 2 \cdot 10^{11}$ Pa, Poisson's ratio $\nu = 0.49$, mass density $\rho = 7800$ kg/m³. Those ones of viscoelastic layer: Young's modulus $E = 2 \cdot 10^9$ Pa, Poisson's ratio $\nu = 0.49$ ($G_{Re} = 750$ MPa, $B_{Re} = 3.33 \cdot 10^4$ MPa), mass density $\rho = 1200$ kg/m³, mechanical loss tangents $\delta_g = 0.2$, $\delta_b = 0$. Piezoelectric element is made of PZT-4 piezoceramics and has the following characteristics: $C_{11} = C_{22} = 13.9 \cdot 10^{10}$ N/m², $C_{12} = 7.78 \cdot 10^{10}$ N/m², $C_{13} = C_{23} = 7.43 \cdot 10^{10}$ N/m², $C_{33} = 11.5 \cdot 10^{10}$ N/m², $C_{44} = 3.06 \cdot 10^{10}$ N/m², $C_{55} = C_{66} = 2.56 \cdot 10^{10}$ N/m², $\beta_{31} = \beta_{32} = -5.2$ C/m², $\beta_{33} = 15.1$ C/m², $\beta_{32} = \beta_{61} = 12.7$ C/m², $e_{11} = e_{22} = 6.45 \cdot 10^{-9}$ F/m, $e_{33} = 5.62 \cdot 10^{-9}$ F/m, $\rho = 7500$ kg/m³.

In order to compare the efficiency of damping of the first two vibration modes between viscoelastic and electro-viscoelastic plates we consider that length and width of viscoelastic layer are equal to length and width of piezoelectric element. Herewith we set that maximal possible thickness of viscoelastic layer is equal to the thickness of the plate $t = 6$ mm. This thickness do not contravene the limitations put on its thickness and changes the mass of the system in less than 2.8%.

It is a well-known fact that the efficiency of application of piezoelectric element is substantially dependent on its layout on the surface. In this case, the location of piezoelectric element for damping each of the vibration modes under consideration is determined according to the approach proposed in paper [8] without viscoelastic layer on the surface of the structure. Center of masses of piezoelectric element should be located at 37 mm distance from the clamp (its coordinates are equal to $x = 37$ mm, $y = 0$ mm) (option 1) for damping the first vibration mode. Center of masses of piezoelectric element should be located at 105 mm distance from the clamp (its coordinates are equal to $x = 105$ mm, $y = 0$ mm) (option 2) for damping the second vibration mode.

Consider a four typical options of possible mutual disposition of viscoelastic layer and piezoelectric element on the surface of the structure (figure 6). Let us study how natural vibration frequencies of the structure affected by adding viscoelastic and piezoelectric elements. At the first stage, we assume that viscoelastic element is made from material with same properties as viscoelastic layer with no mechanical losses ($\delta_g = 0$; $\delta_b = 0$).

Figure 6: Options of possible mutual disposition of viscoelastic and piezoelectric elements.

Table 1 represents the first two natural vibration frequencies of the original plate for two location options of the center of masses of added viscoelastic layer and piezoelectric element for cases when either one of them, or both, of them are present depending on the four options of their mutual disposition, according to the figure 6.

Table 1: The influence of added elastic and piezoelectric structural elements on natural vibration frequencies of the plate.

Option of a structure				
Original: the plate	ω_1	11.24	ω_2	70.39
Location of the center of masses				
Option 1		Option 2		
	ω_1	ω_2	ω_1	ω_2
The plate with the added elastic layer	11.52	70.42	11.22	70.09
The plate with piezoelectric element	13.86	72.33	11.33	77.11
Options of mutual disposition of viscoelastic layer and piezoelectric element				
I	13.96	72.14	11.29	76.66
II	15.28	73.51	11.42	83.54

IV	13.53	71.70	11.17	77.44

Table 1 shows that natural vibration frequencies substantially depend on mutual disposition of piezoelectric element and added viscoelastic layer despite the fact that total mass of the system (the plate with additional elastic layer and piezoelectric element) remains the same.

Table 2: The influence of added viscoelastic and piezoelectric structural elements on natural vibration frequencies of the plate.

	72.22 + i 0.042	0.001	76.91 + i 0.146
IV	13.53 + i 0.019	0.002	11.68 + i 0.060
	71.71 + i 0.255	0.004	77.44 + i 0.072

The obtained results allows to note that the piezoelectric element plays main role in changes of spectrum of natural vibration frequencies. The elastic layer influences on the spectrum much less. The biggest change (36% for the first natural vibratrion frequency, 18.6 % for the second natural vibratrion frequency) occurs when piezoelectric element located above the viscoelastic layer.

Consider the same layout options of an electro-viscoelastic structure but with replacement of the elastic layer by viscoelastic one. The results of calculations are presented in table 2.

The comparison of the data represented in tables 1 and 2 leads to the conclusion that the substitution of viscoelastic material by eleastic one with the same properties has almost no influence on spectrum of natural vibrationfrequencies of the system.

This fact can be usefull for studying the dynamic behavior of electro-viscoelastic structures. Furthermore, the analysis of the results represented in table 2 leads to the following conclusion: in the most common case the attaching of piezoelectric element to viscoelastic structure decreases its damping properties. But this decrease depends on mutual disposition of viscoelastic layer and piezoelectric element. The least influence of piezoelectric element is observed in case when it is located above the viscoelastic layer (option II). When piezoelectric element located nearby of the viscoelastic layer (option IV) the damping properties of electro-viscoelastic structure do not decrease in compare to the purely viscoelastic one.

5 CONCLUSIONS

This paper presents the part of research related to modification of the original elastic structure in order to ensure the damping of specified vibration modes with applied mass and dimensional characteristics limitations. The modification is made by supplementing structure with a viscoelastic layer and connecting a piezoelectric element shunted by an electric circuit.

During this research, the first two vibration modes were taken into account.

The estimation of influence of viscoelastic and piezoelectric elements was demonstrated in order to get the comprehension of contribution of different energy dissipation mechanisms to total loss. The maximal achievable rate of vibration damping and corresponding parameters of viscoelstic layer are determined depending on the number of factors (mechanical properties, area of coverage, location and thickness). This study allowed us to determine physical and mechanical properties of material (from the perliminarly proposed) that can provide the highest values of damping factors with existing limitations on characteristis of a structure. The influence on the results of adding a viscoelastic layer, attaching piezoelectric element and its location relative to the viscoelastic layer are estimated.

Numerically demonstrated the well-known fact that adding piezoelectric elements substantially influence the dynamical properties of a structure only when connected to external electric circuits of arbitrary configuration [9].

Abstract. In this paper, linear dynamical three-dimensional model of thermoelastic piezo-electric shell with variable thickness, which may vanish on a part of the lateral boundary, consisting of several inhomogeneous anisotropic layers with regard to magnetic field is considered. In order to construct dynamical two-dimensional models variational formulation in curvilinear coordinates of the initial-boundary problem corresponding to the three-dimensional model of the shell is obtained. Applying spectral approximation method a sequence of subspaces with special structure of the spaces corresponding to the original three-dimensional problem is constructed and on these subspaces a hierarchy of dynamical two-dimensional models is obtained. The constructed two-dimensional initial-boundary value problems are investigated in suitable spaces of vector-valued distributions with respect to the time variable with values in corresponding weighted Sobolev spaces and the existence and uniqueness of solutions are proved. Moreover, it is proved that the sequence of vector-functions of three space variables restored from the solutions of the two-dimensional problems converges in the corresponding function spaces to the exact solution of the three-dimensional initial-boundary value problem and under additional conditions the rate of convergence is estimated.

1 INTRODUCTION

Piezoelectric materials are widely used to build engineering smart structures, because of the ease of controlling by voltage, low weight and low power requirements. Inhomogeneous and, in particular, functionally graded materials are used to increase the durability and efficiency of engineering constructions undergoing high mechanical and thermal loads. Various parts of smart devices consisting of piezoelectric materials are often plate or shell like structures, and, therefore, construction and investigation of mathematical models of inhomogeneous thermoelastic piezoelectric plates and shells are important from both theoretical and practical

viewpoints. Mathematical models of interaction between elastic, electric and thermal fields in piezoelectric body were developed by W. Voigt [1] and further various models of piezoelectric solids were constructed and investigated by various authors (see [2] and the references given therein).

In order to construct two-dimensional models of thermoelastic piezoelectric shells we use spectral approximation method, which is a generalization of the method of constructing two-dimensional models for plates with variable thickness in the classical theory of elasticity suggested by I. Vekua in [3]. Various two-dimensional models constructed by Vekua were collected in his monograph [4]. The estimates of the order of approximation of static three-dimensional problem by two-dimensional ones constructed in [3] first were obtained in the spaces of classical regular functions in the paper [5], and the reduced two-dimensional models for thin shallow shells constructed in [4] were investigated in Sobolev spaces in [6]. Later on, dimensional reduction methods suggested by I. Vekua in [3, 4] and there generalizations were studied in the papers [7-11].

2 THREE-DIMENSIONAL MODEL

Throughout this paper we denote by $W^{r,2}(D) = H^r(D)$ and $H^r(\hat{\Gamma})$, $r \in \mathbf{R}$, the Sobolev spaces of order r based on the spaces $H^0(D) = L^2(D)$ and $H^0(\hat{\Gamma}) = L^2(\hat{\Gamma})$ of square-integrable functions, respectively, where $D \subset \mathbf{R}^p$, $p \in \mathbf{N}$, is a bounded Lipschitz domain [12] and $\hat{\Gamma} \subset \partial D$ is a Lipschitz surface. We denote by $\mathbf{H}^r(D) = [H^r(D)]^3$, $\mathbf{H}^r(\hat{\Gamma}) = [H^r(\hat{\Gamma})]^3$, $\mathbf{L}^2(D) = [L^2(D)]^3$, $\mathbf{L}^s(\hat{\Gamma}) = [L^s(\hat{\Gamma})]^3$, $s \geq 1$, $r, s \in \mathbf{R}$, the spaces of vector-valued functions. The trace operators we denote by $tr_{\hat{\Gamma}} : H^1(D) \rightarrow H^{1/2}(\hat{\Gamma})$ and $\mathbf{tr}_{\hat{\Gamma}} : \mathbf{H}^1(D) \rightarrow \mathbf{H}^{1/2}(\hat{\Gamma})$. For Banach space X , $C([0, T]; X)$ denotes the space of continuous functions on $[0, T]$ with values in X , $L^q(0, T; X)$, $1 \leq q \leq \infty$, is the space of such functions $g : (0, T) \rightarrow X$ that $\|g(t)\|_X \in L^q(0, T)$. We denote by $g' = dg/dt$ the generalized derivative of function $g \in L^q(0, T; X)$ [13].

Let us consider multilayer thermoelastic piezoelectric shell with initial configuration $\overline{\Omega}^* = \xi(\overline{\Omega})$, where $\overline{\Omega}$ is of the following form $\overline{\Omega} = \bigcup_{k=1}^K \overline{\Omega}_k$,

$$\Omega_k = \{(x_1, x_2, x_3) \in \mathbf{R}^3; h_k^-(x_1, x_2) < x_3 < h_k^+(x_1, x_2), (x_1, x_2) \in \omega \subset \mathbf{R}^2\},$$

where ξ is a C^2 diffeomorphism of $\overline{\Omega}$ onto $\overline{\Omega}^*$, so that the vectors $\mathbf{G}_i(x) = \partial_i \xi(x)$ are linearly independent at all points of $\overline{\Omega}$, ∂_i denotes the partial derivative with respect to x_i ($i = 1, 2, 3$). Since ξ is an injective mapping each point $x^* \in \overline{\Omega}^*$ in Cartesian coordinates $x^* = (x_1^*, x_2^*, x_3^*)$ can be unambiguously written as $x^* = \xi(x)$, $x \in \overline{\Omega}$, and the coordinates x_i of x are the curvilinear coordinates of x^* . The triplets $\{\mathbf{G}_i(x)\}$ and $\{\mathbf{G}^i(x)\}$ form the covariant and contravariant bases at the point $x^* = \xi(x)$, respectively, where $\mathbf{G}_i(x) \cdot \mathbf{G}^j(x) = \delta_{ij}$, δ_{ij} is the Kronecker delta. The mapping ξ defines metric tensor of $\overline{\Omega}^*$ with contravariant components

$G^{ij} = \mathbf{G}^i \cdot \mathbf{G}^j$ and Christoffel symbols $\Gamma_{ij}^p = \mathbf{G}^p \cdot \partial_i \mathbf{G}_j$, $i, j, p = \overline{1, 3}$. $\Omega \subset \mathbf{R}^3$ and $\omega \subset \mathbf{R}^2$ are bounded Lipschitz domains with boundaries $\partial\Omega$ and $\partial\omega$, respectively, $h_k^\pm \in C^0(\bar{\omega}) \cap C_{loc}^{1,1}(\omega)$, $k = 1, \dots, K$, are continuous on $\bar{\omega}$ and Lipschitz continuous in ω , $h_k^+(x_1, x_2) > h_k^-(x_1, x_2)$, for $(x_1, x_2) \in \omega \cup \tilde{\gamma}$, $\tilde{\gamma} \subset \partial\omega$ is a Lipschitz curve, $h_k^+(x_1, x_2) = h_k^-(x_1, x_2)$, for $(x_1, x_2) \in \partial\omega \setminus \tilde{\gamma}$, $h_k^+(x_1, x_2) = h_{k+1}^-(x_1, x_2)$, $k = 1, \dots, K-1$, for $(x_1, x_2) \in \bar{\omega}$. The upper and the lower face surfaces of the layer Ω_k defined by the equations $x_3 = h_k^+(x_1, x_2)$ and $x_3 = h_k^-(x_1, x_2)$, $(x_1, x_2) \in \omega$, we denote by Γ_k^+ and Γ_k^- , respectively, and the lateral surface of the layer Ω_k , where the thickness of Ω_k is positive, we denote by $\tilde{\Gamma}_k = \{(x_1, x_2, x_3) \in \mathbf{R}^3; h_k^-(x_1, x_2) < x_3 < h_k^+(x_1, x_2), (x_1, x_2) \in \tilde{\gamma}\}$.

We assume that each layer $\Omega_k^* = \theta(\Omega_k)$, $k = 1, \dots, K$, of the thermoelastic piezoelectric shell Ω^* consists of inhomogeneous anisotropic material with the mass density $\rho^{k*}(x^*)$ in the initial configuration, the elasticity tensor $(c_{ijpq}^{k*}(x^*))_{i,j,p,q=1}^3$, the piezoelectric $(\varepsilon_{pij}^{k*}(x^*))_{i,j,p=1}^3$ and piezomagnetic $(b_{pij}^{k*}(x^*))_{i,j,p=1}^3$ coefficients, the stress-temperature tensor $(\lambda_{ij}^{k*}(x^*))_{i,j=1}^3$, the permittivity $(d_{ij}^{k*}(x^*))_{i,j=1}^3$ and permeability $(\zeta_{ij}^{k*}(x^*))_{i,j=1}^3$ tensors, the coupling coefficients connecting electric and magnetic fields $(a_{ij}^{k*}(x^*))_{i,j=1}^3$, the thermal conductivity tensor $(\eta_{ij}^{k*}(x^*))_{i,j=1}^3$ and the thermal capacity $\chi^{k*}(x^*)$. We neglect the influence of thermal field on electric and magnetic fields and assume that pyroelectric and pyromagnetic coefficients vanish. The applied body force density we denote by $\mathbf{f}^{k*} = (f_i^{k*})_{i=1}^3 : \Omega_k^* \times (0, T) \rightarrow \mathbf{R}^3$, the density of electric charges we denote by $f^{\varphi, k*} : \Omega_k^* \times (0, T) \rightarrow \mathbf{R}$, and the density of heat sources we denote by $f^{\theta, k*} : \Omega_k^* \times (0, T) \rightarrow \mathbf{R}$. The temperature $\theta^* : \Omega^* \times (0, T) \rightarrow \mathbf{R}$ of the shell vanishes along the boundary $\Gamma^* = \partial\Omega^*$ of the domain Ω^* . The shell is clamped along a part $\tilde{\Gamma}_0^* = \xi(\tilde{\Gamma}_0)$, $\tilde{\Gamma}_0 = \bigcup_{k=1}^K \tilde{\Gamma}_{0,k}$, $\tilde{\Gamma}_{0,k} = \{(x_1, x_2, x_3) \in \tilde{\Gamma}_k; (x_1, x_2) \in \tilde{\gamma}_{0,k}\}$, $\tilde{\gamma}_{0,k} \subset \tilde{\gamma}$, of the lateral surface $\tilde{\Gamma}^* = \xi(\tilde{\Gamma})$, $\tilde{\Gamma} = \{(x_1, x_2, x_3) \in \Gamma = \partial\Omega; (x_1, x_2) \in \tilde{\gamma}\}$, and on the remaining part $\Gamma_1^* = \xi(\Gamma_1)$, $\Gamma_1 = \Gamma \setminus \tilde{\Gamma}_0$, of the boundary surface force with density $\mathbf{g}^* = (g_i^*) : \Gamma_1^* \times (0, T) \rightarrow \mathbf{R}^3$ is given. The electric field \mathbf{E}^* is potential $\mathbf{E}^* = -(\partial\varphi^* / \partial x_i^*)_{i=1}^3$ and electric potential $\varphi^* : \Omega^* \times (0, T) \rightarrow \mathbf{R}$ vanishes along a part $\tilde{\Gamma}_0^{\varphi*} = \xi(\tilde{\Gamma}_0^{\varphi})$, $\tilde{\Gamma}_0^{\varphi} = \bigcup_{k=1}^K \tilde{\Gamma}_{0,k}^{\varphi}$, $\tilde{\Gamma}_{0,k}^{\varphi} = \{(x_1, x_2, x_3) \in \tilde{\Gamma}_k; (x_1, x_2) \in \tilde{\gamma}_{0,k}^{\varphi}\}$, $\tilde{\gamma}_{0,k}^{\varphi} \subset \tilde{\gamma}$, of the lateral surface $\tilde{\Gamma}^*$ of the shell and on the remaining part $\Gamma_1^{\varphi*} = \xi(\Gamma_1^{\varphi})$, $\Gamma_1^{\varphi} = \Gamma \setminus \tilde{\Gamma}_0^{\varphi}$, of the boundary the normal component of the electric displacement with density $\mathbf{g}^{\varphi*} : \Gamma_1^{\varphi*} \times (0, T) \rightarrow \mathbf{R}$ is given. The magnetic field \mathbf{H}^* is potential $\mathbf{H}^* = -(\partial\psi^* / \partial x_i^*)_{i=1}^3$ and magnetic potential $\psi^* : \Omega^* \times (0, T) \rightarrow \mathbf{R}$ vanishes along $\tilde{\Gamma}_0^{\psi*} = \xi(\tilde{\Gamma}_0^{\psi})$, $\tilde{\Gamma}_0^{\psi} = \bigcup_{k=1}^K \tilde{\Gamma}_{0,k}^{\psi}$, $\tilde{\Gamma}_{0,k}^{\psi} = \{(x_1, x_2, x_3) \in \tilde{\Gamma}_k; (x_1, x_2) \in \tilde{\gamma}_{0,k}^{\psi}\}$, $\tilde{\gamma}_{0,k}^{\psi} \subset \tilde{\gamma}$, of the lateral surface $\tilde{\Gamma}^*$ and on the remaining part $\Gamma_1^{\psi*} = \xi(\Gamma_1^{\psi})$,

$\Gamma_1^\psi = \Gamma \setminus \overline{\tilde{\Gamma}_0^\psi}$, of the boundary the normal component of the magnetic induction with density $g^{\psi*} : \Gamma_1^{\psi*} \times (0, T) \rightarrow \mathbf{R}$ is given.

The linear dynamical three-dimensional model of the thermoelastic piezoelectric multilayer shell $\overline{\Omega^*}$ in differential form with quasi-static equations for electro-magnetic fields, where the rate of change of magnetic field is small, i.e. electric field is curl free, and there is no electric current, i.e. magnetic field is curl free, in Cartesian coordinates is given by the following system of partial differential equations [2]:

$$\rho^{k*} \frac{\partial^2 u_i^{k*}}{\partial t^2} - \sum_{j=1}^3 \frac{\partial \sigma_{ij}^{k*}}{\partial x_j^*} = f_i^{k*} \quad \text{in } \Omega_k^* \times (0, T), \quad i = 1, 2, 3, \quad (1)$$

$$\sum_{j=1}^3 \frac{\partial D_j^{k*}}{\partial x_j} = f^{\varphi, k*} \quad \text{in } \Omega_k^* \times (0, T), \quad (2)$$

$$\sum_{j=1}^3 \frac{\partial B_j^k}{\partial x_j} = 0 \quad \text{in } \Omega_k^* \times (0, T), \quad (3)$$

$$\chi^{k*} \frac{\partial \theta^{k*}}{\partial t} - \sum_{i,j=1}^3 \frac{\partial}{\partial x_i^*} \left(\eta_{ij}^{k*} \frac{\partial \theta^{k*}}{\partial x_j^*} \right) + \Theta_0 \frac{\partial}{\partial t} \sum_{i,j=1}^3 \lambda_{ij}^{k*} e_{ij}^*(\mathbf{u}^{k*}) = f^{\theta, k*} \quad \text{in } \Omega_k^* \times (0, T), \quad (4)$$

with mixed boundary conditions

$$\mathbf{u}^* = \mathbf{0} \quad \text{on } \tilde{\Gamma}_0^* \times (0, T), \quad \sum_{j=1}^3 \sigma_{ij}^* n_j^* = g_i^* \quad \text{on } \Gamma_1^* \times (0, T), \quad (5)$$

$$\varphi^* = 0 \quad \text{on } \tilde{\Gamma}_0^{\varphi*} \times (0, T), \quad \sum_{i=1}^3 D_i^* n_i^* = g^{\varphi*} \quad \text{on } \Gamma_1^{\varphi*} \times (0, T), \quad (6)$$

$$\psi^* = 0 \quad \text{on } \tilde{\Gamma}_0^{\psi*} \times (0, T), \quad \sum_{i=1}^3 B_i^* n_i^* = g^{\psi*} \quad \text{on } \Gamma_1^{\psi*} \times (0, T), \quad (7)$$

$$\theta^* = 0 \quad \text{on } \Gamma^* \times (0, T), \quad (8)$$

rigid contact conditions along the interfaces $\Gamma_k^{+*} = \theta(\Gamma_k^+)$, $k = 1, \dots, K-1$,

$$\mathbf{u}^{k*} = \mathbf{u}^{k+1*}, \quad \sum_{j=1}^3 \sigma_{ij}^{k*} n_j^* = \sum_{j=1}^3 \sigma_{ij}^{k+1*} n_j^* \quad \text{on } \Gamma_k^{+*}, \quad (9)$$

$$\varphi^{k*} = \varphi^{k+1*}, \quad \sum_{i=1}^3 D_i^{k*} n_i^* = \sum_{i=1}^3 D_i^{k+1*} n_i^* \quad \text{on } \Gamma_k^{+*}, \quad (10)$$

$$\psi^{k*} = \psi^{k+1*}, \quad \sum_{i=1}^3 B_i^{k*} n_i^* = \sum_{i=1}^3 B_i^{k+1*} n_i^* \quad \text{on } \Gamma_k^{+*}, \quad (11)$$

$$\theta^{k*} = \theta^{k+1*}, \quad \sum_{i,j=1}^3 \eta_{ij}^{k*} \frac{\partial \theta^{k*}}{\partial x_j^*} n_i^* = \sum_{i,j=1}^3 \eta_{ij}^{k+1*} \frac{\partial \theta^{k+1*}}{\partial x_j^*} n_i^* \quad \text{on } \Gamma_k^{+*}, \quad (12)$$

and initial conditions

$$u_i^*(x^*, 0) = u_{0i}^*(x^*), \quad \frac{\partial u_i^*}{\partial t}(x^*, 0) = \dot{u}_{0i}^*(x^*), \quad \theta^*(x^*, 0) = \theta_0^*(x^*) \quad \text{in } \Omega^*, \quad i = 1, 2, 3, \quad (13)$$

where $\mathbf{n}^* = (n_i^*)_{i=1}^3$ is the unit outward normal vector to the corresponding surface, $\mathbf{u}^* = (u_i^*)_{i=1}^3 : \Omega^* \times (0, T) \rightarrow \mathbf{R}^3$ is the mechanical displacement vector-function, $\mathbf{u}^{k*} = \mathbf{u}^*$, $\varphi^{k*} = \varphi^*$, $\psi^{k*} = \psi^*$, $\theta^{k*} = \theta^*$ in Ω_k^* , $\Theta_0 > 0$ is the temperature of thermoelastic piezoelectric body in natural state in the absence of deformation and electromagnetic fields, which is considered as a reference temperature, $\mathbf{u}_0^* = (u_{0i}^*)_{i=1}^3$ and $\mathbf{u}_1^* = (u_{1i}^*)_{i=1}^3$ are the initial displacement and velocity vector-functions, θ_0^* is the initial distribution of temperature, $e_{ij}^*(\mathbf{v}^*) = 1/2(\partial v_i^* / \partial x_j^* + \partial v_j^* / \partial x_i^*)$, $i, j = 1, 2, 3$, $\mathbf{v}^* = (v_i^*)_{i=1}^3$, is the strain tensor, $(\sigma_{ij}^{k*})_{i,j=1}^3$ is the mechanical stress tensor, $\mathbf{D}^{k*} = (D_j^{k*})_{j=1}^3$ is the electric displacement vector and $\mathbf{B}^{k*} = (B_j^{k*})_{j=1}^3$ is the magnetic induction vector in the layer Ω_k^* , which are given by the following constitutive equations:

$$\begin{aligned}\sigma_{ij}^{k*} &= \sum_{p,q=1}^3 c_{ijpq}^{k*} e_{pq}^*(\mathbf{u}^{k*}) + \sum_{p=1}^3 \varepsilon_{pij}^{k*} \frac{\partial \varphi^{k*}}{\partial x_p^*} + \sum_{p=1}^3 b_{pij}^{k*} \frac{\partial \psi^{k*}}{\partial x_p^*} - \lambda_{ij}^{k*} \theta^{k*}, \quad i, j = 1, 2, 3, \\ D_i^{k*} &= \sum_{p,q=1}^3 \varepsilon_{ipq}^{k*} e_{pq}^*(\mathbf{u}^{k*}) - \sum_{j=1}^3 d_{ij}^{k*} \frac{\partial \varphi^{k*}}{\partial x_j^*} - \sum_{j=1}^3 a_{ij}^{k*} \frac{\partial \psi^{k*}}{\partial x_j^*}, \quad j = 1, 2, 3, \\ B_i^{k*} &= \sum_{p,q=1}^3 b_{ipq}^{k*} e_{pq}^*(\mathbf{u}^{k*}) - \sum_{j=1}^3 a_{ij}^{k*} \frac{\partial \varphi^{k*}}{\partial x_j^*} - \sum_{j=1}^3 \zeta_{ij}^{k*} \frac{\partial \psi^{k*}}{\partial x_j^*}, \quad j = 1, 2, 3.\end{aligned}$$

We assume that the coefficients characterizing elastic, thermal, electric and magnetic properties satisfy the following symmetry conditions

$$\begin{aligned}c_{ijpq}^{k*} &= c_{ijqp}^{k*} = c_{jipq}^{k*}, \quad \varepsilon_{pij}^{k*} = \varepsilon_{pji}^{k*}, \quad b_{pij}^{k*} = b_{pji}^{k*}, \\ d_{ij}^{k*} &= d_{ji}^{k*}, \quad a_{ij}^{k*} = a_{ji}^{k*}, \quad \zeta_{ij}^{k*} = \zeta_{ji}^{k*}, \quad \lambda_{ij}^{k*} = \lambda_{ji}^{k*}, \quad i, j, p, q = 1, 2, 3, \quad k = 1, \dots, K.\end{aligned}\tag{14}$$

Let us consider variational formulation of initial-boundary value problem (1)-(13) in curvilinear coordinates, which is equivalent to the differential formulation in the space of smooth enough functions: Find the unknown vector-function $\mathbf{u} \in C([0, T]; \mathbf{V}(\Omega))$, $\mathbf{u}' \in C([0, T]; \mathbf{L}^2(\Omega))$, and functions $\varphi \in C([0, T]; V^\varphi(\Omega))$, $\psi \in C([0, T]; V^\psi(\Omega))$, $\theta \in L^2(0, T; H_0^1(\Omega))$, $\theta' \in L^2(0, T; H^{-1}(\Omega))$, which satisfy the following equations in the sense of distributions on $(0, T)$,

$$\frac{d}{dt}(\mathbf{P}^G \mathbf{u}', \mathbf{v})_{\mathbf{L}^2(\Omega)} + c(\mathbf{u}, \mathbf{v}) + \varepsilon(\varphi, \mathbf{v}) + b(\psi, \mathbf{v}) - \lambda(\theta, \mathbf{v}) = L^u(\mathbf{v}), \quad \forall \mathbf{v} \in \mathbf{V}(\Omega),\tag{15}$$

$$-\varepsilon(\bar{\varphi}, \mathbf{u}) + d(\varphi, \bar{\varphi}) + a(\psi, \bar{\varphi}) = L^\varphi(\bar{\varphi}), \quad \forall \bar{\varphi} \in V^\varphi(\Omega),\tag{16}$$

$$-b(\bar{\psi}, \mathbf{u}) + a(\varphi, \bar{\psi}) + \zeta(\psi, \bar{\psi}) = L^\psi(\bar{\psi}), \quad \forall \bar{\psi} \in V^\psi(\Omega),\tag{17}$$

$$\frac{d}{dt}(\chi^G \theta, \bar{\theta})_{L^2(\Omega)} + \eta(\theta, \bar{\theta}) + \Theta_0 \lambda(\bar{\theta}, \mathbf{u}') = L^\theta(\bar{\theta}), \quad \forall \bar{\theta} \in H_0^1(\Omega),\tag{18}$$

together with the initial conditions

$$\mathbf{u}(0) = \mathbf{u}_0, \quad \mathbf{u}'(0) = \mathbf{u}_1, \quad \theta(0) = \theta_0,\tag{19}$$

where $\mathbf{V}(\Omega) = \{\mathbf{v} \in \mathbf{H}^1(\Omega); \mathbf{tr}_\Gamma(\mathbf{v}) = \mathbf{0} \text{ on } \tilde{\Gamma}_0\}$, $V^\varphi(\Omega) = \{\bar{\varphi} \in H^1(\Omega); tr_\Gamma(\bar{\varphi}) = 0 \text{ on } \tilde{\Gamma}_0^\varphi\}$, $V^\psi(\Omega) = \{\bar{\psi} \in H^1(\Omega); tr_\Gamma(\bar{\psi}) = 0 \text{ on } \tilde{\Gamma}_0^\psi\}$, $H_0^1(\Omega) = \{\bar{\theta} \in H^1(\Omega); tr_\Gamma(\bar{\theta}) = 0 \text{ on } \Gamma\}$,

3 TWO-DIMENSIONAL MODELS

In order to construct the hierarchy of two-dimensional models let us consider the subspaces $\mathbf{V}_N(\Omega)$ and $\mathbf{H}_N(\Omega)$ of $\mathbf{V}(\Omega)$ and $\mathbf{L}^2(\Omega)$, respectively, $\mathbf{N} = (N_1^1, N_2^1, N_3^1, \dots, N_1^K, N_2^K, N_3^K)$, consisting of vector-functions \mathbf{v}_N with components v_{N_i} ($i=1, 2, 3$), which are polynomials with respect to the variable x_3 in each layer Ω_k ,

$$v_{Ni} = v_{Ni}^k = \sum_{r_i^k=0}^{N_i^k} \frac{1}{h_k} \left(r_i^k + \frac{1}{2} \right) v_{Ni}^{r_i^k} P_{r_i^k}(z^k) \quad \text{in } \Omega_k, \quad v_{Ni}^{r_i^k} \in L^2(\omega), \quad 0 \leq r_i^k \leq N_i^k, \quad N_i^k \in \mathbb{N} \cup \{0\}, \quad i=1,2,3,$$

where $z^k = \frac{x_3 - \bar{h}_k}{h_k}$, $h_k = \frac{h_k^+ - h_k^-}{2}$, $\bar{h}_k = \frac{h_k^+ + h_k^-}{2}$, $k=1, \dots, K$, and P_r denotes the Legendre polynomial of order $r \in \mathbb{N} \cup \{0\}$. We also consider the subspaces $V_{N_\varphi}^\varphi(\Omega)$, $N_\varphi = (N_\varphi^1, N_\varphi^2, \dots, N_\varphi^K)$, and $V_{N_\psi}^\psi(\Omega)$, $N_\psi = (N_\psi^1, N_\psi^2, \dots, N_\psi^K)$, of $V^\varphi(\Omega)$ and $V^\psi(\Omega)$, respectively, which consist of the following functions

$$\bar{\varphi}_{N_\varphi} = \bar{\varphi}_{N_\varphi}^k = \sum_{r_\varphi^k=0}^{N_\varphi^k} \frac{1}{h_k} \left(r_\varphi^k + \frac{1}{2} \right) \bar{\varphi}_{N_\varphi}^{r_\varphi^k} P_{r_\varphi^k}(z^k) \quad \text{in } \Omega_k, \quad \bar{\varphi}_{N_\varphi}^{r_\varphi^k} \in L^2(\omega), \quad 0 \leq r_\varphi^k \leq N_\varphi^k, \quad N_\varphi^k \in \mathbb{N} \cup \{0\},$$

$$\bar{\psi}_{N_\psi} = \bar{\psi}_{N_\psi}^k = \sum_{r_\psi^k=0}^{N_\psi^k} \frac{1}{h_k} \left(r_\psi^k + \frac{1}{2} \right) \bar{\psi}_{N_\psi}^{r_\psi^k} P_{r_\psi^k}(z^k) \quad \text{in } \Omega_k, \quad \bar{\psi}_{N_\psi}^{r_\psi^k} \in L^2(\omega), \quad 0 \leq r_\psi^k \leq N_\psi^k, \quad N_\psi^k \in \mathbb{N} \cup \{0\},$$

and subspaces $V_{N_\theta}^\theta(\Omega)$ and $H_{N_\theta}^\theta(\Omega)$ of $H_0^1(\Omega)$ and $L^2(\Omega)$, consisting of the functions

$$\bar{\theta}_{N_\theta} = \bar{\theta}_{N_\theta}^k = \sum_{r_\theta^k=0}^{N_\theta^k} \frac{1}{h_k} \left(r_\theta^k + \frac{1}{2} \right) \bar{\theta}_{N_\theta}^{r_\theta^k} P_{r_\theta^k}(z^k) \quad \text{in } \Omega_k, \quad \bar{\theta}_{N_\theta}^{r_\theta^k} \in L^2(\omega), \quad 0 \leq r_\theta^k \leq N_\theta^k,$$

where $N_\theta^k \in \mathbb{N} \cup \{0\}$, $k=2, \dots, K-1$, $N_\theta^1 \geq 1$, $N_\theta^K \geq 1$, for $K \geq 2$, and $N_\theta^1 \in \mathbb{N}$, $N_\theta^1 \geq 2$, for $K=1$.

Since the functions h_k^+ and h_k^- are Lipschitz continuous in ω from Rademacher's theorem [14] we have that h_k^+ and h_k^- are differentiable almost everywhere in ω and $\partial_\alpha h_k^\pm \in L^\infty(\omega^*)$ for all subdomains ω^* , $\overline{\omega^*} \subset \omega$, $\alpha=1,2$. Therefore, the positiveness of h_k in ω implies that for

any vector-function $\mathbf{v}_N = (v_{Ni})_{i=1}^3 \in \mathbf{V}_N(\Omega)$ the corresponding functions $v_{Ni}^{r_i^k} \in H^1(\omega^*)$, for all ω^* , $\overline{\omega^*} \subset \omega$, i.e. $v_{Ni}^{r_i^k} \in H_{loc}^1(\omega)$, $0 \leq r_i^k \leq N_i^k$, $i=1,2,3$, $k=1, \dots, K$. Similarly, for all functions

$\bar{\varphi}_{N_\varphi} \in V_{N_\varphi}^\varphi(\Omega)$, $\bar{\psi}_{N_\psi} \in V_{N_\psi}^\psi(\Omega)$, $\bar{\theta}_{N_\theta} \in V_{N_\theta}^\theta(\Omega)$, the functions $\bar{\varphi}_{N_\varphi}^{r_\varphi^k}$, $\bar{\psi}_{N_\psi}^{r_\psi^k}$, $\bar{\theta}_{N_\theta}^{r_\theta^k}$ of two space

variables in the expressions of $\bar{\varphi}_{N_\varphi}$, $\bar{\psi}_{N_\psi}$, $\bar{\theta}_{N_\theta}$ belong to $H^1(\omega^*)$, $\overline{\omega^*} \subset \omega$, i.e. $\bar{\varphi}_{N_\varphi}^{r_\varphi^k}$, $\bar{\psi}_{N_\psi}^{r_\psi^k}$,

$\bar{\theta}_{N_\theta}^{r_\theta^k} \in H_{loc}^1(\omega)$, $r_\varphi^k = 0, \dots, N_\varphi^k$, $r_\psi^k = 0, \dots, N_\psi^k$, $r_\theta^k = 0, \dots, N_\theta^k$. Moreover, the norms $\|\cdot\|_{\mathbf{H}^1(\Omega)}$ and $\|\cdot\|_{H^1(\Omega)}$ in the spaces $\mathbf{H}^1(\Omega)$ and $H^1(\Omega)$ define weighted norms $\|\cdot\|_*$ and $\|\cdot\|_{\varphi^*}$, $\|\cdot\|_{\psi^*}$, $\|\cdot\|_{\theta^*}$

of vector-functions $\vec{v}_N = (v_{Ni}^{r_i^k}) \in [H_{loc}^1(\omega)]^{N_{1,2,3}^K}$, $N_{1,2,3}^K = \sum_{k=1}^K (N_1^k + N_2^k + N_3^k + 3)$, and $\vec{\bar{\varphi}}_{N_\varphi} = (\bar{\varphi}_{N_\varphi}^{r_\varphi^k}) \in$

$[H_{loc}^1(\omega)]^{\tilde{N}_\varphi^K}$, $\tilde{N}_\varphi^K = \sum_{k=1}^K (N_\varphi^k + 1)$, $\vec{\bar{\psi}}_{N_\psi} = (\bar{\psi}_{N_\psi}^{r_\psi^k}) \in [H_{loc}^1(\omega)]^{\tilde{N}_\psi^K}$, $\tilde{N}_\psi^K = \sum_{k=1}^K (N_\psi^k + 1)$, $\vec{\bar{\theta}}_{N_\theta} = (\bar{\theta}_{N_\theta}^{r_\theta^k}) \in$

$[H^1_{loc}(\omega)]^{\tilde{N}^k_\theta}$, $\tilde{N}^K_\theta = \sum_{k=1}^K (N^k_\theta + 1)$, such that $\|\vec{v}_N\|_* = \|\mathbf{v}_N\|_{\mathbf{H}^1(\Omega)}$ and $\|\vec{\bar{\varphi}}_{N_\varphi}\|_{\varphi^*} = \|\bar{\varphi}_{N_\varphi}\|_{H^1(\Omega)}$, $\|\vec{\bar{\psi}}_{N_\psi}\|_{\psi^*} = \|\bar{\psi}_{N_\psi}\|_{H^1(\Omega)}$, $\|\vec{\bar{\theta}}_{N_\theta}\|_{\theta^*} = \|\bar{\theta}_{N_\theta}\|_{H^1(\Omega)}$. Using the properties of the Legendre polynomials we can obtain explicit expressions of the norms $\|\cdot\|_*$ and $\|\cdot\|_{\varphi^*}$, $\|\cdot\|_{\psi^*}$, $\|\cdot\|_{\theta^*}$. In particular, $\|\cdot\|_*$ is given by the following expression:

$$\begin{aligned}
 \|\vec{v}_N\|_*^2 = & \sum_{k=1}^K \sum_{i=1}^3 \sum_{r_i^k=0}^{N_i^k} \left(r_i^k + \frac{1}{2} \right) \left[\left\| \sum_{s_i^k=r_i^k}^{N_i^k} \left(s_i^k + \frac{1}{2} \right) (1 - (-1)^{r_i^k+s_i^k}) h_k^{-3/2} v_{Ni}^k \right\|_{L^2(\omega)}^2 + \left\| h_k^{-1/2} v_{Ni}^k \right\|_{L^2(\omega)}^2 + \right. \\
 & \left. \sum_{\alpha=1}^2 \left\| \sum_{s_i^k=r_i^k+1}^{N_i^k} \left(s_i^k + \frac{1}{2} \right) (\partial_\alpha h_k^+ - (-1)^{r_i^k+s_i^k} \partial_\alpha h_k^-) h_k^{-3/2} v_{Ni}^k - h_k^{-1/2} \partial_\alpha v_{Ni}^k + (r_i^k + 1) h_k^{-3/2} \partial_\alpha h_k v_{Ni}^k \right\|_{L^2(\omega)}^2 \right].
 \end{aligned}$$

For components v_{Ni}^k and $\bar{\varphi}_{N_\varphi}^k$, $\bar{\psi}_{N_\psi}^k$, $\bar{\theta}_{N_\theta}^k$ of \vec{v}_N and $\vec{\bar{\varphi}}_{N_\varphi}$, $\vec{\bar{\psi}}_{N_\psi}$, $\vec{\bar{\theta}}_{N_\theta}$, which possess the properties $\|\vec{v}_N\|_* < \infty$ and $\|\vec{\bar{\varphi}}_{N_\varphi}\|_{\varphi^*} < \infty$, $\|\vec{\bar{\psi}}_{N_\psi}\|_{\psi^*} < \infty$, $\|\vec{\bar{\theta}}_{N_\theta}\|_{\theta^*} < \infty$ we can define the traces on $\tilde{\gamma}$. Indeed, the corresponding vector-function of three space variables $\mathbf{v}_N = (v_{Ni})_{i=1}^3$ and functions $\bar{\varphi}_{N_\varphi}$, $\bar{\psi}_{N_\psi}$, $\bar{\theta}_{N_\theta}$ belong to the spaces $\mathbf{V}_N(\Omega) \subset \mathbf{H}^1(\Omega)$ and $V_{N_\varphi}^\varphi(\Omega)$, $V_{N_\psi}^\psi(\Omega)$, $V_{N_\theta}^\theta(\Omega) \subset H^1(\Omega)$, respectively, and using the trace operator $tr_{\tilde{\Gamma}_k}^*$ we define the traces of v_{Ni}^k and $\bar{\varphi}_{N_\varphi}^k$, $\bar{\psi}_{N_\psi}^k$, $\bar{\theta}_{N_\theta}^k$ on $\tilde{\gamma}$, in particular,

$$tr_{\tilde{\gamma}}^*(v_{Ni}^k) = \int_{h^-}^{h^+} tr_{\tilde{\Gamma}_k}^*(v_{Ni}^k) P_{r_i^k}(z^k) dx_3, \quad r_i^k = 0, \dots, N_i^k, \quad i = 1, 2, 3, \quad k = 1, \dots, K.$$

Since the vector-functions \mathbf{v}_N from the subspaces $\mathbf{V}_N(\Omega)$ and $\mathbf{H}_N(\Omega)$, and the functions $\bar{\varphi}_{N_\varphi} \in V_{N_\varphi}^\varphi(\Omega)$, $\bar{\psi}_{N_\psi} \in V_{N_\psi}^\psi(\Omega)$, and $\bar{\theta}_{N_\theta}$ from $V_{N_\theta}^\theta(\Omega)$ and $H_{N_\theta}^\theta(\Omega)$ are uniquely defined by the functions v_{Ni}^k , $\bar{\varphi}_{N_\varphi}^k$, $\bar{\psi}_{N_\psi}^k$, $\bar{\theta}_{N_\theta}^k$ of two space variables, hence considering the original three-dimensional problem (15)-(19) on these subspaces, we obtain the following hierarchy of two-dimensional initial-boundary value problems: Find $\vec{u}_N \in C([0, T]; \vec{V}_N(\omega))$, $\vec{u}'_N \in C([0, T]; \vec{H}_N(\omega))$, $\vec{\varphi}_{N_\varphi} \in C([0, T]; \vec{V}_{N_\varphi}^\varphi(\omega))$, $\vec{\psi}_{N_\psi} \in C([0, T]; \vec{V}_{N_\psi}^\psi(\omega))$, $\vec{\theta}_{N_\theta} \in L^2(0, T; \vec{V}_{N_\theta}^\theta(\omega))$, $\vec{\theta}'_{N_\theta} \in L^2(0, T; (\vec{V}_{N_\theta}^\theta(\omega))')$, which satisfy the following equations in the sense of distributions on $(0, T)$,

$$\frac{d}{dt} R_N(\vec{u}'_N, \vec{v}_N) + c_N(\vec{u}_N, \vec{v}_N) + \varepsilon_{N_\varphi N}(\vec{\varphi}_{N_\varphi}, \vec{v}_N) + b_{N_\psi N}(\vec{\psi}_{N_\psi}, \vec{v}_N) - \lambda_{N_\theta N}(\vec{\theta}_{N_\theta}, \vec{v}_N) = L_N^u(\vec{v}_N), \quad (20)$$

$$-\varepsilon_{N_\varphi N}(\vec{\bar{\varphi}}_{N_\varphi}, \vec{u}_N) + d_{N_\varphi}(\vec{\varphi}_{N_\varphi}, \vec{\bar{\varphi}}_{N_\varphi}) + a_{N_\varphi N_\psi}(\vec{\psi}_{N_\psi}, \vec{\bar{\varphi}}_{N_\varphi}) = L_{N_\varphi}^\varphi(\vec{\bar{\varphi}}_{N_\varphi}), \quad (21)$$

$$-b_{N_\psi N}(\vec{\bar{\psi}}_{N_\psi}, \vec{u}_N) + a_{N_\varphi N_\psi}(\vec{\varphi}_{N_\varphi}, \vec{\bar{\psi}}_{N_\psi}) + \zeta_{N_\psi}(\vec{\psi}_{N_\psi}, \vec{\bar{\psi}}_{N_\psi}) = L_{N_\psi}^\psi(\vec{\bar{\psi}}_{N_\psi}), \quad (22)$$

$$\frac{d}{dt} R_{N_\theta}^\theta(\vec{\theta}_{N_\theta}, \vec{\theta}_{N_\theta}) + \eta_{N_\theta}(\vec{\theta}_{N_\theta}, \vec{\theta}_{N_\theta}) + \Theta_0 \lambda_{N_\theta N}(\vec{\theta}_{N_\theta}, \vec{u}'_N) = L_{N_\theta}^\theta(\vec{\theta}_{N_\theta}), \quad (23)$$

for all $\vec{v}_N \in \vec{V}_N(\omega)$, $\vec{\varphi}_{N_\varphi} \in \vec{V}_{N_\varphi}^\varphi(\omega)$, $\vec{\psi}_{N_\psi} \in \vec{V}_{N_\psi}^\psi(\omega)$, $\vec{\theta}_{N_\theta} \in \vec{V}_{N_\theta}^\theta(\omega)$, and the initial conditions

$$\vec{u}_N(0) = \vec{u}_{N_0}, \quad \vec{u}'_N(0) = \vec{u}_{N_1}, \quad \vec{\theta}_{N_\theta}(0) = \vec{\theta}_{N_\theta 0}, \quad (24)$$

where $\vec{V}_N(\omega) = \{\vec{v}_N = (v_{N_i}^k) \in [H_{loc}^1(\omega)]^{N_{1,2,3}^K}; \|\vec{v}_N\|_* < \infty, tr_{\tilde{\gamma}}(v_{N_i}^k) = 0 \text{ on } \tilde{\gamma}_{0,k}, r_i^k = 0, \dots, N_i^k, i = 1, 2, 3,$

$a(\bar{\varphi}_{N_\varphi}, \bar{\psi}_{N_\psi}), \zeta_{N_\psi}(\vec{\psi}_{N_\psi}, \vec{\psi}_{N_\psi}) = \zeta(\tilde{\psi}_{N_\psi}, \bar{\psi}_{N_\psi}), R_{N_\theta}^\theta(\vec{\theta}_{N_\theta}, \vec{\theta}_{N_\theta}) = (\chi^G \tilde{\theta}_{N_\theta}, \bar{\theta}_{N_\theta})_{L^2(\Omega)}, \eta_{N_\theta}(\vec{\theta}_{N_\theta}, \vec{\theta}_{N_\theta}) =$

$\eta(\tilde{\theta}_{N_\theta}, \bar{\theta}_{N_\theta}),$ for all vector-functions $\vec{v}_N, \vec{v}_N \in \vec{V}_N(\omega), \vec{\varphi}_{N_\varphi}, \vec{\varphi}_{N_\varphi} \in \vec{V}_{N_\varphi}^\varphi(\omega), \vec{\psi}_{N_\psi}, \vec{\psi}_{N_\psi} \in \vec{V}_{N_\psi}^\psi(\omega),$

$\vec{\theta}_{N_\theta}, \vec{\theta}_{N_\theta} \in \vec{V}_{N_\theta}^\theta(\omega),$ corresponding to $\tilde{\mathbf{v}}_N, \mathbf{v}_N \in \mathbf{V}_N(\Omega), \tilde{\varphi}_{N_\varphi}, \bar{\varphi}_{N_\varphi} \in V_{N_\varphi}^\varphi(\Omega), \tilde{\psi}_{N_\psi}, \bar{\psi}_{N_\psi} \in V_{N_\psi}^\psi(\Omega),$

$\tilde{\theta}_{N_\theta}, \bar{\theta}_{N_\theta} \in V_{N_\theta}^\theta(\Omega),$ respectively. The linear forms $L_N^u, L_{N_\varphi}^\varphi, L_{N_\psi}^\psi$ and $L_{N_\theta}^\theta$ are given by the

following expressions:

$$L_N^u(\vec{v}_N) = \sum_{k=1}^K \sum_{i=1}^3 \sum_{r_i^k=0}^{N_i^k} \left(r_i^k + \frac{1}{2} \right) \left[\int_\omega \frac{1}{h_k} v_{N_i}^{r_i^k} \left(f_i^{k,G} + g_i^{k,G,+} \lambda_{k,+} + g_i^{k,G,-} \lambda_{k,-} (-1)^{r_i^k} \right) d\omega + \int_{\gamma_{1,k}} \frac{1}{h_k} tr_{\tilde{\gamma}_k} (v_{N_i}^{r_i^k}) g_i^{k,G} d\gamma_{1,k} \right],$$

$$L_{N_\varphi}^\varphi(\vec{\varphi}_{N_\varphi}) = \sum_{k=1}^K \sum_{r_\varphi^k=0}^{N_\varphi^k} \left(r_\varphi^k + \frac{1}{2} \right) \left[\int_\omega \frac{1}{h_k} \varphi_{N_\varphi}^{r_\varphi^k} \left(f^{\varphi,k,G} - g^{\varphi,k,G,+} \lambda_{k,+} - g^{\varphi,k,G,-} \lambda_{k,-} (-1)^{r_\varphi^k} \right) d\omega - \int_{\gamma_{1,k}^\varphi} \frac{1}{h_k} tr_{\tilde{\gamma}_k} (\varphi_{N_\varphi}^{r_\varphi^k}) g^{\varphi,k,G} d\gamma_{1,k}^\varphi \right],$$

$$L_{N_\psi}^\psi(\vec{\bar{\psi}}_{N_\psi}) = - \sum_{k=1}^K \sum_{r_\psi^k=0}^{N_\psi^k} \left(r_\psi^k + \frac{1}{2} \right) \left[\int_{\omega} \frac{1}{h_k} \vec{\bar{\psi}}_{N_\psi} \left(g^{\psi,k,G,+} \lambda_{k,+} + g^{\psi,k,G,-} \lambda_{k,-} (-1)^{r_\psi^k} \right) d\omega + \int_{\gamma_{1,k}^\psi} \frac{1}{h_k} tr_{\tilde{\gamma}_k}^{r_\psi^k}(\vec{\bar{\psi}}_{N_\psi}) g^{\psi,k,G} d\gamma_{1,k}^\psi \right],$$

$$L_{N_\theta}^\theta(\vec{\bar{\theta}}_{N_\theta}) = \sum_{k=1}^K \sum_{r_\theta^k=0}^{N_\theta^k} \left(r_\theta^k + \frac{1}{2} \right) \int_{\omega} \frac{1}{h_k} \vec{\bar{\theta}}_{N_\theta}^{r_\theta^k} f^{\theta,k,G} d\omega,$$

where $f_i^{k,G} = f^i \sqrt{G}$, $f^{\varphi,k,G} = f^\varphi \sqrt{G}$, $f^{\theta,k,G} = f^\theta \sqrt{G}$ in Ω_k , $g_i^{k,G} = g^i \sqrt{G}$ on $\Gamma_1 \cap \partial\Omega_k$, $g^{\varphi,k,G} = g^\varphi \sqrt{G}$ on $\Gamma_1^\varphi \cap \partial\Omega_k$, $g^{\psi,k,G} = g^\psi \sqrt{G}$ on $\Gamma_1^\psi \cap \partial\Omega_k$, $g_i^{k,G,\pm}(x_1, x_2) = g^i(x_1, x_2, x_3) \sqrt{G}$, for $(x_1, x_2, x_3) \in \Gamma^{k,\pm} \cap \Gamma_1$, $g^{\varphi,k,G,\pm}(x_1, x_2) = g^\varphi(x_1, x_2, x_3) \sqrt{G}$, for $(x_1, x_2, x_3) \in \Gamma^{k,\pm} \cap \Gamma_1^\varphi$, $g^{\psi,k,G,\pm}(x_1, x_2) = g^\psi(x_1, x_2, x_3) \sqrt{G}$, for $(x_1, x_2, x_3) \in \Gamma^{k,\pm} \cap \Gamma_1^\psi$, and otherwise $g_i^{k,G,\pm} \equiv g^{\varphi,k,G,\pm} \equiv g^{\psi,k,G,\pm} \equiv 0$, $\gamma_{1,k} = \tilde{\gamma}_k \setminus \tilde{\gamma}_{0,k}^+$, $\gamma_{1,k}^\varphi = \tilde{\gamma}_k \setminus \tilde{\gamma}_{0,k}^\varphi$, $\gamma_{1,k}^\psi = \tilde{\gamma}_k \setminus \tilde{\gamma}_{0,k}^\psi$, $\lambda_{k,\pm} = \sqrt{1 + (\partial_1 h_k^\pm)^2 + (\partial_2 h_k^\pm)^2}$, $k=1, \dots, K$, $v^k = \int_{h_k^-}^{h_k^+} v^k P_r(z_k) dx_3$, for all functions $v^k \in L^2(\Omega_k)$, $r \in \mathbf{N} \cup \{0\}$.

For the constructed two-dimensional initial-boundary value problem (20)-(24) for thermoelastic piezoelectric shell the following existence and uniqueness theorem is proved.

Theorem 1. Suppose that $\Omega \subset \mathbf{R}^3$ is a bounded Lipschitz domain, $\tilde{\gamma}_0^\varphi \neq \emptyset$, $\tilde{\gamma}_0^\psi \neq \emptyset$, $\rho, \chi \in L^\infty(\Omega)$, $\rho(x) > \alpha_\rho = \text{const} > 0$, $\chi(x) > \alpha_\chi = \text{const} > 0$, for almost all $x \in \Omega$, c_{ijpq} , ε_{pij} , b_{pij} , d_{ij} , ζ_{ij} , a_{ij} , η_{ij} , $\lambda_{ij} \in L^\infty(\Omega)$, $\partial \lambda_{ij} / \partial x_q \in L^3(\Omega)$, $i, j, p, q = 1, 2, 3$, and conditions (14) and

$$\sum_{i,j,p,q=1}^3 c_{ijpq} \xi_{ij} \xi_{pq} \geq \alpha_c \sum_{i,j=1}^3 (\xi_{ij})^2, \quad \forall \xi_{ij} \in \mathbf{R}, \xi_{ij} = \xi_{ji}, \quad \sum_{i,j=1}^3 \eta_{ij} \xi_i \xi_j \geq \alpha_\eta \sum_{i=1}^3 (\xi_i)^2, \quad \forall \xi_i \in \mathbf{R},$$

$$\sum_{i,j=1}^3 d_{ij} \xi_j \xi_i + 2 \sum_{i,j=1}^3 a_{ij} \bar{\xi}_j \xi_i + \sum_{i,j=1}^3 \zeta_{ij} \bar{\xi}_j \bar{\xi}_i \geq \alpha \sum_{i=1}^3 ((\xi_i)^2 + (\bar{\xi}_i)^2), \quad \forall \xi_i, \bar{\xi}_i \in \mathbf{R},$$

are fulfilled. If the given functions satisfy the following conditions

$$h_k^{-1/2} f_i^k \in L^2(0, T; L^2(\omega)), \quad \lambda_{k,\pm}^{3/4} \frac{d^\alpha g_i^{k,G,\pm}}{dt^\alpha} \in L^2(0, T; L^{4/3}(\omega)), \quad h_k^{-1/4} \frac{d^\alpha g_i^{k,G}}{dt^\alpha} \in L^2(0, T; L^{4/3}(\gamma_{1,k})),$$

$$h_k^{-1/6} \frac{d^\alpha f^{\varphi,k}}{dt^\alpha} \in L^2(0, T; L^{6/5}(\omega)), \quad \lambda_{k,\pm}^{3/4} \frac{d^\alpha g^{\varphi,k,G,\pm}}{dt^\alpha} \in L^2(0, T; L^{4/3}(\omega)), \quad h_k^{-1/4} \frac{d^\alpha g^{\varphi,k,G}}{dt^\alpha} \in L^2(0, T; L^{4/3}(\gamma_{1,k}^\varphi)),$$

$$\lambda_{k,\pm}^{3/4} \frac{d^\alpha g^{\psi,k,G,\pm}}{dt^\alpha} \in L^2(0, T; L^{4/3}(\omega)), \quad h_k^{-1/4} \frac{d^\alpha g^{\psi,k,G}}{dt^\alpha} \in L^2(0, T; L^{4/3}(\gamma_{1,k}^\psi)), \quad h_k^{-1/6} \frac{d^\alpha f^{\theta,k,G}}{dt^\alpha} \in L^2(0, T; L^{6/5}(\omega)),$$

where $\alpha = 0, 1$, $r_i^k = 0, \dots, N_i^k$, $i = 1, 2, 3$, $r_\varphi^k = 0, \dots, N_\varphi^k$, $r_\psi^k = 0, \dots, N_\psi^k$, $r_\theta^k = 0, \dots, N_\theta^k$, $k = 1, \dots, K$, and $\vec{u}_{N_0} \in \vec{V}_N(\omega)$, $\vec{u}_{N_1} \in \vec{H}_N(\omega)$, $\vec{\theta}_{N_\theta} \in \vec{H}_{N_\theta}^\theta(\omega)$, then initial-boundary value problem (20)-(24) possesses a unique solution.

In the following theorem we present the results on the relationship between the obtained two-dimensional and original three-dimensional initial-boundary value problems, where we use the following Hilbert spaces

$$H_{h_{1,K}^{\pm}}^{1,1,s}(\Omega) = \{v; \partial_3^{r-1} v \in H^1(\Omega), \partial_\alpha h_k^{\pm} \partial_3^r v \in L^2(\Omega_k), 1 \leq k \leq K, \alpha = 1, 2, r = 1, \dots, s\}, \quad s \in \mathbf{N}.$$

Theorem 2. If $\Omega \subset \mathbf{R}^3$ is a bounded Lipschitz domain, $\tilde{\Gamma}_0^\varphi \neq \emptyset$, $\tilde{\Gamma}_0^\psi \neq \emptyset$, $\mathbf{u}_0 \in \mathbf{V}(\Omega)$, $\mathbf{u}_1 \in \mathbf{L}^2(\Omega)$, $\theta_0 \in L^2(\Omega)$, $\mathbf{f} = (f^i)_{i=1}^3 \in L^2(0, T; \mathbf{L}^2(\Omega))$, $\mathbf{g} = (g^i)_{i=1}^3, \mathbf{g}' \in L^2(0, T; \mathbf{L}^{4/3}(\Gamma_1))$, $f^\varphi, (f^\varphi)' \in L^2(0, T; L^{6/5}(\Omega))$, $g^\varphi, (g^\varphi)' \in L^2(0, T; L^{4/3}(\Gamma_1^\varphi))$, $g^\psi, (g^\psi)' \in L^2(0, T; L^{4/3}(\Gamma_1^\psi))$, $f^\theta \in L^2(0, T; L^{6/5}(\Omega))$, $\rho, \chi \in L^\infty(\Omega)$, $\rho(x) > \alpha_\rho = \text{const} > 0$, $\chi(x) > \alpha_\chi = \text{const} > 0$, for almost all $x \in \Omega$, $c_{ijpq}, \varepsilon_{pji}, b_{pji}, d_{ij}, \zeta_{ij}, a_{ij}, \eta_{ij}, \lambda_{ij} \in L^\infty(\Omega)$, $\partial \lambda_{ij} / \partial x_q \in L^3(\Omega)$, $i, j, p, q = 1, 2, 3$, conditions (14), (25) are fulfilled, and the functions $\mathbf{u}_{N_0} \in \mathbf{V}_N(\Omega)$, $\mathbf{u}_{N_1} \in \mathbf{H}_N(\Omega)$, $\theta_{N_{\theta 0}} \in H_{N_{\theta}}^\theta(\Omega)$, corresponding to the initial conditions $\bar{u}_{N_0} \in \bar{V}_N(\omega)$, $\bar{u}_{N_1} \in \bar{H}_N(\omega)$, $\bar{\theta}_{N_{\theta 0}} \in \bar{H}_{N_{\theta}}^\theta(\omega)$ of the two-dimensional problems, tend to $\mathbf{u}_0, \mathbf{u}_1$ and θ_0 in the spaces $\mathbf{H}^1(\Omega)$, $\mathbf{L}^2(\Omega)$ and $L^2(\Omega)$, respectively, as $N_{\min} = \min_{1 \leq k \leq K, 1 \leq i \leq 3} \{N_i^k, N_\varphi^k, N_\psi^k, N_\theta^k\} \rightarrow \infty$, then three-dimensional problem (15)-(19) possesses a unique solution and functions $\mathbf{u}_N(t)$, $\varphi_{N_\varphi}(t)$, $\psi_{N_\psi}(t)$, $\theta_{N_\theta}(t)$ restored from the solutions \bar{u}_N , $\bar{\varphi}_{N_\varphi}$, $\bar{\psi}_{N_\psi}$, $\bar{\theta}_{N_\theta}$ of two-dimensional problem (20)-(24), possess the following properties

$$\begin{aligned} \mathbf{u}_N(t) &\rightarrow \mathbf{u}(t) && \text{in } \mathbf{H}^1(\Omega), \\ \mathbf{u}'_N(t) &\rightarrow \mathbf{u}'(t) && \text{in } \mathbf{L}^2(\Omega), \\ \theta_{N_\theta}(t) &\rightarrow \theta(t) && \text{in } L^2(\Omega), \end{aligned} \quad \begin{aligned} \varphi_{N_\varphi}(t) &\rightarrow \varphi(t) && \text{in } H^1(\Omega), \\ \psi_{N_\psi}(t) &\rightarrow \psi(t) && \text{in } H^1(\Omega), \end{aligned} \quad \text{for all } t \in [0, T], \text{ as } N_{\min} \rightarrow \infty.$$

In addition, if $\|d^r \mathbf{u} / dt^r\|_{L^2(0, T; (H_{h_{1,K}^{\pm}}^{1,1,s_r}(\Omega))^3)} \leq c$, $s_r \in \mathbf{N}$, $r = 0, 1, 2$, $s_0 \geq s_1 \geq s_2 \geq 1$, $s_1 \geq 2$,

$$\|\varphi'\|_{L^2(0, T; H_{h_{1,K}^{\pm}}^{1,1,s_1^\varphi}(\Omega))} \leq c, \|\psi'\|_{L^2(0, T; H_{h_{1,K}^{\pm}}^{1,1,s_1^\psi}(\Omega))} \leq c, s_1^\varphi, s_1^\psi \in \mathbf{N}, s_1^\varphi \geq 2, s_1^\psi \geq 2, \|d^{\bar{r}} \theta / dt^{\bar{r}}\|_{L^2(0, T; H_{h_{1,K}^{\pm}}^{1,1,s_{\bar{r}}^\theta}(\Omega))} \leq c,$$

$c = \text{const} > 0$ is independent of h_k^\pm , $s_{\bar{r}}^\theta \in \mathbf{N}$, $\bar{r} = 0, 1$, $s_0^\theta \geq s_1^\theta \geq 1$, $s_0^\theta \geq 2$, then for suitable initial data \bar{u}_{N_0} , \bar{u}_{N_1} and $\bar{\theta}_{N_{\theta 0}}$ the following estimate is valid

$$\begin{aligned} &\|\mathbf{u} - \mathbf{u}_N\|_{C([0, T]; \mathbf{H}^1(\Omega))} + \|\mathbf{u}' - \mathbf{u}'_N\|_{C([0, T]; \mathbf{L}^2(\Omega))} + \|\varphi - \varphi_{N_\varphi}\|_{C([0, T]; H^1(\Omega))} + \|\psi - \psi_{N_\psi}\|_{C([0, T]; H^1(\Omega))} \\ &+ \|\theta - \theta_{N_\theta}\|_{C([0, T]; L^2(\Omega))} + \|\theta - \theta_{N_\theta}\|_{L^2(0, T; H^1(\Omega))} \leq \frac{(h_{\max})^s}{(N_{\min})^s} o(T, \mathbf{N}, \mathbf{N}_\varphi, \mathbf{N}_\psi, \mathbf{N}_\theta), \end{aligned}$$

where $s = \min\{s_2, s_1 - 1, s_1^\varphi - 1, s_1^\psi - 1, s_1^\theta, s_0^\theta - 1\}$, $h_{\max} = \max_{(x_1, x_2) \in \omega} \{h_k(x_1, x_2); k = 1, \dots, K\}$,

$o(T, \mathbf{N}, \mathbf{N}_\varphi, \mathbf{N}_\psi, \mathbf{N}_\theta) \rightarrow 0$, as $N_{\min} \rightarrow \infty$.

4 CONCLUSIONS

In this paper, we investigated initial-boundary value problem with mixed boundary

conditions for displacement, electric and magnetic potentials corresponding to linear three-dimensional model for multilayer inhomogeneous anisotropic thermoelastic piezoelectric shell with regard to magnetic field. We obtained a variational formulation of the three-dimensional problem in curvilinear coordinates in corresponding spaces of vector-valued distributions and proved existence and uniqueness of solution. We constructed a hierarchy of two-dimensional models for multilayer thermoelastic piezoelectric shell and studied the existence and uniqueness of solutions of the corresponding initial-boundary value problems. Moreover, we investigated the relationship between the obtained two-dimensional and original three-dimensional models.

Key words: Composite structures, finite element, high-order model, Zig-Zag function, piezoelectric patch analysis

Abstract. This paper presents a C^0 8-node quadrilateral finite element (FE) for geometrically linear piezoelectric plates/shells. It is based on a high-order kinematics proposed in [1] for the mechanical part. The approximation of the electric potential must be able to model piezoelectric patches, and a constant value is considered on each elementary domain while a cubic variation in each layer is used, based on the polynomial expansion given in [2]. Furthermore, Murakami's ZigZag functions [3] is superimposed for the three displacement components for improving the accuracy for multilayered modeling. A plate/shell FE is obtained with nine degrees of freedom (dof) per node for the mechanical part, twelve dofs if the ZigZag functions are included, [4].

This FE is evaluated on some standard piezo-electric plate/shell tests including sensor and actuator configurations. Tests concerning bimorph piezoelectric beam/plate/shell are presented in order to assess the high-order kinematics and the ZigZag effect. The role of electrode segmentation, i.e. the size of equipotential surfaces, on the electro-mechanical response has been also considered.

1 INTRODUCTION

Research and development concerning high-performance structures are very intense since some decades. Structural health monitoring, active vibration damping, and energy harvesting are some examples of possible applications of a multifunctional structural component. Piezoelectric materials permit to convert mechanical and electrical energy at frequency ranges that are most interesting for technical applications such as vibration damping and rapid shape adaptation [5]. Development of theoretical and numerical models for this kind of structures is very important and active. For this purpose and in the framework of two-dimensional plate/shell models, different choices can be made for the mechanical approximation and the following classification is classically admitted for the variation in the thickness direction: (i) Equivalent Single Layer (ESL) models, in which the number of unknowns is independent of the layer number; (ii) Layer-Wise (LW) descriptions, for which the number of unknowns and, thus, the computational cost increases with the number of layers. While most developments employ an ESL description for the mechanical behavior, and particularly the First order Shear Deformation Theory (FSDT), a Layer-Wise description is necessary for the piezoelectric approximation to impose electric boundary conditions at each piezoelectric layer interfaces, i.e., the electrodes, within the stack. Inside each piezoelectric layer, the electric potential can be linear, quadratic or higher and a comparison has been proposed in [6].

A review of different approaches is available in [7, 8] and in the framework of the Carrera Unified Formulation (CUF) in [9]. For the FE approximations, a recent review limited to shell models is also given in [10].

The limitation of the FSDT model is related to the constant transverse displacement hypothesis, inducing no thickness change and the use of the reduced 2D constitutive law. The use of the full 3D constitutive law is an important feature for a consistent representation of complex physical interactions like multi-field coupling. Furthermore, accurate modeling of thick structures needs the transverse normal stress and the 3D constitutive law.

Therefore, a high-order model is chosen with sinus function for the in-plane displacements and quadratic assumption along the thickness of the transverse deflection. Thus, the 3D constitutive law is retained and a parabolic distribution of the transverse shear strains and a non linear variation of the transverse normal strain are recovered. In order to introduce transverse strain discontinuities required to fulfill the interlaminar equilibrium, Murakami's Zig-Zag function (MZZF) [3] is superimposed to the high-order ESL kinematics for the 3 displacement components. Note that MZZF does not depend on the constitutive coefficients and is, hence, attractively simple in conjunction with three-dimensional constitutive laws including multi-field coupling. Based on this kinematics, an 8-node plate Finite Element (FE) is proposed, free of numerical illness such as transverse shear and Poisson lockings, oscillation and spurious mechanics [1]. The approximation of the electric potential must be able to model piezoelectric patches, and a constant value is considered on each elementary domain while a cubic variation in each layer is used, based on the polynomial expansion given in [2, 11].

The paper is organized as follows: Section 2 describes the plate problem, the approximations for the displacement and the electric potential and the system to be solved. The resulting FE are evaluated in Section 3 for a composite plate, in order to talk about the electrode segmentation modelling.

2 Description of the plate problem

2.1 Governing equations

Let us consider a plate occupying the domain $\mathcal{V} = \Omega \times [-\frac{e}{2} \leq z \leq \frac{e}{2}]$ in a Cartesian coordinate system $(x_1, x_2, x_3 = z)$. The plate is defined by an arbitrary surface Ω in the (x_1, x_2) plane, located at the midplane for $z = 0$, and by a constant thickness e .

The displacement is denoted $\vec{u}(x_1, x_2, z)$ and the electric potential is $\phi(x_1, x_2, z)$. $\epsilon_{ij}(x_1, x_2, z)$ and $\vec{E}(x_1, x_2, z)$ are the strain tensor components and the electric field vector, respectively, deduced from primal variables by the geometric relations. Furthermore, $\sigma_{ij}(x_1, x_2, z)$ and $\vec{D}(x_1, x_2, z)$ are the conjugated fluxes (stress tensor components and dielectric displacement vector, respectively) obtained from the constitutive equations given in the next subsection.

2.1.1 Constitutive relation

The 3D constitutive equation for a linear piezoelectric material is given by the following set of coupled equations [12] for a layer (k) :

$$[\sigma^{(k)}] = [C^{(k)}] [\epsilon^{(k)}] - [e^{(k)}]^T [E^{(k)}] \quad (1a)$$

$$[D^{(k)}] = [e^{(k)}] [\epsilon^{(k)}] + [\epsilon^{(k)}] [E^{(k)}] \quad (1b)$$

where we denote by $[C]$ the matrix of elastic stiffness coefficients taken at constant electric field, by $[e]$ the matrix of piezoelectric stress coefficients and by $[\epsilon]$ the matrix of electric permittivity coefficients taken

at constant strain. The explicit form of these matrices can be found in [10] for an orthotropic piezoelectric layer polarized along the thickness direction z . Eq. (1a) expresses the piezoelectric *converse* effect for actuator applications, whereas Eq. (1b) represents the piezoelectric *direct* effect which is exploited in sensor applications. Note that the constitutive law is expressed in the local reference frame associated to each layer.

2.1.2 The weak form of the boundary value problem

The classical piezoelectric variational formulation of [13] is employed in which the primary field variables are the “generalized displacements”, i.e. the displacement field, and the electrostatic potential. Using a matrix notation and for admissible virtual displacements \bar{u}^* and electric potential ϕ^* (virtual quantities are denoted by an asterisk), the variational principle is given by:

$$\begin{aligned} \int_{\mathcal{V}} \rho [u^*]^T [\ddot{u}] d\mathcal{V} = & - \int_{\mathcal{V}} [\epsilon(u^*)]^T [\sigma(u, \phi)] d\mathcal{V} + \int_{\mathcal{V}} [u^*]^T [f] d\mathcal{V} + \int_{\partial\mathcal{V}_F} [u^*]^T [F] d\partial\mathcal{V} \\ & + \int_{\mathcal{V}} [E(\phi^*)]^T [D(u, \phi)] d\mathcal{V} - \int_{\mathcal{V}} q \phi^* d\mathcal{V} - \int_{\partial\mathcal{V}_Q} Q \phi^* d\partial\mathcal{V} \end{aligned} \quad (2)$$

where $[f]$ is the body force vector, $[F]$ the surface force vector applied on $\partial\mathcal{V}_F$, q the volume charge density, Q the surface charge density supplied on $\partial\mathcal{V}_Q$ and ρ is the mass density. Finally, $\epsilon(u^*)$ and $E(\phi^*)$ are the virtual strain and virtual electric field that satisfy the compatibility gradient equations. In the remainder of this article we will refer only to static problems, for which the left-hand side term is set to zero. Furthermore, body forces and volume charge densities will be discarded ($[f] = [0]$; $q = 0$).

2.2 The mechanical part

2.2.1 The displacement field

Based on the sinus model, see [14], a new plate model which takes into account the transverse normal stress is presented in this section. This extension is based on following developments

- various models for beams, plates and shells based on the refined sinus theory, see [14, 15, 16, 17, 18, 19];
- our previous paper on a 7 parameter model for thermo-mechanical analysis [1].

In the framework of ESL approach, the kinematics of our model is assumed to have the following particular form

$$\begin{cases} U_1(x_\alpha, z) = u^0_1(x_\alpha) + z u^1_1(x_\alpha) + f(z) u^f_1(x_\alpha) \\ U_2(x_\alpha, z) = u^0_2(x_\alpha) + z u^1_2(x_\alpha) + f(z) u^f_2(x_\alpha) \\ U_3(x_\alpha, z) = u^0_3(x_\alpha) + z u^1_3(x_\alpha) + z^2 u^2_3(x_\alpha) \end{cases} \quad (3)$$

where $\alpha \in \{1, 2\}$ and $i \in \{1, 2, 3\}$. In Eq. (3), the superscript is associated to the expansion order in z while the subscript is related to the component of the displacement. Thus, u^0_i are the displacements of a point of the reference surface while (u^1_α, u^f_α) are measures for rotations of the normal transverse fiber about the axis $(0, x_\alpha)$. The functions u^{α}_3 permit to have a non-constant deflection for the transverse fiber and allow to have non zero transverse normal stretch. Furthermore, the quadratic assumption for the transverse displacement avoids the occurrence of Poisson (or thickness) locking, see [1].

In the context of the sinus model, we have

$$f(z) = \frac{e}{\pi} \sin \frac{\pi z}{e} \quad (4)$$

It must be noticed that the classical homogeneous sinus model [14] can be recovered from Eq. (3) assuming $u^1_\alpha = -u^0_{3,\alpha}$, and neglecting the unknown functions u^α_3 .

2.2.2 The Murakami's Zig-Zag terms

In order to evaluate the influence of Zig-Zag terms [3] in a high-order ESL model, the following displacement per layer (k) are added to Eq. (3):

$$\begin{cases} U_1^{(k)}(x_\alpha, z) = Z^{(k)}(z) u^{z_1}(x_\alpha) \\ U_2^{(k)}(x_\alpha, z) = Z^{(k)}(z) u^{z_2}(x_\alpha) \\ U_3^{(k)}(x_\alpha, z) = Z^{(k)}(z) u^{z_3}(x_\alpha) \end{cases} \quad (5)$$

with

$$Z^{(k)}(z) = (-1)^k \zeta_k(z) \quad \text{and} \quad \zeta_k(z) = \frac{2}{e_k} \left(z - \frac{1}{2}(z_k + z_{k+1}) \right) \quad (6)$$

where e_k is the thickness of the k^{th} layer while (z_k, z_{k+1}) are the bottom and top coordinates of this layer. It is obvious that $Z^{(k)}(z)$ is a piecewise linear function with bi-unit amplitude for all the layers as we have $\zeta_k(z) \in [-1, 1]$. Note that, despite the $Z^{(k)}(z)$ function depends on the layer index inside the stack, the amplitudes u^{z_i} are unique for the whole laminate, i.e., the ESL framework is still preserved.

2.3 The electric part

On each elementary domain Ω_e , the electric potential is assumed to be constant. Therefore, no variation with respect to x_α is considered. A cubic layerwise (LW) description is used across the thickness, according to the approximation introduced in [2] and used in [11]: In each layer (k), the electric potential distribution is described by the normal electric field components at the bottom and top surfaces, denoted E_{3b} and E_{3t} , respectively, and the potential difference $\Delta\phi$ between top and bottom surface. Using these dofs, the approximation of the electric potential can be written as:

$$[\phi^{(k)}] = [F_\phi] [Cst_\phi^{(k)}] [q_\phi^{e(k)}] \quad (7)$$

where the following definitions have been introduced:

$$[F_\phi] = [1 \quad z \quad z^2 \quad z^3]; \quad [q_\phi^{e(k)}]^T = [E_{3b}^{(k)} \quad \Delta\phi^{(k)} \quad E_{3t}^{(k)}] \quad (8)$$

and $[Cst_\phi^{(k)}]$ is a (4×3) matrix containing constant coefficients. The electric field vector in each layer $[E^{(k)}]$ is then obtained as:

$$[E^{(k)}] = \begin{bmatrix} 0 \\ 0 \\ -\phi_{,3}^{(k)} \end{bmatrix} = [F_E] [Cst_E^{(k)}] [q_\phi^{e(k)}] \quad \text{with} \quad [F_E] = [1 \quad z \quad z^2] \quad (9)$$

where $[Cst_E^{(k)}]$ is a (3×3) matrix. So, the adopted approximation yields a quadratic transverse electric field across the thickness of each layer.

2.4 The system to be solved

The FE approximations are not detailed here for the sake of brevity and can be found elsewhere [10, 1]. The eight-node quadrilateral finite element is used and classical FE approximation is used for the geometry. A special treatment is used to control the transverse shear locking by using a dedicated interpolation for $\gamma_{\alpha 3}^0$ according to the methodology presented in [1]. Note that since the electric potential is assumed to be constant on each elementary domain, there is no need to introduce any FE approximation for this field.

The elementary matrices are then deduced considering the bi-dimensional weak form obtained from Eq. (2). Assembling each elementary contribution in the global reference frame, the following discrete form of the coupled piezoelectric system is obtained:

$$\begin{bmatrix} [K_{uu}] & [K_{u\phi}] \\ [K_{u\phi}]^T & [K_{\phi\phi}] \end{bmatrix} \begin{bmatrix} [q_u] \\ [q_\phi] \end{bmatrix} = \begin{bmatrix} [L_u] \\ [L_\phi] \end{bmatrix} \quad (10)$$

where $[K_{uu}]$, $[K_{\phi\phi}]$ and $[K_{u\phi}]$ are the global stiffness, dielectric and piezoelectric matrices of the plate, respectively. The mechanical dofs are in the vector $[q_u]$, while the electrical dofs are in the vector $[q_\phi]$ and we have at the elementary level

$$\begin{aligned} [q_u^e] &= \left[(u^0_1 \ u^0_2 \ u^0_3 \mid u^1_1 \ u^1_2 \ u^1_3 \mid u^f_1 \ u^f_2 \ u^2_3 \mid u^z_1 \ u^z_2 \ u^z_3)_{i=1,8} \right] \\ [q_\phi^e] &= \left[(E_{3b}^{(k)} \ \Delta\phi^{(k)} \ E_{3t}^{(k)})_{k=1,Nl} \right] \end{aligned} \quad (11)$$

with Nl the number of layers. From the mechanical point of view, the Zig-Zag dofs can be activated or not and comparisons will be presented in the next section dedicated to numerical evaluations using no Zig-Zag dof (P9), using only in-plane Zig-Zag dof u^z_α (P9Z) and with all the Zig-Zag dof u^z_i (P9ZZ). Finally, the three models use 9, 11 or 12 kinematical unknown functions and the associated FE has 72, 88, 96 mechanical dofs per element, respectively.

Since the electric potential is assumed constant on each FE, the assembly involves only the approximation along the thickness. A piezoelectric patch comprising several FEs can be defined through the imposition of the equipotential condition between electrodes: the same $\Delta\phi$ is imposed on the piezoelectric layer for all elements belonging to the same patch. From the numerical point of view, this is accomplished through linear homogeneous and non-homogeneous Multi-Point Constraints (MPC) using penalty function method.

In Eq. (10), the load vectors $[L_u]$ and $[L_\phi]$ represent the external loading from applied forces and prescribed charges, respectively. Essential boundary conditions (i.e., prescribed displacements and electric potentials) are imposed numerically by a penalty technique. The coupled system is then solved by the classical static condensation procedure for the electrical dof:

$$[q_\phi] = [K_{\phi\phi}]^{-1}([L_\phi] - [K_{u\phi}]^T [q_u]) \quad (12a)$$

which yields the following purely mechanical system with a modified equivalent stiffness matrix:

$$\left[[K_{uu}] - [K_{u\phi}][K_{\phi\phi}]^{-1}[K_{u\phi}]^T \right] [q_u] = [L_u] - [K_{u\phi}][K_{\phi\phi}]^{-1}[L_\phi] \quad (12b)$$

In the remainder of the paper, $[L_\phi] = [0]$ will be considered.

3 Numerical results: clamped composite plate

This test is interesting to evaluate the segmentation of a piezoelectric layer using different number of patches. It considers the sensory response of a cantilever, rectangular, hybrid sandwich plate with one edge clamped and other edges free subjected to a uniform pressure load according to the following data [20]:

geometry rectangular plate $a \times b$ with $a = 10 \text{ mm}$, $a/b = 2$ and total thickness $e = 1 \text{ mm}$ (length-to-thickness ratio $S = 10$)

materials seven-layers plate $(pz, 0^\circ, 90^\circ, core, 90^\circ, 0^\circ, pz)$; the outer piezoelectric layers of thickness $0.1 e$ are made out of PZT-5A material; each layer constituting the laminated skins has a thickness $0.04 e$ and the core thickness equals $0.64 e$. The material properties for PZT-5A, skin layers and core are given in Tab. 1

boundary conditions clamped at $x_1 = 0$; uniform pressure load p_0 ; piezoelectric layers can be in open circuit ($\Delta\phi$ let free) or in closed circuit ($\Delta\phi = 0$)

mesh three regular meshes 5×2 , 10×4 and 20×8 are used

results and locations transverse displacement at the tip and piezoelectric potential in the element close to the clamped edge. They are made non-dimensional according to

$$\bar{u}_3 = u_3 (10^2 E_2^{(core)}) / (e S^4 p_0) \quad \bar{\phi} = \phi (10^4 E_2^{(core)} d_0) / (e S^2 p_0) \quad \text{with } d_0 = 374 \cdot 10^{-12} \text{ CN}^{-1}$$

Table 1: Material properties employed in the considered problems.

This test can be used to compare the effect of the electrode segmentation: using the proposed FE meshes, the electrode sensor surface is subdivided in 1, 10, 40, 160 patches through the imposition of equipotential conditions.

Tab. 2 presents the convergence properties of the P9 FE when only one patch is used for each piezoelectric layer. In the open circuit configuration, the equipotential condition enforces $\Delta\phi$ in each layer to be the same for all elements. In the closed circuit condition, $\Delta\phi = 0$ for all elements (equipotential condition) and the maximum electric potential value inside the piezoelectric layers is reported. Note that the cubic approximation for ϕ allows to recover the electric potential induced by the local bending of the piezoelectric layers.

elec BC	mesh	5×2	10×4	20×8
OC	\bar{u}_3	22.649 (-1.9)	22.967 (-0.5)	23.089
	$\Delta\phi_{bottom}$	-23.003 (-2.7)	-23.408 (-1.0)	-23.649
	$\Delta\phi_{top}$	24.473 (-2.6)	24.886 (-1.0)	25.129
CC	\bar{u}_3	23.370 (-1.9)	23.698 (-0.3)	23.833
	$\bar{\phi}_{Max}$	-3.307	-5.212	-7.295

Table 2: Clamped composite plate with only one electric patch: convergence results for open circuit (OC) and closed circuit (CC).

The maximum displacement is located at the center of the tip edge $(a, b/2)$ while the maximum induced electric potential (ϕ_{max} for closed circuit) is in the FE close to the clamped edge. For the open circuit, the convergence is very fast for both displacement and electric potential difference – the percentage of error with respect to the 20×8 mesh results is indicated in parentheses. For the closed circuit, an asymptotic value is recovered for the displacement whereas ϕ_{max} still increases with mesh refinement; this is due to the decreasing size of the FE at the clamp, which increasingly localizes the bending deformation of the piezoelectric layers.

The distribution of the electric potential across the thickness is illustrated for the two electric boundary conditions in Fig. 1. The non-linear variation across the bottom and top piezoelectric layers is visible on both graphs and increases with mesh refinement. Due to the equipotential condition, it has no influence on the $\Delta\phi_{max}$ for the open circuit (left) but it is directly related to the Φ_{max} for the closed circuit (right). This non-linear effect measures the local bending deformation of the piezoelectric layers and is accordingly larger at the clamped edge than at the free tip of the plate.

Finally, the effect of electrode segmentation is discussed in Tab. 3 for the open circuit boundary condition. The corresponding distribution along the length of the plate of the electric potential difference is illustrated in Fig. 2 for all considered meshes and electrode segmentations. The induced potential difference $\Delta\phi$ reported in Tab. 3 is taken at the electrode next to the clamped edge, i.e., where it has its maximum value. Comparing the results for 10 patches obtained with two different meshes allows to appreciate the role of the mesh refinement: a finer mesh increases the tip displacement and enhances the sensed voltage. The same mesh with 10×4 elements is then used with two different number of electric patches, i.e., with different sizes of the equipotential surfaces: a very small influence on the tip deflection can be seen, with \bar{u}_3 slightly larger when the equipotential surfaces are larger; on the contrary, the electric potential induced at the clamped edge is clearly higher the smaller the electrode. Finally, considering the 20×8 with 160 patches (i.e., one electrode per FE), the tip displacement is slightly higher due to the refined mesh and the sensed voltage is further increased due to both, the larger deflection and the reduced electrode's size at the clamp.

4 Conclusion

This paper has presented a new family of FE for piezoelectric composite plates. A high-order ESL kinematic model is considered that includes the sinus function for the in-plane displacements, a quadratic polynomial expansion for the transverse displacement and Zig-Zag functions for introducing slope discontinuities at layers' interfaces for both, the in-plane and the transverse displacements. A LW cubic approximation is used for the electric potential in order to capture its non-linear distribution induced by the local bending of the piezoelectric layer; the elementary domain is considered as an equipotential surface (constant electric potential).

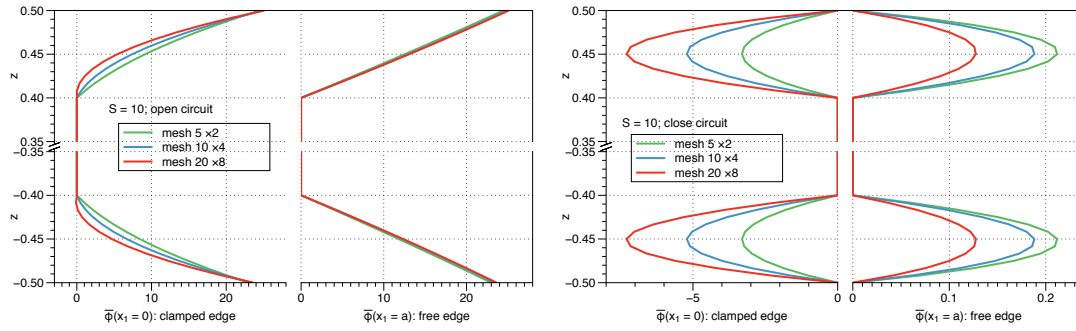

Figure 1: Clamped composite plate: electric potential distribution across the thickness for the OC (left) and CC (right) electric boundary conditions.

patch Nb	10	40	160
mesh	5×2	10×4	20×8
\bar{u}_3	22.230	22.533	22.510
$\Delta\Phi_{bottom}$	-62.776	-63.503	-80.004
$\Delta\Phi_{top}$	64.071	64.827	81.147

Table 3: Clamped composite plate in OC configuration: evaluations for different FE meshes and equipotential surface sizes.

Figure 2: Clamped composite plate in OC configuration: distribution along the length of the sensed voltage at the top (left) and bottom (right) piezoelectric layer for different meshes and electrode segmentation.

The element has been validated through linear static case studies for both sensor and actuator configurations as well as homogeneous and laminated plates. The role of electrode segmentation, i.e., the size of equipotential surfaces, on the electro-mechanical response has been also evaluated. The results are in good agreement for actuator and sensor configurations for thin to very thick cases. The proposed P9ZZ FE, using only 12 mechanical dof per node, is very accurate, simple to use, without any numerical problem and could be used for a large range of plate problems involving piezoelectric patches or layers. Future works are pointed towards the extension of this model to piezoelectric shell structures.

Key words: Soft actuators, soft robots, smart skin, morphable texture, phase transition

Abstract. Soft robotics is an expanding and promising field that deeply transforms the way we design actuators and sensors. Despite recent progress, there is still a need for electrically driven actuators being capable of providing large motions under low voltage. We explore here the concept of phase transition-driven actuators, in which the actuation only results from the large expansion taking place during a liquid to a gas phase transition. We demonstrate that such a concept can be used for creating original applications, including a morphable skin with controllable texture and a soft gripper. It would be very challenging, if not impossible, to design such actuators with other actuation technologies while preserving the same compactness.

1 INTRODUCTION

Soft robotics emerged a few years ago as a new trend in the design of artificial robotics system. By leveraging the unique properties of highly deformable materials and systems, new functions can be imagined, including improved interaction between the robotic system and the user, complex mode of deformations bringing more flexibility compared to classical rigid-part based robots, integral processing through 3D printing. As in any robotic system, the success of such technology heavily relies on the availability of high-performance sensors and actuators.

Soft actuators are usually based on externally provided pressurized fluid (pneumatic and hydraulic systems) [1], shape memory polymer, electroactive polymers such as conductive soft polymers (PEDOT/PSS for example [7]), or piezoceramic fibers. These systems all suffer limitations that prevent today to explore the full potential of soft robotics. These limitations vary from one technology to another: high voltage, limited actuation (strain), need for bulky and expensive power sources. So there is still a need for an actuation principle that can provide large actuation, ideally based on electrical energy at relatively low voltage.

We propose here to explore the concept of Joule heating induced phase transition to the design of new families of actuators. In this concept, the transition from liquid to gas of well-chosen liquid based on electrically induced heating is leveraged. Such systems raise many challenges including the design of efficient heating element and microstructure.

We demonstrate this concept on two application.

The first example is an all-polymer base polymorph skin with controllable surface texture [2]. We present here an e-skin for which we control the surface morphology based on an electrical stimulus. Such skin is fully polymer-based, based on the concept of phase transition, and will find interesting applications in any process where the morphology of the surface plays an important role in controlling the interaction between the system and its environment such as drag control in pipe or gripping.

The second application is about the development of soft grippers that can experience large deformation and where the internal actuating pressure is only provided by phase transition [3]. We show here how a well-designed electrode and a predesigned cavity with sufficient liquid can result in a high performing system.

2 Experimental section

The proposed family of actuators relies on a very simple observation: liquid to gas phase-transition is one of the physical process coming with the largest dimensional expansion. On the other hand, phase-transition is a thermally activated process that can be easily controlled by providing heat energy to the system. Finally, heat energy is easily provided in-the-volume of any conductive material by making appropriate use of the Joule effect.

Then, the objective becomes to use at best the electrical-thermal-mechanical coupling. First, a heating element is designed to provide an adequate amount of heat when subjected to an electrical current. Second, a functional material should exhibit phase-transition when subjected to this additional heat. Finally, this expanding functional material should be properly mechanically constrained to force the system to deform in the way desired for the actuation.

This process is obviously not new as it is very similar to the one used in conductive polymer-based actuators such as PEDOT/PSS. PEDOT:PSS features a strong coupling between its chemical, mechanical and electrical behaviors which has resulted in many applications in the field of electro-mechanical actuators [6]. The mechanism of actuation comes from the hygroscopic nature of PSS that very easily absorbs water from the environment. Water molecules can actually exist in very different configurations. As shown by [5] based on the observation of isosteric heat of sorption, water molecules will mainly be adsorbed on hydrophilic sulfonic acid groups at low sorption degree. At higher sorption degree, the active sites are totally saturated and the water is in a free-water configuration. Absorbed water molecules increase the distance between PEDOT:PSS grains, causing a volume increase. When an electric current is applied, the Joule effect results in the generation of in-the-volume heat, consequently changing the temperature. It results in releasing the previously absorbed water molecules, which translates into geometrical shrinking at the macroscale. PEDOT:PSS based actuators can be operated under low voltages (0-10V) that makes them particularly appealing for wearable electronics applications [4].

However, this phase transition is relatively inefficient in PEDOT/PSS that only exhibits a few percent strain when actuated. This is due to the microstructural disorganization of the phase-changing domain, and to the very limited fluid content. Our objective is to design from scratch the microstructure so it actually features very high actuating properties.

2.1 Example 1: a morphable skin based on phase-transition

In this first example, we create an e-skin with a controllable texture. An elementary module is presented figure 1(a,b). E-skin can then be created by using periodical arrays of such elementary modules. As detailed above, this component requires a heating element, a functional material expanding under a thermal stimulus, and a constraining material to force the motion.

The heating element is here made of PEDOT/PSS by mixing an aqueous dispersion of PEDOT:PSS

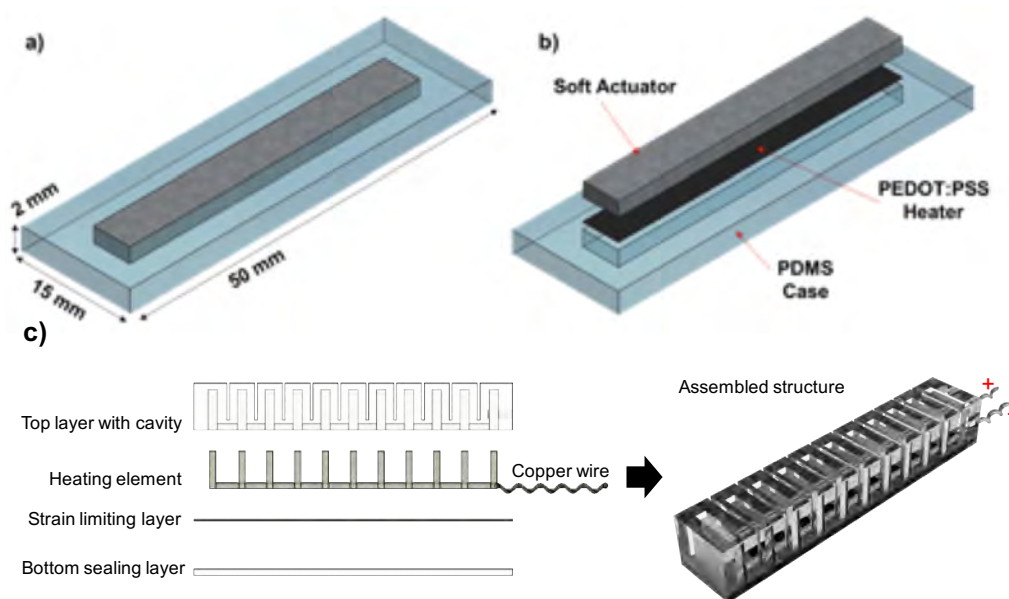

Figure 1: (a,b) The structure of the morphable skin based on phase-transition, (c) components of the phase-transition based soft gripper (left), assembled structure of soft gripper (right).

Clevios PH1000 (HC Starck) with 3% mass ratio of Ethylene glycol (EG) (Sigma-Aldrich). This blend is then magnetically stirred at 500 RPM for 6 hours so an homogeneous solution is obtained. The solution was later on drop-casted on a petri dish base coated with a Teflon sheet and subsequently cured inside a fume hood, at room temperature, for 48 hours, in order to obtain a 50 μm - thick film. To precisely cut the solution-casted PEDOT:PSS film, a CO₂ laser cutter PLS 6.75 (Universal Laser Systems) was used, with the following optimized parameters: power 3%, speed 5%, pulse per inch 1000, and focus distance of Z-axis of 4 mm.

The soft actuator itself (the functional material expanding when exposed to temperature increase) is here created by encapsulating liquid-phase containing bubbles inside an expandable silicone rubber (here, Ecoflex 00-50). The technology is then similar to the one proposed by [3]. One of the advantages is the simplicity of the fabrication. However, the main drawback is that the microstructure can not be very well controlled and then actuation properties can not be optimized. We are using as phase-transition liquid ethanol at 96% (VWR Chemicals) based on an optimization process for the fluid that was detailed in [2] where we compared different fluids. The preparation was optimized by mixing a 20% mass ratio of ethanol with Ecoflex. The silicone elastomer of Ecoflex (part A) and ethanol were first mixed for 2 min, the silicone crosslinker of Ecoflex (part B) was then added and mixed for another 2 min, at the recommended 1:1 mass ratio of part A and part B. The mixture was subsequently poured into a 3D-printed acrylonitrile butadiene styrene (ABS) mold and cured for 3 hours, at room temperature.

Then comes the assembly with the constraining material. To assemble the device, the Ecoflex based soft actuator was placed on a customized 3D-printed ABS mold. It was then covered with the PEDOT:PSS film to build the heating element. Contact electrodes were assembled on the PEDOT:PSS film, using copper wires fixed with colloidal silver liquid (Electron Microscopy Sciences). For the casing, PDMS was prepared using a silicon-based elastomer and curing agent Sylgard 184 (Dow Corning), with a 10:1 mass ratio. This PDMS is much stiffer than the soft actuator so it has an in-plane constraining

effect: the soft actuator can not expand in-plane and has to expand out-of-plane, resulting in the creation of the macroscopic texture. The mixture was degassed under vacuum for 30 min to remove air bubbles. Finally, PDMS was poured into the mold and cured at room temperature, for 48 hours, to package all the components.

This e-skin is here obtained by casting due to limitations in the available equipment. However, we should note that it is fully polymer based. It is fully printable and compatible with major printing technologies that makes it very easy to upscale.

2.2 Example 2: a soft gripper based on phase-transition

The soft actuator has four main components: a top layer with eleven cavities made of silicon rubber (Ecoflex-50), a heating element passing through all the cavities, a strain limiting layer and a flat bottom layer made of silicon rubber (Ecoflex-50); see Figure 1(c). We adopted a casting process using two different 3D-printed molds to fabricate the top and bottom layers, respectively. We poured Ecoflex-50 into the mold for the top layer and cured the material at 50 °C for at least 3 h. We then poured Ecoflex-50 into another mold for the bottom layer, inserted a thin cotton fabric (strain limiting layer that was already wetted with Ecoflex-50) into the mold, and cured the material (the mold was only filled halfway). Heating element made by twisting stainless steel micro-fibers was connected to copper wires for electrical connection and inserted into the cavities of the top layer. A valve for pouring actuation liquid was made in one of the cavities of the top layer. To make final assembly, we poured Ecoflex-50 to fully fill the remaining half of the mold of the bottom layer, and laid the top layer (with heating element and valve) over the mold of bottom layer. Once the Ecoflex was all cured, the liquid (ethanol) was pumped into the cavities through the valve, and the valve was fully patched with Ecoflex-50 to avoid leakage.

3 Results and discussion

3.1 Example 1: a morphable skin based on phase-transition

We can observe in figure 2(a) the progressive change in the shape of one module when subjected to a 6 V (0.7 A) electrical loading. The actuation of the device was monitored using a drop shape analyzer (Kruss), where an in-situ video was captured (as supplementary content), and image post-processing was carried out using ImageJ (an open source computer software). We can see that a substantial change in shape can be obtained using the phase-transition technology. Such a change in change would be difficult to achieve with classical actuators.

Using this module as a building block, we have shown that complete morphable skins can be fabricated and used in various applications including smart piping and active drag reduction at the fluid/pipe interface [2].

The main problem in this first technology is the limited durability of the heating element that is here made of PEDOT/PSS. To verify the lifetime and reliability of our device, we performed a cyclic test. Each cycle was composed of two periods: a heating period of 7 min in which the power was on, and a cooling period of 5 min with the power off. The voltage supplied during the heating period was 7 V, and a microscope (Leica S6D MC 190 HD) was used to capture images at the end of the 7 min period, to obtain the maximal actuation; image post-processing was once again carried out using ImageJ. We can observe that the actuation capabilities of the device are decreasing with the number of cycle (figure 2(b)). That is a consequence of the progressive degradation of the PEDOT/PSS electrodes, that results both in progressive increase in actuation power and decrease in actuation amplitude. This issue has been solved in the next generation where metallic porous electrodes are used as demonstrated in the next subsection.

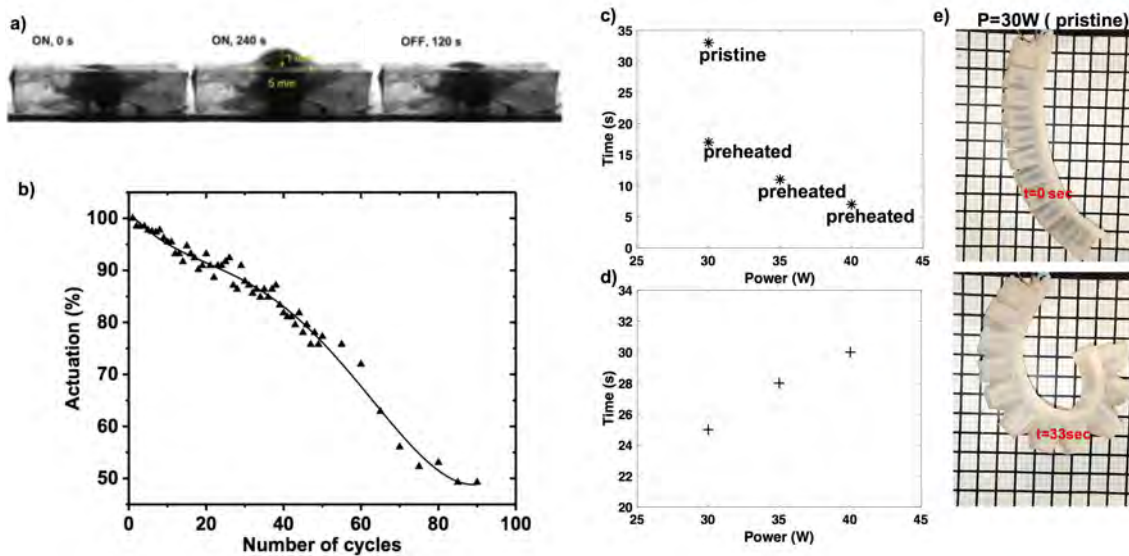

Figure 2: Example 1 (morphable skin): (a) progressive change in cross section of a single module of the morphable-skin, (b) the evolution of actuation amplitude with time. Example 2 (soft gripper): (c) time response of forward actuation, (d) time response of reverse actuation, (e) initial and actuated state of soft gripper at $P = 30$ W.

3.2 Example 2: a soft gripper based on phase-transition

Figure 2(c-d) shows the relationship between input power and the time required to actuate the soft gripper forward and reverse, respectively. Figure 2(c) shows that during forward actuation without pre-heating the gripper took 33 s to move from initial (resting) position to the full actuation. The heating element made of twisted steel micro-fibers was able to introduce a relatively uniform and quick heat flow to the fluid (ethanol). The liquid-to-vapor transition provided a sufficient pressure in the cavities, and due to the asymmetry (stiffness and geometry), a bending motion was created. The time requires was reduced by almost 80% when the gripper was pre-heated, while the power input was increased from 30 to 40 W. Pre-heating increases the internal heat energy that helps reduce the actuation time. Figure 2(d) shows that the reverse actuation took 25 s at 30 W power input; the time required to reverse was naturally longer when the input power was increased. Figure 2(e) shows the undeformed (pristine) and deformed state of the soft gripper. Nevertheless, reverse actuation time of 30 s at 40 W to restore from deformed to undeformed state is still considered fast for this passive cooling method. Furthermore, an appreciable bending configuration more than 180° could be achieved using relatively lower input voltage (25-40 V) in comparison to dielectric electro active polymers that require very high voltage source (kV) for large actuation strain.

Some remarks can be made with respect to our soft gripper. The corrugated design of the top layer with 11 cavities provides a significant increase of surface area with moderate increase in dead volume in comparison to a classical rectangular cavity. The increase of surface area improves the rate of convection heat transfer ($Q = hA\Delta T$) and enables a faster reverse motion. It should be noted that an active cooling system, e.g., peltier-based, water-based or air-based cooling, may improve the time required for reversibility, but this would increase the size and the energy consumption of our system. Our fast response, low voltage, large actuation soft gripper is considered promising for portable humanoid hand that deals with delicate objects and fast picking pace.

4 CONCLUSIONS

We demonstrate here that using phase-transition concepts for practical actuators is a viable alternative for soft robotics. The key-to-success is the ability to provide proper electrodes capable of ensuring simultaneously the electrical conduction, Joule effect-based heat generation, the heat transfer to the fluid and good durability. Here, we proposed two actuators: one based on conductive polymer, and another one based on porous metallic electrodes.

Key words: Carbon nanotubes, Eringen's nonlocal elasticity, mass sensor, external forcing, beam theory, boundary conditions

Abstract. In this effort, we investigate the necessary considerations for the modeling of carbon nanotubes (CNTs) acting as nano-scale mechanical resonators for the detection and mass identification of nanoparticles deposited on or within the CNT. Thus, we provide an overview of several studies that were conducted in this research group in the last several years related to this topic. Each of these studies help us to achieve the end goal of this research in order to develop reduced-order models of CNT-based mass sensors that are able to reflect the physical system, reliably predict phenomena occurring at the nano-scale, and can both qualitatively and quantitatively match and predict the response based on existing and future experimental trials for the proposed systems. In general, we study the CNT-based systems from a mechanics, dynamics, and vibrations point of view. Therefore, we consider theories in non-classical continuum mechanics to model the size-dependent phenomena, utilize Hamilton's principle to derive the nonlinear governing equations of the mass sensor, and account for various other system parameters. We have found that there are many factors that have a profound effect the system's static / dynamic response, stability, and sensitivity. These include, but are not limited to, the CNT length and diameter, the location and geometry of the deposited particle, the number of deposited particles, the size-dependent parameter, and external forces and excitations.

1 INTRODUCTION

Following the initial discovery of carbon nanotubes (CNTs) in the early 1990s by Iijima and his colleagues [1, 2], they have been studied, researched, and utilized in numerous applications for their unique properties. Some of the most notable properties of CNTs, which can be classified as allotropes of carbon with a cylindrical structure, include their high strength, high Young's modulus, high surface area-to-volume ratio, and impressive thermal and electrical properties. Due to these unique properties, several applications of the nanostructures have been reported in the literature, such as CNTs acting as targeted drug delivery devices, energy devices, nano-scale biomedical sensors, energy storage devices, or sensors for the detection and mass identification of single or grouped deposited atoms or molecules [3-6]. As such, there have been significant efforts in this research group that have focused on the development of reduced-order

models of CNT-based mass sensors.

It should be noted that when considering nano-scale mass sensors, the main operating principle of the system rely on measuring an induced shift in the natural frequency or amplitude of the CNT. This shift is between the states before and after a particle or particles have been deposited on or within the CNT in order to detect and identify their mass and thereby determine the detection sensitivity of the device [6]. Further, because certain pristine CNTs can possess ultra-high-quality factors, some studies have shown that the mass detection system is able to obtain a zeptogram ($1 \text{ zg} = 10^{-21} \text{ g}$) and yoctogram ($1 \text{ yg} = 10^{-24} \text{ g}$) resolution [7]. Additionally, the resolution of the CNT, *i.e.*, the smallest mass that can be detected for a specified frequency shift is dependent on a number of factors, such as temperature changes, exposure to a magnetic field, harmonic, or parametric excitations. For example, the mechanical behavior of nanostructures is highly dependent on different types of temperature changes in severe environments. Thus, it is required to include thermal effects to investigate the static and vibrational characteristics, which has been the subject of several research efforts in recent years [8-10]. Besides, any external forcing may alter the behavior and response of the system. This leads to an investigation on the nonlinear dynamics of forced single-walled carbon nanotube-based bio-mass sensors under uniform and non-uniform temperature distributions.

Other factors that can affect the system are different types of phenomena that occur at the nanoscale. Utilizing theories in classical continuum mechanics, which represent particles as a point mass subject only to translation, have been shown to fail at the nano-scale. Rather, at the nano-scale, particles should be represented as nano-volumes subjected to translation, rotation, and/or deformation. Depending on the crystallographic structure and size of the material, an appropriate theory in non-classical continuum mechanics should be selected. Of the available theories, Eringen's nonlocal theory has most notably been used to study the static and dynamic responses of CNTs. This theory represents particles as point masses subject to translation [11]. However, the stress at one point is influenced by the strain of all other points in the surrounding medium. In this work, a differential version of this theory is applied to include the residual stress. Additionally, while utilizing a nonclassical or nonlocal theory to account for the change in the behavior and response of a system at the nanoscale, it is also important to utilize an appropriate theory depending on the geometry of the CNT [9]. For example, for high aspect ratio CNTs, some researchers have shown the Euler-Bernoulli beam theory is appropriate, while Timoshenko beam theory is better suited for low aspect ratio, short, and stout structures.

After considering possible parameters and system modifications depending on the CNT size and environment, a set of nonlinear governing equations of motion, boundary conditions, and continuity conditions can be derived. In this case, the authors present the reduced-order model for a case in which the CNT-based mass sensor has one attached particle and is subject to uniform, linear, and nonlinear temperature rises and undergoes harmonic excitations. Then, the mathematical model is solved using the Method of Multiple Scales [12], while the proposed analytical solution satisfying clamped boundary conditions is employed to solve the nonlinear equations. Then, CNT-based mass sensors under uniform [13] and nonuniform temperature profiles through the thickness of the carbon nanotube and under a harmonic excitation force are studied, along with the effects of the nonlocal parameter, particle mass and location, surface temperature difference, and CNT dimensions.

2 DEVELOPMENT OF NONLOCAL NONLINEAR REDUCED-ORDER MODELS

To model a system at the nano-scale, it is important to first study the system from a physical or experimental point of view to understand what is happening physically. When that is understood, reasonable assumptions can be made on the accuracy, qualitative, and quantitative predictions. Some of these considerations are shown in Figure 1. One of the first things to consider is what theory is used to represent the displacement and strain field of the CNT depending on its dimensions. For example, Euler-Bernoulli beam theory is appropriate for high aspect ratio CNTs, while low aspect ratio CNTs should be modeled with Timoshenko beam theory to include the effects of shear deformation and rotary inertia. The most inclusive model is a shell model that may need to be used for thin-walled CNTs. However, this model is considerably more complicated. So, for the sake of simplicity, noting that the authors have not exceeded the limits of applicability of the beam models, they are used more often. Another consideration in the model is how to represent the deposited particles. For example, the authors must decide whether to model the mass as a point mass or a nano-volume. Additionally, it should be noted that the location and number of masses also affect the dynamic response of the structure. Lastly, it is important to include external factors, such as thermal or magnetic loadings or harmonic or parametric excitations.

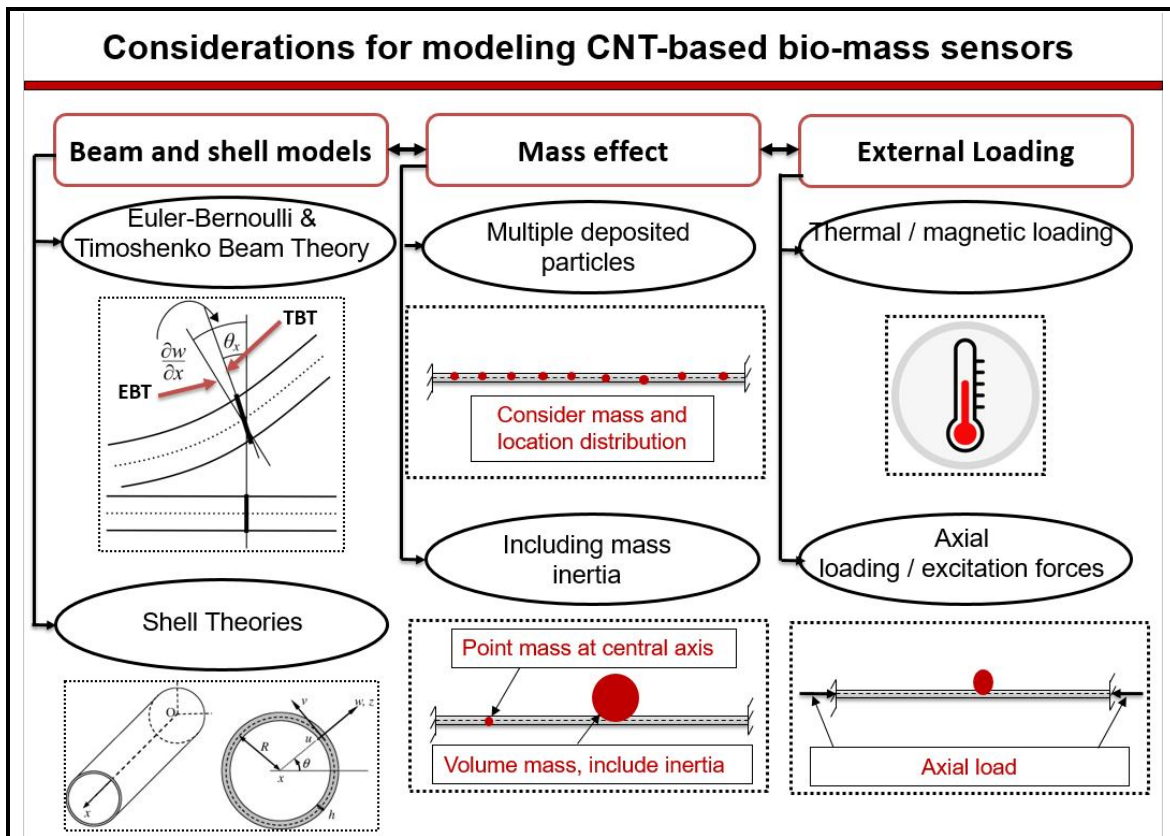

Figure 1. Considerations in the development of reduced-order models for CNT-based mass sensors.

At this point, several studies can be performed by neglecting or including different levels of assumptions and parameters. In this study, a focus is placed on two studies, namely, comparisons between Euler-Bernoulli beam theory and Timoshenko beam theory for different aspect ratio and CNTs and the dynamic response of CNT-based mass sensors under uniform, linear, and nonlinear temperature rise and harmonic excitation.

2.1 Eringen's nonlocal elasticity and the consideration of size-dependent phenomena

To model a system at the nano-scale, it is important to include size-dependent phenomena and/or to include the material structure. This is because at the nano-scale, the size of the structure is on the same order of magnitude as the internal lengths. Due to the material structure and properties of CNTs, Eringen's nonlocal theory is used to account for the size dependent phenomena in the structure. Using Eringen's nonlocal elasticity theory, the stress at one point in the medium is influenced by the strain of all other surrounding points. Thus, the nonlocal stress field, σ_{ij} is given as [12]:

$$\sigma_{ij}(x) = \int_{\Omega} \alpha(|x' - x|, e) t_{ij}(x) d\Omega(x') \quad (1)$$

where t_{ij} represents the local stress field, α is regarded as an attenuation function, and $e = e_0 a / l$ is the nonlocal parameter depending on the internal characteristic length, a , the external characteristic length, l , and material parameter, e_0 , that is determined by matching the longitudinal and transverse acoustic dispersions using approximations from atomic lattice dynamics or experiments. Because the integro-differential equations in Eringen's nonlocal elasticity are difficult to solve, the simplified differential form is used, yielding:

$$(1 - (e_0 a)^2 \nabla^2) \sigma_{ij} = c_{ijkl} \varepsilon_{kl} \quad (2)$$

2.2 Representation of uniform, linear, and nonlinear thermal loading

After introducing Eringen's nonlocal elasticity theory, the considered system and different thermal configurations are introduced and shown in Fig. 2. It should be noted that the CNT is of length L , a particle of mass m is deposited at location x_m , and that the harmonic excitation forces are denoted by F_1 and F_2 . Additionally, the three temperature rise expressions are provided in equations (3-5). UTR, LTR, and NLTR denote uniform temperature rise, linear temperature rise, and nonlinear temperature rise, respectively. These different representations of the temperature are expressed as:

$$\Delta T_{UTR} = T_{UTD} - T_{ref} \quad (3)$$

$$\Delta T_{LTR}(r) = \left(\frac{T_o - T_i}{r_o - r_i} \right) (r - r_o) + T_o - T_{ref} \quad (4)$$

$$\Delta T_{NLTR} = \frac{(T_o - T_i)}{\ln(r_o/r_i)} \ln(r) + \frac{(T_o + T_i)}{2} - \frac{(T_o - T_i)}{2 \ln(r_o/r_i)} \ln(r_i r_o) - T_{ref} \quad (5)$$

where T_{ref} represents the convenient ambient temperature, T_{UTD} denotes a uniform temperature distribution, T_o and T_i are the outer and inner surface temperature, respectively. The outer and inner radius of the CNT are given by r_o and r_i , as shown in Fig. 2.

Figure 2. Uniform, linear, and nonlinear temperature distribution through the radial component of the CNT.

2.3 Von Kármán geometric nonlinearity and beam theories

In this study, only clamped-clamped CNTs are considered. Thus, it is important to include the effects of the mid-plane stretching of end-constrained beams. This is done through a modification of the strain tensor, shown in equation (6) as:

$$\varepsilon_{ij} = \frac{1}{2} \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) + \frac{1}{2} \left(\frac{\partial u_k}{\partial x_i} \frac{\partial u_k}{\partial x_j} \right) \quad (6)$$

Equation 6 is defined as the von Kármán strain tensor. Then, a comparison can be made between Euler-Bernoulli beam theory and Timoshenko beam theory, in which the shear deformation and rotary inertia are included. Thus, the strain field for both theories are shown in equations (7-9).

$$\varepsilon_{xx,TBT} = \frac{\partial u}{\partial x} + z \frac{\partial \phi}{\partial x} + \frac{1}{2} \left(\frac{\partial w}{\partial x} \right)^2 \quad (7)$$

$$\gamma_{xz,TBT} = 2\varepsilon_{xz} = \frac{\partial w}{\partial x} + \phi \quad (8)$$

$$\varepsilon_{xx,EBT} = \frac{\partial u}{\partial x} - z \frac{\partial^2 w}{\partial x^2} + \frac{1}{2} \left(\frac{\partial w}{\partial x} \right)^2 \quad (9)$$

In the remaining development of the governing equations, Euler-Bernoulli beam theory is used, while the derivation with the Timoshenko beam theory is omitted for brevity. However, it should be noted that the comparisons between the two models are discussed in later sections.

2.4 Governing equations of motion for a CNT-based mass sensor under thermal loading and external harmonic excitation

As earlier discussed, the authors present the governing equations of motion of the CNT under different types of thermal loads and harmonic excitation considering Euler-Bernoulli beam theory and the von Kármán strain tensor to include the effects of the geometric nonlinearity. The system is shown in Fig. 3.

Figure 3. A bridged CNT-based nanoscale mass sensor subjected to external harmonic excitation and thermal loadings.

Then, using the extended Hamilton's principle, which is presented as:

$$\delta H = \int_{t_1}^{t_2} (\delta T_b + \delta T_m - \delta \Pi + \delta V) dt = 0 \quad (10)$$

where the authors include the first variation of the CNT, the deposited particle, the strain energy, and the work done by external forces, the normalized form of equations of motion for the carbon nanotube-based mass sensor exposed to a harmonic excitation force and three types of thermal loadings can be expressed as [13]:

$$\begin{aligned} W_{1,2}^{(4)} + \ddot{W}_{1,2} - \left(\frac{1}{2} \int_0^\eta (W'_{1,2})^2 d\chi + \frac{1}{2} \int_\eta^1 (W'_{2,2})^2 d\chi - T_n H \right) W''_{1,2} + 2\bar{\xi} \dot{W}_{1,2} \\ - e^2 \left[\ddot{W}''_{1,2} - \left(\frac{1}{2} \int_0^\eta (W'_{1,2})^2 d\chi + \frac{1}{2} \int_\eta^1 (W'_{2,2})^2 d\chi \right) W_{1,2}^{(4)} + 2\bar{\xi} \dot{W}''_{1,2} \right] - e^2 H T_n W_{1,2}^{(4)} \\ = \bar{F}_{1,2} \cos(\Omega \tau) \end{aligned} \quad (11)$$

and the corresponding dimensionless boundary conditions and continuity equations can be derived as follows [13]:

$$W_1(0) = W'_1(0) = W_2(1) = W'_2(1) = 0 \quad (12)$$

$$\begin{aligned} W_1(\eta) = W_2(\eta); \quad W'_1(\eta) = W'_2(\eta); \quad W''_1(\eta) = W''_2(\eta); \\ W'''_1(\eta) - W'''_2(\eta) + e^2 \left[\left(\frac{1}{2} \int_0^\eta (W'_1)^2 d\chi + \frac{1}{2} \int_\eta^1 (W'_2)^2 d\chi \right) - H T_n \right] \\ (W'''_1(\eta) - W'''_2(\eta)) - \ddot{W}_1 \mu(\eta) = 0 \end{aligned} \quad (13)$$

where details on the dimensionless variables and derivation procedure can be found in [13]. It should be noted that W_1 and W_2 refer to the transverse displacements of the first and the second portions of the mechanical resonator, e denotes the dimensionless nonlocal parameter, and μ is the mass ratio. Furthermore, the damping ratio and forcing terms have been included. Additionally, information can also be found on details for the linear analysis, Method of Multiple Scales formulation, and the static pre-/post-buckling configurations of the proposed CNT systems in [3] and [13].

3 RESULTS AND DISCUSSION

3.1 Euler-Bernoulli beam theory vs. Timoshenko beam theory

In this section, the authors compared the linear dynamic response of CNTs modeled as Euler Bernoulli beams (EBT) versus Timoshenko beams (TBT). The results are shown in Table 1 for fixed diameter, varying length, and varying nonlocal parameters. In this case, a single-walled carbon nanotube (SWCNT) is considered with a diameter of 0.8 nm, wall thickness of 0.34 nm, and a Young's modulus of 1 TPa [14]. In this table, there are a few interesting trends to be discussed. The first is that as the length of the CNT increases, so does the aspect ratio since the diameter remains constant. In this case, the discrepancy between EBT and TBT diminishes, which is expected. However, because the TBT model includes the effects of shear deformation and rotary inertia, it will always predict a lower natural frequency and higher deflection than EBT. Further, the discrepancy between the theories is pronounced for stout beams, particularly in the second and third natural frequencies. The next interesting result to study is the effect of

the nonlocal parameter of the system. In this case, clamped-clamped boundary conditions were considered. Thus, it is expected that increasing Eringen's nonlocal parameter will decrease the stiffness and thereby the linear natural frequency. However, it is shown that as the length of the CNT increases, the overall effect of the nonlocal parameter becomes negligible. This set of results is important for CNT-based mass sensors because it is imperative to ensure that the most appropriate beam or shell theory is utilized depending on the geometry of the CNT, with emphasis on its aspect ratio.

Table 1. Comparison of the first three natural frequencies of nonlocal CNT nanobeams modeled as Euler-Bernoulli beams vs. Timoshenko beams for different CNT lengths and nonlocal parameters.

CNT Length (nm)	Natural frequencies (GHz)	Nonlocal parameter (nm)					
		$e_0a = 0$		$e_0a = 1$		$e_0a = 2$	
		EBT	TBT	EBT	TBT	EBT	TBT
$L = 10$	ω_1	1433.73	1229.05	1352.71	1014.09	1172.03	803.37
	ω_2	3952.13	2506.21	3267.11	1866.33	2334.12	1389.08

	ω_3	19.37	19.07	19.35	18.35	19.27	16.90

3.2 Uniform, linear, and nonlinear temperature distributions

In order to perform a crucial study to explain how the surface temperature difference ($T_o - T_i$) and various types of temperature rise could affect the dynamic characteristics of the carbon nanotube-based mass detector, the first natural frequency shift considering the deposited Neon atom with the mass of 33.51 yg for three distinct levels of the surface temperature difference, as presented in Fig. 4. These results are given with assuming no forcing in the model. A close scrutiny of the obtained results reveals that in the pre-buckling region, the assumption of uniform and linear temperature gradients across the radius of the CNT estimates higher frequency shifts compared to the nonlinear temperature distribution. On the contrary, considering the non-linear thermal gradient yields the largest values of the frequency shift and hence the highest mass detection sensitivities of the CNT-based mass sensor in the post-buckling configuration. In addition, by improving the surface temperature difference, the discrepancy among the results under UTD, LTD, and NLTD in both the natural frequency and the frequency shift would rise drastically.

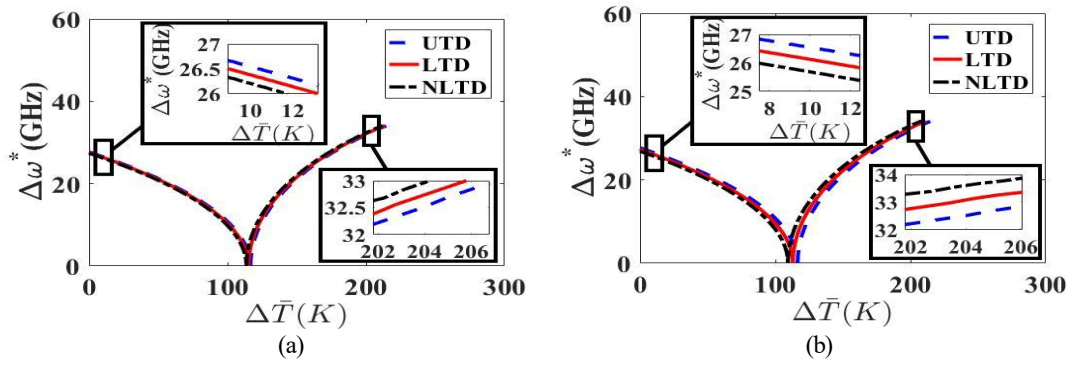

Fig. 4. The first natural frequency shift of the CNT subjected to UTD, LTD, and NLTD, considering $m_g=33.51$ yg, $L = 40$ nm, $D=0.8$ nm, $e_0a = 0.032$ nm, no forcing, and the surface temperature difference of (a) 20 K, (b) 50 K.

In Fig. 5 and Table 2, a comparison between the linear and nonlinear frequency shifts is presented, where the CNT-based mass detector is subjected to uniform, linear, and nonlinear thermal loadings. In the following discussion, the considered Q-factor and excitation force amplitude for the nonlinear dynamic response of the system are set equal to 10 and 1, respectively. Notably, the maps of the linear and nonlinear frequency shifts versus the location of the deposited mass are perfectly similar for the CNT under the first and the second mode vibrations. It is clearly seen that for both linear and nonlinear oscillation regimes, the maximum shifts induced in the first and the second frequencies are obtained for an atomic-scale particle placed at $\eta=0.5$ and $\eta \approx 0.3$ or $\eta \approx 0.7$, respectively. Moreover, it can be deduced that in all three thermal load conditions the assumption of the linear dynamic behavior of the CNT estimates larger values for the frequency shift and hence higher mass detection sensitivities compared to the nonlinear forced oscillation regime.

It is worth noting that the values of the percentage deviation of the nonlinear resonance frequency shift from the linear frequency shift in the first mode are higher than those in the second mode for the CNT under the aforementioned three thermal loading conditions. Moreover, it can be concluded that the assumption of the nonlinear temperature distribution through the thickness of the nanobeam yields the largest values of the percentage deviation of the nonlinear resonance frequency shifts. This is attributed to the fact that the softening effect of NLTD is more significant compared to the weakening effects of LTD and UTD on the structure of the CNT-based resonator. Consequently, the lowest values of the frequency shift and hence the highest percent deviations of the resonance frequency shifts are obtained in the case of NLTD.

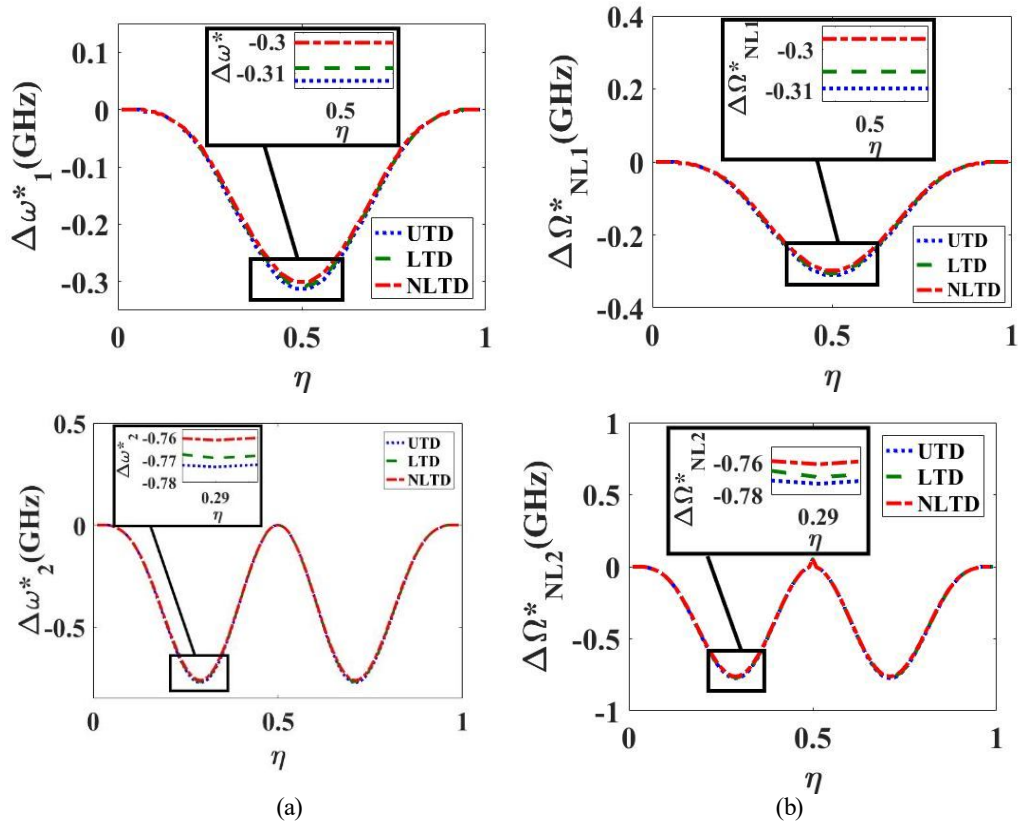

Fig. 5. The first and second frequency shift versus the location of the deposited atomic-scale mass with $Q=10$, $L=40$ nm, $m=0.218$ yg, $D=0.8$ nm, $\Delta T=0$ K, $e_0a=0.032$ nm, $(To-Ti)_{LTD}=(To-Ti)_{NLTD}=60$ K, for the two different values of the dimensionless excitation force amplitude (a) (linear natural frequency), (b) (nonlinear resonance frequency).

In what follows, the nonlinear response of the forced CNT-based resonator under external harmonic excitation is examined. In Figs. 6(a) and 6(b), the frequency-response functions near the first natural frequency (ω_1^*) of the nanobeam are plotted for different values of the excitation force amplitude and Q-factor. By inspecting the plots in Fig. 6, it can be found that Q-factor has remarkable impact on the large amplitude vibrations and nonlinear dynamic responses of the nanoscale structure. In fact, by augmenting Q-factor the nonlinear resonance frequency of the system increases dramatically. Further, it can be seen that the increase of the excitation force amplitude results in higher amplitude responses of the CNT. This is predicted because the nonlinear maximum displacement of the CNT-based resonator is proportional to the excitation force amplitude. These curves are especially important for mass sensing applications of CNTs, where detecting the induced shift in the resonance behavior of the nanostructure plays an important role in mass measurement.

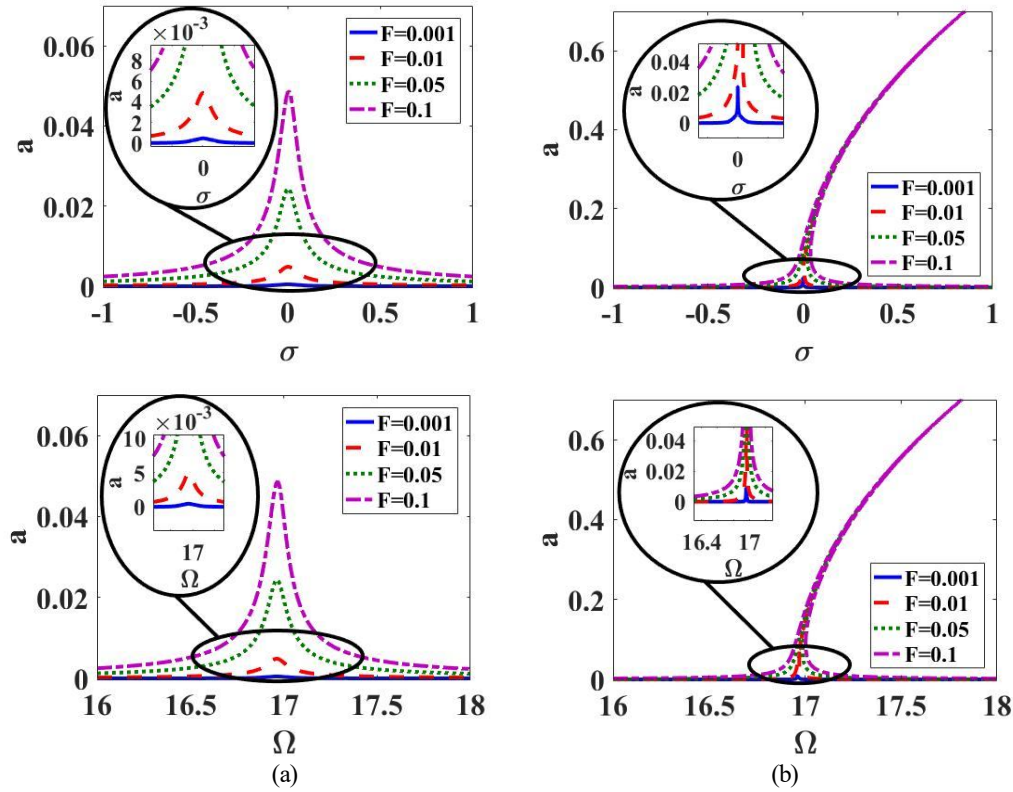

Fig. 6. The effects of the normalized excitation force amplitude on the variations of the nonlinear dimensionless real amplitude versus the detuning parameter and the nonlinear dimensionless excitation frequency considering $\Delta T=50$ K, $\eta=0.5$, $m=0.218$ yg, $L=40$ nm, $D=0.8$ nm, $e_0 a=0$ nm, and two different values of Q-factor of: (a) $Q=10$ and (b) $Q=100000$.

4 CONCLUSIONS

This study focused on several research works conducted by this research group and collaborators on CNT-based mass sensors. Several investigations on the behavior, response, and limits of applicability of the systems were presented. The authors worked to develop reduced-order models capable of detecting and identifying the mass of attached nanoparticles. In order to do so, a nonlocal continuum-based approach to account for phenomena occurring at the nanoscale, namely, Eringen's nonlocal elasticity. Additionally, many other possible considerations were discussed in the development of the models. These include selecting the appropriate beam or shell theory, such as Euler-Bernoulli beam theory or Timoshenko beam theory, and including the von Kármán geometric nonlinearity due to mid-plane stretching for end-constrained systems. Other factors that should be considered are the geometry of the particle, its geometry, its location with respect to the central axis of the CNT, and inclusion of multiple continuity conditions if multiple masses are attached. Finally, external factors were discussed, including possible axial uniform or nonuniform thermal or magnetic loads and harmonic or parametric excitations. Taking into account several of the discussed considerations, Hamilton's principle is used to derive the nonlocal nonlinear equations of motion for the system

and nondimensionalized for the case of a CNT-based mass sensor subject to thermal loading and harmonic excitations. Finally, both a linear and nonlinear analysis were performed in selected studies to determine the effects of each parameter on the system's sensitivity. These variables include the CNT length to diameter ratio, shear factor, nonlocal parameter, and landing location and effective geometry of the nanoscale object along the longitudinal axis of the CNT. Our preliminary studies show that shear deformation and rotary inertia effects will be significant for short, stout beams and at relatively high frequencies of vibration. Further, the results demonstrate the significance of the impacts of various temperature distributions, *i.e.*, UTD, LTD, and NLTD on the dynamic responses of CNT-based mass detectors in both the pre- and post-buckling configurations. From the obtained results, it is concluded that the vibration frequencies and frequency shifts of the CNT-based resonator are strongly dependent on the type of the temperature distribution and the surface temperature difference, leading to varying system sensitivity and resolution. Our derived model and analysis can be utilized by other researchers in this field who are conducting experiments at nano-scale. Our obtained results can be used as a good reference and can hopefully help to reduce the need to computationally expensive high-fidelity models at nano-scale, or costly experiments that are difficult to conduct.

Key words: Composites, nanocomposites, vibration, piezoelectric fillers, damping

Abstract.

This paper describes the promising ability for dissipating mechanical energy of composite structures thanks to a passive damping concept based on the local transduction-dissipation phenomenon. This concept involves nanocomposites layers filled with unleaded piezoelectric and electrically conductive particles. Here nanocomposites were processed by extrusion and damping layers were obtained by hot press. Engineering Polyamide (PA) and high performance poly ether ketone ketone (PEKK) were used as host matrices. After the process step, damping layers were embedded in composite sandwich beams and honeycomb composites panels with different payloads configurations. The macroscopic piezoelectric behaviour of nanocomposites was achieved after poling step. The dynamic response of nanocomposites has been characterized by dynamic mechanical analysis and vibration tests before and after the polarization. The analysis of stress-strain hysteresis loops and the frequency response function (FRF) of composites structures showed non-linear effects, high dissipated energy up to 40 % and high vibration mitigations up to 50 % for the different structures. Results bring promising dissipative behaviour for aerospace applications.

1 INTRODUCTION

With the growing interest of carbon fibre composites, bringing new functionalities has become a main challenge of the last years [1]. High performance composites brought many advantages like weight reduction and advantageous stiffness/weight ratio plus the ability to manufacture complex shaped structures. However, the reduced amount of fasteners decrease the damping capacity and increase the vibration levels: Enhancing the dynamical and vibroacoustic responses of composites structures is a topic of great interest in the aerospace industry.

The current counter strategies consist in ensuring structures reliability by active control [2], design modifications, add-on extrinsic macroscopic elements [3], in order to adapt the dynamic response. However these solutions could increase the overall mass of targeted structures. For real weight and cost reductions, it is proposed to bring this functionality at material's scale integrated in polymers and organic matrix composites (Figure 1).

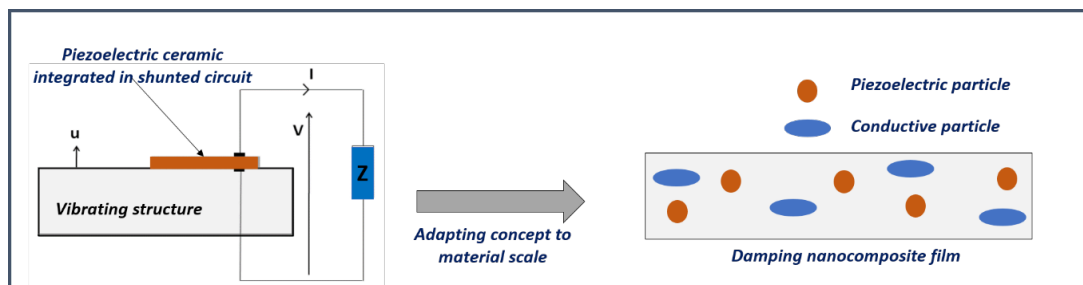

Figure 1. Passive control based on piezoelectric material: integrating functionality at material scale

The concept studied in this paper consists in dispersing piezoelectric and electrically dissipative particles in a polymer (Figure 1) in order to add a new contribution - the local transduction-dissipation [4] - to overall damping generally obtained thanks to structural, stick-slip and viscous contributions [5]. While piezoelectric particles ensure the mechano-electrical transduction the conductive particles locally dissipate the created charges in the polymer matrix by the Joule effect. This concept was recently studied by Carponcin et al. [6] with large damping efficiency by the synergy of PZT and CNT particles. Some works have pointed out the importance of the poling step conditions to improve piezoelectric [7-9] and damping behavior in nanocomposites [10].

Here the elaboration of a nanocomposite for vibration reduction is proposed based on thermoplastic polymer. The dynamic behaviour of composites structures containing the damping nanocomposite was followed by dynamic mechanical analysis and vibration tests in order to bring proofs about efficiency of the local transduction-dissipation phenomenon.

2 EXPERIMENTAL PROCEDURES

- Materials

Polyamide (PA) and Poly Ether ketone Ketone (PEKK) were provided by Arkema in powder or pellets shape. Both thermoplastic polymers were chosen as host matrices for its high mechanical properties, low moisture absorption and elevated thermal degradation. Micrometer sized BaTiO_3 (Sigma Aldrich) or NaNbO_3 (CIRIMAT Toulouse) ceramic particles were used as piezoelectric fillers while carbon black (CB – Sigma Aldrich) or carbon nanotubes (CNT – Arkema) were used as conductive fillers.

- Nanocomposites and composites processing

Fillers were dispersed by twin screw extruder in the thermoplastic matrix. The volume fraction of piezoelectric fillers is ranged between 10% and 30%. Homogenous dispersion is mandatory in order to avoid electrical breakdown during polarization and to maintain the mechanical properties of the polymer matrix. Moreover nanocomposites must be necessary insulator to achieve polarization. The volume fraction of conductive particles is directed linked to their aspect ratio (length over diameter) and their electrical percolation threshold when dispersed in a polymer matrix. A three phase nanocomposite film PA/ BaTiO_3 /NTC is shown in figure 2a).

Once the film was processed, it was embedded in the composite structure. Two different structures were studied: Sandwich beams (100 mm x 20 mm) where the damping nanocomposite is constrained between carbon fiber reinforced polymer plies (CFRP) as shown in Figures 2b) and 2c), and carbon-fiber aluminum-honeycomb sandwich panels (500 mm x 500 mm) where the damping film was integrated as a patch in the surface (figure 2d). For this last structure different payloads were fixed to the structure in order to explore larger energy and frequency ranges.

Figure 2. a) SEM image of a three-phase PA/ BaTiO_3 /NTC nanocomposite where BaTiO_3 particles appears in white while NTC are almost impossible to observe, b) Schematic representation of a constrained damping-layer between composites plies, c) sandwich beam sample for vibrations test, d) carbon-fiber aluminum-honeycomb sandwich panel containing the damping-film in the surface.

After consolidation, composites structures were poled under high electric field above glass transition temperature of the polymer matrix and for 1 min long. Polarization leads to the orientation of electric dipoles of ferroelectric particles and promotes piezoelectricity.

Shear stress-strain hysteresis loops were obtained by an ARES strain control rheometer in the rectangular shear mode before and after the poling step. Tests were performed at room temperature. When shear stress $\sigma(\omega)$ is plotted as a function of the shear strain $\gamma(\omega)$, $\sigma(\omega)$ describe a loop where its area represents the dissipated energy during one period. According to Piollet et al. [11], the stress-strain loops were mathematically modified by subtracting the linear part following $\sigma' = \sigma - P\gamma$, where P is the hysteresis slope measured at 0.1 % of deformation.

Vibration tests were performed with an electrodynamic shaker LDS V830-335 SPA16K 10KN from BRÜEL & KJÆR. A sinusoidal load of constant amplitude was applied for the different composites structures. Test were carried on at different load amplitudes (0,25g to 4g) in a large frequency range (0 to 2kHz) in order to observe the effects of poling on the overall structure behavior. The dynamic response as a function of excitation frequency was followed through a frequency response function (FRF) where resonance frequencies, as well as the damping levels were studied.

3 RESULTS AND DISCUSSIONS

Stress-strain hysteresis loops obtained for a PA/BaTiO₃/NTC damping nanocomposites at 25 °C were analyzed before and after polarization. Figure 3a) shows hysteresis loops for the non-poled samples at different strain rate.

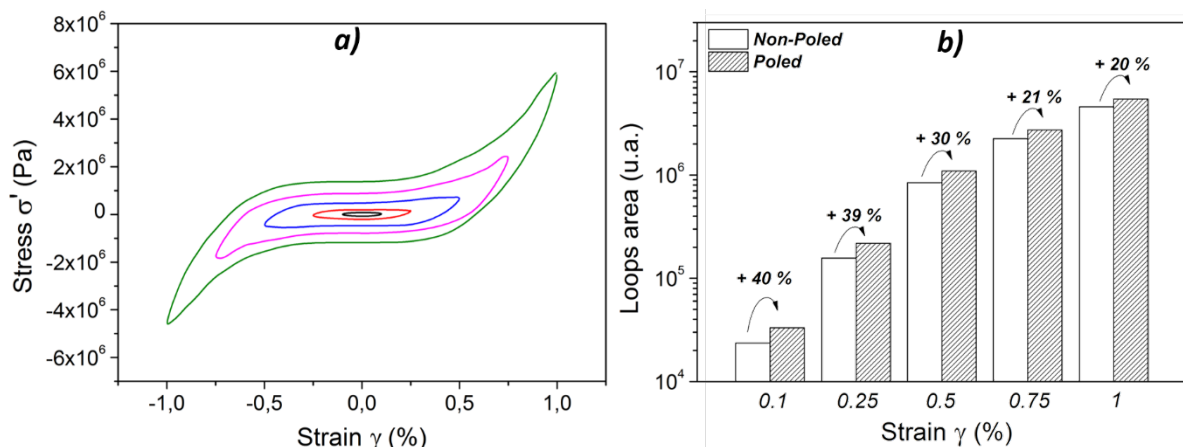

Fig. 3. a) Measured hysteresis loops at different strain rate at 25 °C of a damping film after the subtraction of the linear part, b) Hysteresis loops area at 25 °C as a function of strain, before and after polarization

The shape of the loops is complex and vary strongly with amplitude. Since the ellipsoid shape is characteristic of a linear behavior, here results highlight high nonlinear effects. The area of the loops is reported on Figure 3b) before and after polarization for different amplitudes. The hysteresis loops areas are significantly increased from 20 to 40 % after polarization: The local transduction-dissipation phenomenon leads to an important increase of dissipated energy.

Figure 4 presents the evolution of the frequency response function FRF of a damping nanocomposite in the sandwich beam configuration (Figures 2b and 2c) in the vicinity of the second bending vibration mode. The peak amplitude at resonance decreases when the imposed acceleration increases. This behavior is related to nonlinearities. After polarization, a small shift of the resonance peak to the low frequencies (softening effect). This phenomenon was already reported [6], however is not clear yet how polarization could lead to this shift. Polarization also is responsible for an amplitude decrease: While for an excitation level of 0,25g, the amplitude drop represents 54 % of initial amplitude. When excitation level attained 1g, the amplitude decrease represents 40% of initial amplitude. In average, the resonance amplitude decrease ratio is near to 45 %. These results show how the synergy between piezoelectric and conductive particles improves the damping of composite sandwich beams. Piezoelectric particles convert the energy of the mechanical vibrations into electrical charges and CNTs allow the evacuation of these charges by local conduction.

The damping nanocomposite was surface bonded in a representative aerospace structure. The system “Damping film + Composite” structure (Figure 2d) was manufactured following industrial processes. Vibration tests were later performed by fixing the panel horizontally over vibration shaker’s head. The evaluation of the nonlinear effects brought by the polarization and amplitude load on the resonance frequencies and dissipative energy are very complex: Plus, the modal properties varies significantly between two different payload configurations. In order to simplify our understanding, only the first and second bending vibration modes were analyzed before and after polarization at 0,25g (Figure 5).

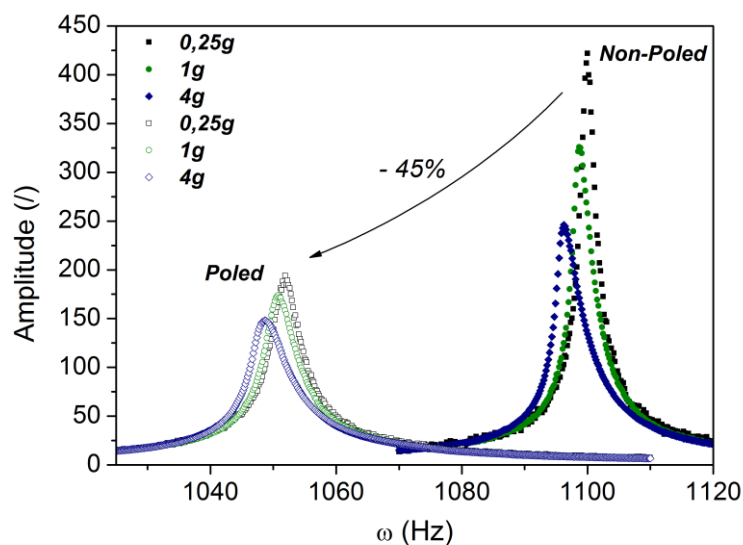

Figure. 4. FRF of the 2nd bending vibration mode of a composite sandwich beam containing the damping film before and after polarization

Figure. 5. FRF of the 1st and 2nd bending vibration modes of carbon-fiber aluminum-honeycomb sandwich panel containing the damping film before and after polarization

As it was observed for composites sandwich beams, polarization causes an amplitude decrease of 45 % and 23 % for the first and the second modes respectively. Equivalent damping performances were observed in both structures. Despite of the complexity of the structure, the transduction-dissipation phenomenon was proved by enhancing vibration mitigation to composite structures.

4 CONCLUSIONS

- A promising passive damping concept based on local transduction-dissipation phenomenon for aerospace composites structures was studied. The damping material is based on nanocomposite, where micrometer ceramic and carbon particles are homogeneously dispersed in a thermoplastic polymer.
- Processed nanocomposites films were embedded in composites sandwich-beams and carbon-fiber aluminum-honeycomb sandwich panels with different payloads configurations. The structures were poled after consolidation in order to promote piezoelectricity.
- Experimental shear tests on sandwich-beams highlighted strong non-linear effects, frequency and amplitude dependency by following stress-strain hysteresis loops. Moreover, an increase of the loops area and so the dissipated energy from 20 to 40 % was reported after polarization.

- Experimental vibration tests were performed on sandwich-beams. The resulting FRF showed strong non-linear behavior and amplitude decrease of the second bending mode up to 45% in average for different load amplitudes.
- Finally, experimental behavior performed in carbon-fiber aluminum-honeycomb sandwich panels containing the damping nanocomposite in the surface was followed. At low frequencies, results showed important decrease of amplitude up to 45 % for the first mode and 25 % for the second mode. The performance of the concept was proved in a representative aerospace structure.
- Further investigation containing multiscale physics and modeling of the material contribution to damping performances will be devoted.

Key words: Carbon nanotube, Eringen's nonlocal elasticity, mass sensor, nanoparticles, detection sensitivity, frequency shift.

Abstract. This study focuses on the free vibrations of carbon nanotubes (CNTs) with clamped-clamped boundary conditions and multiple deposited nanoparticles. The purpose of this work is to extend the limits of applicability for the theoretical modeling of nanoscale CNT-based mass sensors. Previous studies focused on determining the induced frequency shift or amplitude shifts that arise due to the deposition of a single nanoparticle on or within the CNT. In this effort, the reduced-order model is extended to include an arbitrary number of masses deposited on the CNT. This is a more realistic representation of experiments at the nanoscale. To perform a free vibration analysis, the governing equations are first derived by virtue of Hamilton's principle, considering Euler-Bernoulli beam theory. To account for the effects of mid-plane stretching for end constrained beams, the von Kármán geometric nonlinearity is included and effectively modifies the strain field. Eringen's nonlocal elasticity theory is employed to account for size dependent phenomena. Each deposited particle breaks up the displacement field, leading to continuity equations for the deflection, slope, moment, and shear. After all the governing equations, boundary conditions, and continuity conditions are obtained, a parametric study is performed to determine the impacts of increasing the number of nanoparticles that are deposited onto the CNT on the sensitivity of the carbon-nanotube based sensor. Results show that, even when keeping the total deposited mass constant, the number of particles and their location can significantly shift the natural frequencies and the mode shapes of the nano-sensor.

1 INTRODUCTION

Nowadays many researchers are aware of the potential to use carbon nanotubes (CNTs) in a variety of nanoscale applications. Since their initial discovery in the early 1990s [1, 2], CNTs have been widely studied for their unique mechanical, optical, thermal, and electrical properties. To clarify, CNTs are essentially rolled sheets of graphene with cylindrical structure that can have diameters on the order of several nanometers and lengths varying from several nanometers to a few microns in length. Further, the CNTs exist either as single-walled or multi-walled structures. In this research group, studies are primarily conducted from a theoretical, mechanics,

dynamics, and vibrations points of view through the development of reduced-order models. In the development of these models, there are several factors that must be considered. For example, in modelling structures at the nanoscale, it is important to consider the limits of applicability of classical continuum mechanics. At this scale, the size of the considered structure can approach the internal lengths in the structure and classical continuum mechanics assumptions can fail. In that case, particles in a continuum should no longer be treated simply as point masses subject only to translation, but rather as nano-volumes that can rotate, deform, and translate [3]. One of the most widely used theories is Eringen's nonlocal elasticity theory [4, 5]. This theory accounts for the effects of neighboring particles in a medium through an attenuation function. When the model is simplified to its differential form, it can be applied in a variety of models that need to take size-dependent effects into account [5-8].

After noting that CNTs can be used in a variety of applications, we narrow it down to considering CNTs to act as a nano-scale mechanical resonator or sensor that aims at detecting and identifying the mass of particles that are distributed on or within the CNT. The reason that they are considered in this application is that CNTs have a very high Young's modulus and therefore vibrate at a very high natural frequency. So, depositing even the smallest mass onto the CNT can cause a measurable shift in the frequency that can be converted back to an equivalent deposited mass. As such, there have been many efforts that focus on developing reduced-order models for CNT-based mass sensors [9-14].

So, for this work, we aim to extend the limits of applicability of CNT-based mass sensor by accounting for an arbitrary number of particles. The displacement field is defined by the Euler-Bernoulli beam theory. To account for mid-plane stretching of end-constrained beams, the von Kármán geometric nonlinearity is included. For size-dependent effects, we modify the stress field using Eringen's nonlocal theory. Then, to determine the governing equations of motion, boundary conditions, and continuity conditions, we utilize the Hamilton's principle. Finally, a free vibration analysis is performed to determine the shifts in the natural frequency for different numbers of deposited particles and varying centers of mass.

2 SIZE-DEPENDENT NONLINEAR GOVERNING EQUATIONS OF MOTION

In this section, the derivation for the governing equations of motion, boundary conditions, and continuity conditions are presented for the CNT-based mass sensor with multiple deposited nanoparticles. Consider a single-walled CNT of length L , diameter D , and wall thickness h , as shown in Figure 1. The total number of deposited nanoparticles is denoted by N . The location and individual mass of each particle are denoted by x_{mi} and m_i , respectively, where $i = 1, 2, 3, \dots, N$.

Figure 1. Schematic of CNT-based mass sensor with N deposited nanoparticles.

The total mass of the deposited particles can be represented by:

$$M = \sum_{i=1}^N m_i \quad (1)$$

In this study, the displacement field is defined according to Euler-Bernoulli beam theory, as shown in equation. (2). The von Kármán strain tensor, shown in equation (3), is used to determine the CNT's strain field, shown in equation (4).

$$u_x(x, z) = u(x) - z \frac{\partial w}{\partial x}; \quad u_y(x, z) = 0; \quad u_z(x, z) = w(x) \quad (2)$$

$$\varepsilon_{ij} = \frac{1}{2} \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) + \frac{1}{2} \left(\frac{\partial u_k}{\partial x_i} \frac{\partial u_k}{\partial x_j} \right) \quad (3)$$

$$\varepsilon_{xx} = \frac{\partial u}{\partial x} - z \frac{\partial^2 w}{\partial x^2} + \frac{1}{2} \left(\frac{\partial w}{\partial x} \right)^2 \quad (4)$$

Then, to account for each deposited mass, the displacement field is broken up as:

$$u(x, t) = \begin{cases} u_1(x, t), & 0 \leq x \leq x_{m1} \\ u_2(x, t), & x_{m1} < x \leq x_{m2} \\ \vdots & \\ u_{N+1}(x, t), & x_{mN} < x < L \end{cases}, \quad w(x, t) = \begin{cases} w_1(x, t), & 0 \leq x \leq x_{m1} \\ w_2(x, t), & x_{m1} < x \leq x_{m2} \\ \vdots & \\ w_{N+1}(x, t), & x_{mN} < x < L \end{cases} \quad (5)$$

where $u(x, t)$ and $w(x, t)$ represent the longitudinal and transverse displacement of the CNT, respectively. In breaking up the displacement field, continuity conditions are introduced at the location of each deposited mass. Before finalizing the derivations for the governing equations, it is important to note that Eringen's nonlocal theory is used in this study to account for the behavior and response of the structure at the nanoscale. The reason that it is important to include this theory into the derived model is that when the size of the considered structure is comparable to the internal lengths of the structure, size dependent behaviors appear. Because of the material structure of the CNT, it has been shown that Eringen's nonlocal elasticity theory is appropriate for CNTs. In this theory, each particle is modeled as a point mass, as in classical continuum mechanics. However, the stress at one reference point is influenced by the strain of all other points in the medium. Therefore, the nonlocal stress field σ_{ij} is represented as [3, 4]:

$$\sigma_{ij}(x) = \int_{\Omega} \alpha(|x' - x|, e) t_{ij}(x) d\Omega(x') \quad (6)$$

In this case, the local stress field is denoted by t_{ij} , α is an attenuation function that captures the effects of the neighboring particles. The nonlocal parameter is given as $e = e_0 a / l$. This parameter depends on the several other parameters including the internal and external characteristic lengths, represented by a and l , respectively. Additionally, the material parameter, e_0 , that is determined from the longitudinal and transverse acoustic dispersions can be found from molecular dynamics simulations or experiments. Noting that the integral formulation leads to equations that are difficult to solve analytically, the simplified differential form is used, yielding:

$$(1 - (e_0 a)^2 \nabla^2) \sigma_{ij} = c_{ijkl} \varepsilon_{kl} \quad (7)$$

Considering the displacement field, strain field, and size-dependency through Eringen's nonlocal elasticity, the governing equations of motion can be determined using the Hamilton's principle, given as:

$$\delta H = \int_{t_1}^{t_2} (\delta T_b + \sum_{i=1}^N \delta T_{mi} - \delta \Pi) dt = 0 \quad (8)$$

It should be noted that δT_b , δT_{mi} , and $\delta \Pi$ represent the first variation of the kinetic energy of the CNT, the first variation of the kinetic energy of each deposited particle, and the first variation of the potential energy, respectively. The full expressions for each term are omitted for brevity, but more details on these terms can be found in [9]. After determining the variations of the energy and substituting them into Hamilton's principle, the final nondimensional equations of motion are derived as:

$$\begin{aligned} & W_i^{(4)} + \ddot{W}_i - \left(\frac{1}{N+1} \int_0^{\eta_1} (W'_{1})^2 d\chi + \sum_{j=2}^N \frac{1}{N+1} \int_{\eta_j}^{\eta_{j+1}} (W'_j)^2 d\chi + \frac{1}{N+1} \int_{\eta_N}^{\eta_{N+1}} (W'_{N+1})^2 d\chi \right) W''_i \\ & - e^2 \left[\ddot{W}''_i - \left(\frac{1}{N+1} \int_0^{\eta_1} (W'_{1})^2 d\chi + \sum_{j=2}^N \frac{1}{N+1} \int_{\eta_j}^{\eta_{j+1}} (W'_j)^2 d\chi + \frac{1}{N+1} \int_{\eta_N}^{\eta_{N+1}} (W'_{N+1})^2 d\chi \right) W_i^{(4)} \right] \\ & = 0 \end{aligned} \quad (9)$$

where $i = 1, 2, 3, \dots, N$. Then, the boundary and continuity conditions are:

$$W_1(0) = W'_1(0) = W_{N+1}(1) = W'_{N+1}(1) = 0 \quad (10)$$

$$\begin{aligned} & W_i(\eta_i) = W_{i+1}(\eta_i); \\ & W'_i(\eta_i) = W'_{i+1}(\eta_i); \\ & W''_i(\eta_i) = W''_{i+1}(\eta_i); \\ & W'''_i(\eta_i) - W'''_{i+1}(\eta_i) \\ & + e^2 \left[\left(\frac{1}{N+1} \int_0^{\eta_1} (W'_{1})^2 d\chi + \sum_{j=2}^N \frac{1}{N+1} \int_{\eta_j}^{\eta_{j+1}} (W'_j)^2 d\chi + \frac{1}{N+1} \int_{\eta_N}^{\eta_{N+1}} (W'_{N+1})^2 d\chi \right) \right] \\ & (W'''_i(\eta_i) - W'''_{i+1}(\eta_i)) - \ddot{W}_i \mu_i(\eta_i) = 0 \end{aligned} \quad (11)$$

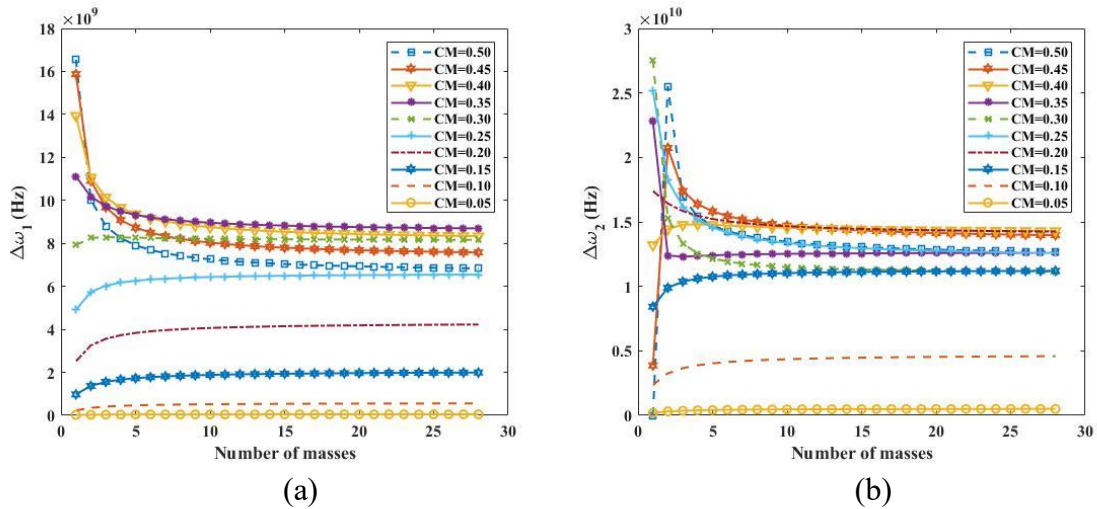

In this case, W denotes the nondimensional transverse displacement. The nondimensional mass of each particle is denoted by μ_i , the nondimensional location of each particle is represented by η_i . Finally, e represents the nondimensional nonlocal parameter and N represents the total number of deposited particles. Further details on these nondimensional parameters and derivation details can be found in [9]. After obtaining the full set of governing equations, the system is linearized for an eigenvalue problem analysis. In doing so, the shifts in the natural frequencies and the changes in the mode shapes due to each deposited particle can be determined. Results for varying the location and number of masses are presented in the next section.

3 RESULTS AND DISCUSSION

The novelty of this work lies in investigating and discussing the importance in the differences between attaching a single nanoparticle on or within a CNT versus attaching multiple particles. One might predict that if the *total* mass that is deposited on the surface remains constant, denoted by M , that the shift in the natural frequencies before and after the particles have been deposited will also be constant. However, this is not the case. To demonstrate this phenomenon, we vary the number of deposited particles and the center of mass while keeping the total mass deposited on the surface constant.

3.1 Variations in the frequency shift by varying the number of deposited particles and center of mass

In Figure (2), the first, second, and third natural frequency shifts as a function of the number of deposited particles for varying centers of mass are presented. In all cases, the total mass M , remains constant. Furthermore, when more than one particle is considered, each particle has the same mass of $m_i = M/N$. This was done to study the effects of the location and effective center while maintaining the total mass. It is also possible to keep the mass of *each* particle constant and increase the total number of particles. In that case, the shift in the frequency would keep increasing as the number of particles increases. However, the purpose of Figure (2) is to show that if that total mass remains constant, the number of masses and their center of mass can significantly alter the frequency shift. To further explain, we consider specific configurations. The case where $CM = 0.5$ implies that particles are uniformly distributed across the entire length of the CNT. The case where $CM = 0.45$ implies that the particles are uniformly distributed along the first 90% of the beam. This trend continues until the particles are only uniformly distributed along the first 10% of the CNT, leading to $CM = 0.05$.

(c)

Figure 2. Shifts in the first, second, and third natural frequencies for a constant total deposited mass as a function of the number of masses and their center of mass.

In discussing the meaning of Figure 2, it should be mentioned that when only one particle is deposited, the maximum first natural frequency shift is obtained when the particle is deposited at the center, which makes sense physically. However, in keeping the center of mass a constant, increasing the number of particles that are uniformly distributed decreases the shift in the first natural frequency until reaching a nearly constant value at approximately 10 masses. This trend continues until reaching a critical value in the first mode in which increasing the number of masses increases the shift in the frequency. This can be seen in the bottom half of Figure 2(a). In addition, it can be seen in Figure 2(a), that there are different scenarios that lead to the same shift in the first natural frequency. In order to differentiate between the cases, we study the second and third shifts in the natural frequencies to eliminate the possibility of multiple scenarios leading to the exact same dynamic response. If the shifts in the natural frequencies are not enough to determine the scenario, it is possible to then look at the difference in the mode shapes. In studying Figures 2(b) and 2(c), it is shown that the behavior is not as uniform for the second and third shifts in the frequencies as they are for the first natural frequency shift. This is explained by the fact that in the first natural frequency, there is only one *optimal* location to deposit a single mass – the center of the CNT. Additionally, in the first mode, there are only two locations that lead to a complete inability to detect a shift in the frequency, and that is at the two ends of the beam. This is simpler than the cases of the second and third natural frequencies shifts. In these cases, even when only one deposited particle is considered, there are more than one *optimal* location to deposit a single mass and more than one location in which the shift in the second and third natural frequency is minimal or completely zero. Thus, it is shown that even by keeping the total mass deposited on the system constant, the dynamic response is still significantly affected by the number of particles and their center of mass.

3.2 Effects of the center of mass for a fixed number of deposited particles

After determining that the number of masses can significantly change the dynamic response of the CNT, the impact of the center of mass is further investigated. Because the total mass remains constant, there is a critical value for the number of masses that no longer leads to greater

shifts in the frequency. To be on the safe side, we investigate the case where 20 masses have been deposited. Then, by varying the center of mass, as shown in Figure 3, it is demonstrated that the *location* of the particles, even when there is a high number of them will change the shift in the natural. So, if one can determine the total number of masses that have been deposited on the surface, it is also possible to determine the optimal distribution in which the maximum frequency shift can be obtained. What is interesting is that these optimal locations vary as a function of the number of deposited particles and that the predicted locations are not as straightforward as they are for the case of a single deposited particle.

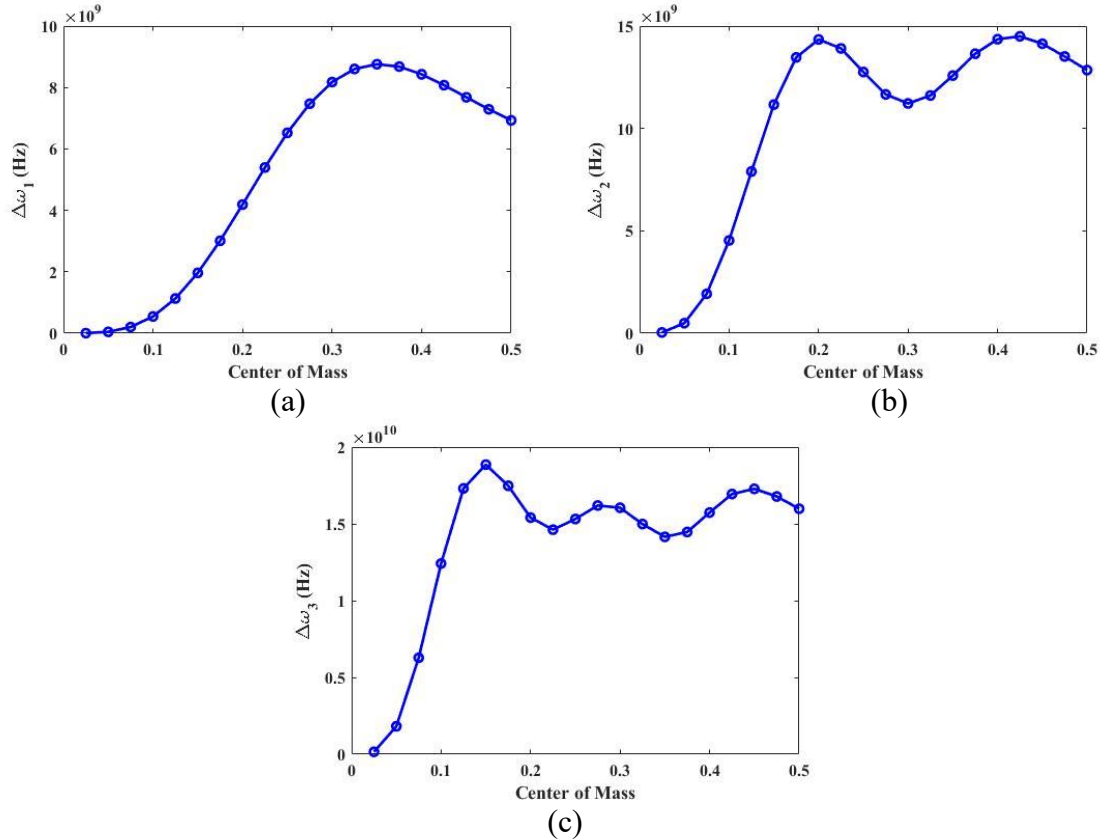

Figure 2. Shifts in the first, second, and third natural frequencies for a constant total deposited mass for 20 deposited particles as a function of the center of mass.

4 CONCLUSIONS

This study focused on determining the differences between the frequency shifts and mode shapes of CNT-based mass sensors, in which the total deposited mass remains constant, but the location and number of deposited particles varies. One might have predicted that in keeping the total mass, M , constant, that the obtained shift in the frequency would also be constant. This was not the case. It was shown that by varying the center of mass of the deposited particles, the shift in the frequency can be dramatically different. Further, even in keeping a constant center of mass and a constant total deposited mass, the number of masses alters the response of the system. This occurs until reaching a critical number of masses in which the shift in the frequency no longer varies as a function of the number of particles. This result is useful in that one can obtain the critical number of masses that are needed to approach a fixed behavior

of the system, which can be useful in reducing time and complications in both experiments and high-fidelity simulations. Additionally, it was shown that for a fixed number of deposited particles, the center of mass significantly changes the shift in the first, second, and third natural frequencies. Compared to a single deposited particle, the response differs. Overall, this study aides in extending the limits of applicability and robustness of reduced-order models for CNT-based mass sensors.

Abstract: Distributed optical fiber systems based on optical frequency domain reflectometry (OFDR) have received extensive attention in the field of structural health monitoring. By calculating the spectral offset by cross-correlation analysis of the reference Rayleigh backscattering spectrum (RBS) and the measured RBS, it is converted into the strain of the structural. The system based on OFDR has high spatial resolution and strain measurement accuracy. However, when the fiber is subjected to large strain (more than $5000\mu\epsilon$), the amplitude of the RBS signal will be sharply attenuated. Further, the cross-correlation analysis failed and the strain could not be demodulated. In this paper, a large-strain demodulation method for OFDR distributed fiber is proposed. The dynamic reference RBS of sub-region is used to replace the traditional fixed reference RBS to break the limitation of large strain measurement. The large strain measurement of the tensile test of composite laminates shows that the fiber strain demodulation method proposed in this paper can measure the large strain above $10000\mu\epsilon$ stably and reliably.

1 INTRODUCTION

Distributed optical fiber measurement technology based on OFDR which has high spatial resolution, high sensitivity and large dynamic measurement range, is used in the field of health monitoring [1]. Since M.Froggatt and Moore [2] applied OFDR technology to distributed fiber strain measurement in 1998, significant progress has been made in fiber strain demodulation methods [3]. RBS in the fiber is caused by the refractive index profile along the length of the fiber, which can be seen as weak fiber Bragg gratings with periodic variations [4]. Changes in strain or temperature cause spectral shifts in the local RBS of the fiber, and the offset is proportional to the amount of temperature or strain change [2]. Therefore, strain or temperature information can be obtained by measuring the spectral shift in the RBS.

Usually, a cross-correlation function is used to compare the RBS of the two sets of fibers in the initial state and the deformed state, and the maximum correlation coefficient is used to determine the offset of the corresponding RBS [5]. For example,

Boyd et al. [6] and Du et al. [7] used this method to measure small temperature changes in a low temperature environment from the RBS offset. However, the above-mentioned traditional strain demodulation method is only suitable for the case where the RBS offset is small, and cannot be applied to the large-scale offset of the RBS [8]. In particular, when the strain is large, the RBS signal of the fiber is abruptly attenuated, resulting in an uncorrelated measurement of the RBS and the reference RBS [9]. Therefore, the development of large strain demodulation methods for distributed optical fibers is a research topic worthy of attention.

Based on the strain demodulation principle of fiber RBS, a large strain partitioning strategy is applied. This paper proposes a method of sub-region dynamic reference RBS method to replace the original fixed reference RBS. The measured RBS of the sub-region is used as the reference RBS of the current sub-region, and the cross-correlation analysis is performed with the measured RBS of the current sub-region to determine the relative strain value of the current sub-region, and the final absolute strain is accumulated value. Finally, a composite strained plate tensile test with large strain (above $10000\mu\epsilon$) was performed to verify the effectiveness of the proposed large strain demodulation method.

2 PRINCIPLE

2.1 Distributed optical fiber strain measurement system based on OFDR

As shown in Fig.1, the OFDR system consists of a tunable linear swept laser, five couplers, two photodetectors, and an A/D digital capture card. The laser output from the tunable linear swept laser is divided into two optical paths through the coupler 1, that is, the auxiliary interferometer optical path and the main interferometer optical path.

In the auxiliary interferometer, the laser is split into two beams by the coupler 2, one of which passes through the delay fiber and merges with the other light in the coupler 3, which is a typical Mach-Zehnder interference beam path. Finally, the synthesized light passes through the photodetector and acts as an external clock to trigger the A/D digital acquisition card to work, converting the electrical signal into a digital signal that can be used for signal processing. The auxiliary interference optical path is used as an external clock for triggering the measurement interferometer, and a sinusoidal signal period is used as a clock signal for the purpose of compensating for the frequency scanning nonlinearity of the light source.

In the measuring interferometer, the laser is split into two beams by the coupler 4, one of which passes through the circulator and merges with the other light in the coupler 5 for collecting RBS data in the fiber under test. Finally, after the synthesized light passes through the balanced photodetector, the RBS data is triggered by the auxiliary interference optical path.

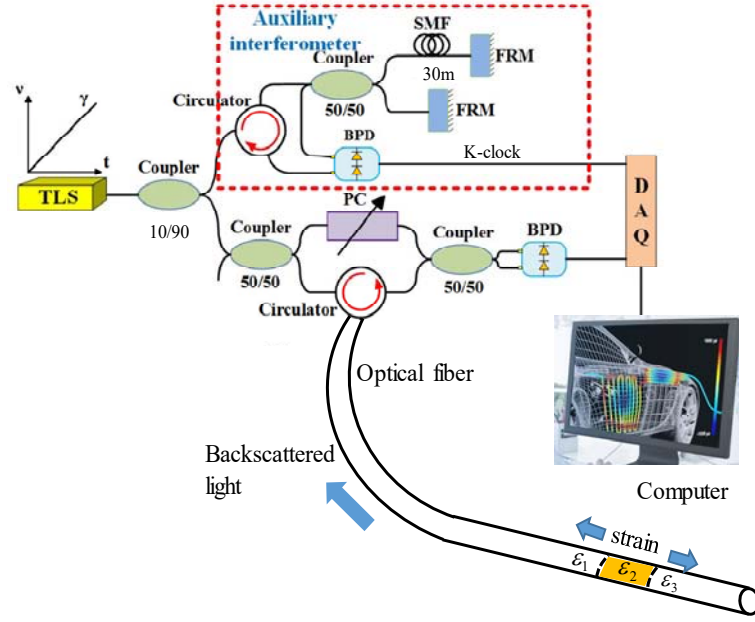

Figure 1: OFDR system

M. Forrgatt et al. [2] first proposed a distributed strain measurement method based on RBS in 1998. It was found that the RBS in the fiber shifts under strain or temperature change without changing the shape. By recording the RBS of the fiber before deformation (defined as the reference RBS) and the deformed RBS (defined as measuring the RBS), the spectral offset can be obtained by cross-correlation analysis. Convert to the corresponding strain information.

It is assumed that the i -th subset of the reference RBS is represented as $Ri(m)$, referred to as the reference subset, where m is the subset length, as shown in Figure 2(a). The i -th subset of the measured RBS can be expressed as $Mi(m)$, referred to as the measurement RBS subset, which is characterized by the fact that the intensity is constant but a wavelength offset $\Delta\lambda$ occurs. Since the strain causes the fiber to produce an elastic effect [10], the wavelength shift $\Delta\lambda$ can be describe as

$$\Delta\lambda = \lambda_0 \left\{ 1 - \frac{n_{eff}}{2} [p_{12} - (p_{11} - p_{12})]v \right\} \varepsilon = k\varepsilon, \quad (1)$$

where λ_0 is the center wavelength, p_{11} and p_{12} are the elastic coefficients of the fiber material, n_{eff} is the effective refractive index of the fiber, v is the Poisson's ratio of the fiber material, k is the strain sensitivity coefficient of the fiber relative to the wavelength shift, and ε is the fiber strain.

Assume that the fiber is a pure quartz material, then $p_{11} = 0.112$, $p_{12} = 0.270$, $v = 0.17$, and $n_{eff} = 0.456$. When the center wavelength of the light source is 1550 nm, the strain sensitivity coefficient $k = 1.2 \text{ pm}/\mu\varepsilon$ can be obtained.

It can be seen that when $\Delta\lambda$ is negative, it means that the measured RBS moves toward the low wavenumber direction (called blue shift), and the fiber is subjected to tensile strain ($\varepsilon > 0$). Conversely, when $\Delta\lambda$ is positive, it means that the measured RBS moves toward the high wavenumber direction (called red shift), and the fiber is subjected to compressive strain ($\varepsilon < 0$). The above is the basic principle of measuring

the strain using the fiber RBS.

2.2 Dynamic reference RBS

To control the difference between the reference RBS and the measured RBS, it means to adjust the measurable strain range. The large strain is divided into n intervals, as shown in FIG. 3, and the relative strain $\Delta\epsilon_i$ in the i -th sub-region satisfies the fault tolerance range of the cross-correlation analysis. Taking the measured RBS of the $(i-1)$ -th sub-region as the reference RBS of the i -th sub-region, the relative offset of the sub-region can be obtained by cross-correlation analysis with the scattering spectrum of the i -th sub-region. $\Delta\lambda_i$. Thus, the relative offsets in all intervals are accumulated as the absolute offset corresponding to the large strain.

Figure 2: Principle of large strain partition measurement based on dynamic reference Rayleigh backscattering spectrum

Different from the traditional method, the initial state is different as the fixed reference RBS. The core of the above-mentioned large-strain partition demodulation principle is to measure the RBS signal M_{i-1} of the $(i-1)$ -th sub-region as the i -th sub-element. The reference RBS R_i of the region is called the dynamic reference RBS because the reference RBS is continuously updated as $F_i = G_{i-1}$.

Then, cross-correlation analysis is performed on the measured RBS signal M_i , thereby obtaining the relative wavelength shift amount $\Delta\lambda_i$, and summing with the previous $i-1$ times to obtain the final absolute offset

$$\Delta\lambda = \sum_{i=1}^i \Delta\lambda_i, \quad (2)$$

where i is the number of partitions with large strain. The final absolute strain $\epsilon = k\Delta\lambda$ is converted using the strain sensitivity coefficient k .

3 EXPERIMENT

The fiber used in the experiment was a standard single-mode fiber (SMF-28), and a precision displacement stretching device was used to calibrate the strain sensitivity coefficient of the fiber. In the axial tensile calibration experiment of the optical fiber, a given tensile displacement is applied to the optical fiber with a displacement step of 0.5 mm and a displacement range of [0, 5] mm. In the calibration experiment, the OFDR system was used to acquire the RBS of the fiber, and the ZNCC correlation function was used to determine the spectral offset. The tunable linear scan laser used in the calibration experiment was an Agilent 81680A with a spectral scan range of 1520 to 1540 nm and a scan rate of 40 nm/s.

The glass fiber reinforced composite laminate tensile test was used to verify the effectiveness of large strain measurement method. As shown in Fig. 6(a), an optical fiber was pasted on the surface of the sample and cured for 24 hours. For comparison, four positions A, B, C, and D were selected to paste the one-way strain gauge.

Figure 3: (a) Optical fiber and strain gauge attached composite laminate (b) tensile setup

The composite laminate was fixed in a stretching device with a self-designed fixture as shown in Fig. 6(b). The test machine (CSS-50T) was used for stretching, and the force control mode was used for grading loading. The loading step was 20kN, and the total loading was 200 KN with 10 steps. 11 sets of the RBS data was collected after force loading. The first set of the RBS data was recorded from the fiber with the initial state, and other 10 sets of the RBS data was recorded after different loads.

4. RESULTS AND DISCUSSION

4.1 Rayleigh backscattering spectrum in optical fiber

The RBS signal in spectral domain are transformed into the distance domain using FFT, and the amplitude of the RBS signal in the distance direction of the optical fiber can be obtained. As shown in FIG. 8, the RBS signal is transformed into the distance domain with force of 0kN, 80kN, 100kN, 200kN, where the gray shaded area is the fiber segment pasted on the composite board. It can be seen from Fig. 8 that as the external load increases, the RBS intensity measured by the optical fiber is

continuously attenuated. For example, when the load is 80kN, the signal strength is attenuated by about 9dB; when the load is raised to 200kN, the signal attenuation is more than 15dB, which is only about 5dB away from the intensity of the noise. In contrast, fibers that are not attached to a composite panel (unstressed) have a constant signal strength. The above experimental results show that as the fiber load increases, the RBS intensity in the fiber will decrease with the attenuation. When the fiber deformation reaches a certain level, the RBS signal will be submerged in the noise, thus the traditional strain demodulation method have failed.

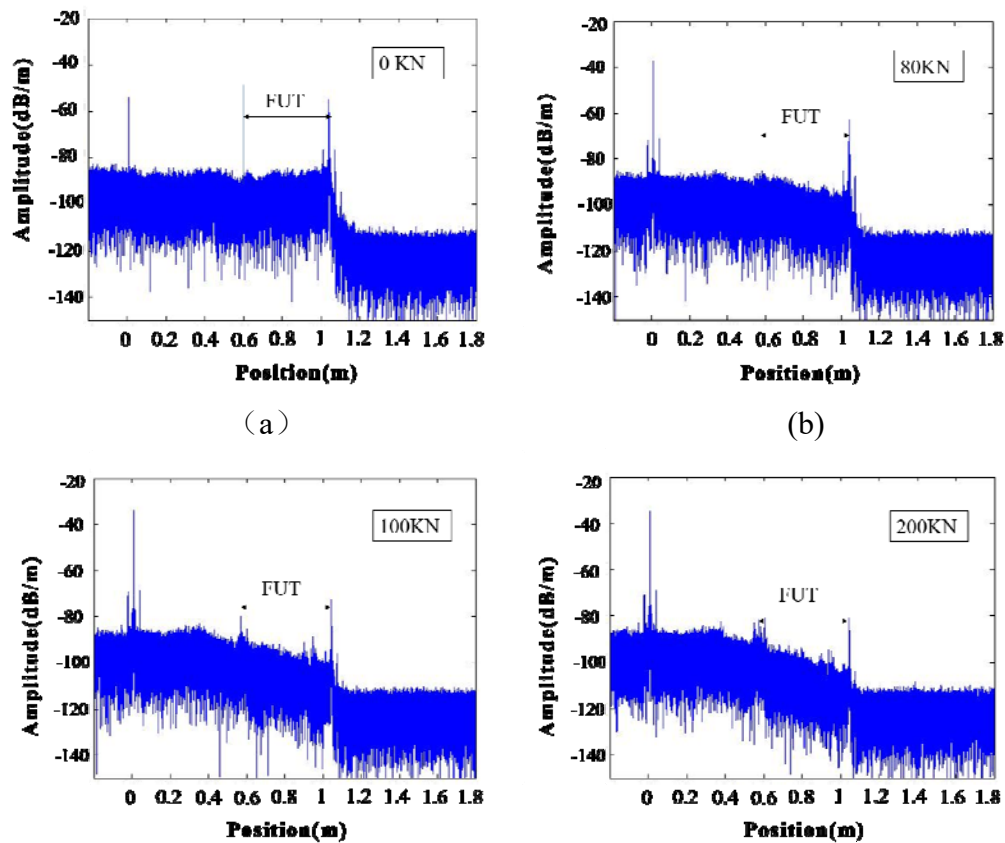

Figure 4: Rayleigh backscattering spectral distribution along fiber length under different loads of (a) 0kN, (b) 80kN, (c) 100kN and (d) 200kN

4.2 Strain demodulation

Fig. 10(a)(b) is a structural strain value of 11 sets of RBS data obtained by using the conventional demodulation method and the improved strain demodulation method proposed by the present invention.

When the strain is solved by the traditional demodulation method (Fig. 10a), the strain value generated under the first two-stage test force (0~40kN) can be demodulated more stably and accurately, and the result is compared with the proposed improved strain demodulation method. Consistent. When loaded to the third level (40kN~80kN), a wide range of noise-like erroneous results begin to appear.

In contrast, the strain obtained by the large strain measurement method proposed in this paper increases linearly and stably after the end of each stage of loading, and

there is no erroneous result of the mutation, and the strain value collected with the adjacent strain gauge is very good. The anastomosis, as shown by position A in Fig. 8(b), the strain values measured by the strain gauges under the loading of each stage are [1335, 2247, 3224, 4264, 5031, 5998, 6983, 7989, 10368] $\mu\epsilon$. The strain values measured by the optical fiber in the adjacent position A are [1343, 2260, 3250, 4291, 5114, 6020, 7010, 8104, 9187, 10572] $\mu\epsilon$, and it can be seen that when the strain exceeds 10000 $\mu\epsilon$, the accuracy of the measurement result can be Up to 1.97%. At position B, the results measured by the strain gauges are [1039, 1641, 2613, 3713, 4598, 5612, 6515, 7498, 8481, 9597] $\mu\epsilon$, and the strain values measured by the fiber are [1052, 1687, 2666, 3791, 4687, 5718, 6625, 7604, 8593, 9739] $\mu\epsilon$, when the strain exceeds 10000 $\mu\epsilon$, the precision can reach 1.5%.

(a)

(b)

Figure 5: Strain demodulation results obtained by (a) the conventional demodulation method and (b)

It can be seen from Fig. 10 that the improved demodulation method proposed by the present invention can decompose larger strain information stably and accurately because of the demodulation strategy of the dynamic reference RBS. The reason why this method has obvious advantages in demodulating large strains is that it has a certain fault tolerance when using cross-correlation function for correlation analysis, that is, the cross-correlation function can distinguish between the reference RBS and the measured RBS. Changes, but such changes beyond a certain range can also lead to errors in cross-correlation analysis. The conventional demodulation method uses the fixed reference RBS as the RBS signal acquired by the fiber in the initial state, compared to the measured RBS signal amplitude acquired after the first and second stages of loading. The change is small, so that it can be demodulated more stably and accurately. As the amplitude of the measured RBS signal acquired after the third stage loading is larger and larger, the difference between the amplitude of the reference RBS signal and the measured RBS signal is also larger and larger, resulting in cross correlation. The analysis failed, resulting in a noise-like meaningless demodulation result. The demodulation method proposed in this paper adopts the dynamic reference RBS. Since the reference RBS is replaced with the recently acquired RBS signal before each demodulation, the RBS and the measured Rayleigh spectrum will be referenced. The difference in the scatter spectrum is controlled to a minimum, which improves the reliability and accuracy of the cross-correlation analysis to some extent.

4. CONCLUSION

OFDR-based distributed fiber strain measurement is a method that is easy to acquire structural strain information in a large area. However, large strains tend to cause the micro-bending of the fiber to cause amplitude attenuation of the Rayleigh scatter signal, and the correct strain information cannot be obtained using conventional demodulation methods. Based on the demodulation principle of the traditional demodulation method, this paper proposes a dynamic reference Rayleigh scattering spectrum method to improve the accuracy and reliability of strain information measurement. The experimental results show that the large strain measurement method proposed in this paper is used for distributed optical fiber measurement with large strain ($10000\mu\epsilon$) up to 1.9% measurement accuracy.

Abstract. This article presents a theoretical and experimental study of the relationships between the stress, strain, and magnetic field emitted from epoxy-based Terfenol-D composite materials that are intended for stress sensing applications. The experimental results were analyzed and simulated by a new model that accounts for the inherent hysteretic and non-linear mechanical behavior of the epoxy. The results reveal a critical strain above which the perfect bonding between the Terfenol-D and the epoxy does not valid. This critical strain is very close to the transition strain, at which non-180° domain switching is finished and the magnetization rotation becomes the dominant process in the Terfenol-D. Comparisons between simulations and experimental results, obtained at strains smaller than the critical strain, revealed that most of the hysteresis in the magnetic field versus stress curves is derived from the inherent hysteresis in the stress-strain behavior of the epoxy. These results encourage the search for a more suitable epoxy that provides better bonding with Terfenol-D and smaller hysteresis. Despite the drawbacks of the currently used epoxy, both measured and simulated curves showed that for strain amplitudes smaller than the critical strain, the magnetic field vs. stress curve is approximately linear and has a minor amount of hysteresis, making the sensor suitable for stress-sensing applications.

1 INTRODUCTION

Magnetostrictive materials, such as Terfenol-D [1, 2], demonstrate stress induced magnetic field changes that can be utilized in force and stress sensing applications [3]. In particular, magnetostrictive composites, in which TD particles are incorporated into an epoxy matrix, enable overcoming the brittleness of TD and forming sensors with complicated shapes, such as thin washer shaped sensors for measuring compressive forces in bolted joints [4].

Stress-induced magnetic field changes in magnetostrictive composites have been studied in several previous works (e.g.[4–10]). In particular, Ref.[6] presented a model for the magneto-mechanical behavior of magnetostrictive composites that was based on an assumed sequence of micro-scale physical processes that occur during the material preparation and testing. The model provides a one-to-one relation between the applied stress and the magnetic field induced by the sample. Recently, it was demonstrated that the sequence of physical processes is reversed

upon unloading, and nearly reversible behavior is observed [4,5]. Nevertheless, a certain amount of hysteresis, which has not been accounted for in the previous model [6], has been observed experimentally [4,5]. The hysteresis induces measurement errors in sensing applications; therefore, its study is of significant importance.

The source for the hysteresis, e.g., whether due to the energy barrier for non-180° domain switching or due to the inherent viscoelastic behavior of the epoxy, is still unclear. Specifically, the relative contributions of the epoxy, the TD and the interface (bonding) between them to the hysteresis and irreversibility are unknown. In addition, the effect of the strain amplitude on the hysteresis and irreversibility has not yet been explored. One possible effect, which may occur at large strains, is a change in the strain compatibility at the interface between the epoxy and the TD, i.e., it is possible that at high strains there are no longer perfect bonding conditions, as has been assumed in the previous model [6].

In this study, we identified the effect of the inherent hysteretic and non-linear mechanical behavior of the epoxy on the magneto-mechanical response of the composite material. To this end, we introduced an expansion of the previous model presented in Ref. [6]. Specifically, we replaced the previously assumed linear stress vs. strain response of the epoxy material with real stress vs. strain curves measured using a monolithic epoxy sample. In addition, we introduced and applied a procedure for determining if the perfect bonding condition is valid under large strains.

The paper also presents a much more comprehensive comparison between model simulations and experimental results. Specifically, we compared both the magnetic field vs stress curves (as has been done previously [5,6]) and stress vs. strain curves (which have not been compared before) for the same tests. These comparisons demonstrate that the same values of the input parameters provided a good fit between the model simulations and measurements of all three variables (stress, strain, and magnetic field) in different tests (e.g., different strain amplitudes) and in samples with different volume fractions of TD. This result provides a significant validation of the model.

2 EXPANDED MODEL

In this section, we first (section 2.1) briefly survey the sequence of magneto-mechanical processes that occur during all stages of sample preparation and testing and emphasize important aspects relevant to this study. In section 2.2, we present the main assumptions of the model. In particular, we point on one assumption that has to be verified (Eq. (1)) and one assumption that constitutes an oversimplification, which requires revision (Eq. (4)). Then, in section 2.3, we present methods for expanding the model and testing the validity of its assumption.

2.1 Sequence of magneto-mechanical processes that occur during material preparation and testing

In the sample preparation stage, during the curing of the epoxy, the mixture of TD particles and liquid epoxy is subjected to an external magnetic field with an aim of poling the TD magnetization along the magnetic field direction. The sequence of magneto-mechanical processes that occur during this stage and the critical (hardest) process that eventually determines the efficiency of the poling process have been explored in Ref. [4]. Microscopy

observations showed that due to this poling process, TD particles are arranged in chains along the direction of the external magnetic field, which is denoted by the z -axis [6,10]. Each chain contains many particles closely packed together, and the chains are separated from each other by relatively large distances [6,10]. In light of these observations, Yoffe et al. [6] modeled the composite material as long cylindrical fibers of TD embedded in an epoxy matrix.

When the epoxy matrix is fully cured, the external magnetic field is turned off. At this stage, the average magnetization of the composite material tends to decrease due to the demagnetization energy related to the magnetic field induced by the sample. However, strain compatibility between the epoxy and the TD prevents magnetic processes that are associated with strain changes. Recently, we showed that in a significant portion of the TD volume, the magnetization passes 180° domain switching that is not accompanied by strain changes [5]. It was shown that this process results in a decrease of the initial magnetic field B_0 , which is induced by the sample before the compression test, by more than an order of magnitude.

Under uniaxial compression, the TD first undergoes non- 180° domain switching (DS). During this stage, the ratio B/B_0 (where B is the temporal magnetic field induced by the sample) is determined by the volume fraction x of the material, in which non- 180° DS occurred. The model calculations showed that during this stage, the slope of the magnetic field versus stress curve, which is a measure of the force-sensing sensitivity, is constant and maximal [6]. There is a critical load at which the stress-induced DS process is completed and $x = 1$.

Above that critical load, magnetization rotation (MR) off the easy axes can occur. Throughout this stage, B/B_0 is determined by the direction cosines α_i between the local magnetization and the z -axis. This process requires considerably higher energy and in accordance a considerably higher load. As a result, during the MR stage, the slope of the magnetic field versus stress curve decreases and the magnetic field tends towards zero at high stress values [6].

2.2 The model's assumptions

The simulation procedure begins with expressing all variables of the magneto-mechanical problem as a function of the degrees of freedom, i.e., x in the non- 180° DS regime and α_i in the MR stage. Then, the values of the x and α_i are calculated by expressing and minimizing the overall energy of the system. It was shown that during loading, the mechanical energy of the system is larger than the demagnetization energy by orders of magnitude [6]. In addition, it was shown that if the composite material is not constrained in the transverse plane, the contribution of the strains and stresses in the transverse plane to the total energy is negligible compared to other energy terms that are related to the axial strain and stress. Therefore, to a very good approximation, x and α_i are determined only by the axial stresses and strains. Therefore, in this paper, we use an abbreviated (scalar) notation of the stresses and strains that considers only the axial stresses and strains along the z -axis.

One of the basic assumptions of the model was perfect bonding between the TD cylinders and the epoxy matrix [6], which imposes that

$$\varepsilon_{TD} = \varepsilon_{EP} = \varepsilon \quad (1).$$

Here, ε_{TD} and ε_{EP} are the strains in the TD and epoxy, respectively, and ε is the strain imposed by the loading machine on the composite sample. Based on Eq. (1) and on the transverse isotropy of the TD cylinders, it was shown [6] that the axial stresses in the TD σ_{TD} and the epoxy σ_{EP} are uniform and satisfy the equation

$$\sigma = \sigma_{TD}\nu + \sigma_{EP}(1-\nu) \quad (2),$$

where σ is the average stress (traction) imposed by the loading machine and ν is the TD volume fraction. Equations (1) and (2) constitute the simple rule of mixture for the axial stresses and strains along the z -axis.

The overall strain in the TD is expressed by

$$\varepsilon_{TD} = \frac{\sigma_{TD}}{E_{TD}} + \Delta\varepsilon^{MS} \quad (3).$$

Here, the first term represents the elastic strain, where E_{TD} is the Young's modulus of TD, and the second term represents the strain change due to magnetization changes, which is determined by changes in x and α_i (see Ref. [6] for the expressions of $\Delta\varepsilon^{MS}$). In previous studies [5,6], a linear Hooke's law of the form

$$\sigma_{EP} = E_{EP}\varepsilon_{EP} \quad (4),$$

was assumed to describe the relation between the axial stress σ_{EP} and strain ε_{EP} in the epoxy, where E_{EP} is the epoxy's Young's modulus. This assumption is a significant oversimplification, which ignores the inherent hysteretic and non-linear mechanical behavior of the epoxy.

Previous comparisons of measured and calculated magnetic field vs stress curves implied that part of the TD particles do not undergo magnetization switching. These "impaired" particles behave as a stiff elastic material that increases the effective Young's modulus of the matrix [5,6]. Several possible reasons for the existence of impaired particles have been discussed in Ref. [5]. Nevertheless, the assumed existence of impaired particles has yet to be validated.

2.3 Methods for expanding the model and testing the validity of its assumptions

To account for the hysteretic and non-linear mechanical behavior of the epoxy, we replace Eq. (4) with the equation

$$\sigma_{EP} = \begin{cases} f^{load}(\varepsilon_{EP}) & \frac{\partial \sigma_{EP}}{\partial t} > 0 \\ f^{unload}(\varepsilon_{EP}) & \frac{\partial \sigma_{EP}}{\partial t} < 0 \end{cases} \quad (5),$$

where $f^{load}(\varepsilon_{EP})$ and $f^{unload}(\varepsilon_{EP})$ are stress vs. strain curves measured using a monolithic epoxy sample. The curves $f^{load}(\varepsilon_{EP})$ and $f^{unload}(\varepsilon_{EP})$ depend on the strain amplitude, i.e., the maximal strain in the experiment. Therefore, the strain amplitudes in the tests of the monolithic epoxy sample should be the same as the strain amplitudes in the tests of the composite samples.

The validity of the perfect bonding condition (Eq. (1)) can be investigated based on measurements of the stress vs. strain curves of a monolithic epoxy sample $\sigma_{EP}(\varepsilon)$ and the composite sample $\sigma(\varepsilon)$. Note that $\sigma_{EP}(\varepsilon)$ and $\sigma(\varepsilon)$ depend on the strain amplitude, and therefore, stress vs. strain curves with the same strain amplitude should be compared. By rephrasing Eq. (2), we can calculate the stress in the TD as a function of the strain as follows:

$$\sigma_{TD}(\varepsilon) = \frac{\sigma(\varepsilon) - (1-\nu)\sigma_{EP}(\varepsilon)}{\nu} \quad (6),$$

where $\sigma_{EP}(\varepsilon)$ and $\sigma(\varepsilon)$ are the measured functions. The substitution of Eq. (6) into Eq. (3) provides

$$\varepsilon_{TD}(\varepsilon) = \frac{\sigma(\varepsilon) - (1-\nu)\sigma_{EP}(\varepsilon)}{\nu E_{TD}} + \Delta\varepsilon^{MS} \quad (7).$$

The value of $\Delta\varepsilon^{MS}$ in Eq. (7) is bounded to be less than $\frac{3}{2}\lambda_{111} = 0.25\%$ [5,6]. Moreover, when the non-180° domain switching process ends, at a transition strain of approximately $\varepsilon_t = \frac{8}{3}\lambda_{111} = 0.43\%$ [5,6], the value of $\Delta\varepsilon^{MS}$ is already $\frac{4}{3}\lambda_{111} = 0.22\%$. This means that at $\varepsilon > \varepsilon_t$, $\Delta\varepsilon^{MS}$ is practically constant and Eq. (7) can be further simplified to

$$\varepsilon_{TD}(\varepsilon) \cong \frac{\sigma(\varepsilon) - (1-\nu)\sigma_{EP}(\varepsilon)}{\nu E_{TD}} + 0.25\% \quad (8).$$

Eqns. (7) and (8) can be used for evaluating the validity of Eq. (1), according to which $\varepsilon_{TD} = \varepsilon$.

To test the assumed existence of impaired particles and their effect on the magneto-mechanical behavior, we compare measured and calculated results of both magnetic field vs stress curves and stress vs. strain curves, for the same test. Such a comparison, performed on different samples, can provide much stronger conclusions regarding the existence of the impaired particles.

3 EXPERIMENTAL SETUP AND METHODOLOGY

The samples and their preparation procedure were the same as detailed in Refs. [5,6]. The TD particles were manufactured by Etrema Products, USA and were sieved for particle sizes smaller than $38\ \mu m$. The epoxy was prepared by mixing Hexion Epon 8280 resin with Hexion Epikure 3140 curing agent, in a ratio of 2:1. The sealed mold with the liquid composite material was placed for curing under an external magnetic field of $170\ kA/m$ for 7 days. Cylindrical samples with TD volume fraction of 18.4% and 10.8% were prepared and tested. The samples had a diameter of 6.35 mm and a length of 12.7 mm, in agreement with the compressive testing standard, ASTM D-695.

The magneto-mechanical test setup was the same as detailed in Ref. [5]. An MTS hydraulic mechanical testing machine, equipped with Sensotec 31/1432-08 load cell, was used for performing compression tests under a constant displacement rate. The average strain was measured by an EIR LE-05 laser extensometer system, using two light reflecting strips that were taped 1 mm from the sample ends. The magnetic field induced by the sample was

measured by Honeywell HMC1021S sensor that was mounted at the height of the center of the sample and at a radial distance of 10 mm from the sample.

4 EXPERIMENTAL RESULTS

4.1 Mechanical response of monolithic epoxy

Figure 1 presents stress vs. strain curves of a monolithic epoxy sample. The measurements were performed at a constant strain rate of $6.6 \times 10^{-5} \text{ s}^{-1}$ and up to different strain amplitudes, as indicated in the figure's legend. As shown, no distinguishable residual strain, which indicates plasticity, occurred except for minor non-repeatable behavior at small strains, which is likely related to changes in the contact region, as explained in Refs. [4,5].

The stress vs. strain curves presented in Fig. 1 demonstrate noticeable hysteresis that increases with the strain amplitude. In addition, the stress vs. strain relation is non-linear, especially at small strains. For instance, the slope of the curve changes from 0.7 GPa at small strains to 1.85 GPa at large strains. The hysteresis and non-linearity are typical of epoxy materials and are in agreement with the results reported in previous studies on other epoxy materials [12,13].

Figure 1: Stress vs. strain curves of the monolithic epoxy sample measured under different strain amplitudes.

4.2 Magneto-mechanical behavior of magnetostrictive composites

Figure 2 presents magneto-mechanical measurements obtained from a composite sample with 18.4% vol. TD particles. The measurements were taken at a constant strain rate of $6.6 \times 10^{-5} \text{ s}^{-1}$ and up to different strain amplitudes. A comparison of the stress vs. strain curves of the composite sample (Fig. 2(a)) and the monolithic sample (Fig. 1) reveals two observations. First, both curves have the same shape and demonstrate a similar mechanical behavior. Second, the

composite sample is stiffer, as expected due to the much larger Young's modulus of TD [14] compared with the modulus of the epoxy.

The stress vs. strain curves shown in Fig. 2(a) demonstrate no distinguishable residual strain that could indicate on an irreversible process. High levels of reversibility are also observed in Figs. 2(b) and 2(c), which present the magnetic field vs. the strain and the stress. In particular, upon unloading, the magnetic field reverts approximately to the same value at zero stress. This observation indicates that the sequence of magneto-mechanical processes is reversible, as demonstrated in Refs. [4,5].

Figure 2(c) demonstrates the transition from non-180° DS to MR, as explained in section 2.1. Non-180° DS occurs at small stresses, up to approximately 17 MPa. In this range, the magnetic field vs. stress curve is approximately linear. At higher stresses, the MR process is dominant and the magnetic field vs. stress curve is non-linear and approaches to zero at high stress values.

The most interesting result demonstrated by Fig. 2 is that the hysteresis is strongly dependent on the strain amplitude; a similar trend as demonstrated by the monolithic epoxy sample in Fig. 1. However, the hysteresis is mainly prominent in the stress vs. strain and magnetic field vs. strain curves. In fact, the hysteresis in the magnetic field versus stress curves (Fig. 2(c)) remains small, even at large strain amplitudes. In particular, at a strain amplitude of 0.5%, which is related to a stress of 17 MPa, the magnetic field vs. stress curve is approximately linear and has a minor amount of hysteresis (less than 4% of the full-scale output). This observation indicates the suitability of using magnetostrictive composites in force-sensing applications over this range of stress values.

5 COMPARISON OF SIMULATED AND MEASURED CURVES

Figures 3 and 4 compare measured and simulated curves for composite samples with 18% (Fig. 3) and 10.4% (Fig. 4) TD. For each sample, both the magnetic field vs. strain and stress vs. strain curves are shown for two different strain amplitudes. In part of the simulated curves, there is an artificial jump at the point of maximal strain due to the switching between $f^{load}(\varepsilon_{EP})$ and $f^{unload}(\varepsilon_{EP})$. This jump occurs because, in order to assure that the data of $f^{load}(\varepsilon_{EP})$ and $f^{unload}(\varepsilon_{EP})$ cover the entire strain range used in tests of the composite samples, we chose the strain amplitudes in the tests of the monolithic epoxy sample to be slightly larger (by less than 10%) than the strain amplitudes in the composite sample tests. In a portion of the measured curves, the response at very low stress values (below 3 MPa) was omitted because the curves measured over this range were non-repeatable due to changes in the contact region, as explained in section 4.1.

Table 1. Input parameters used in the simulations.

Property	Value	Reference
Magnetostriction coefficient λ_{111}	$1.64 \cdot 10^{-3}$	[2]
Young's modulus E_{TD} of TD	30 GPa	[14]
Magnetocrystalline anisotropy coefficient K_1	$-0.6 \cdot 10^5 \text{ J/m}^3$	[2]
Fraction of impaired TD particles	0% (green curve) 50% (blue curve)	

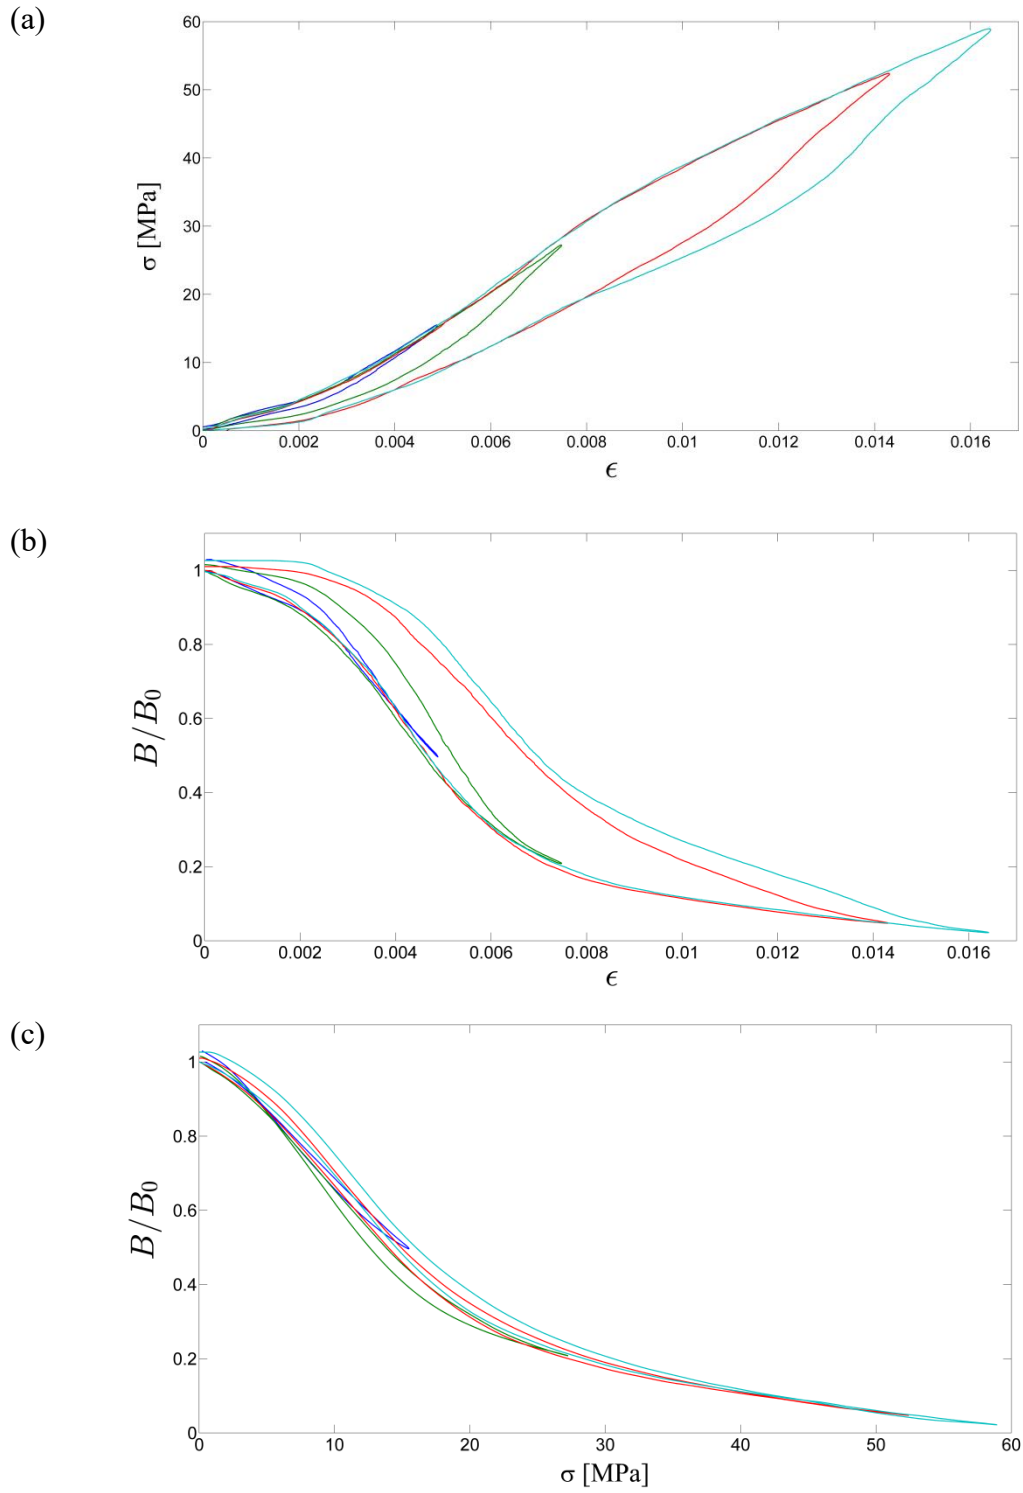

Figure 2: Stress vs. strain (a), magnetic field vs. strain (b) and magnetic field vs. stress (c) curves measured under different strain amplitudes.

The input parameters used in the calculated curves are listed in Table 1. It is important to emphasize that all input parameters were taken from the literature, except for the volume fraction of impaired TD particles. All sub-figures in Figs. 3 and 4 present two different simulated curves: one with no impaired particles (dashed green curves) and one in which 50% of the TD volume is occupied by impaired particles (dashed blue curves). The figures show that simulations with no impaired particles do not fit the measured results. On the other hand, simulations with 50% impaired particles demonstrate reasonable agreement with all measured curves presented in Figs. 3 and 4. This result provides significant evidence for the existence of impaired TD particles, particularly because the same values of the input parameters and the same portion of impaired TD particles were used in all simulations that fit all measured curves presented in Figs. 3 and 4.

Simulations of the magnetic field vs. stress curves presented in Figs. 3 and 4 reproduce the hysteresis in the measured curves well. This observation indicates that the inherent hysteresis in the mechanical response of the epoxy accounts for most of the hysteresis in the magnetic field versus stress response of the composite material. On the other hand, the amount of hysteresis in the simulated stress vs. strain curves is smaller than that in the measured curves. This observation implies that there is an additional mechanism that increases the hysteresis in the stress vs. strain curves of the composite material. It is likely that this mechanism is not related to the magneto-mechanical response of the TD, because it has no effect on the magnetic field vs stress curves.

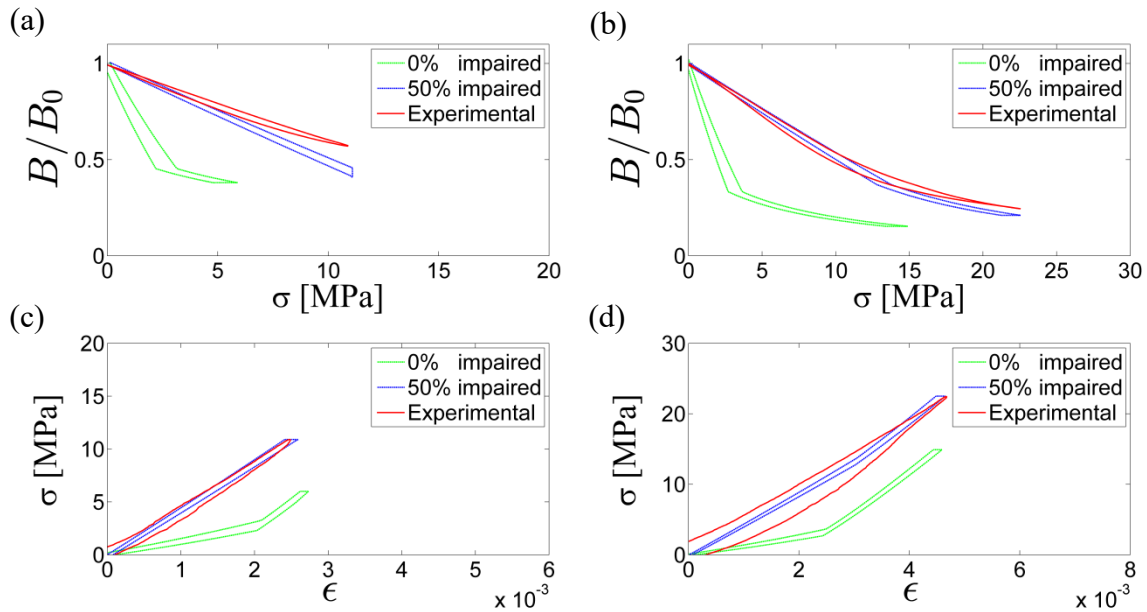

Figure 3: Comparison of the simulated and measured results for the 18% TD volume fraction sample: (a) magnetic field vs stress, strain amplitude 0.28%, (b) magnetic field vs stress, strain amplitude 0.45%, (c) stress vs stain, strain amplitude 0.28%, and (d) stress vs strain, strain amplitude 0.45%.

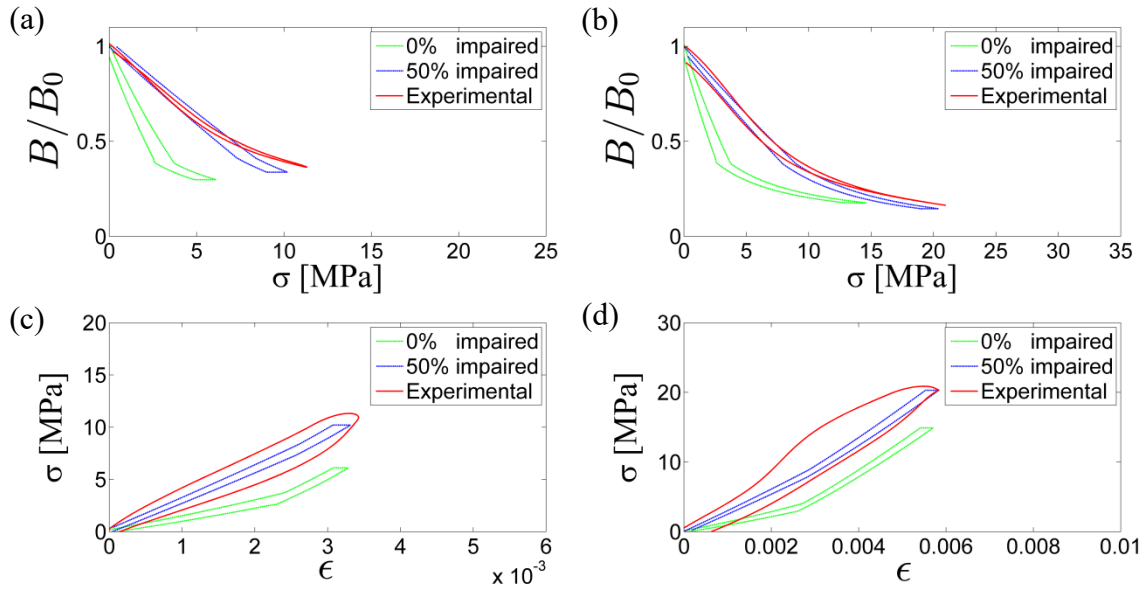

Figure 4: Comparison of the simulated and measured results the 10.4% TD volume fraction sample: (a) magnetic field vs stress, strain amplitude 0.35%, (b) magnetic field vs stress, strain amplitude 0.6%, (c) stress vs strain, strain amplitude 0.35%, and (d) stress vs strain, strain amplitude 0.6%.

All curves shown in Figs. 3 and 4 have strain amplitudes smaller than 0.6%. For larger strain amplitudes, comparisons of the simulated and measured curves revealed a significant discrepancy. In the following, we use the procedure discussed in section 2.3 and show that this discrepancy occurs because at larger strains, the perfect bonding assumption, as is formulated in Eq. (1), is no longer valid.

Figure 5 shows a plot of ϵ_{TD} vs. ϵ . The blue curve represents the perfect bonding assumption, according to which $\epsilon_{TD} = \epsilon$ (Eq. (1)). The green curve was calculated by substituting the measured $\sigma_{EP}(\epsilon)$ and $\sigma(\epsilon)$ curves into Eq. (7). Eq. (7) also has a contribution from $\Delta\epsilon^{MS}(\epsilon)$, which was taken from the simulations. It is observed that up to a critical strain of approximately $\epsilon_c = 0.4\%$, ϵ_{TD} is approximately equal to ϵ , i.e., in agreement with Eq. (1). This result is in accordance with the agreement between the simulations and measurements, as presented in Figs. 3 and 4 for small strains up to $\epsilon = 0.6\%$. On the other hand, above $\epsilon_c = 0.4\%$, ϵ_{TD} deviates from ϵ and becomes significantly smaller than ϵ at large strains.

The observed critical value of $\epsilon_c = 0.4\%$ is very close to the transition strain $\epsilon_t = 0.43\%$, at which the non-180° DS is expected to be finished according to the model [5,6]. At $\epsilon > \epsilon_t$, Eq. (8) can be used for calculating $\epsilon_{TD}(\epsilon)$ directly from the measured $\sigma_{EP}(\epsilon)$ and $\sigma(\epsilon)$ curves, without relying on the simulations. This calculation fully overlaps with the green curve presented in Fig. (5). This means that the difference between ϵ_{TD} and ϵ does not stem from the simulation of $\Delta\epsilon^{MS}(\epsilon)$. Thus, Fig. 5 provides direct evidence that at large strains, Eqns. (1) and (2) are not fulfilled. The observation that at large strains (and in accordance large stresses)

ϵ_{TD} becomes smaller than ϵ indicates that above a certain stress level, there is not perfect bonding between the TD cylinders and the epoxy matrix.

Figure 5: ϵ vs. ϵ_{TD} . The blue curve represents the basic model's assumption of perfect bonding ($\epsilon_{TD} = \epsilon$). The green curve was calculated based on Eqns. (7) and (8).

5 CONCLUSIONS

In this paper, we present a combination of experimental and theoretical studies of the magneto-mechanical response of epoxy-based TD composite materials for stress-sensing applications. We introduced an expanded model that accounts for the hysteretic and non-linear mechanical behavior of the epoxy by replacing the previously assumed linear stress vs. strain relations [6] with real stress vs. strain curves measured using a monolithic epoxy sample.

A direct evaluation of the strain in the TD, based on measured stress vs. strain curves in a monolithic epoxy and in composite samples, allowed us to test the validity of a basic model assumption, which is the perfect bonding between the TD and the matrix. This analysis (see Fig. 5) revealed a critical strain of approximately $\epsilon_c = 0.4\%$. Below this value, the strain in the TD is approximately equal to the strain in the matrix and the average strain applied to the sample, i.e., the perfect bonding assumption is fulfilled. Above this value, the strain in the TD becomes smaller than the applied strain. Under strains larger than 0.6%, this difference becomes significant and Eqns. (1) and (2), which constitute a basic assumption of the model, are not fulfilled. The observed critical strain ϵ_c is very close to the transition strain $\epsilon_t = 0.43\%$, at which the non-180° DS is expected to be finished according to the model [5,6].

Comparisons of measured and calculated curves demonstrated the necessity of the assumption regarding the presence impaired particles. Simulations with 50% impaired particles demonstrated reasonable agreement with all results of measurements performed at strains below 0.6%. It should be noted that the same values of input parameters and the same concentration of impaired particles were used in all simulations and provided a good fit with all measurement results. Specifically, the same simulations fit the measurements of all three variables (stress, strain, and magnetic field) in tests performed with different strain amplitudes and in samples

with different volume fractions of TD. This result largely validates the model and provides significant evidence for the existence of impaired TD particles and their effect on the magneto-mechanical behavior of the composite material.

Our experimental results (Fig. 2) showed that the amount of hysteresis is strongly dependent on the strain amplitude. Simulations of magnetic field vs stress curves reproduced the hysteresis well in the measured curves and indicated that most of the hysteresis is derived from the inherent hysteretic behavior of the epoxy. Simulations of stress vs. strain curves demonstrated that there is an additional source of hysteresis that affects only the mechanical behavior and is probably not related to the response of the TD.

This study provided several valuable insights for the development of stress sensing applications. In particular, it revealed the significant effect of the epoxy on the studied system, which determines the amount of hysteresis and the critical strain above which the perfect bonding between TD and epoxy is not fulfilled. Our results motivate the search for a more suitable epoxy that provides better performance in these two important respects. Despite the drawbacks of the currently used epoxy, both measured and simulated curves showed that for strain amplitudes smaller than 0.5%, the magnetic field vs. stress curve is approximately linear and has a minor amount of hysteresis. This observation indicates the suitability of using magnetostrictive composite materials in force-sensing applications over this range of applied strains.

Abstract. Recently, an experimental setup dedicated to the characterization of GMM magneto-mechanical behavior under constant stress has been designed. This setup is able to reduce the dynamic stress variations induced by magnetic excitation variations below 0.1 MPa. The present work focuses on the effect of loading boundary conditions on the measurement of material properties of Terfenol-D under stress levels from 0 to 90 MPa. Comparison of measurement results obtained under controlled and uncontrolled stress conditions show that uncontrolled boundary conditions can be responsible for errors of several percent on the measurement of the maximum and remnant magnetic induction. The measurement of strain is even more sensitive to the boundary conditions, with errors up to 40% and 30% on the longitudinal and transverse strain, respectively. In addition, evolutions in the measurement of susceptibility and (longitudinal and transverse) piezomagnetic properties reach +30%, +125% and +300% respectively. This work highlights the utmost importance to precisely control the boundary conditions for an accurate characterization of GMM properties under mechanical loading.

1 INTRODUCTION

Giant Magnetostrictive Materials (GMM), such as Terfenol-D and Galfenol, are used to design actuators and sensors converting a magnetic input into a mechanical response, or conversely, a mechanical input into a magnetic signal. The design of magneto-mechanical systems is optimized based on a good knowledge of the material properties. Under standard operating conditions, these materials are subjected to stress. However, the behavior of these materials is highly nonlinear and very sensitive to mechanical loading [1, 2]. It is therefore important to characterize their properties under mechanical loading.

Various experimental setups have been used for the experimental characterization of GMM under mechanical stress. In the case of Galfenol and Terfenol-D, material properties obtained under mechanical loading with these setups show great variability [3, 4, 5, 6, 7, 8, 9]. These differences are due to different compositions of the materials tested, but also to imperfect control of loading boundary conditions.

This work deals with the role of loading boundary conditions on the material properties measurement of Terfenol-D under stress. In a first part, the characterization setup is described. In a second part, the experimental setup is used to characterize the effect of loading boundary conditions on the magneto-mechanical behavior as well as on magnetic and piezomagnetic properties of this GMM under stress.

2 EXPERIMENTAL SETUP

2.1 Magneto-mechanical characterization rig

The characterization setup is designed to measure magnetization and strain in a ferromagnetic specimen subjected simultaneously to magnetic field and uniaxial stress applied in the direction parallel to the magnetic field. A tension-compression machine is used for the application of stress, and a magnetic circuit has been designed for the application of the magnetic field (figure 1).

Figure 1: Magneto-mechanical characterization rig.

The electromagnetic device is constituted of two U-shaped ferrite yokes ensuring the closure of the magnetic flux. Associated to a power amplifier, a series circuit of four primary coils (one wound around each yoke – 600 turns each – and two around the specimen – 265 turns each) produces the magnetic field. Two coaxial magnetic columns (Permendur 49) connect the specimen to the apparatus and close the magnetic path.

The samples characterized in this study are cylindrical Terfenol-D rods with 3 cm height and 5 mm radius manufactured by TdVib LLC. This setup has been optimized to ensure the homogeneity of magnetic field and stress in a 15 mm height measurement area [10]. Measurements are performed at room temperature.

2.2 Characterization setup

The acquisition of measurement signals and the control of magnetic field and stress are performed by a DS 1006 dSPACE processor board, connected to a computer. Control of applied stress and position of the crosshead are ensured by the internal servo-controller of the compression machine. All the elements connected to the dSPACE acting during experiments are shown in figure 2. The magnetic field (H), the magnetic induction (B) and the strain components (S), are evaluated in the measurement area (figure 1).

The force (F) applied by the tension-compression machine (Zwick/Roell Z030) is measured using a 10 kN load cell. A Kepco 72-14MG amplifier is used to produce current (I) in the four primary coils (figure 1). This current is measured and used in a Proportional-Integral-Derivative (PID) control loop feedback. The magnetic field (H) is measured using a GM08 Gaussmeter and a transverse Hall probe. The variation of magnetic induction (δB) in the sample is calculated in real time through the integration of the induced voltage of a B-coil (65 turns) wound around the sample. The reference state for the evaluation of B is the demagnetized state [11].

The strain is measured through two rosette strain gauges glued face to face on the surface of the sample. Using a 4 channels strain gauge conditioner, two values on longitudinal direction (S_L) and one value on the transverse direction (S_T) are evaluated. In addition, shear strain (S_S) is calculated using gauge value in the 45° direction, S_L and S_T . A ball-and-socket joint (B&S joint) is placed between the load cell and the piezo stack actuator to minimize misalignment between the longitudinal direction of the sample and the column.

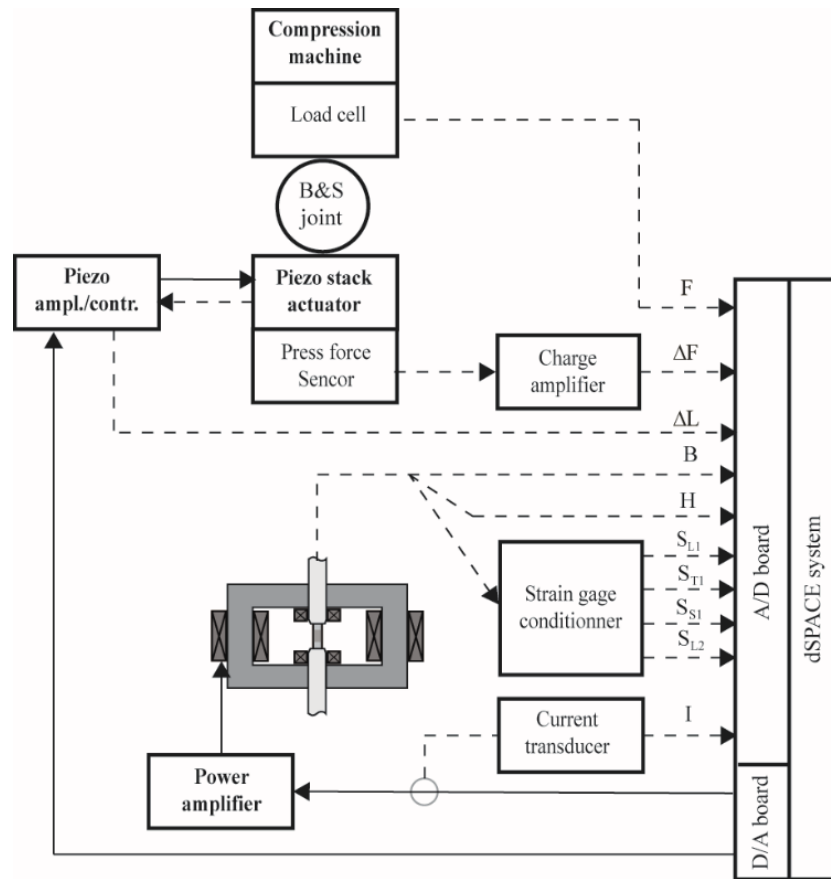

Figure 2: Measurement setup synoptic. Elements in bold are mechanical or electrical sources of the system.

The control of the dynamic force (ΔF) induced by the magnetic excitation is ensured by the combination of a piezoelectric force sensor, a piezo stack actuator and a PID control loop feedback. The piezoelectric press force sensor, associated to a charge amplifier, provides the dynamic component of the force. The actuator is a preloaded high load actuator, equipped with a positioning system to provide position information (ΔL) to the piezo amplifier/controller. The piezo amplifier/controller is a High-Performance Piezo amplifier. The system then ensures the cancellation of the dynamic force through the displacement provided by the actuator, controlled on the loop.

More details on the experimental setup are available in [11].

3 EFFECT OF LOADING BOUNDARY CONDITION ON THE MEASUREMENT OF TERFENOL-D PROPERTIES UNDER MECHANICAL LOADING

The magneto-mechanical behavior of Terfenol-D under various compression stress levels has been characterized using this experimental setup. Compression stresses will be considered positive. The lower level of stress is obtained by positioning the Permendur column alone on the top of the sample. This configuration is considered as the “stress-free condition” When connecting the top Permendur column to the compression machine, pre-stress levels (σ_0) of 125, 400, 700 kPa and 1, 2, 4, 8, 12, 16, 20, 25, 30, 35, 40, 45, 50, 55, 60, 70, 80, 90 MPa have been applied to the samples. For each level of stress, samples are submitted to a half periodic

sinusoidal magnetic loading, reaching 100 kA/m (H_{max}), at 1 Hz frequency. Tests are done under controlled stress conditions (CSC) and no-controlled stress conditions (noCSC). The reference state is the demagnetized state under pre-stress. Data presented in this work are raw data.

3.1 Measurement of magnetization and magnetostriction curves under controlled and no-controlled stress conditions

Figures 3 and 4 show the measured magnetization and magnetostriction (longitudinal and transverse) curves under compression stress levels in the two stress control conditions.

Figure 3: Magnetic behavior of Terfenol-D specimen for various uniaxial applied compressive stress under controlled stress conditions (CSC) and uncontrolled stress conditions (noCSC).

Magnetization curves are very sensitive to pre-stress levels. The decrease of induction with applied stress – for a given magnetic field – is very significant. The pre-stress significantly decreases the values of remnant and maximum magnetic induction (at 100 kA/m), B_r and B_{max} respectively. The values obtained under CSC can be up to 20% higher for B_r and up to 10% higher for B_{max} compared to the values obtained under noCSC.

Figure 4 shows that the magnetostrictive behavior is much more affected by stress than the magnetic behavior. The effect of stress on magnetostriction is non monotonic: the magnetostriction level first increases with stress, and then decreases. The maximum variations of magnetostriction with respect to magnetic field are observed at 16 MPa. At this stress level, the longitudinal and transverse strain measured under CSC can be up to 41% and 28% higher, respectively, than under noCSC.

Figure 4: Longitudinal and transverse magnetostrictive behavior of Terfenol-D specimen for various uniaxial applied compressive stress under controlled stress conditions (CSC) and uncontrolled stress conditions (noCSC).

Whatever the level of pre-stress applied, the fluctuations of stress under CSC do not exceed 0.1 MPa. In contrast, the cancellation of this control system results in very significant fluctuations of stress. Table 1 presents the maximum stress variation levels ($\Delta^b \sigma_\theta$) observed under noCSC.

Table 1: Maximum stress variations during magnetic excitation under uncontrolled stress conditions.

σ_θ (MPa)	4	16	40	55	90
$\Delta^b \sigma_\theta \text{ max}$ (MPa)	8.6	10.6	7.2	5.2	2.5

These fluctuations are the direct image of longitudinal magnetostriction (figure 4) since the setup elastically responds to the deformation of the sample. Their levels are clearly unacceptable for an accurate characterization of the material properties.

3.2 Measurement of magnetic and piezomagnetic properties of Terfenol-D under controlled and no-controlled stress conditions

In this part, evolutions of magnetic susceptibility as well as longitudinal and transverse piezomagnetic properties of Terfenol-D sample are studied in function of the applied stress levels under the two stress conditions. These properties are calculated from a linear extrapolation of the magnetic and magnetostrictive curves, at the end of the cycle (near $H = 0$). These properties are presented on figure 5, under CSC and noCSC.

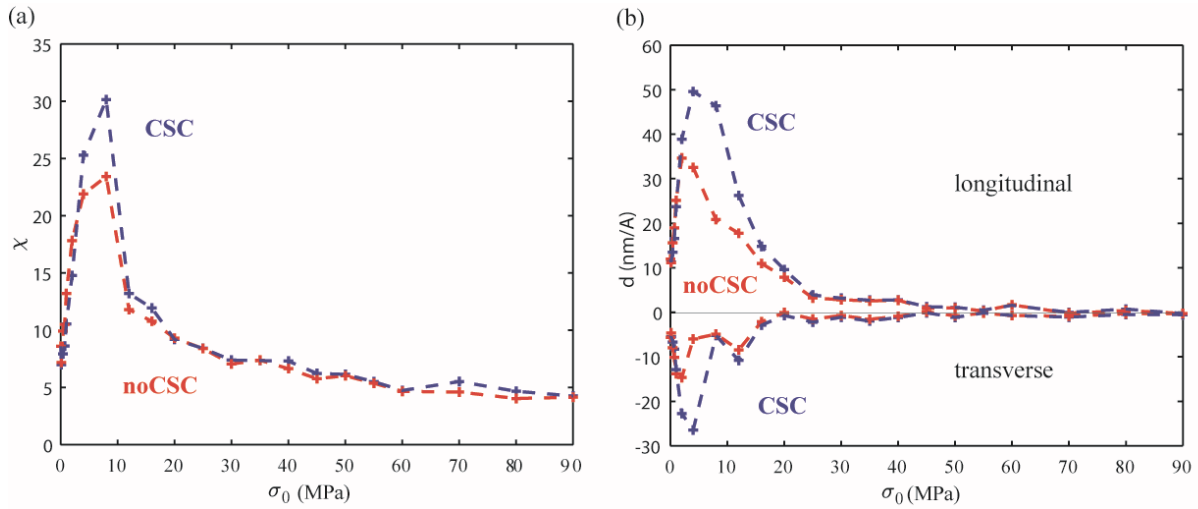

Figure 5: Magnetic susceptibility (a) and longitudinal and transverse piezomagnetic properties (b) of Terfenol-D specimen for various uniaxial applied compressive stress under controlled stress conditions (CSC) and no-controlled stress conditions (noCSC).

As expected, evaluation of material properties are very sensitive to the pre-stress levels. Maximum evolution of +30%, +125% and +300% are observed between magnetic susceptibility and longitudinal and transverse piezomagnetic values measured under CSC and noCSC. These plots clearly show the great importance to control the loading boundary condition when characterizing the properties of GMM under stress.

4 CONCLUSIONS

In this work, an experimental setup dedicated to the characterization of GMM properties under constant pre-stress has been described. Measurements have been performed on a Terfenol-D sample to show the dependence of magneto-mechanical behavior to compressive pre-stress levels from 0 to 90 MPa. Measurements obtained under control stress conditions (CSC) have been compared to those obtained without using the stress control (noCSC).

Under CSC, the setup can control the stress induced by the magnetic excitation and reduce it to levels below 0.1 MPa. Under noCSC, dynamic stress is very significant, and reaches 10.6 MPa at 16 MPa pre-stress level. The magnetization curves are sensitive to the stress control conditions. The values obtained under CSC can be up to 20% higher for the remnant magnetic induction and up to 10% higher for the maximum magnetic induction (at 100 kA/m) compared to the values obtained under noCSC. Longitudinal and transverse magnetostrictive behaviors have shown greater sensitivity to the control stress condition, with maximum differences about 40% and 30% respectively. Similarly, measured magnetic susceptibility and longitudinal and transverse piezomagnetic properties present maximum evolutions of +30%, +125% and +300% respectively, in function of the stress control condition.

This work emphasizes the great importance to accurately control the boundary conditions when characterizing the material properties of GMM, such as Terfenol-D, under stress.

Abstract. Electro-active polymers (EAP) are a kind of smart structures that undergo dimensional change in response to an applied electrical field. Due to their biocompatibility, conformability, low Young's modulus, high strain capabilities and relative low cost, EAPs are promising materials for the next generation of micro-scaled robotic devices. This paper describes the first result of the study of the terpolymer P(VDF-ter-TrFE-ter-CTFE), a relaxor ferroelectric characterized by its large electromechanical coupling, as the building block of a surgical micro-robot actuator. In order to deal with the large number of parameters involved in this active material (number of layers, material composition, substrate materials, etc), we develop a finite element model to support the experimental development.

INTRODUCTION

Different approaches have been studied to develop the automation of endoscopic surgical operations in order to assist surgeons in terms of efficiency and precision. From endoscopic capsules [1], [2] to traditional wire actuated poly-articulated snake like robot (figure 1) [3], [4] the research field is full of innovative perspectives.

Recently, smart materials have emerged as a key element for the conception of endoscopic surgical robot thanks to their compact design, dexterity and low cost. Among them, Nitinol, a shape memory alloy has been reported (figure 2) for a magnetic resonance imaging concentric tube robot actuator [5].

EAPs are another emerging family of promising materials for surgical automated actuator where biocompatibility, high strains and conformity to soft materials are desired features. EAPs can be classified into two categories: ionic EAPs and electronic EAPs [6]. The electrical activation of ionic EAPs is due to the migration of ions or electrically charged molecules. Whereas, electronic EAPs are activated by applied electric fields and Coulomb forces. Polypyrrole a CP Ionic Polymer has been used for an endoscopic medical robot [7]. Although Polypyrrole requires low voltage actuation compared to electronic

Figure 1: Endoscopic capsule robot [1] (left) and wire actuated snake like robot [4] (right)

Figure 2: Nitinol actuator robot [5]

EAP and can hold strain under applied voltage which is essential in the case of a robot actuator, it exhibits a slow response time and induce a low actuation torque. On the contrary, electrostrictive polymers present a rapid response and the ability to generate large actuation force. Despite their high strain and energy density, electrostrictive materials require high actuation voltages which represents a major drawback that limited their implementation into real-life applications. To counter these issues, a multilayered concept is proposed. Due to the complexity of soft polymeric microstructures, analytical modeling will be performed to guide experimental design and fabrication of these electrostrictive based surgical actuators. In order to achieve large and controlled deformation a number of parameter (thickness, polymer formulation and passive materials composition) have been studied to lead the actuator design to reach the optimal performances. Concretely, Finite Element Model (FEM) results have enable to identify the curvature behaviour of the actuator to settle the control theory. In the context of surgical endoscopic robot, EAP smart material integration have raised others challenge in terms of control. Indeed, traditional discreet joints actuators and rigid links robots description is no more available for continuum soft robots. Smart materials actuators are part of the robot shape. Soft robots can reach an infinite number of degrees of freedom. A single EAP continuum actuator is equivalent with three discreet joints with the Denavit- Hartenberge (DH) modelling strategy [8],[9] (cf figure 3).

All three joints are related to the smart material curvature k as shown in figure 1. The DH parameters are linked to the soft robot parameters by a matrix integrated in the kinematic model.

Table 1: DH modified virtual table

This paper is organized as follow. In the first section the electrostriction formulation and mechanism will be briefly presented. Then in section two the electro-mechanical behaviour of the EAP and the structure will be introduced to present the experimental model. This will lead to section three with the development of a finite element model (FEM) of a multilayer composite actuator designed to validate the feasibility in terms of maximum bending under electric field, materials characteristics, and number of layers. Finally, the results of the precedent section will induce the future expectation of this smart material and open the way to further integrated in a surgical robot structure.

1 Electrostriction

While electrostriction was long considered a higher-order nonlinear effect requiring stronger electric fields than typically used for piezoelectrics, the emergence of a new class of highly electrostrictive materials, known as relaxor ferroelectrics, has opened the path to the use of electrostriction as an alternative to the piezoelectricity for the large-strain actuation applications. In addition to the large strain capabilities, a major advantage of the electrostriction over the ferroelectric mechanism is that it enables a reproducible, non-hysteretic response. Various relaxor ferroelectric PVDF-based polymers have been reported to date such as electron-beam irradiated P(VDF-co-TrFE) copolymer or defect-modified P(VDF-co-TrFE) with added bulky CFE or CTFE monomers. In the case of P(VDF-ter-TrFE-ter-CTFE) it is the introduction of the third bulky monomer (CTFE) that disrupts the conformations ordering of the chains into the crystal and create ferroelectric nano-domains transforming it from a ferroelectric to a relaxor ferroelectric polymer [10], [11]. P(VDF-ter-TrFE-ter-CTFE) present a high dielectric constant (50), high electrostrictive strain (4%), good elastic energy densities with a reversible response time in the milliseconds range. These features make it extremely promising materials for smart actuators. [12],[13]. In particular, considering that single use tools are preferred in surgical robotic to reduce the sterilization cost and the risk of infection, the repeatability expectation of such a device would be reduced. The control processors and

voltage generator would not be embedded.

2 Experimental model

The mechanical behaviour of the relaxor ferroelectric is presented in [14] showing a quadratic evolution of the strain under electric field (figure 4). The curvature can be written as a function of E^2 with E

Figure 4: Electrostrictive response (strain) for a relaxor ferroelectric [14]

the electric field in V/m . When fixed at one side to a passive material, the strain is constraint to generate a bending in one direction. This assembly enables to use the EAP as a robot arm (figure 5) .

Figure 5: Structure of an EAP bending actuator

We have developed an experimental model to quantify the strain of the terpolymer P(VDF-ter-TrFE-ter-CTFE) provided by Piezotech S.A.S (Arkema group, France) with a ratio of 8% mol CTFE and an electrostrictive coefficient of $3.10^{18} m^2/V^2$. The polymer has been metalized with two aluminium electrodes and one passive substrate as in figure 6.

Materials and results

The EAP material fixed in the passive substrate has shown a reversible and repeatable bending under electric field with a maximum at $100 V/\mu m$ (figure 7). Nevertheless, such limited bending was mainly due to the fact that the applied electric field was kept significantly lower than the electric field breakdown of the terpolymers inducing low strain. In order to tackle these issues and to achieve high

Figure 6: Schematic design of the experimental actuator

Component	Material	Young Modulus	Thickness	Electrostrictive coefficient
Passive substrate	PEN	5 GPa	50 μm	0
EAP	P(VDF-TrFE-CTFE)-8% CTFE	0.2 GPa	7 μm	$3.10^{-18} \text{m}^2/\text{V}^2$
Electrode	Al	70 GPa	300 nm	0

Table 2: Material characteristics for the FEM

deformation, two approaches have been investigated. First, the metal electrodes have been substituted by a low Young's modulus conductive polymer, (PEDOT:PSS) to increase the actuator bending at the same electric field conditions. Secondly, a multilayered/stacked approach has been developed to enhance the electro-mechanically induced force and displacement while keeping the applied voltage to an acceptable limit (500 V). In the multilayered configuration, electroded EAP films are layered on top of each other. The films are alternatively connected with high voltage and ground potential similar to a parallel capacitor connection. The conception of multilayered EAP actuators is a challenging task that should provide valuable insights on the influence of numerous geometrical and physical parameters on the device performance. Thanks to the quadratic behaviour of the strain, the voltage can be alternatively disposed without

Figure 7: Monolayer 7 μm thin EAP actuator with Aluminium electrodes at 100V/ μm (left) and breakdown voltage result at 150V/ μm (right)

changing the bending side. So, for N layers of EAP material we need N + 1 layers of electrode (figure

8).

Figure 8: Multilayer beam actuator spatial convention

3 Finite element modelling

A model has been developed on abaqus, based on mechanical theory. The gap between global actuator dimension and polymer layer thickness (300 nm and 2 μm respectively) drove us to the design of a composite shell model with (SI millimetre analogy). Since the electrostrictive quadratic behaviour is not implemented on the software, we have made a thermal behaviour analogy by using a Fortran user subroutine. In order for our model to be used into a surgical robot actuator, the following boundary conditions have to be considered: the composite EAP must be able to bend itself by almost 100 degrees. The electric field has to be kept lower than the terpolymer breakdown electric field and thus considering the actuator dimensions, the maximum voltage should be kept at 500 V. Consequently, the presented FEM drives us finding the optimal actuator configuration in terms of layer's number, material characteristics and composite elements thickness (figure 11).

3.0.1 Composite materials behaviour

Terpolymer P(VDF-TrFE-CTFE) is an elastic isotrope material [13]. Its temperature dependency has not been taken into account in this study. The horizontal strain (X and Z axis) is expressed as follow in equation 2 and shown in figure 9. ϵ_0 is the strain at $y = 0$, ρ is the radius of curvature and $k = \frac{1}{\rho}$. e_p , e_e and e_s are respectively the terpolymer, electrode and substrate layers thickness [12].

$$\epsilon^x(y) = \epsilon_0^x + \frac{y}{\rho} = \epsilon_0^x + yk_x; \quad -e_s \leq y \leq n(e_e + e_p) \quad (1)$$

$$\epsilon^z(y) = \epsilon_0^z + \frac{y}{\rho} = \epsilon_0^z + yk_z; \quad -e_s \leq y \leq n(e_e + e_p) \quad (2)$$

For the polymer and electrode layers, $\epsilon_{elastic} = \epsilon_{total} - \epsilon_{electrostrictive}$ with $\epsilon_{electrostrictive} = M_i E^2$ with M_i the electrostrictive coefficient matrix and E the electric field in V/m.

$$\epsilon_x^{el}(y) = \epsilon_0^x + yk_x - M_x^i E^2; \quad -e_s \leq y \leq n(e_e + e_p) \quad (3)$$

$$\epsilon_z^{el}(y) = \epsilon_0^z + yk_z - M_z^i E^2; \quad -e_s \leq y \leq n(e_e + e_p) \quad (4)$$

$M_i = M_p$ for the terpolymer and $M_i = 0$ for the electrode and the substrate materials. The horizontal plane stress can be written as in equation 5.

$$\begin{pmatrix} \sigma_x \\ \sigma_z \\ \tau_{xz} \end{pmatrix}_i = \begin{pmatrix} Q_{11} & Q_{12} & Q_{16} \\ Q_{12} & Q_{22} & Q_{26} \\ Q_{16} & Q_{26} & Q_{66} \end{pmatrix}_i \begin{pmatrix} \epsilon_x^{el} \\ \epsilon_z^{el} \\ \gamma_{xz} \end{pmatrix}_i \quad (5)$$

Q_{ij} 's are the plane stress reduced elastic constants in the plate axes of the i^{th} layer. We can then introduce the resultant stress as:

$$\begin{pmatrix} N_x \\ N_z \\ N_{xz} \end{pmatrix} = \sum_{i=0}^{n+1} \begin{pmatrix} Q_{11} & Q_{12} & Q_{16} \\ Q_{12} & Q_{22} & Q_{26} \\ Q_{16} & Q_{26} & Q_{66} \end{pmatrix}_i \int_{h(i)} \begin{pmatrix} \epsilon_{xx} \\ \epsilon_{zz} \\ \gamma_{xz} \end{pmatrix}_i \quad (6)$$

With $h(i)$ the layer thickness depending on the material i .

Figure 9: Multilayer beam convention with $\epsilon(0) = \epsilon_0$

3.0.2 Materials and results

In the figure 10 left, we have studied the influence of the number of layers. In this model, the total EAP thickness is fixed to $10 \mu\text{m}$ and divided into the number of layers. The voltage is also stuck at 500 V so that increasing the number of layers increases the electric field. The graphic shows the elements final position alongside the actuator length. For a five layer EAP of $2 \mu\text{m}$ each, the electric field is $250 \text{ V}/\mu\text{m}$. Studying the influence of the number of layers has highlighted the capability of reaching the expected bending performance as shown in figure 10 left. The electrode's Young Modulus of 0.02 GPa is no longer increasing the stiffness of the composite material. We have been looking for the best substrate material for this configuration (figure 10 right) and Pebax (0.3 GPa) (provided by Arkema) would suit. The figure 11 shows the bending performances of the composite actuator with characteristics from table

Figure 10: Spatial representation of the actuator behaviour depending of the number of layers N (left) and radius of curvature depending on the substrate Young Modulus (right)

3. This configuration enables a maximum bending of 110 degrees for a $50 \times 2 \text{ mm}$ EAP actuator at 500V as defined. The displacement induced force is also under study. However for the experimental device the number of layer is restricted by the design feasibility in the laboratory conditions.

Figure 11: Five ($2 \mu\text{m}$ thin) layers actuator with polymer electrodes under $50 \text{ V}/\mu\text{m}$

Component	Material	Layers	Young Modulus	Thickness	Electrostrictive coefficient
Passive substrate	Pebax	1	0.2 GPa	10 μm	0
EAP	P(VDF-TrFE-CTFE)	5	0.3 GPa	2 μm	$3 \cdot 10^{-18}$ m/V
Electrode	Polymer	6	0.02 GPa	300 nm	0

Table 3: Material characteristics for the FEM

Conclusion

This paper has presented EAP actuators in the context of endoscopic robots in the medical area. Among other smart materials studied for this application, EAP and more specifically electrostrictive polymers has been selected for their large electromechanical strain. Those smart materials can be integrated into a robot structure to perform self-bending. A composite beam, made of a passive substrate, has been experimentally evaluated and has highlighted the high voltage requirement to achieved large bending. Although, To decrease the electric field and improve the bending, a multilayer composites smart material has been designed on abaqus. This model has demonstrated the efficiency of this formulation in terms of bending, and a five layers actuator of 2 μm each was found to be the optimized configuration to achieved the expected performances. Finally, an experimental multilayer device will be made from this results to confirm the achievement and readjust the theoretical parameters. The FEM will also evaluate the displacement induced force at the distal tip of the actuator to deal with external perturbations. Finally, to validate this smart material as an effective robotic actuator, the next step will be to focus on the repeatability of the actuation and the control accuracy. Indeed, as a robotic structure, the control of the smart material by an external power source has to be accurate and robust. An EAP actuated robot could be designed with serial actuators as in figure 12 to increase the degrees of freedom.

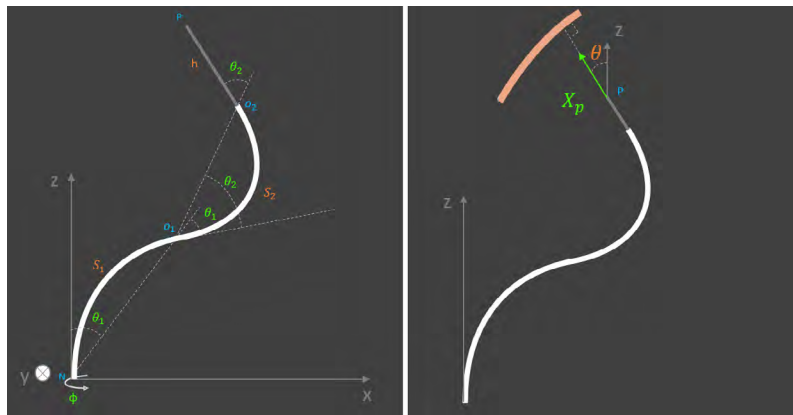

Figure 12: Structure and parameters of the two EAP actuator robot structure (left). Description of the control of the orientation between the distal tip and the target (left).

Key words: Flexoelectricity, nanobeam, energy harvesting, strain gradient theory

Abstract. Flexoelectricity can be defined as an electromechanical coupling between polarization and strain gradient. In contrast with piezoelectricity, flexoelectricity is largely dominant at the nanoscale. Using a developed electromechanical model of a BaTiO_3 nanobeam, we simulate the dynamic behavior of the device when it is subject to a base harmonic excitation representing mechanical vibrations from the environment. The coupled electromechanical model is first derived using the Hamilton's principle and accounting for the von Karman strain for relatively large displacements and takes into account an initial static displacement due to residual stresses. The Galerkin approximation is used to discretize the space domain for the transverse displacement and the electric potential. The nonlinear dynamic response of the nanobeam and the generated electrical voltage are solved for limit-cycle solutions. The results depicted higher power density generation when the aspect ratio of the nanobeam is varied. It is found that the initial deflection can mitigate the expected performance of the device.

1 INTRODUCTION

Flexoelectric effect is an electromechanical coupling that can be used to enhance electrical response from mechanical stimuli for nanoscale structures [1, 2]. For nanobeams, taking into account interactions between electric polarization strain and strain gradient should be accompanied by other interactions of the same order of approximation. Elastic strain gradient theory can be used in this case to fulfill this requirement.

The flexoelectric effect was observed in centrosymmetric as well as noncentrosymmetric dielectric materials [3]. It was used as a transduction mechanism for actuators, sensors and energy harvesting applications [4, 5, 2].

Because relatively large displacements are easily obtained at the nanoscale, several researchers proposed the introduction of geometric nonlinearity in the modeling of nanobeams [6]. For energy harvesting applications accounting for large displacements only few attempts are found in the literature. Wang et al. [7] investigated the nonlinear response of a cantilever nanobeam for energy harvesting applications and concluded that the flexoelectric effect can extremely improve the harvested power (five times). Kumar et al. [8] proposed a bistable mechanism by using a pair of magnet placed at the tip of cantilever beam. They reported very large bandwidth response of the energy harvester when compared to a linear design. Rojas et al. [9] simulated the frequency-response of clamped-clamped and clamped-hinged nanobeam energy harvesters by taking into accounts the von Karman nonlinear strain. They reported that

size dependent model should be used to model flexoelectric nanobeam and reported large bandwidth only for the clamped-hinged nanobeam since their model was not able to capture the generated polarization for the clamped-clamped case.

In the proposed work, a piezoelectric flexoelectric clamped-clamped nanobeam is proposed as energy harvester. The analytical model takes into account a bidirectional electric field and strain gradient in the longitudinal and transverse directions to calculate the harvested voltage when base excitation is applied.

2 Nonlinear model of a Piezoelectric flexoelectric Nanobeam

A prismatic nanobeam, shown in Figure 1, is considered with length L along the x -axis, thickness h and width b . The nanobeam is made of BaTiO₃ material with density ρ . Two conductive electrodes cover its upper and lower faces. The Euler-Bernoulli beam theory is used to model the nanobeam when

Figure 1: Clamped-clamped nanobeam made of BaTiO₃ material.

it undergoes relatively large displacements. The associated geometric nonlinearities are modeled using the von Karman strain. With low electric fields and non significant stress-strain hysteresis effects, one can consider a linear material behavior. We use the following enthalpy density of the nanobeam material [10]

$$H = W^L(\mathbf{S}, \nabla \mathbf{S}, \mathbf{P}) - \frac{1}{2} \epsilon \phi_{,i}^2 + P_i \phi_{,i} \quad i = x, y, z$$

where W^L is the internal energy density, \mathbf{S} is the Cauchy strain tensor, $\nabla \mathbf{S}$ is the strain gradient tensor, \mathbf{P} is the polarization vector, $\phi(x, z, t)$ is the potential of the electric field and ϵ is the permittivity of the media.

The internal energy density W^L can be expressed as [6]

$$W^L = \frac{1}{2} a_{11} P_x^2 + \frac{1}{2} a_{33} P_z^2 + \frac{1}{2} c_{11} \epsilon_{xx}^2 + d_{11} \epsilon_{xx} P_x + d_{31} \epsilon_{xx} P_z + f_{11} \epsilon_{xx,x} P_x + f_{14} \epsilon_{xx,z} P_z + \frac{1}{2} g_{11} \epsilon_{xx,x}^2 + \frac{1}{2} g_{11} \epsilon_{xx,z}^2 \quad (1)$$

where \mathbf{a} is the dielectric susceptibility tensor, \mathbf{c} is the elastic constant tensor, \mathbf{d} is the piezoelectric constant tensor, \mathbf{f} is the flexoelectricity tensor and \mathbf{g} is the strain gradient coefficients.

The axial strain component can be expressed by [11]

$$\epsilon_{xx} = u' + \frac{1}{2} w'^2 - z w'' \quad (2)$$

where $u(x, t)$ is axial displacement and $w(x, t)$ is the transverse displacement, prime corresponds to derivative with respect to x .

We use the Hamilton's principle to derive the governing electroelastic equations and the associated boundary conditions, it is given by

$$\int_{t_1}^{t_2} \left(\delta K - \int_V \delta H dV \right) dt = 0 \quad (3)$$

where K is the kinetic energy given by

$$\delta K = - \int_0^L m (\ddot{w} \delta w + \ddot{u} \delta u) dx \quad (4)$$

where $m = \rho b h$ is the mass per unit length, F is an external excitation.

Therefore, Equation (3), yields the governing equations

$$m\ddot{u} - N' = 0 \quad (5)$$

$$m\ddot{w} - M'' - (Nw')' = F \quad (6)$$

$$P_{x,x} + P_{z,z} - \epsilon \phi_{,xx} - \epsilon \phi_{,zz} = 0 \quad (7)$$

$$\phi_{,x} - E_1 = 0 \quad (8)$$

$$\phi_{,z} - E_3 = 0 \quad (9)$$

and the associated boundary conditions

$$u = 0, u' = 0, w = 0, \quad (10)$$

$$M + \tilde{N} w' = 0, \tilde{M} = 0, \text{ and } \phi' = 0$$

where

$$M = \int_A (z T_{11} + \tilde{T}_{113} - z \tilde{T}'_{111}) dA \quad (11)$$

$$\tilde{M} = \int_A (z \tilde{T}_{111}) dA \quad (12)$$

$$N = \int_A (T_{11} - \tilde{T}'_{111}) dA \quad (13)$$

$$\tilde{N} = \int_A \tilde{T}_{111} dA \quad (14)$$

and

$$T_{11} = c_{11} \epsilon_{xx} + d_{11} P_x + d_{31} P_z \quad (15)$$

$$\tilde{T}_{111} = f_{11} P_x + g_{11} \epsilon_{xx,x} \quad (16)$$

$$\tilde{T}_{113} = f_{14} P_z + g_{11} \epsilon_{xx,z} \quad (17)$$

$$-E_1 = a_{11} P_x + d_{11} \epsilon_{xx} + f_{11} \epsilon_{xx,x} \quad (18)$$

$$-E_3 = a_{33} P_z + d_{31} \epsilon_{xx} + f_{14} \epsilon_{xx,z} \quad (19)$$

A simplification is proposed in this case where the axial displacement is eliminated in the equations by assuming that the axial stress component N is constant along the nanobeam when the axial inertial is neglected [11, 6]. As a result, the polarization vector is expressed as

$$P_x = -\frac{1}{a_{11}} \left(\phi_{,x} - \left(z + \frac{d_{31} f_{14}}{\bar{E} a_{33}} \right) (d_{11} w'' + f_{11} w''') + \frac{d_{11}}{2L} \int_0^L w'^2 dx \right) \quad (20)$$

$$P_z = -\frac{1}{a_{33}} \left(\phi_{,z} - \left(z d_{31} + f_{14} + \frac{d_{31}^2 f_{14}}{\bar{E} a_{33}} \right) w'' + \frac{d_{31}}{2L} \int_0^L w'^2 dx \right) \quad (21)$$

When energy harvesting or sensing applications are sought, the voltage accross the electrodes $V(t)$ follows the Gauss's law given by [2]

$$\frac{V}{R} = \frac{1}{h} \frac{d}{dt} \int (P_z - \epsilon \phi_{,z}) dx dy dz \quad (22)$$

where R is the external electrical resistance load.

As a result, one can deduce the equation governing the voltage variation as follows:

$$\frac{bL}{h} \left(\epsilon + \frac{1}{a_{33}} \right) \dot{V} + \frac{V}{R} = \frac{b}{a_{33}} \left(f_{14} + \frac{d_{31}^2 f_{14}}{\bar{E} a_{33}} \right) \int_0^L \dot{w}'' dx - \frac{b d_{31}}{a_{33}} \int_0^L \dot{w}' w' dx \quad (23)$$

On the other hand, we assume that the electrical potential ϕ can be approximated by [2, 6]

$$\phi(x, z, t) = \phi(x, t) \cos\left(\frac{\pi}{h} z\right) + \frac{z + h/2}{h} V \quad (24)$$

where $\phi(x, t)$ represent the longitudinal variation of the electric potential.

Using the polarization components in Equations (20) and (21), the electric potential in Equation (24), we obtain the nonlinear expression of the bending moment M , \tilde{M} and \tilde{N} , defined in Equations (11) to (14), in terms of the deflection w and the longitudinal potential ϕ . They are given by

$$M = -k_1 w'' + k_2 w'''' + \frac{2A d_{31}}{\pi a_{33}} \phi - \frac{A f_{14}}{a_{33}} \frac{V}{h} - \frac{d_{31} f_{14}}{a_{33}} \frac{A}{2L} \int_0^L w'^2 dx \quad (25)$$

$$N = \frac{\bar{E} A}{2L} \int_0^L w'^2 dx - \frac{d_{31} A}{a_{33}} \frac{V}{h} - \frac{2A}{a_{11} \pi} (d_{11} \phi' - f_{11} \phi'') + \frac{d_{11} f_{14} A k_2}{a_{33} \bar{E} I} w'''' \quad (26)$$

$$\tilde{M} = \frac{d_{11} f_{11} I}{a_{11}} w'' - k_2 w'''' \quad (27)$$

$$\tilde{N} = \frac{d_{11} d_{31} f_{11} f_{14} A}{a_{11} a_{33} \bar{E}} w'' - \frac{f_{14} d_{31} A k_2}{a_{33} \bar{E} I} w'''' - \frac{2 f_{11} A}{a_{11} \pi} \phi' - \frac{d_{11} f_{11}}{a_{11}} \frac{A}{2L} \int_0^L w'^2 dx \quad (28)$$

where k_1 and k_2 are given in the Appendix, $\bar{E} = (c_{11} - \frac{d_{11}^2}{a_{11}} - \frac{d_{31}^2}{a_{33}})$ and $I = \frac{bh^3}{12}$ is the second moment of area of the nanobeam's cross-section.

A nondimensional form of the equations is obtained by using the following variables:

$$\hat{w} = \frac{w}{h}, \quad \hat{\phi} = \frac{\phi}{\phi_0}, \quad \hat{x} = \frac{x}{L}, \quad \hat{z} = \frac{z}{h} \quad \text{and} \quad \hat{t} = \frac{t}{\tau} \quad (29)$$

where

$$\tau = \sqrt{\frac{m L^4}{k_1}} \quad \text{and} \quad \phi_0 = \frac{\pi k_1 a_{33}}{2 b L^2 d_{31}}$$

Following Baroudi and Najar [6], Equations (6) and (7) are used to calculate the associated mode shapes for the transverse displacement and the longitudinal potential. These mode shapes are used in a Galerkin procedure to obtain a reduced order model of the governing equations. For a single mode approximation based on the following expressions:

$$\hat{w}(\hat{x}, \hat{t}) = q(\hat{t}) \Psi(\hat{x}) \quad (30)$$

$$\hat{\phi}(\hat{x}, \hat{t}) = p(\hat{t}) \Phi(\hat{x}) \quad (31)$$

where the mode shapes functions Ψ and Φ are given in [6].

The modal equations are obtained by applying Equations (30) and (31) to Equations (6), (7) and (23). The result is given by

$$\ddot{q} + 2\mu\dot{q} + (\kappa_1 + \kappa_0 V)q + \kappa_3 q^3 = f \cos \Omega t \quad (32)$$

$$\dot{V} + \gamma_1 V + \gamma_2 q \dot{q} = 0 \quad (33)$$

where the p parameter has been eliminated between Equations (6) and (7), ω is the base excitation frequency and the other coefficients are given in the Appendix.

The mode shapes shown in Figures 2 are obtained for a BaTiO₃ material with the geometrical and physical properties given by Table 1. The characteristic nonlocal elastic length scale [5, 12] is defined as $l_0 = \sqrt{g_{11}/c_{11}} = 2\text{nm}$.

Table 1: Geometrical and physical properties of the BaTiO₃ with plane stress assumptions [13, 14, 15]

Length	L (nm)	400
Thickness	h (nm)	1
Width	b (nm)	20

3 Energy harvesting from the nonlinear response of the nanobeam

In this section, we analyze the nonlinear dynamics of the nanobeam by numerically solving Equation (32) when a static component is present. The static component is introduced to simulate the presence of an initial deflection that can be observed in these nanosystems due to fabrication residual stresses. Consequently, the modal displacement $q(t)$ can be expressed as the sum of the static component around which a dynamic motions is achieved, that is,

$$q(t) = q_s + \eta(t) \quad (34)$$

Therefore, extracting the static equation expressed by $\omega_0^2 q_s + 3\kappa_3 q_s^3 = f_s$, Equation (32) is rewritten as

$$\ddot{\eta} + 2\mu\dot{\eta} + \omega_0^2 \eta + \kappa_0 V \eta + 3\kappa_3 q_s \eta^2 + \kappa_3 \eta^3 + \kappa_0 q_s V = f \cos \Omega t \quad (35)$$

$$\dot{V} + \gamma_1 V + \gamma_2 q_s \dot{\eta} + \gamma_2 \eta \dot{\eta} = 0 \quad (36)$$

here $\omega_0^2 = \kappa_1 + 3\kappa_3 q_s^2$.

Limit-cycle solutions of Equations (35) and (36) are obtained using the Finite Difference Method (FDM) [16, 17].

In Figure 3, the frequency-response curves of the transverse displacement of the clamped-clamped nanobeam are shown for different values of the thickness. As shown, the maximum deflection is obtained for the largest simulated thickness ($h = 10\text{nm}$), however in this case, the bandwidth is very small and a snap-through response is observed at 10nm of maximum displacement because of the imposed initial deflected configuration. The corresponding harvested voltage is displayed in Figure 4. As shown the maximum harvested voltage is also obtained for $h = 10\text{nm}$ with a small bandwidth and a snap-through response. It turns out that best performances are obtained for the 5nm thick nanobeam where very no jumps are observed for a 1.8MHz bandwidth.

Figure 3: Frequency-response curves of the clamped-clamped nanobeam maximum deflection around the first mode, for different values of the thickness. $q_s = 0.5$ and $F = 100m$.

Figure 4: Frequency-response curves of the clamped-clamped nanobeam maximum harvested voltage around the first mode, for different values of the thickness. $q_s = 0.5$ and $F = 100m$.

Figure 5: Frequency-response curves of the clamped-clamped nanobeam maximum deflection around the first mode, for different values of the thickness. $q_s = 0.5$ and $F = 100m$.

As long as the the initial deflected configuration can dramatically perturb the performance of the device, one can investigate their influence on the response of the nanobeam. In Figure 5 and 6, the maximum deflection and harvested voltage are shown for different values of the initial configuration parameter q_s . As depicted by these figures, the absence of initial deflection or when q_s is small (less than 0.5) no snap-through is observed and consequently the bandwidth response is very large (more than 2 MHz). Also, large harvested voltages can be achieved for large values of q_s however in this case the bandwidth is only around 0.5MHz. For intermediate values of q_s poor performance of the

energy harvester are observed. In these figures, one can also observe that the value of q_s can control the frequency-response hardening and softening behaviors and reduces the snap-through region.

Figure 6: Frequency-response curves of the clamped-clamped nanobeam maximum harvested voltage around the first mode, for different values of the thickness. $q_s = 0.5$ and $F = 100m$.

4 Conclusion

An electromechanical model of a BaTiO₃ single layer clamped-clamped nanobeam is developed for energy harvesting applications. The coupled electromechanical model takes into accounting the piezoelectric and the flexoelectric effects for transverse and longitudinal polarization along with the presence of the nonlinear von Karman strain taking into account relatively large displacements. The model also incorporates residual stresses, due to fabrication, that can generate initial deflection of the nanobeam. The Galerkin approximation is used to discretize the space domain for the transverse displacement and the electric potential. The obtained reduced-order model is solved for limit-cycle solutions of the deflection of the nanobeam and the generated electrical voltage across a resistance load. The results depicted higher power density generation when the aspect ratio of the nanobeam is varied. It is found that if initial deflection is taking into account, intermediate values of the thickness gives better performance that high aspect ratio designs in terms of generated voltage and bandwidth. The effect of the initial deflection was also investigated in this work, the results showed that either small or large values can be used to increase the performance with a preference for the small deflections. Intermediate values revealed bad achievements of the device.

Appendix

We let $\Gamma(f, g) = \int_0^1 f g dx$:

$$\begin{aligned} \kappa_0 &= \frac{k_{11}L^2}{k_1h} \Gamma(\Psi', \Psi'), \quad \kappa_1 = J_1 + J_4 \frac{J_6}{J_5}, \quad \kappa_2 = J_2 + \frac{k_{12}L}{k_1} \Gamma(\Psi', \Psi') \frac{J_6}{J_5} \int_0^1 \Phi'_k(x) dx, \quad \kappa_3 = \frac{k_{13}h^2}{k_1} \Gamma(\Psi', \Psi')^2 \\ \Theta &= \frac{k_3L^2}{h^2k_1} \int_0^1 \Psi''(x) dx, \quad f = \frac{L^3}{k_1h} F \int_0^1 \Psi dx, \quad \gamma_1 = \frac{\tau}{bLRh}, \quad \gamma_2 = \frac{hd_{31}}{L^2a_{33}} \Gamma(\Psi', \Psi') \end{aligned}$$

where

$$J_1 = \Gamma(\Psi'', \Psi'') + \frac{k_2}{L^2 k_1} \Gamma(\Psi''', \Psi''') + \frac{k_4}{L k_1} \Gamma(\Psi'', \Psi'''), J_2 = \frac{3k_{10}h}{2k_1 L} \Gamma(\Psi', \Psi') \times \int_0^1 \Psi_k'''(x) dx$$

$$J_4 = -\frac{k_5 L^2}{k_1 h} \Gamma(\Psi'', \Phi) + \frac{k_6 L}{k_1 h} \Gamma(\Psi'', \Phi') + \frac{k_7 L}{k_1 h} \Gamma(\Psi''', \Phi'), J_5 = \Gamma(\Phi', \Phi') + \frac{k_9 L^2}{k_8}$$

$$J_6 = -\frac{k_5 h}{k_8} \Gamma(\Phi, \Psi'') - \frac{k_6 h}{k_8 L} \Gamma(\Phi', \Psi'') - \frac{k_7 h}{k_8 L^2} \Gamma(\Phi', \Psi''')$$

and

$$k_0 = \frac{d_{11} d_{31} f_{14}}{a_{11} a_{33} \bar{E}}, k_1 = \bar{E} I + \left(g_{11} - \frac{f_{14}^2}{a_{33}} \right) A - \frac{A d_{31}^2 f_{14}^2}{a_{33}^2 \bar{E}}, k_2 = \left(g_{11} - \frac{f_{11}^2}{a_{11}} \right) I$$

$$\bar{k}_2 = k_2 + \frac{A d_{31}^2 f_{14}^2}{a_{33}^2 \bar{E}^2} \left(g_{11} - \frac{f_{11}^2}{a_{11}} \right), k_3 = \frac{A f_{14}}{a_{33}} \left(1 + \frac{d_{31}^2}{a_{33} \bar{E}} \right), k_4 = -\frac{d_{11} f_{11}}{a_{11}} \left(I + \frac{A d_{31}^2 f_{14}^2}{a_{33}^2 \bar{E}^2} \right)$$

$$k_5 = -\frac{2d_{31}A}{\pi a_{33}}, k_6 = k_0 \frac{2A}{\pi}, k_7 = k_6 \frac{f_{11}}{d_{11}}, k_8 = -\frac{A}{4} \left(\epsilon + \frac{1}{a_{11}} \right), k_9 = -\frac{A \pi^2}{4h^2} \left(\epsilon + \frac{1}{a_{33}} \right)$$

$$k_{10} = k_0 f_{11} A, k_{11} = -\frac{A d_{31}}{a_{33}}, k_{12} = -\frac{2A d_{11}}{a_{11} \pi}, k_{13} = \frac{\bar{E} A}{2}, k_{14} = -\frac{A}{2} \left(\epsilon + \frac{1}{a_{33}} \right)$$

Key words: Vibration suppression of robot, Active dynamic absorber, Multibody system.

Abstract. The serial robots are typically able to cover large workspace, but their mass/stiffness ratio does not allow to combine high accuracy and high dynamic of the end-effector operations. Widely spread usage of serial robots, even for tasks as drilling, leads to high accuracy demands through its workspace. Absolute measurement of the end-point for position feedback can be challenging due to objects or even workpiece in workspace, but mainly, inbuilt motors of the serial robot cannot response in frequency range high enough as vibration of the end-point is. Instead, additional spring-mass system is attached to the robot to suppress vibrations. Narrow frequency range of passive dynamical absorber can be extended with active elements between robot and absorber, which is also necessary due to robots eigenfrequencies and eigenvalues variability. As feedback input, for more robustness, relative sensing is considered, such as accelerometers or geophones for velocity. As an active absorber control algorithm, firstly, the LQR control with state observer has been designed. Finally, the prepared experimental demonstrators are presented.

1 INTRODUCTION

Vibration has negative effect in many engineering applications, whether we talk about drilling head vibration causing low workpiece surface quality, base vibration in precise instruments such as electron microscopes or about airflow induced vibration of complex structures reducing its lifetime. In robotics, there are types of manipulators such as serial robots or cable manipulators, that are typically able to cover large workspace, which usually implies high mass/stiffness ratio. Such robots are not capable of high accuracy while performing operations with high dynamic of the end-effector tool or external excitation. During last decades, there has been an intensive development of serial robots in order to increase their production efficiency, including their non-traditional usage e.g. for drilling [1].

The still open problem is what can be achieved through the accurate measurement of absolute end-effector motion and its subsequent use to compensate for control loop errors between robot motors and the end-effector. The first thing is difficulty of such a measurement, considering large workspace in complex industrial environment, end-point operation “inside” of the

workpiece or even obstacle created by robot's own body. Second thing is, that motors of those manipulators are not capable of operation in such high frequency range as the vibration is placed in. Consequently, more robust additional sensing and mechanical solution are important.

The usage of dynamic absorbers with active elements is one of the promising methods. Both, passive and active absorbers, have been widely used for vibration suppression and the benefit of mounting a passive vibration absorber on the primary structure with the objective of the amplitudes reducing has been known for decades [4]-[6]. The frequency band, where the classical passive absorber suppresses vibrations efficiently, is relatively narrow, being centered at the natural frequency of the absorber. Thus, the tunable [2] and especially the fully active absorbers can significantly improve the vibration suppression efficiency in a wide frequency band. Another reason for active additional structure is that robots operating in large workspaces usually have strong variability of eigenfrequencies and eigenmodes in different work positions.

Same reason also leads us to multi degree of freedom (multi-DoF) level of design, since tool high dynamics, external excitation or robot eigenvalues are rarely fixed to the local coordinates. One of the main questions for n -DoF mechanical resonator is, whether to design n single-DoF absorbers (n autonomous active spring-mass systems) or one n -DoF absorber with n (or more) active spring elements. From recent literature, let us point to passive multi-DoF tuned absorber investigated in [7], where 2-DoF and 3-DoF mass absorbers are tested on experimental demonstrator. This paper supports theory, that passive multi-DoF absorber is more capable of vibration suppression than multiple single-DoF absorbers with equal mass. After attaching 3-DoF absorber, main structure shows 86.5% amplitude reduction, which is improved about 29.5% then using 2-DoF absorber of equal mass. Vibration suppression for robotic machining in 3D using 1-DoF semi-active absorber attached to actual robotic arm with milling head is theoretically and experimentally tested in [8]. In this case, single-DoF mass-spring absorber was based on magnetorheological elastomers material and was designed for chatter occurring in around 7 to 20 Hz. Since there is only 1-DoF absorber, its direction has to be based on chatter direction of the robot, and roughness of milled surface is then improved by 30% (passive) or by 50% (semi-active). The application of two single-DoF passive absorbers is experimentally investigated in [9], where housing of the polishing tool attached to the serial robot is damped using two dynamical absorbers based on Eddy currents. There is about 60% acceleration amplitude reduction of the end-point compared to the case without absorbers.

Let us also point to vibration problematic in surgery robotics, where the precise motion is required [10], to an active absorber tuned by dual-loop controller and tested on a helicopter vibration suppression in [11] or to the multiple passive absorbers tuned for primary and secondary mode shapes of wind turbine to suppress the vibration [12], and many other uses.

In majority of applications the absorbers are considered as passive or semi-active, where the active elements adjust the absorber stiffness or damping. Even though they can reduce vibration substantially, they cannot achieve full suppression, thus, the absorber needs to be turned to an ideal absorber, which imitates zero damping and natural frequency equal to the excitation frequency. Although, the absorbing device should be as efficient as possible already in its passive form, without usage of the feedback control of actuators, which leads to the primary optimization of stiffness and mass properties and absorber placement.

The preliminary study [3] considered active 6-DoF cubic hexapod absorber mounted on 3D robot arm. Its results in simulation model are very promising in passive as well as in active form, as far as one fixed position of robot is externally excited. Further study leads to passive

optimization, active control algorithm design as well as to optimization of sensors placement, type and count. Since at most three of all the six spatial DoFs of the damping mass are available for controlling single translational vibration mode of the main structure [7], the 2D simulation model of robot arm and 3-DoF absorber will be used to optimize properties of such an absorber. Firstly, the LQR control with state observer has been designed, concerning sensing by accelerometers on end-effector and on absorber's body. Simultaneously with the optimization of mechanical design, sensing strategies and control algorithms, the appropriate demonstrators have been prepared, based on the voice coils AVM60-25 (Figure 5a) as actuators for testing.

2 SIMULATION MODEL

2.1 Structure

As mentioned above, target of this study are light structures with large workspace, but relatively bad ratio of mass/stiffness, e.g. cable structures or serial robotic arm (Figure 7b), which is also subject of our study. In order to simulate experiments, mathematical model of flexible 3-DoF serial robotic arm in 2D space was developed (Figure 1). It consists of three bodies attached with rotational joints to each other, where the last point of the last body is the end-point of the robot. This point is supposed to be kept still as well as (not necessarily) to be excited by external force, since those two usually collocate. The stiffness of individual bodies is achieved by cutting it into several elements joined elastically to each other and, also, by rotational stiffness between the post-joint element and rotor of the motor. Single-DoF or multi-DoF absorbers are then attached to elements using springs with dampers and actuators.

Figure 1: Simulation model with multi-DoF absorber

To prevent the model from computational inaccuracies, the whole system is described using independent variables only. Thus, as far as independent equations are considered, robotic arm is then divided into several types of subparts (**Figure 2**), which can be arbitrarily combined into resultant robot design: a) simple element (**Figure 2a**), which is single mass rigid body attached to previous and following elements with three springs (two translational and one rotational), and external forces can be applied to this element; b) joint set (**Figure 2b**), which consist of pre-joint element (3 equations), post-joint element (1 additional equation for rotation) and rotor mass with stiff gear-box (1 additional equation for rotation); c) single-DoF element (**Figure 2c**), which consists of simple element with one or more attached single-DoF absorbers (1 additional equation for each absorber) attached to the element using prismatic constraint; d) multi-DoF absorber (**Figure 2d**), which is single mass rigid body attached to robotic arm only using springs and actuators (no constraints), which in equations are represented only by external forces between absorber and relevant elements of the robotic arm (based on current state vector). Types b) and c) only (non-trivial) are described by matrix/vectors (2) and (3) respectively in mean of independent equations (1) below **Figure 2**.

Figure 2: Types of elements of the robot simulation model (respectively):
a) simple element; b) joint set; c) single-DoF absorber; d) multi-DoF absorber; e) element cut

Newton-Euler equations of motion of simple element or multi-DoF absorber are trivial, thus are not displayed in following list. Firstly, list of variable description follows:

\vec{q}	vector of independent variables containing kinematics of robot and absorbers
$\mathbf{M}(\vec{q})$	mass matrix as a function of independent variables \vec{q}
$\vec{N}(\vec{q}, \dot{\vec{q}})$	vector of constraints as a function of independent variables \vec{q} and it's time derivative $\dot{\vec{q}}$
$\vec{f}(\vec{u}, \vec{q}, \dot{\vec{q}})$	vector of right sides of equations as a function of $\vec{q}, \dot{\vec{q}}$ and force inputs \vec{u}
m_i	mass of i-th element of the robot
\mathbf{m}_i	diagonal 2D matrix of mass m_i
$m_{w,k}$	mass of k-th motor of the robot
m_h	mass of the single-DoF absorber
$I_{S,i}$	moment of inertia of i-th element of the robot, with respect to its center of mass
$I_{w,k}$	moment of inertia of k-th motor of the robot
I_h	moment of inertia of single-DoF absorber
$\vec{r}_{SP,i}$	radius vector from center of mass of i-th element to previous element attachment point P, in global system
$\vec{r}_{SL,i}$	radius vector from center of mass of i-th element to following element attachment point L, in global system
$\vec{r}_{SH,i}$	radius vector from center of mass of i-th element to single absorber attachment point H, in global system
${}^i\vec{r}$	radius vector in i-th element local coordinate system
\vec{r}^\perp	radius vector perpendicular to original \vec{r} vector
φ_i	global rotation of i-th element of the robot
ω_i	angular velocity of i-th element of the robot
γ	angle between element's x-axis and motion axis of the single-DoF absorber
c	scalar distance of single-DoF absorber from its free position
\vec{R}	translational elastic force between i-th and previous element
$M_{R,i}$	rotational elastic force between i-th and previous element
\vec{F}_i	external translational force applied to the i-th element
M_i	external rotational force applied to the i-th element
\vec{G}_i	gravitational force acting on i-th element
$\vec{G}_{w,k}$	gravitational force acting on k-th motor of the robot
\vec{G}_h	gravitational force acting on single-DoF absorber
$\mathbf{S}_\varphi()$	rotational matrix

$$\mathbf{M}(\vec{q})\ddot{\vec{q}} + \vec{N}(\vec{q}, \dot{\vec{q}}) = \vec{f}(\vec{u}, \vec{q}, \dot{\vec{q}}) \quad (1)$$

$$\mathbf{M}(\vec{q})_i = \begin{bmatrix} m_i + m_{i+1} + m_{w,k} & (m_{i+1} + m_{w,k})\vec{r}_{SL,i}^\perp & -m_{i+1}\vec{r}_{SP,i+1}^\perp & \vec{0} \\ \vec{r}_{SL,i}^{\perp T}(m_{i+1} + m_{w,k}) & I_{S,i} + \vec{r}_{SL,i}^{\perp T}(m_{i+1} + m_{w,k})\vec{r}_{SL,i}^\perp & -\vec{r}_{SL,i}^{\perp T}m_{i+1}\vec{r}_{SP,i+1}^\perp & \emptyset \\ -\vec{r}_{SP,i+1}^{\perp T}m_{i+1} & -\vec{r}_{SP,i+1}^{\perp T}m_{i+1}\vec{r}_{SL,i}^\perp & I_{S,i+1} + \vec{r}_{SP,i+1}^{\perp T}m_{i+1}\vec{r}_{SP,i+1}^\perp & \emptyset \\ \vec{0}^T & \emptyset & \emptyset & I_{w,k} \end{bmatrix} \quad (2)$$

$$\begin{aligned}

 \end{aligned}$$

2.2 Kinematics and dynamics

Kinematics and dynamics of the simulation model is set as follows. The main bodies of the robot are meant to be prisms of length [1.0; 0.8; 0.5] m, so the workspace radius is around 2 m, and of weight [8; 7; 4] kg. Each of those bodies has its stiffness in all three axes – in both translations (axial and shear) and in rotation (bending) (as shown in **Figure 2e**) – and the values are set with respect to the size and cross-section of each body. Each stiff constrain has also its slight damping (around thousandths of stiffness value). Overall dynamics is designed in way, that the robot's eigenfrequencies in “neutral” position of the robot are placed into interval around 15 Hz and higher, taking “neutral” position to be in motor rotations of [60°; -105°; 60°] as shown in **Figure 1**. Since rigid bodies with only elasticity in joints is not sufficient enough to represent real structure behavior, all bodies are cut into several elements. Each element carries part of the body mass and stiffness of the body is spread over all elements in accordance to serial springs addition. Which means, that resultant stiffness of the elements-stacked body is same as before, only the corresponding count of higher extra eigenfrequencies occurs. Bode diagram (**Figure 3**) of the robot shows acceleration amplitude and phase of the end-point in all directions in response to the unit force in the global y axis applied in the same point (which is usually the case). As we can see, 4 of model eigenfrequencies are below the 100 Hz, which – considering voice-coil type of the actuators – is manageable limit for small amplitudes and loads. When mentioned slight damping (~1‰) is applied to the robot, some of the highest frequencies disappears due to overdamping (as can be seen in Bode diagram **Figure 1** in

following chapter), which has no influence in our study, since lower frequencies are subject of interest. Base of this study is then suppression of vibrations of the end-point when externally excited in the same point in area of first few eigenfrequencies of the robot.

Figure 3: Bode diagram (end-point acceleration) - undamped model of the robot (without absorber)

3 ACTIVE ABSORBER DESIGN AND CONTROL

3.1 Absorber mechanical design

As mentioned in [7], most three of all the six spatial DoFs of the damping absorber are available for controlling single translational vibration mode of the main structure. Simulation in 2D is then planar reduction of such a case. Main attention of the study is focused to 3-DoF single mass absorber in order to lower mass and space requirements. It consists of the single main body with mass and inertia and is attached to the robot's arm with three linear springs arranged to be perpendicular to each other, as seen in **Figure 1**. Springs of the multi-absorber may be attached to various elements of the same robot body (**Figure 1**), if they are small enough compared to the absorber. Linear springs contains slight damping and, for further active control, colinear voice-coil actuators represented by raw force along those springs.

3.2 Passive absorber tuning

In order to perform active vibration suppression, it is important to begin with properly tuned passive absorber, which is able to damp some eigenfrequency at certain suppression level. Considering fix geometrical parameters, there are dynamical parameters left. Since the lowest eigenfrequency is usually the one with the highest amplitudes, the goal is to tune all three absorber's eigenfrequencies to this value – in our case it is 19.6 Hz. Both, global and local optimization methods were used to adjust mass, position of the center of mass, inertia and stiffness of springs to values 2.17 kg, [0 -0.033] m, 0.006 kg·m² and 2.14e4 N·m⁻¹ respectively. Comparison of both cases – before and after attaching of the absorber to the end-effector – is then shown in Bode diagram (**Figure 4**), represented by position amplitudes of the end-point in one direction (for better readability) in response to same direction external force input. Slight eigenfrequency redistribution can be seen, because another three eigenfrequencies were added to the system. Although we can retune absorber properties in order to suppress different

frequency interval or to be effective also in different robot positions, at this moment, there is no more we can do about variability of vibration suppression in general perspective. Therefore, active approach takes place from now on.

3.3 Active vibration suppression control design

Various control algorithms, such as LQR, PID regulator, fixed order H_∞/H_2 or DR, may be considered to actuate the absorber along with feedback from proper type and amount of sensors. The delayed resonator (DR) concept [13]-[18] has been researched in 1990s and is based on tuning of the absorber to the ideal absorber. Such an approach makes the absorber to mimic zero damping and it needs to be tuned to the excitation frequency. It is simple and effective concept with robust sensing of the structure based on single accelerometer, although, this analytical approach has been applied in 1D only so far.

In this paper, the LQR control with state observer is being designed, concerning sensing by accelerometers attached to the end-effector and, also, to the absorber's body. First of all, a proper linearization of whole system (robot with absorber) needs to be performed, which provides us with A B C and D state-space matrices. Another step is to include crucial problem of realistic robot sensing implementation in order to use an observer of the system state. The goal is to use as few of sensors as possible and the sensors to be robust, such as accelerometers or geophones – basically to avoid of any global absolute position measuring, which can be an unreachable requirement in industry environment. Firstly, it is convenient to include already existing robot sensors which is always known joints encoders of position and velocity. Secondly, to even be able to design an LQR we need to measure end-point kinematics. For sake of robustness, acceleration of the end-point in all axes is measured, since vibrations can be observed through acceleration measurement as well as through position measurement. Thus, this particular sensor can be also used for system observation. Thirdly, once an absorber is being designed, there may be placed sensors of body acceleration in all axes of the absorber and, also, encoders of spring elements for elongation (and its change) measurement. When all mentioned sensors are considered, the observation of the whole linear model is very few of all states. Even acceleration/velocity sensing of all robot's elements are not sufficient enough, until their global positions are unknown. Therefore, order reduction of the linear model is necessary for proper observer design.

Since the ability of actuators to work in certain frequency range, model order reduction (using Hankel singular numbers) is focused on the dynamics in this particular frequency range, which means up to approximately 100 Hz. The new state-space low-order model consists of matrices A_r B_r C_r and D_r , and original 51 states were reduced down to 14 states. Using pole placement method, an observer matrix L_{obsv} belonging to all measured outputs was created for observer to be as fast as possible. The whole system Bode diagram, when output-based observer LQR is considered, is shown in **Figure 4** as third line and it compares its amplitudes of one direction position of the end-point in response to the same direction force input to passive absorber and original system cases. Difference in frequency damping between passive and active approach is visible only in lower frequency range, since voice-coil actuators are able to effectively work in frequency range up to 100 Hz. In simulation design, these actuators are represented by the low-pass filter with time constant of 0.01 of second.

4 PREPARATION OF EXPERIMENTAL DEMONSTRATORS

Two demonstrators are being prepared in order to experimentally verify functionality of the active vibration absorbers for multibody chains of robotic type. Different actuators can be used. The piezoactuators typically have a wide range of operating frequencies, but exhibit quite small range of strokes (dozens, at most hundreds of micrometers) and their inherent stiffness is high. The voice-coil actuators (VCA) (**Figure 5a**) are more suitable for the active absorbers because they have significantly larger range of strokes and almost zero inherent stiffness. Consequently, the modal properties of the absorber can be tuned not only by optimization of mass properties but also by tuning of stiffness of springs added in parallel to voice-coil actuators. The size of prepared demonstrators has been adapted to the available VCA AVM60-25 with 26N stable force and 110N peak force. The VCA amplitude characteristics are in **Figure 5b**.

The aim of the first demonstrator (**Figure 6**) is testing of dynamical properties of absorber “leg” including mounting spherical joints and translational guidance of voice coil actuator.

Figure 6: First demonstrator for vibrational testing of leg with spherical joints

The kinematics and other mechanical properties of spatial multi-DOF active absorber can be optimized in many ways. Taken into account that the modal properties of typical serial robot (**Figure 7b**) vary considerably and heterogeneously within the workspace, some regular architecture of absorber is an appropriate choice. The hexapod of cubic geometry created by actuators is considered (**Figure 7a**). The similar structure has been used also for 6 DOF active vibration isolation in [19]. The robot arm eigenmodes are typically geometrically complex including translations and rotations in several directions. The target of mechanical optimization of demonstrator of hexapod absorber is to achieve 6 identical eigenfrequencies equal to average value of the most critical (typically first) eigenfrequency of robot chain.

5 CONCLUSIONS

The concept of active dynamic absorbers for use on robotic mechanisms was introduced and formulated. Reducing the vibration of the robots by means of active absorbers has the advantage that it can only be realized with the help of local sensors, for example with accelerometers. In addition, the active absorbers allow the adaptation to the highly variable modal properties of the robot during motion in the workspace. The problem was primarily solved for the model of a flexible plane robot. The mechanical structure of the 3 DOF absorber has been designed so that it has a multiple eigenfrequency equal to the first eigenfrequency of the robotic arm. The control was implemented using the LQR method with observer considering accelerometers on the body of the absorber and on the robot arm. The research of the whole topic is still in progress, so, many questions remain opened. The experiments with both demonstrators equipped by the purchased voice-coils start just now. The currently considered active cubic hexapod structure with multiple natural frequency equal to average natural frequency of the most critical eigenmode seems to be the most suitable choice, however there are also other variants of implementation, namely the set of 1DOF absorbers spread over the arm of the robot.

Abstract. This study proposes a new strategy based on the proper generalized decomposition method to solve the forced vibration problem in bi-dimensional piezoelectric composite beams. The approach considers a classical harmonic space-frequency description of the problem and redefines it by approximating the coupled displacement and electric potential fields as a sum of separated functions of x (beam axis coordinate), z (thickness axis coordinate) and ω (mechanical load frequency). The methodology consists of an iterative algorithm that solves three one-dimensional problems at each iteration. The result is a 2D solution in frequency domain with 1D computational complexity. The main goal is to propose a new method to model vibration-based energy harvester devices reducing both the complexity of the model and the computational cost without losing accuracy.

1 INTRODUCTION

In recent years, energy harvesting (EH) devices are becoming an alternative to provide energy in many different low-powered applications. Among the several energy harvesting mechanisms, the vibration-based approach seems to be the most suitable one for engineering structures subject to continuous ambient vibration. Particularly, the piezoelectric energy conversion is a very versatile option able to harvest energy from different ambient sources. Most piezoelectric EH devices designs are based on cantilever beams, including unimorph, bimorph and functionally graded piezoelectric material (FGPM) beams configurations. The conventional approach to evaluate the performance of these devices is the use of simplified models (single degree of freedom systems, beam theory, etc.) or numerical techniques based on the finite element (FE) method. Equivalent Single Layer (ESL) models have been used for such problems: FSDT (First-order Shear Deformation Theory), HSDT (High-order Shear Deformation Theory) or refined theory in [1], [2] and [3], respectively. It should be also noted the systematic approach by Carrera, the so-called Carrera's Unified Formulation, that includes a wide family of models [4].

In order to reduce the computational cost without losing accuracy in the solution, the proper generalized decomposition (PGD) method [5] is used herein as a reduction model. Note that the method has been already applied to take into account the electro-mechanical coupling in [6]. Also in [7], the coupled

problem variables are decomposed into space, frequency and electrical load. In this last reference by Qin et al., the authors point out that the 3D spatial component dominates the performance of the simulation process. To reduce the computational cost, in the present approach both the displacements and the electric potential are written as a sum of products of unidimensional functions of spatial coordinates x and z (beam axis and thickness directions respectively) and frequency ω . Finally, the deduced non-linear problem implies the resolution of three linear problems alternatively. The main objective of this work is to develop a new PGD-based approach for the parametric study of energy harvesters to effectively reduce the complexity of the models and the CPU time.

2 REFERENCE PROBLEM DESCRIPTION

In the present study, a straight composite beam of length L with a rectangular uniform cross section of thickness h and depth b is considered. The beam consists of NC layers, piezoelectric or not, assumed to be orthotropic in the beam axes. The x axis is taken along the longitudinal beam axis whereas y and z are the two axes of symmetry of the rectangular cross section (see Figure 1).

Figure 1: The laminated beam with embedded piezoelectric layers and coordinate system.

Hereafter, the y coordinate is neglected and the beam is considered in the (x, z) plane, i.e., in the domain $\Omega = \Omega_x \times \Omega_z = [0 \leq x \leq L] \times [-\frac{h}{2} \leq z \leq \frac{h}{2}]$. An additional step towards compactness in notation is achieved by renaming the coordinates such that $x \rightarrow x_1$, $y \rightarrow x_2$ and $z \rightarrow x_3$.

2.1 Governing equations

The formulation of the piezoelectric problem is based on the equations of motion of the elastodynamics and Gauss' law of the electrostatics, which are given by

$$\nabla \cdot [\sigma] + [b] = \rho \frac{\partial^2 [u]}{\partial t^2} \quad (1a)$$

$$\nabla \cdot [D] - q = 0 \quad (1b)$$

where $[\sigma]$ is the stress, $[b]$ is the prescribed body load, ρ is the density of the material, $[u]$ is the mechanical displacement, $[D]$ is the electric displacement and q is free electric volume charge. The two-dimensional formulation of the piezoelectric problem in absence of body loads and free electric volume charge can be reduced to

$$\frac{\partial \sigma_{11}}{\partial x_1} + \frac{\partial \sigma_{13}}{\partial x_3} = \rho \frac{\partial^2 u_1}{\partial t^2}, \quad \frac{\partial \sigma_{13}}{\partial x_1} + \frac{\partial \sigma_{33}}{\partial x_3} = \rho \frac{\partial^2 u_3}{\partial t^2}, \quad \frac{\partial D_1}{\partial x_1} + \frac{\partial D_3}{\partial x_3} = 0 \quad (2)$$

2.2 Constitutive relation

The constitutive equations with piezoelectric coupling for a layer k are

$$\begin{aligned} [\sigma^{(k)}] &= [C^{(k)}][\varepsilon] - [e^{(k)}]^\top [E] \\ [D^{(k)}] &= [e^{(k)}][\varepsilon] + [\epsilon^{(k)}][E] \end{aligned} \quad (3)$$

where $[\varepsilon]$ is the strain and $[E]$ is the electric field. Assuming plane stress in the xy -plane and vanishing out of plane electric displacement ($\sigma_{22} = \sigma_{12} = \sigma_{23} = D_2 = 0$), the constitutive equations read

$$\begin{aligned} \begin{bmatrix} \sigma_{11}^{(k)} \\ \sigma_{33}^{(k)} \\ \sigma_{13}^{(k)} \end{bmatrix} &= \begin{bmatrix} \bar{C}_{11}^{(k)} & \bar{C}_{13}^{(k)} & 0 \\ \bar{C}_{13}^{(k)} & \bar{C}_{33}^{(k)} & 0 \\ 0 & 0 & \bar{C}_{55}^{(k)} \end{bmatrix} \begin{bmatrix} \varepsilon_{11} \\ \varepsilon_{33} \\ \gamma_{13} \end{bmatrix} - \begin{bmatrix} 0 & \bar{e}_{31}^{(k)} \\ 0 & \bar{e}_{33}^{(k)} \\ \bar{e}_{15}^{(k)} & 0 \end{bmatrix} \begin{bmatrix} E_1 \\ E_3 \end{bmatrix} \\ \begin{bmatrix} D_1^{(k)} \\ D_3^{(k)} \end{bmatrix} &= \begin{bmatrix} 0 & 0 & \bar{e}_{15}^{(k)} \\ \bar{e}_{31}^{(k)} & \bar{e}_{33}^{(k)} & 0 \end{bmatrix} \begin{bmatrix} \varepsilon_{11} \\ \varepsilon_{33} \\ \gamma_{13} \end{bmatrix} + \begin{bmatrix} \bar{\epsilon}_{11}^{(k)} & 0 \\ 0 & \bar{\epsilon}_{33}^{(k)} \end{bmatrix} \begin{bmatrix} E_1 \\ E_3 \end{bmatrix} \end{aligned} \quad (4)$$

where the components of the constitutive matrices are expressed by

$$\bar{C}_{11}^{(k)} = C_{11}^{(k)} - \frac{C_{12}^{(k)2}}{C_{22}^{(k)}}, \quad \bar{C}_{13}^{(k)} = C_{13}^{(k)} - \frac{C_{12}^{(k)}C_{23}^{(k)}}{C_{22}^{(k)}}, \quad \bar{C}_{33}^{(k)} = C_{33}^{(k)} - \frac{C_{23}^{(k)2}}{C_{22}^{(k)}}, \quad \bar{C}_{55}^{(k)} = C_{55}^{(k)} \quad (5)$$

$$\bar{e}_{31}^{(k)} = e_{31}^{(k)} - e_{32}^{(k)} \frac{C_{12}^{(k)}}{C_{22}^{(k)}}, \quad \bar{e}_{33}^{(k)} = e_{33}^{(k)} - e_{32}^{(k)} \frac{C_{23}^{(k)}}{C_{22}^{(k)}}, \quad \bar{e}_{15}^{(k)} = e_{15}^{(k)} \quad (6)$$

$$\bar{\epsilon}_{11}^{(k)} = \epsilon_{11}^{(k)}, \quad \bar{\epsilon}_{33}^{(k)} = \epsilon_{33}^{(k)} + \frac{e_{32}^{(k)2}}{C_{22}^{(k)}} \quad (7)$$

being $C_{ij}^{(k)}$ the stiffness coefficients, $e_{ij}^{(k)}$ the piezoelectric constants and $\epsilon_{ij}^{(k)}$ the permittivity coefficients for the 3D problem.

For the analysis of piezoelectric problems it is useful to use the notation proposed by Barnett and Lothe [8]. With this notation, the mechanical displacement and electric potential, the strain and electric field, the stress and electric displacement, and the elastic and electric coefficients can be grouped for the 2D problem as

$$\begin{bmatrix} \sigma_{11}^{(k)} \\ \sigma_{33}^{(k)} \\ \sigma_{13}^{(k)} \\ D_1^{(k)} \\ D_3^{(k)} \end{bmatrix} = \begin{bmatrix} \bar{C}_{11}^{(k)} & \bar{C}_{13}^{(k)} & 0 & 0 & \bar{e}_{31}^{(k)} \\ \bar{C}_{13}^{(k)} & \bar{C}_{33}^{(k)} & 0 & 0 & \bar{e}_{33}^{(k)} \\ 0 & 0 & \bar{C}_{55}^{(k)} & \bar{e}_{15}^{(k)} & 0 \\ 0 & 0 & \bar{e}_{15}^{(k)} & -\epsilon_{11}^{(k)} & 0 \\ \bar{e}_{31}^{(k)} & \bar{e}_{33}^{(k)} & 0 & 0 & -\epsilon_{33}^{(k)} \end{bmatrix} \begin{bmatrix} \varepsilon_{11} \\ \varepsilon_{33} \\ \gamma_{13} \\ -E_1 \\ -E_3 \end{bmatrix} \quad (8)$$

In addition, using the Maxwell's law $[E] = -\nabla\phi$ to derive the electric field vector from the electric potential ϕ , and the kinematic relations $[\varepsilon] = 1/2\{\nabla[u] + \nabla[u]^\top\}$, the piezoelectric problem can be formulated only in terms of the generalized displacements defined as

$$[\hat{u}] = [u_1 \quad u_3 \quad \phi]^\top \quad (9)$$

2.3 Classical and new variational formulation of the boundary value problem

In the following, a single harmonic mechanical excitation, $[F_d(t)] = [f_d] e^{i\omega t}$, is assumed as a basic problem. The response of a linear solid in absence of body loads and free electric volume charge subjected to a harmonic excitation is presumed to have the same frequency as the applied load, $[u(M, t)] = [u(M)] e^{i\omega t}$ and $\phi(M, t) = \phi(M) e^{i\omega t}$, with $[u(M)]$ and $\phi(M)$ containing the displacements and electric potential amplitudes. Under these assumptions, the classical variational principle of a piezoelectric beam subjected to a mechanical harmonic load can be expressed as:

find $([u(M)], \phi(M)) \in U \times \Phi$ (space of admissible displacement and electric potential) such that

$$\int_{\Omega} [\varepsilon(\delta u)]^T [\sigma] dV - \int_{\partial_F \Omega} [\delta u]^T [f_d] dS = \omega^2 \int_{\Omega} \rho [\delta u]^T [u] dV, \quad (10a)$$

$$\int_{\Omega} [E(\delta \phi)]^T [D] dV = 0, \quad \forall ([\delta u], \delta \phi) \in \delta U \times \delta \Phi \quad (10b)$$

Eq. (10) can be solved for a given value of the load frequency ω so that the set of the load frequency within an interval $[\omega_{min}, \omega_{max}]$ involves the resolution of many problems. In order to avoid this iterative strategy, a new formulation as in [9] is proposed

find $([u(M, \omega)], \phi(M, \omega)) \in U \times \Phi$ (space of admissible generalized displacement) such that

$$\int_{\omega} \int_{\Omega} [\varepsilon(\delta u)]^T [\sigma] dV d\omega - \int_{\omega} \int_{\partial_F \Omega} [\delta u]^T [f_d] dS d\omega = \int_{\omega} \int_{\Omega} \omega^2 \rho [\delta u]^T [u] dV d\omega, \quad (11a)$$

$$\int_{\omega} \int_{\Omega} [E(\delta \phi)]^T [D] dV d\omega = 0, \quad \forall ([\delta u], \delta \phi) \in \delta U \times \delta \Phi \quad (11b)$$

To complete the boundary value problem, a prescribed displacement $[u(M, t)] = [u_d(t)]$ and electric potential $\phi(M, t) = \phi_d(t)$ are imposed on $\partial_u \Omega$ and $\partial_{\phi} \Omega$ respectively.

3 APPLICATION OF THE PGD METHOD

The Proper Generalized Decomposition (PGD) was first proposed in [5]. This method is based on an *a priori* construction of the solution in separate variables. In the literature, the PGD has been used in order to separate spatial variables and also to consider problem parameters as extra-coordinates. In this approach, the PGD is used to consider both the spatial variable separation and the introduction of the load frequency as an extra-coordinate in the solution of the electrodynamic problem in piezoelectric composites.

3.1 Separated representation

The unknowns of the problem, i.e. the generalized displacements, composed by the longitudinal and transversal displacements $[u] = [u_1 \quad u_3]^T$ and the electric potential ϕ are built as

$$\begin{bmatrix} u_1(x, z, \omega) \\ u_3(x, z, \omega) \end{bmatrix} = \sum_{i=1}^N g^i(\omega) \begin{bmatrix} f_1^i(z) v_1^i(x) \\ f_3^i(z) v_3^i(x) \end{bmatrix} \quad (12)$$

$$\phi(x, z, \omega) = \sum_{i=1}^N g_{\phi}^i(\omega) f_{\phi}^i(z) v_{\phi}^i(x) \quad (13)$$

where (g^i, g_ϕ^i) defined in $[\omega_{min}, \omega_{max}]$, (f_1^i, f_3^i, f_ϕ^i) defined in Ω_z and (v_1^i, v_3^i, v_ϕ^i) defined in Ω_x are functions which must be computed during the resolution process for each enrichment step $i = 1, 2, \dots, n, \dots, N$.

Eq. (12) can be written in a more compact way as

$$[u] = \sum_{i=1}^N g^i [F^i] [v^i] = \sum_{i=1}^N g^i [V^i] [f^i] \quad (14)$$

where

$$[v^i] = \begin{bmatrix} v_1^i(x) \\ v_3^i(x) \end{bmatrix}, \quad [V^i] = \begin{bmatrix} v_1^i(x) & 0 \\ 0 & v_3^i(x) \end{bmatrix}, \quad [f^i] = \begin{bmatrix} f_1^i(z) \\ f_3^i(z) \end{bmatrix}, \quad [F^i] = \begin{bmatrix} f_1^i(z) & 0 \\ 0 & f_3^i(z) \end{bmatrix} \quad (15)$$

This separated representation is also used in the following to express the virtual displacement δu and the virtual electric potential $\delta \phi$ used as test functions in Eq. (11)

$$[\delta u] = \delta g [F] [v] + g [V] [\delta f] + g [F] [\delta v] = \delta u_\omega + \delta u_f + \delta u_v \quad (16)$$

$$\delta \phi = \delta g_\phi f_\phi v_\phi + g_\phi \delta f_\phi v_\phi + g_\phi f_\phi \delta v_\phi = \delta \phi_\omega + \delta \phi_f + \delta \phi_v \quad (17)$$

3.2 The problem to be solved

Regarding the definition of the unknowns of the problem, an iterative procedure must be introduced to find the solutions for each enrichment step i . Assuming that the first $(n-1)$ functions have been already computed, the solution for iteration n can be expressed by

$$[u] = [\bar{u}] + g [V] [f] = [\bar{u}] + g [F] [v], \quad \phi = \bar{\phi} + g_\phi f_\phi v_\phi \quad (18)$$

where $([\bar{u}], \bar{\phi})$ are the displacement and potential solution at iteration $(n-1)$ defined by

$$[\bar{u}] = \sum_{i=1}^{n-1} [u^i] = \sum_{i=1}^{n-1} g^i [F^i] [v^i] = \sum_{i=1}^{n-1} g^i [V^i] [f^i], \quad \bar{\phi} = \sum_{i=1}^{n-1} \phi^i = \sum_{i=1}^{n-1} g_\phi^i f_\phi^i v_\phi^i \quad (19)$$

Taking into account the constitutive law and introducing Eqs. (16-17) in the weak form expressed by Eq. (11) the problem is decomposed into three pair coupled equations, which are

$$\begin{aligned} \int_\omega \int_\Omega \left([\varepsilon(\delta u_\omega)]^\top [C] [\varepsilon(\bar{u} + g F v)] - [\varepsilon(\delta u_\omega)]^\top [e]^\top [E(\bar{\phi} + g_\phi f_\phi v_\phi)] \right) dV d\omega \\ - \int_\omega \int_\Omega \omega^2 \rho [\delta u_\omega]^\top [\bar{u} + g F v] dV d\omega = \int_\omega \int_{\partial_F \Omega} [\delta u_\omega]^\top [f_d] dS d\omega \end{aligned} \quad (20a)$$

$$\int_\omega \int_\Omega \left([E(\delta \phi_\omega)]^\top [e] [\varepsilon(\bar{u} + g F v)] + [E(\delta \phi_\omega)]^\top [\epsilon] [E(\bar{\phi} + g_\phi f_\phi v_\phi)] \right) dV d\omega = 0 \quad (20b)$$

$$\begin{aligned} \int_\omega \int_\Omega \left([\varepsilon(\delta u_f)]^\top [C] [\varepsilon(\bar{u} + g V f)] - [\varepsilon(\delta u_f)]^\top [e]^\top [E(\bar{\phi} + g_\phi f_\phi v_\phi)] \right) dV d\omega \\ - \int_\omega \int_\Omega \omega^2 \rho [\delta u_f]^\top [\bar{u} + g V f] dV d\omega = \int_\omega \int_{\partial_F \Omega} [\delta u_f]^\top [f_d] dS d\omega \end{aligned} \quad (21a)$$

$$\int_\omega \int_\Omega \left([E(\delta \phi_f)]^\top [e] [\varepsilon(\bar{u} + g V f)] + [E(\delta \phi_f)]^\top [\epsilon] [E(\bar{\phi} + g_\phi f_\phi v_\phi)] \right) dV d\omega = 0 \quad (21b)$$

$$\begin{aligned} \int_{\omega} \int_{\Omega} \left([\varepsilon(\delta u_v)]^T [C] [\varepsilon(\bar{u} + g F v)] - [\varepsilon(\delta u_v)]^T [e]^T [E(\bar{\phi} + g_{\phi} f_{\phi} v_{\phi})] \right) dV d\omega \\ - \int_{\omega} \int_{\Omega} \omega^2 \rho [\delta u_v]^T [\bar{u} + g F v] dV d\omega = \int_{\omega} \int_{\partial_F \Omega} [\delta u_v]^T [f_d] dS d\omega \end{aligned} \quad (22a)$$

$$\int_{\omega} \int_{\Omega} \left([E(\delta \phi_v)]^T [e] [\varepsilon(\bar{u} + g F v)] + [E(\delta \phi_v)]^T [\epsilon] [E(\bar{\phi} + g_{\phi} f_{\phi} v_{\phi})] \right) dV d\omega = 0 \quad (22b)$$

From Eqs. (20),(21) and (22), a non-linear piezoelectric problem is defined. The simplest non-linear resolution strategy to solve these equations is the fixed point method. The iterative procedure is explained though the pseudo-code in Algorithm 1. The fixed point loop is iterated m times until reaching a fixed solution for each enrichment step n which composes the final solution.

Algorithm 1 Non-linear resolution strategy: PGD algorithm.

```

3.3 Variational problem defined on load frequency domain: Step 1

In order to simplify the notation, the functions $[f^{(m)}], [v^{(m)}], f_{\phi}^{(m)}, v_{\phi}^{(m)}$, which are assumed to be known, will be denoted as $\tilde{f}, \tilde{v}, \tilde{f}_{\phi}, \tilde{v}_{\phi}$ (and subsequently \tilde{F}, \tilde{V} in matrix form) and the function $g^{(m+1)}, g_{\phi}^{(m+1)}$ to be computed will be denoted as g, g_{ϕ} . The functions $\bar{g}^i, \bar{f}^i, \bar{v}^i, \bar{g}_{\phi}^i, \bar{f}_{\phi}^i, \bar{v}_{\phi}^i$ are the solutions at the previous enrichment steps $i = 1, 2, \dots, (n-1)$. The strain and electric fields in Eq. (20) are defined in matrix notation as

$$[\varepsilon(g \tilde{F} \tilde{v})] = g [\Sigma_z(\tilde{f})] [\tilde{\mathcal{E}}_v], \quad [E(g_{\phi} \tilde{f}_{\phi} \tilde{v}_{\phi})] = g_{\phi} [\Sigma_z^{\phi}(\tilde{f}_{\phi})] [\tilde{\mathcal{E}}_{v_{\phi}}], \quad (23)$$

with

$$[\Sigma_z(\tilde{f})] = \begin{bmatrix} 0 & \tilde{f}_1 & 0 & 0 \\ 0 & 0 & \tilde{f}_3' & 0 \\ \tilde{f}_1' & 0 & 0 & \tilde{f}_3 \end{bmatrix}, \quad [\tilde{\mathcal{E}}_v] = [\tilde{v}_1 \ \tilde{v}_1' \ \tilde{v}_3 \ \tilde{v}_3']^T \quad (24)$$

$$[\Sigma_z^{\phi}(\tilde{f}_{\phi})] = \begin{bmatrix} 0 & -\tilde{f}_{\phi}' \\ -\tilde{f}_{\phi}' & 0 \end{bmatrix}, \quad [\tilde{\mathcal{E}}_{v_{\phi}}] = [\tilde{v}_{\phi} \ \tilde{v}_{\phi}']^T \quad (25)$$

where the prime (') stands for the classical derivation. Thus, the variational problem defined in Eq. (20) is then

$$k_{\omega}^{vv} g - k_{\omega}^{v\phi} g_{\phi} - \omega^2 m_{\omega} g = f_{\omega} + \omega^2 \sum_{i=1}^{n-1} \bar{g}^i \mu_{\omega}^i - \sum_{i=1}^{n-1} \bar{g}^i \sigma_{\omega}^{vv^i} + \sum_{i=1}^{n-1} \bar{g}_{\phi}^i \sigma_{\omega}^{v\phi^i} \quad (26a)$$

$$k_{\omega}^{\phi v} g + k_{\omega}^{\phi\phi} g_{\phi} = - \sum_{i=1}^{n-1} \bar{g}^i \sigma_{\omega}^{\phi v^i} - \sum_{i=1}^{n-1} \bar{g}_{\phi}^i \sigma_{\omega}^{\phi\phi^i} \quad \forall \quad \omega \in [\omega_{min}, \omega_{max}] \quad (26b)$$

being

$$\begin{aligned} k_{\omega}^{vv}(\tilde{f}, \tilde{v}) &= \int_{\Omega} [\tilde{\mathcal{E}}_v]^T [\tilde{\Sigma}_z]^T [C] [\tilde{\Sigma}_z] [\tilde{\mathcal{E}}_v] dV, & k_{\omega}^{v\phi}(\tilde{f}, \tilde{v}, \tilde{f}_{\phi}, \tilde{v}_{\phi}) &= \int_{\Omega} [\tilde{\mathcal{E}}_v]^T [\tilde{\Sigma}_z]^T [e]^T [\tilde{\Sigma}_z^{\phi}] [\tilde{\mathcal{E}}_{v_{\phi}}] dV, \\ k_{\omega}^{\phi v}(\tilde{f}, \tilde{v}, \tilde{f}_{\phi}, \tilde{v}_{\phi}) &= \int_{\Omega} [\tilde{\mathcal{E}}_{v_{\phi}}]^T [\tilde{\Sigma}_z^{\phi}]^T [e] [\tilde{\Sigma}_z] [\tilde{\mathcal{E}}_v] dV, & k_{\omega}^{\phi\phi}(\tilde{f}_{\phi}, \tilde{v}_{\phi}) &= \int_{\Omega} [\tilde{\mathcal{E}}_{v_{\phi}}]^T [\tilde{\Sigma}_z^{\phi}]^T [\epsilon] [\tilde{\Sigma}_z^{\phi}] [\tilde{\mathcal{E}}_{v_{\phi}}] dV \end{aligned} \quad (27)$$

$$\begin{aligned} \sigma_{\omega}^{vv^i}(\tilde{f}, \tilde{v}, \tilde{u}) &= \int_{\Omega} [\tilde{\mathcal{E}}_v]^T [\tilde{\Sigma}_z]^T [C] [\tilde{\Sigma}_z^i] [\tilde{\mathcal{E}}_v^i] dV, & \sigma_{\omega}^{v\phi^i}(\tilde{f}, \tilde{v}, \tilde{\phi}) &= \int_{\Omega} [\tilde{\mathcal{E}}_v]^T [\tilde{\Sigma}_z]^T [e]^T [\tilde{\Sigma}_z^{\phi^i}] [\tilde{\mathcal{E}}_{v_{\phi}}^i] dV, \\ \sigma_{\omega}^{\phi v^i}(\tilde{f}, \tilde{v}, \tilde{u}) &= \int_{\Omega} [\tilde{\mathcal{E}}_{v_{\phi}}]^T [\tilde{\Sigma}_z^{\phi}]^T [e] [\tilde{\Sigma}_z^i] [\tilde{\mathcal{E}}_v^i] dV, & \sigma_{\omega}^{\phi\phi^i}(\tilde{f}, \tilde{v}, \tilde{\phi}) &= \int_{\Omega} [\tilde{\mathcal{E}}_{v_{\phi}}]^T [\tilde{\Sigma}_z^{\phi}]^T [\epsilon] [\tilde{\Sigma}_z^{\phi^i}] [\tilde{\mathcal{E}}_{v_{\phi}}^i] dV \end{aligned} \quad (28)$$

$$m_{\omega}(\tilde{f}, \tilde{v}) = \int_{\Omega} [\tilde{v}]^T [\tilde{F}]^T \rho [\tilde{F}] [\tilde{v}] dV, \quad \mu_{\omega}^i(\tilde{f}, \tilde{v}, \tilde{u}) = \int_{\Omega} [\tilde{v}]^T [\tilde{F}]^T \rho [\tilde{F}^i] [\tilde{v}^i] dV \quad (29)$$

$$f_{\omega}(\tilde{f}, \tilde{v}) = \int_{\partial F \Omega} [\tilde{v}]^T [\tilde{F}]^T [f_d] dS \quad (30)$$

By using the system expressed by Eq. (26), the values of $g(\omega)$, $g_{\phi}(\omega)$ can be calculated explicitly for any ω considered in the range $[\omega_{min}, \omega_{max}]$. Note that there are specific values so-called natural frequencies ω_n for which resonance is detected.

3.4 Variational problem defined on Ω_z : Step 2

At this step the functions $g^{(m+1)}, [v^{(m)}], g_{\phi}^{(m+1)}, v_{\phi}^{(m)}$, assumed to be known, will be denoted as $\tilde{g}, \tilde{v}, \tilde{g}_{\phi}, \tilde{v}_{\phi}$ and the function $[f^{(m+1)}], f_{\phi}^{(m+1)}$ to be computed will be denoted as f, f_{ϕ} . The strain and electric field in Eq. (21) are defined in matrix notation as

$$[\mathcal{E}(\tilde{g} \tilde{V} f)] = \tilde{g} [\Sigma_x(\tilde{v})] [\mathcal{E}_f], \quad [E(\tilde{g}_{\phi} \tilde{v}_{\phi} f_{\phi})] = \tilde{g}_{\phi} [\Sigma_x^{\phi}(\tilde{v}_{\phi})] [\mathcal{E}_{f_{\phi}}], \quad (31)$$

with

$$[\Sigma_x(\tilde{v})] = \begin{bmatrix} \tilde{v}'_1 & 0 & 0 & 0 \\ 0 & 0 & 0 & \tilde{v}_3 \\ 0 & \tilde{v}_1 & \tilde{v}'_3 & 0 \end{bmatrix}, \quad [\mathcal{E}_f] = [f_1 \ f'_1 \ f_3 \ f'_3]^T \quad (32)$$

$$[\Sigma_x^{\phi}(\tilde{v}_{\phi})] = \begin{bmatrix} -\tilde{v}'_{\phi} & 0 \\ 0 & -\tilde{v}_{\phi} \end{bmatrix}, \quad [\mathcal{E}_{f_{\phi}}] = [\tilde{f}_{\phi} \ \tilde{f}'_{\phi}]^T \quad (33)$$

Introducing the above expression into Eq. (21), the variational problem defined on Ω_z is

$$\begin{aligned} \gamma_\omega \int_{\Omega_z} [\delta \mathcal{E}_f]^\top [k_x^{ff}] [\mathcal{E}_f] dz - \theta_\omega \int_{\Omega_z} [\delta \mathcal{E}_f]^\top [k_x^{f\phi}] [\mathcal{E}_{f\phi}] dz - \alpha_\omega \int_{\Omega_z} [\delta f]^\top [m_x] [f] dz = \\ \beta_\omega \int_{\partial_F \Omega_z} [\delta f]^\top [f_x] dz + \sum_{i=1}^{n-1} \left(\alpha_\omega^i \int_{\Omega_z} [\delta f]^\top [\mu_x^i] dz - \gamma_\omega^i \int_{\Omega_z} [\delta \mathcal{E}_f]^\top [\sigma_x^{ff^i}] dz \right. \\ \left. + \theta_\omega^{g\phi^i} \int_{\Omega_z} [\delta \mathcal{E}_f]^\top [\sigma_x^{f\phi^i}] dz \right) \quad (34a) \end{aligned}$$

$$\begin{aligned} \theta_\omega \int_{\Omega_z} [\delta \mathcal{E}_{f\phi}]^\top [k_x^{\phi f}] [\mathcal{E}_f] dz + \eta_\omega \int_{\Omega_z} [\delta \mathcal{E}_{f\phi}]^\top [k_x^{\phi\phi}] [\mathcal{E}_{f\phi}] dz = \\ - \sum_{i=1}^{n-1} \left(\theta_\omega^{g^i} \int_{\Omega_z} [\delta \mathcal{E}_{f\phi}]^\top [\sigma_x^{\phi f^i}] dz - \eta_\omega^i \int_{\Omega_z} [\delta \mathcal{E}_{f\phi}]^\top [\sigma_x^{\phi\phi^i}] dz \right) \quad (34b) \end{aligned}$$

where the coefficients integrated in the Ω_x domain are

$$\begin{aligned} [k_x^{ff}(\tilde{v})] &= \int_{\Omega_x} [\tilde{\Sigma}_x]^\top [C] [\tilde{\Sigma}_x] dx, & [k_x^{f\phi}(\tilde{v}, \tilde{v}_\phi)] &= \int_{\Omega_x} [\tilde{\Sigma}_x]^\top [e]^\top [\tilde{\Sigma}_x^\phi] dx, \\ [k_x^{\phi f}(\tilde{v}, \tilde{v}_\phi)] &= \int_{\Omega_x} [\tilde{\Sigma}_x^\phi]^\top [e] [\tilde{\Sigma}_x] dx, & [k_x^{\phi\phi}(\tilde{v}_\phi)] &= \int_{\Omega_x} [\tilde{\Sigma}_x^\phi]^\top [\epsilon] [\tilde{\Sigma}_x^\phi] dx \quad (35) \end{aligned}$$

$$\begin{aligned} [\sigma_x^{ff^i}(\tilde{v}, \tilde{u})] &= \int_{\Omega_x} [\tilde{\Sigma}_x]^\top [C] [\tilde{\Sigma}_x^i] [\tilde{\mathcal{E}}_f^i] dx, & [\sigma_x^{f\phi^i}(\tilde{v}, \tilde{\phi})] &= \int_{\Omega_x} [\tilde{\Sigma}_x]^\top [e]^\top [\tilde{\Sigma}_x^i] [\tilde{\mathcal{E}}_{f\phi}^i] dx, \\ [\sigma_x^{\phi f^i}(\tilde{v}_\phi, \tilde{\phi})] &= \int_{\Omega_x} [\tilde{\Sigma}_x^\phi]^\top [e] [\tilde{\Sigma}_x^i] [\tilde{\mathcal{E}}_f^i] dx, & [\sigma_x^{\phi\phi^i}(\tilde{v}_\phi, \tilde{u})] &= \int_{\Omega_x} [\tilde{\Sigma}_x^\phi]^\top [\epsilon] [\tilde{\Sigma}_x^i] [\tilde{\mathcal{E}}_{f\phi}^i] dx \quad (36) \end{aligned}$$

$$[m_x(\tilde{v})] = \int_{\Omega_x} [\tilde{V}]^\top \rho [\tilde{V}] dx, \quad [\mu_x^i(\tilde{v}, \tilde{u})] = \int_{\Omega_x} [\tilde{V}]^\top \rho [\tilde{V}^i] [\tilde{f}^i] dx \quad (37)$$

$$[f_x(\tilde{v})] = \int_{\partial_F \Omega_x} [\tilde{V}]^\top [f_d] dx \quad (38)$$

and the ones integrated in the load frequency domain are

$$\begin{aligned} \gamma_\omega = \int_{\omega} \tilde{g}^2 d\omega, \quad \gamma_\omega^i = \int_{\omega} \tilde{g} \tilde{g}^i d\omega, \quad \alpha_\omega = \int_{\omega} \omega^2 \tilde{g}^2 d\omega, \quad \alpha_\omega^i = \int_{\omega} \omega^2 \tilde{g} \tilde{g}^i d\omega, \quad \beta_\omega = \int_{\omega} \tilde{g} d\omega, \\ \theta_\omega = \int_{\omega} \tilde{g} \tilde{g}_\phi d\omega, \quad \theta_\omega^{g\phi^i} = \int_{\omega} \tilde{g} \tilde{g}_\phi^i d\omega, \quad \theta_\omega^{\phi g^i} = \int_{\omega} \tilde{g}_\phi \tilde{g}^i d\omega, \quad \eta_\omega = \int_{\omega} \tilde{g}_\phi^2 d\omega, \quad \eta_\omega^i = \int_{\omega} \tilde{g}_\phi \tilde{g}_\phi^i d\omega \quad (39) \end{aligned}$$

The variational problem defined by Eq. (34) is a linear expression that must be solved in the Ω_z domain.

3.5 Variational problem defined on Ω_x : Step 3

The problem in the Ω_x domain is analogous to the one presented in the previous section for the domain Ω_z . At this step, the functions $g^{(m+1)}, [f^{(m+1)}], g_\phi^{(m+1)}, f_\phi^{(m+1)}$, which are assumed to be known, will be denoted as $\tilde{g}, \tilde{f}, \tilde{g}_\phi, \tilde{f}_\phi$ and the functions $[v^{(m+1)}], v_\phi^{(m+1)}$ to be computed will be denoted as v, v_ϕ .

With the expression of the strain being $[\varepsilon(\tilde{g} \tilde{f} v)] = \tilde{g} [\Sigma_z(\tilde{f})][\mathcal{E}_v]$, and the electric field $[E(\tilde{g}_\phi \tilde{f}_\phi v_\phi)] = \tilde{g}_\phi [\Sigma_z^{\phi}(\tilde{f}_\phi)][\mathcal{E}_{v_\phi}]$, the variational problem defined on Ω_x becomes

$$\begin{aligned} \gamma_\omega \int_{\Omega_x} [\delta \mathcal{E}_v]^\top [k_x^{vv}] [\mathcal{E}_v] dx - \theta_\omega \int_{\Omega_x} [\delta \mathcal{E}_v]^\top [k_x^{v\phi}] [\mathcal{E}_{v_\phi}] dx - \alpha_\omega \int_{\Omega_x} [\delta v]^\top [m_x] [v] dx = \\ \beta_\omega \int_{\partial_v \Omega_x} [\delta v]^\top [v_x] dx + \sum_{i=1}^{n-1} \left(\alpha_\omega^i \int_{\Omega_x} [\delta v]^\top [\mu_x^i] dx - \gamma_\omega^i \int_{\Omega_x} [\delta \mathcal{E}_v]^\top [\sigma_x^{vv^i}] dx \right. \\ \left. + \theta_\omega^{g\phi^i} \int_{\Omega_x} [\delta \mathcal{E}_v]^\top [\sigma_x^{v\phi^i}] dx \right) \quad (40a) \end{aligned}$$

$$\begin{aligned} \theta_\omega \int_{\Omega_x} [\delta \mathcal{E}_{v_\phi}]^\top [k_x^{\phi v}] [\mathcal{E}_v] dx + \eta_\omega \int_{\Omega_x} [\delta \mathcal{E}_{v_\phi}]^\top [k_x^{\phi\phi}] [\mathcal{E}_{v_\phi}] dx = \\ - \sum_{i=1}^{n-1} \left(\theta_\omega^{\phi g^i} \int_{\Omega_x} [\delta \mathcal{E}_{v_\phi}]^\top [\sigma_x^{\phi v^i}] dx - \eta_\omega^i \int_{\Omega_x} [\delta \mathcal{E}_{v_\phi}]^\top [\sigma_x^{\phi\phi^i}] dx \right) \quad (40b) \end{aligned}$$

where the coefficients integrated in the load frequency domain are expressed by Eq. (39) and those integrated in the Ω_z domain are analogous to the ones presented before for Ω_x domain.

4 FINITE ELEMENT DISCRETIZATION

To numerically compute the solution, a discrete representations of functions $g, [f], [v], g_\phi, f_\phi, v_\phi$ is needed. For the load frequency domain, a uniform discretization of the interval $[\omega_{min}, \omega_{max}]$ is established. The size of the discrete functions g, g_ϕ associated with the mesh in the load frequency domain is denoted as n_ω . The trapezoidal rule is used for the approximation of the integrals involving these functions as in Eq. (39). On the other hand, a classical finite element approximation is used in domains Ω_x and Ω_z . The element vectors of degrees of freedoms (dofs) associated with the mesh in Ω_x and Ω_z are $[q_e^v], [q_e^{v\phi}]$ and $[q_k^f], [q_k^{f\phi}]$ respectively. The displacement field, the electric potential and also the derived strain and electric fields are expressed by

$$[v_e] = [N_x][q_e^v], \quad [\mathcal{E}_v^e] = [B_x][q_e^v], \quad [v_{\phi_e}] = [N_{\phi x}][q_e^{v\phi}], \quad [E_{v_\phi}^e] = [B_{\phi x}][q_e^{v\phi}] \quad (41)$$

$$[f_k] = [N_z][q_k^f], \quad [\mathcal{E}_f^k] = [B_z][q_k^f], \quad [f_{\phi_k}] = [N_{\phi z}][q_k^{f\phi}], \quad [E_{f_\phi}^k] = [B_{\phi z}][q_k^{f\phi}] \quad (42)$$

where the matrices $[N_x], [B_x], [N_z], [B_z], [N_{\phi x}], [B_{\phi x}], [N_{\phi z}], [B_{\phi z}]$ contain the shape functions, their derivatives and the Jacobian components. The total number of elements in $\Omega_x = \bigcup_{e=1}^{n_x} \Omega_x^e$ and $\Omega_z = \bigcup_{k=1}^{n_z} \Omega_z^k$ domains are denoted as n_x and n_z , respectively. The interpolation can be different for each domain and also for the mechanical and electric unknowns separately.

The introduction of the FE discretization in the Eq. (34) lead to the electro-mechanical linear system

$$\left(\begin{bmatrix} K_{ff} & -K_{ff\phi} \\ -K_{f\phi f} & -K_{f\phi\phi} \end{bmatrix} - \begin{bmatrix} M_f & 0 \\ 0 & 0 \end{bmatrix} \right) \begin{bmatrix} q^f \\ q^{f\phi} \end{bmatrix} = \begin{bmatrix} F_f \\ 0 \end{bmatrix} + \begin{bmatrix} R_f \\ R_{f\phi} \end{bmatrix} \quad (43)$$

where

- $[q^f], [q^{f\phi}]$ are the vector of dofs associated with the finite element mesh in Ω_z for the mechanical and electric unknowns respectively.
- $[K_{ff}], [K_{ff\phi}], [K_{f\phi f}], [K_{f\phi f\phi}]$ are the stiffness, electro-mechanical and electric matrices obtained by assembling the elementary matrices $[K_{ff}^k], [K_{ff\phi}^k], [K_{f\phi f}^k], [K_{f\phi f\phi}^k]$.

$$[K_{ff}^k(\tilde{v})] = \gamma_\omega \int_{\Omega_z^k} [B_z]^\top \left[\sum_{e=1}^{n_x} [k_x^{ff}(\tilde{v}_e)] \right] [B_z] dz \quad (44)$$

$$[K_{ff\phi}^k(\tilde{v}, \tilde{v}_\phi)] = \theta_\omega \int_{\Omega_z^k} [B_z]^\top \left[\sum_{e=1}^{n_x} [k_x^{f\phi}(\tilde{v}_e, \tilde{v}_{\phi_e})] \right] [B_{\phi z}] dz \quad (45)$$

$$[K_{f\phi f}^k(\tilde{v}, \tilde{v}_\phi)] = \theta_\omega \int_{\Omega_z^k} [B_{\phi z}]^\top \left[\sum_{e=1}^{n_x} [k_x^{\phi f}(\tilde{v}_e, \tilde{v}_{\phi_e})] \right] [B_z] dz \quad (46)$$

$$[K_{f\phi f\phi}^k(\tilde{v}_\phi)] = \eta_\omega \int_{\Omega_z^k} [B_{\phi z}]^\top \left[\sum_{e=1}^{n_x} [k_x^{\phi\phi}(\tilde{v}_{\phi_e})] \right] [B_{\phi z}] dz \quad (47)$$

- $[M_f]$ is the mass matrix obtained by assembling the elementary mass matrices $[M_f^k]$.

$$[M_f^k(\tilde{v})] = \alpha_\omega \int_{\Omega_z^k} [N_z]^\top \left[\sum_{e=1}^{n_x} [m_x(\tilde{v}_e)] \right] [N_z] dz \quad (48)$$

- $[F_f]$ is the load vector obtained by assembling the elementary load vectors $[F_f^k]$.

$$[F_f^k(\tilde{v})] = \beta_\omega \int_{\partial_F \Omega_z^k} [N_z]^\top \left[\sum_{e=1}^{n_x} [f_x(\tilde{v}_e)] \right] dz \quad (49)$$

- $[R_f], [R_{f\phi}]$ are the equilibrium and electric residuals respectively, obtained by assembling the elementary residual vectors $[R_f^k], [R_{f\phi}^k]$.

$$[R_f^k(\tilde{v}, \bar{u}, \bar{\phi})] = \sum_{i=1}^{n-1} \left(\theta_\omega^{g\phi^i} \int_{\Omega_z^k} [B_z]^\top \left[\sum_{e=1}^{n_x} [\sigma_x^{f\phi^i}(\tilde{v}_e, \bar{\phi})] \right] dz - \gamma_\omega^i \int_{\Omega_z^k} [B_z]^\top \left[\sum_{e=1}^{n_x} [\sigma_x^{ff^i}(\tilde{v}_e, \bar{u})] \right] dz + \alpha_\omega^i \int_{\Omega_z^k} [N_z]^\top \left[\sum_{e=1}^{n_x} [\mu_x^i(\tilde{v}_e, \bar{u})] \right] dz \right) \quad (50)$$

$$[R_{f\phi}^k(\tilde{v}_\phi, \bar{u}, \bar{\phi})] = \sum_{i=1}^{n-1} \left(\theta_\omega^{g\phi^i} \int_{\Omega_z^k} [B_{\phi z}]^\top \left[\sum_{e=1}^{n_x} [\sigma_x^{\phi f^i}(\tilde{v}_{\phi_e}, \bar{\phi})] \right] dz + \eta_\omega^i \int_{\Omega_z^k} [B_{\phi z}]^\top \left[\sum_{e=1}^{n_x} [\sigma_x^{\phi\phi^i}(\tilde{v}_{\phi_e}, \bar{u})] \right] dz \right) \quad (51)$$

Analogously, the introduction of the FE discretization in the Eq. (40) lead to the electro-mechanical linear system

$$\left(\begin{bmatrix} K_{vv} & -K_{vv\phi} \\ -K_{v\phi v} & -K_{v\phi v\phi} \end{bmatrix} - \begin{bmatrix} M_v & 0 \\ 0 & 0 \end{bmatrix} \right) \begin{bmatrix} q^v \\ q^{v\phi} \end{bmatrix} = \begin{bmatrix} F_v \\ 0 \end{bmatrix} + \begin{bmatrix} R_v \\ R_{v\phi} \end{bmatrix} \quad (52)$$

where the components of the linear system have an interpretation similar to that already presented.

5 MODELING ENERGY HARVESTER CONFIGURATION

The most popular energy harvester configuration is the bimorph cantilever connected to an electric load (usually a resistor) in series (see Figure 2). For this to be possible, very thin electrodes are deposited on the piezoelectric layers. The mechanical influence of these electrodes can be considered negligible but in the electric field they impose equipotential conditions. In order to incorporate circuit elements (e.g. the electric load) on the problem formulation, the *equivalent capacitance matrix* can be used as in [7]. This method consists on adding a so-called equivalent capacitance matrix to the dielectric matrix of the problem; the one that involves the dielectric matrix $[\epsilon]$. This new matrix is formulated as follows: for each circuit element l connected between the i th and j th components, define a vector $[V_l]$ of size of the electrical unknowns whose components are all null except the i th and j th whose values are 1 and -1 respectively. The equivalent capacitance matrix of element l is defined as $-j/\omega \tilde{Z}_l [V_l][V_l]^\top$, with j de imaginary number and $\tilde{Z}_l = -Z_l$ if l is a capacitor or $\tilde{Z}_l = Z_l$ if l is a resistor/inductor, being Z_l the impedance of l .

Figure 2: Energy harvester configuration: bimorph cantilever with a resistor in series.

For a classical energy harvester configuration connected to a single resistor in series, electrodes 2 and 3 are grounded, while a resistor of impedance R is connected between electrodes 1 and 4 as in Figure 2. As these conditions are established for a constant coordinate z , the equivalent capacitance matrix is introduced in Eq. (43), where $K_{f_\phi f_\phi}$ is redefined as $K_{f_\phi f_\phi} + \hat{K}_{f_\phi f_\phi}$, with

$$\hat{K}_{f_\phi f_\phi} = -\lambda_\omega \frac{j}{R} [V][V]^\top \quad (53)$$

where $\lambda_\omega = \int_\omega 1/\omega d\omega$.

6 CONCLUSIONS

This research work proposed a new methodology based on the PGD method to solve the forced vibration problem in bi-dimensional piezoelectric composite beams. A classical harmonic space-frequency description of the dynamic problem is considered and a variable separation in the spatial domain is introduced. For both spatial coordinates x (beam axis coordinate) and z (thickness coordinate), a finite element discretization is applied while a linear interpolation is proposed for the load frequency ω . The new approach is developed though an iterative algorithm in which the problem to be solved is split into three 1D problems: one associated to the load frequency ω , one associated with the z coordinate and the other associated to the x coordinate, . The number of dofs of the two last problems can be given as

- Problem on Ω_z : $Ndof_z^M = 2(n_z(N_z^M - 1) + 1)$, $Ndof_z^E = n_z(N_z^E - 1) + 1$.
- Problem on Ω_x : $Ndof_x^M = 2(n_x(N_x^M - 1) + 1)$, $Ndof_x^E = n_x(N_x^E - 1) + 1$.

where n_x, n_z are the total number of elements and $N_x^M, N_z^M, N_x^E, N_z^E$ are the number of nodes per element in Ω_x and Ω_z domains respectively. The superscripts M and E accounts for the interpolation of the mechanical and electrical unknowns. The total cost of the computation depends on the number of enrichment steps N used to represent the final solution. Furthermore, the proposed process requires, for each enrichment step, m iterations of the fixed point method which involves the resolution of one equation with n_ω unknowns and two linear systems of $Ndof_x$ and $Ndof_z$ dofs respectively. In contrast, in a classical layerwise FE approach, the calculation implies n_ω resolutions with $\frac{Ndof_x \times Ndof_z}{2}$ dofs. The advantages of the proposed approach in terms of the reduction of the computational cost become relevant when the number of numerical layers and the number of elements in axis direction is high. The most immediate future extensions of this document would involve parametric comparative studies of different laminates configurations for energy harvesting purposes to validate the proposed method.

Key words: Continuum robot, Pneumatic artificial muscles, Bio-inspired

Abstract. Continuum robotic manipulators are those that continuously bend to interact with unexpected objects in various orientations. These robots are typically extensions of hyper-redundant robot and more recently being built completely soft material, soft robots. Hyper-redundant robots by definition have a large number of joints and actuators, leading to heavy designs. Conversely, soft robots attempt to overcome this limitation, by using lightweight, low stiffness materials which deform to eliminate joints. The downside of these low stiffness materials, is a reduction in load capacity of these manipulator. This work studies a three section contractile pneumatic artificial muscles actuated manipulator. PAMs were chosen for their high force and stroke behavior. The arm is compared with a second version achieved by adding an ossicle-inspired structure similar to those found in the arms of sea-stars, with the goal of increasing the load capability of a multi-section pneumatic artificial muscle actuated manipulator. This work considers the planar projection of the workspace of the manipulator with and without ossicles. The pneumatic muscles are actuated in various loading conditions to determine the impact of load on the position of the end of the manipulator. With ossicles there is a benefit to the load carrying capability without sacrificing load performance.

1 INTRODUCTION

Soft robots are an emerging field of robotics which lack the rigid structure of traditional manipulators. Like hyper-redundant manipulators, soft robots are used for their flexibility and ability to conform to unexpected shapes. Soft robots have been used for crawling with smart material actuators [11] and grasping with pneumatic actuation such as the PneuNets [5] and pneumatic artificial muscles (PAMs) [7]. PAMs have been used in numerous rigid robot arms [15], legs [3], and non-robotic applications like trailing edge flaps [17].

Pneumatic artificial muscles are soft actuators composed of a braided sleeve surrounded by an elastomeric bladder, which either extends or contracts when pressurized [10]. The soft nature of PAMs makes them a natural choice for a soft robotic manipulator, having been used in soft robotic manipulators constructed of both extensile [12] and contractile [1] PAMs. Contractile PAMs were chosen in this work due to the higher force and work output that they achieve [13]. A tendency of PAM actuated soft robotics arms is to deform in less desirable ways as a result of the compliant nature of the inactive actuators. For example, the extensile PAM arm has points along the muscle groups connected to prevent this undesired

motion [12]. To achieve a similar goal, structures similar in function to the ossicles found on brittle stars are added to the contractile PAM manipulator and evaluated.

In soft robotics, there is interest in taking existing actuators and externally augmenting their structure to provide a new desired behavior [6]. Galloway et al. added an exterior sleeve to the bending fiber-reinforced actuators to control and limit the bending to a subset of shapes, which can approach joint-like structures with certain sleeve designs. These actuators were incorporated into a gripper that could more securely grasp desired shapes such as boxes [6]. Deimel and Brock present a tapered pneumatic fiber-reinforced actuator, PneuFlex, used on a soft hand which can complete a variety of different grasps with five finger and two palm actuators [4]. Additionally, Galloway et al. developed two soft grippers comprised of fiber-reinforced hydraulic actuators for deep sea sampling [5]. The first is an actuator that couples bending and twisting by incorporating a single fiber reinforcement to wrap around an object, and the second takes the PneuNet bellows actuators and incorporates fiber reinforcements to increase the pressure capability.

Soft robot modeling is based on the hyper-redundant robot modeling approximation as a continuum [2]. This can be applied as a geometrically exact continuous model [14] or there can be simplifying assumptions, such as constant curvature [18]. Tatlicioglu et al. calculated the planar dynamic model using the constant curvature assumption for a three-section PAM manipulator. The model developed includes gravitational energy as well as the energy to extend and bend a segment. The energies were integrated over each section of the arm to find the total energy and calculate the Lagrangian dynamics [16].

Constant curvature methods are calculated in terms of state variables of section curvature, bending plane, and length, but for a three actuator intrinsic manipulator, there is not direct control of these values. To develop models in terms of the control lengths and forces of the muscles, Godage et al. introduced shape functions based on the polynomial relationships between the length of the actuators for a PAM actuated continuum robot [8]. The expansions used in that work allow the mathematical singularity associated with a straight arm configuration to be avoided. This work was extended by considering the center of gravity of the section assuming uniform weight distribution. The formulation compared the total energy to both the integral and discretized formulations for a single section, applying a mass correction factor of $1/0.57$ [9].

This work investigates a three-section PAM manipulator and studies the effect of adding an ossicle-inspired backbone to the arm. For a single section the addition of ossicles has been shown to improve the load capabilities of a PAM actuated structure. The manipulator is tested through five different muscle combinations with five load conditions at each. The manipulator is also tested and modeled both with, and without, ossicles to evaluate the effect of adding this structure.

The ossicle structure was designed to interact and limit bending at approximately 45° , a similar model could be incorporated at angles above the design value to improve the model at high angles for the medial and distal sections. To improve modeling and reduce the effects of non-active PAMs, the ossicle structure could be sized such that the PAMs are contracted and pressurized when in a straight arm position, allowing the initial stiffness of the system to be tailored to the desired application. Additionally operation in environments which reduce gravitational impact, space or water, would be beneficial. One way to improve model fitting is improving PAM modeling in the low force and pressure regime. Solutions include a low and high pressure model, higher order PAM modeling or additional considerations of effects on PAM behavior, such as bending.

2 Constant Curvature Modeling

The manipulator modeled in this work has three bending sections connected at rigid plates, Fig 1. Each section has three PAMs which are offset by 120° . The section break between each section and at the end

of the arm is defined by the rigid PAM end fittings and the rigid plate to which the PAM are secured. These rigid section dividers also serve as a point of measurement for the poses at the beginning and end of a section. The modeling done in this work used the constant curvature assumption in each bending section, and then calculates the center of masses for the section as well as the rigid section breaks. The energies at these center of masses are calculated to find the Lagrangian dynamics with respect to the PAM lengths. This work assumed the weight of each section is evenly distributed throughout that section. The ossicle weight is assumed to be part of the bending section, but no additional influence of the ossicles is modeled.

Figure 1: Three section arm with ossicles installed.

Constant curvature kinematics appear in the review by Webster [18]. The constant curvature modeling equations are expressed for the position and orientation of section i , where section $i = 1$ is the proximal section. The rotation of the section is oriented so that the x-axis is in the same plane at the beginning and end of each section.

$$p_{CC_i}(s) = \begin{bmatrix} h_i \cos \phi_i \frac{1 - \cos \theta_i s}{\theta_i} \\ h_i \sin \phi_i \frac{1 - \cos \theta_i s}{\theta_i} \\ h_i \frac{\sin \theta_i s}{\theta_i} \end{bmatrix} \quad (1)$$

$$R_{CC_i} = \begin{bmatrix} \cos^2 \phi_i (\cos \theta_i - 1) + 1 & \sin \phi_i \cos \phi_i (\cos \theta_i - 1) & \cos \phi_i \sin \theta_i \\ \sin \phi_i \cos \phi_i (\cos \theta_i - 1) & \sin^2 \phi_i (\cos \theta_i - 1) + 1 & \sin \phi_i \sin \theta_i \\ -\cos \phi_i \sin \theta_i & -\sin \phi_i \sin \theta_i & \cos \theta_i \end{bmatrix} \quad (2)$$

Expressions for the section length, l , bending angle, θ , and plane of bending, ϕ . A 2D representation of the proximal section orientation is shown in Fig. 2 with a point mass after $s = 1$ representing the concentration of mass of the section plate. For the distal section this mass would also include any added mass during experimental testing.

The bending plane expression changes based on the orientation of the PAMs relative to the section definition. The derivation method of ϕ for different PAM orientations can be found in the Constant Curvature Review [18]. The first and third section have PAM $i1$ on the positive x-axis, and the second section has PAM $i2$ on the negative x-axis.

Figure 2: Single section orientation used in this work. Gravity acts in the positive \hat{z}_0 direction and ϕ_i is a rotation about \hat{z}_{i-1} .

$$h_i = h_{i0} + \frac{l_{i1} + l_{i2} + l_{i3}}{3} \quad (3)$$

$$\theta_i = \frac{2\sqrt{l_{i1}^2 + l_{i2}^2 + l_{i3}^2 - l_{i1}l_{i2} - l_{i1}l_{i3} - l_{i2}l_{i3}}}{3r_i} \quad (4)$$

$$\phi_{i=1,3} = \tan^{-1} \left(\frac{\sqrt{3}(l_{i2} - l_{i3})}{(l_{i2} + l_{i3} - 2l_{i1})} \right) \quad (5)$$

$$\phi_{i=2} = \tan^{-1} \left(\frac{\sqrt{3}(l_{i3} - l_{i1})}{(2l_{i2} - l_{i3} - l_{i1})} \right) \quad (6)$$

Identities for $\sin(\tan^{-1})$ and $\cos(\tan^{-1})$ can be used to rewrite the expressions in terms of PAM lengths and remove a number of the trigonometric functions from the expressions for position and orientation.

$$\sqrt{x_i^2 + y_i^2} = 2\sqrt{l_{i1}^2 + l_{i2}^2 + l_{i3}^2 - l_{i1}l_{i2} - l_{i1}l_{i3} - l_{i2}l_{i3}} = 3r_i\theta \quad (7)$$

$$p_{CC_i}(s) = \begin{bmatrix} \frac{h_i x_i}{3r_i} \frac{1 - \cos \theta_i s}{\theta_i^2} \\ \frac{h_i y_i}{3r_i} \frac{1 - \cos \theta_i s}{\theta_i^2} \\ h_i \frac{\sin \theta_i s}{\theta_i} \end{bmatrix} \quad (8)$$

$$R_{CC_i} = \begin{bmatrix} 1 + \frac{x_i^2}{9r_i^2} \frac{\cos \theta_i - 1}{\theta_i^2} & \frac{x_i y_i}{9r_i^2} \frac{\cos \theta_i - 1}{\theta_i^2} & \frac{x_i}{3r_i} \frac{\sin \theta_i}{\theta_i} \\ \frac{x_i y_i}{9r_i^2} \frac{\cos \theta_i - 1}{\theta_i^2} & 1 + \frac{y_i^2}{9r_i^2} \frac{\cos \theta_i - 1}{\theta_i^2} & \frac{y_i}{3r_i} \frac{\sin \theta_i}{\theta_i} \\ -\frac{x_i}{3r_i} \frac{\sin \theta_i}{\theta_i} & -\frac{y_i}{3r_i} \frac{\sin \theta_i}{\theta_i} & \cos \theta_i \end{bmatrix} \quad (9)$$

A Taylor expansion can be performed on the resulting functions of θ leaving the pose of the section in terms of only the PAM lengths. These expressions are differentiable and can be used to find the velocities of the center of gravities of the soft section as well as the rigid end plates.

The center of mass of a section can be found by integrating the position through the section, the integrals of these Taylor expandable functions can be used to find the position with a polynomial function of PAM lengths. The center of mass formulation is inspired by the work of Godage et al. [9], but this

work separates the effect of the break between sections where a large amount of the mass is located from the continuously bending lightweight PAM section.

$$\beta_i = \int_0^1 p_{CC_i} ds = \begin{bmatrix} \frac{h_i x_i}{3r_i} \int_0^1 \frac{1 - \cos \theta_i s}{\theta_i^2} \\ \frac{h_i y_i}{3r_i} \int_0^1 \frac{1 - \cos \theta_i s}{\theta_i^2} \\ h_i \int_0^1 \frac{\sin \theta_i s}{\theta_i} \end{bmatrix} \quad (10)$$

$$\frac{1 - \cos \theta_i s}{\theta_i^2} = -\frac{s^2}{2} + \frac{\theta_i^2 s^4}{24} - \frac{\theta_i^4 s^6}{720} + O(\theta_i^6 s^8) \quad (11)$$

$$\frac{\sin \theta_i s}{\theta_i} = s - \frac{\theta_i^2 s^3}{6} + \frac{\theta_i^4 s^5}{120} + O(\theta_i^6 s^7) \quad (12)$$

The positions of the center of masses of the bending sections, p_{β_i} , and non-bending section breaks, p_{M_i} can be found with the following equations, where p_i is the end of the i^{th} bending section and section divider, and $p_{M_{icli}}$ is the position of the end of the section divider with respect to the end of the previous section.

$$p_i = p_{CC_i}(1) + R_{CC_i} p_{M_{icli}} \quad (13)$$

$$p_{\beta_1} = \beta_1 \quad (14)$$

$$p_{\beta_2} = p_1 + R_{CC_1} \beta_2 \quad (15)$$

$$p_{\beta_3} = p_1 + R_{CC_1} p_2 + R_{CC_1} R_{CC_2} \beta_3 \quad (16)$$

$$p_{M_1} = p_{CC_1}(1) + \frac{1}{2} R_{CC_1} p_{M_{icli}} \quad (17)$$

$$p_{M_2} = p_1 + R_{CC_1} p_{CC_2}(1) + \frac{1}{2} R_{CC_1} R_{CC_2} p_{M_{icli}} \quad (18)$$

$$p_{M_3} = p_1 + R_{CC_1} p_2 + R_{CC_1} R_{CC_2} p_{CC_3}(1) + \frac{1}{2} R_{CC_1} R_{CC_2} R_{CC_3} p_{M_{icli}} \quad (19)$$

The partial derivatives with respect to the change in length can be taken to form the Jacobian relationship of the point velocity to the PAM velocities. The Jacobians can be used to find the gravity vector, G ,

$$G = \frac{\partial V_E}{\partial l} = (J_{\beta_1} m_1 + J_{\beta_2} m_2 + J_{\beta_3} m_3 + J_{M_1} M_1 + J_{M_2} M_2 + J_{M_3} M_3)^T \begin{bmatrix} 0 \\ 0 \\ g \end{bmatrix} \quad (20)$$

and can be related to the PAM force

$$G(l) = F(L_0, l, P) \quad (21)$$

the PAM force model is modeled according Pillsbury et al. [13]. Additional sources of potential energy not captured by the PAM force model such as the bending energy to bend pressurized PAMs could be further investigated to improve the model fit if necessary.

Dynamic validation will be required in the future, but as a initial step quasi-static validation of this model will be conducted using the arm with ossicles. The arm with ossicles will also be compared to an ossicle-free arm.

3 Testing of Ossicle Arm

The three section arm with three PAMs per section was experimentally evaluated with and without an ossicle-inspired structure running the length of each section. The arm was tested in five configurations that sweep out all the single muscle per section motions. For evaluating the performance, any additional single muscle combinations are mirrored by the ones tested in this study. The PAMs were manually pressurized beginning with the most distal section, then the medial section and finally the proximal section. The depressurization was done in the reverse order, proximal, medial, then distal. The order was chosen to minimize effects of unactuated PAMs in the more distal sections. The series of test were conducted with and without ossicles. The distal sections of the appendage have been previously compared by considering the angle achieved at the end of the section under load, but this comparison is complicated for multi-section appendages due to differences in the behavior of distal sections effecting the proximal sections. To compare the two cases the area traced by the tip will be compared at each load case. This captures the cumulative effect of the ossicles throughout the arm.

3.1 Model Validation

To validate the modeling techniques the average pressure versus angle was compared to the average modeled pressure for that angle. The average error was calculated separately for each section and load case and averaged over the five tests. The model output was calculated using the positions and PAM length determined from the experimental data. The model performs best for low loads and more distal sections, Fig. 3. Figure 4 shows the modeling results for the distal section with no weight the medial section with the max test load of 250 g, and the proximal section with 100 g.

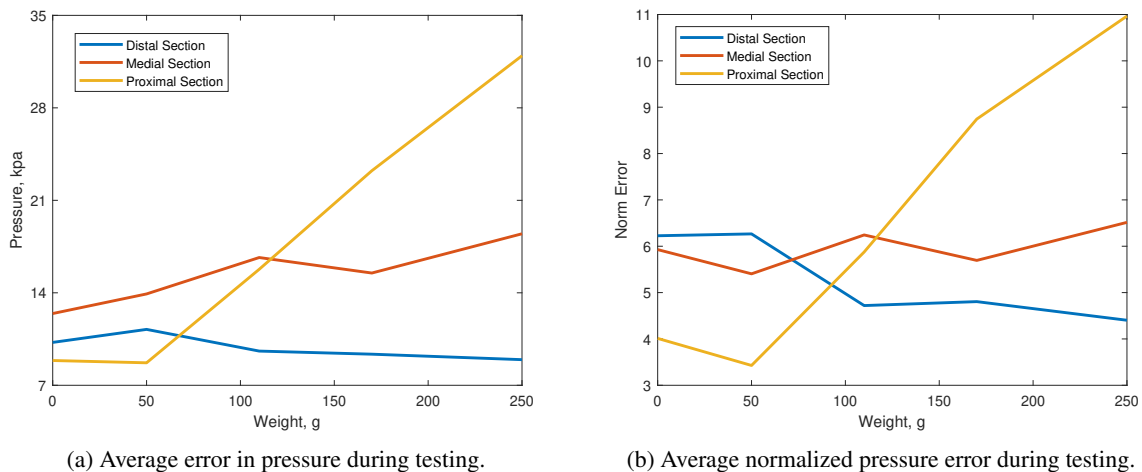

Figure 3: Modeling errors for all five test cases across all five loading conditions.

The ossicle structure was designed to interact and limit bending at approximately 45° , a similar model could be incorporated at angles above the design value to improve the model at high angles for the medial and distal sections. To improve modeling and reduce the effects of non-active PAMs, the ossicle structure could be sized such that the PAMs are contracted and pressurized when in a straight arm position, allowing the initial stiffness of the system to be tailored to the desired application. Additionally operation in environments which reduce gravitational impact, space or water, would be beneficial. One way to improve

(a) Distal section with no load.

(b) Medial section with 250 g of weight.

(c) Proximal section with 110 g of weight at the tip.

Figure 4: Angle pressure relationship modeling results for three test cases.

model fitting is improving PAM modeling in the low force and pressure regime. Solutions include a low and high pressure model, higher order PAM modeling or additional considerations of effects on PAM behavior, such as bending.

3.2 Effect of Ossicles

To study the effect of adding ossicles to the arm, the five motions that were tested can be rotated by 120° and 240° to represent the same combination of muscles for the other two proximal section PAMs. Four of the motions are non-planar and can be reflected about the plane of the proximal PAM, and then rotated for the remaining twelve motions. This procedure generates all 27 combinations of one active PAM per section. The procedure to track the tip position of the arm for a single motion is shown in a top down view in Fig. 5.

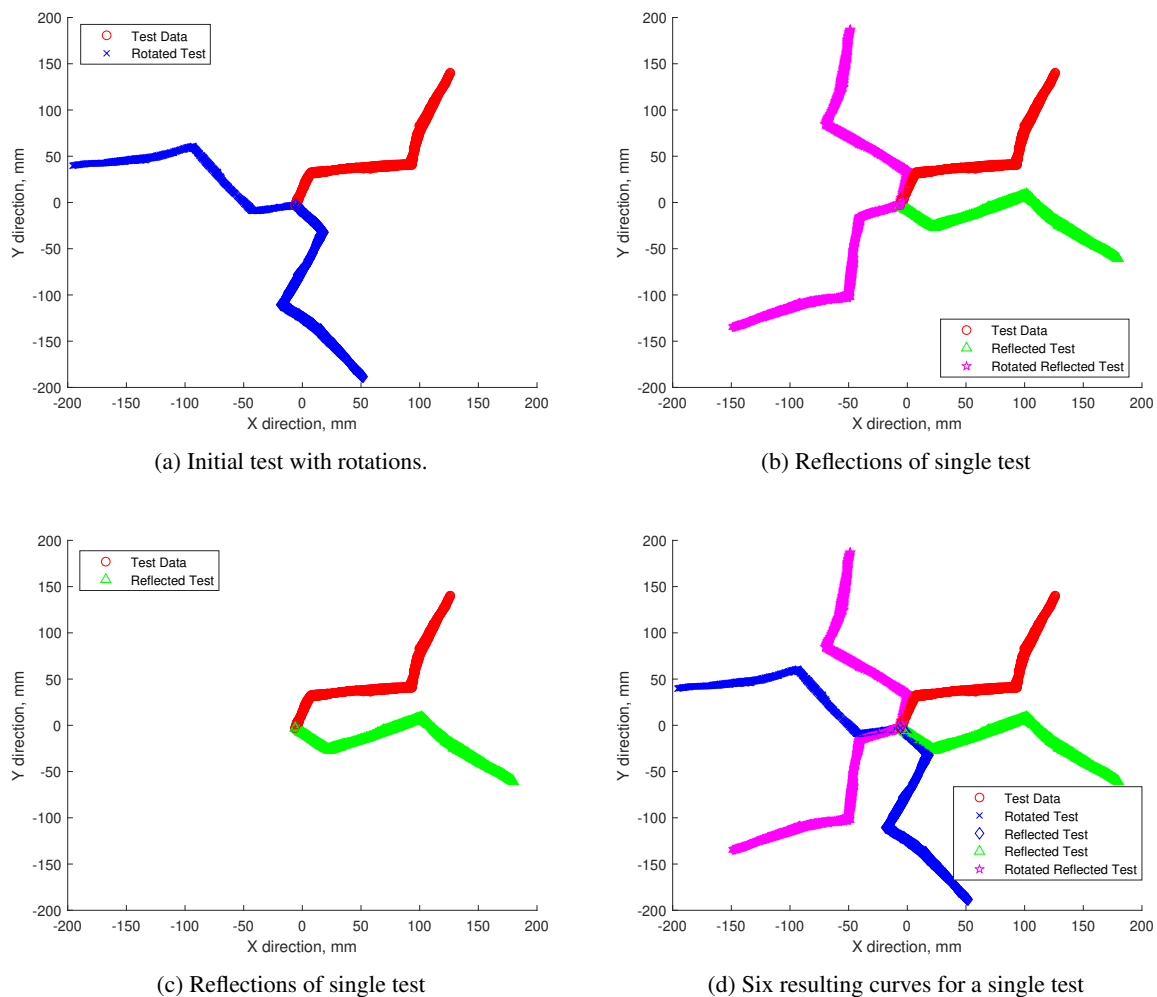

Figure 5: Procedure to construct other tip traces for untested muscle combinations.

This procedure was applied to both the ossicle and non-ossicle tests for each of the five loading conditions. Ossicles have been shown to improve the load capacity of a single section PAM soft robot. To

compare the cumulative effect of ossicles in each section, we consider the X-Y planar projection. This projection will be used to bound the area reached by the arm to compare the effect of adding ossicles. The boundary enclosing these curves were found using a shrink factor of $s = .091$. This shrink factor was chosen by performing a sweep of shrink factors from $s = 0$ to $s = 1$, where $s = 0$ represents a convex hull of the set of points. The chosen shrink factor provided the minimum area ratio for the unloaded test case. The planar projections for the zero load and 250 g load cases are shown in Fig. 6. The ratio of the areas comparing the effect of adding ossicles to the soft structure is shown for all five load cases in Fig. 7. The average area ratio in the no load case of the sweep conducted was 1.15.

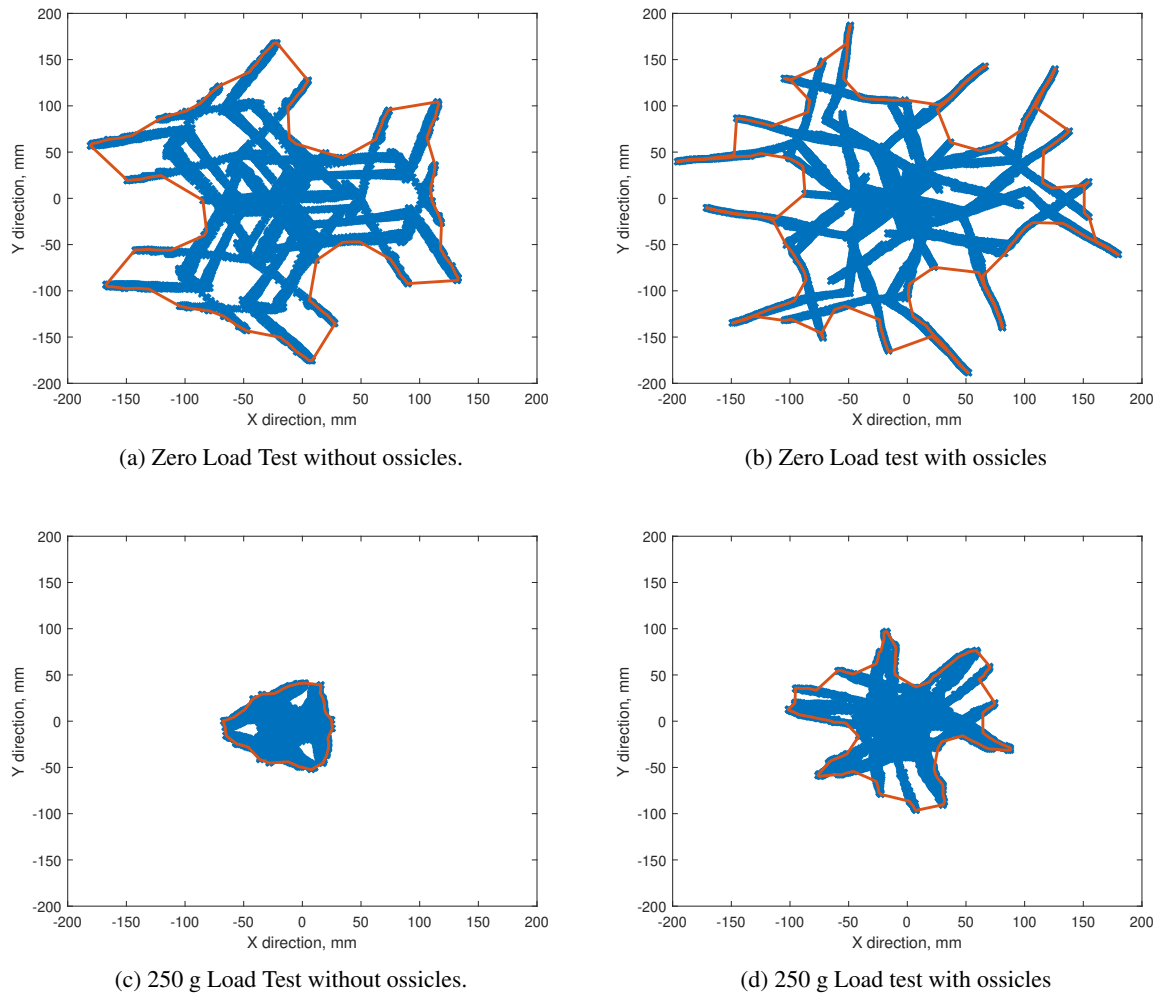

Figure 6: Planar view of test results for no load and highest load 250 g. Colors are consistent with Fig. 5, red is the boundary for the given shrink factor, blue is the processed data.

4 Conclusions

In this work a three section, nine PAM soft robotic manipulator constructed, modeled, and tested. This manipulator was tested with five different muscles combinations and five load cases to study the

(a) Bounded area for each load case with and without ossicles. (b) Ratio of bounded area of the ossicle test case compared to the no ossicle test case.

Figure 7: Effect of load on ossicle structure.

static model and effect of adding a bio-inspired ossicle structure. The constant curvature center of mass model developed was shown to work best at low loads and for the more distal sections. Improvements to PAM modeling and ossicle design should help improve the static modeling especially for the proximal section. Overall the addition of ossicles improved the ability of the manipulator to handle loads placed at the tip. When 250 g was hung from the end of the arm, the arm with ossicles was able to reach an area 2.6 times greater than that reached by the ossicle-free arm.

Abstract. Soft Robots achieve desired motion by deformation of their elastic links and offer the ability to adapt to unstructured environments and manipulate objects of varying sizes. Inherent elasticity and continuity allow for whole-arm operations such as grasping, wrapping, and lifting without damaging the manipulated object. In order to find the right base orientation and geometrical configuration of a continuum pneumatic arm (CPA) for tasks that require keeping the manipulated object at a fixed orientation, an approach to solve the forward kinematics and analyze the robot's workspaces is developed. The studied soft robotic arm is composed of multiple sections where each consists of three extensile pneumatic artificial muscles (PAMs) acting as both actuator and structure of the arm. The work includes analysis of the effective workspaces of the arm defined by points in space that the end-effector can reach, as well as fixed orientation workspaces (FOWs) defined by position of the end-effector at a given orientation. FOWs provide useful information for operations that require keeping manipulated object at constant angles such as in, e.g. boring, sealing, pushing/pulling handles or inserting bolts during on-site maintenance or repair of vehicles. The workspaces are characterized by metrics associated with their three-dimensional shape, volume and dexterity.

1 Introduction

Pneumatic artificial muscles (PAMs) are compliant actuators that offer high force-to-weight ratio and do not have any moving parts. PAMs are composed of elastomeric, tubular bladder surrounded by a braided sleeve and two end-fittings that seal the bladder and hold the sleeve's ends (Fig. 1). Once pressurized, PAMs contract or extend depending on the braid angle: contractile for angles larger than 35.26° , and extensile when the angles are smaller. Extensile PAMs (E-PAM) offer an advantage over contractile PAMs in terms of stroke. Theoretically, 200% extension can be achieved at the braid angle of 22° [12] although in practice for extensile McKibben muscles values up to 80% has been reported [6,8]. The exceptionally large stroke of extensile PAMs and relatively high force makes them a viable choice for continuum robots.

Figure 1: Overview of pneumatic artificial muscle

Continuum robots are bio-inspired robots which change their shape by contraction, extension and bending of actuators. So far, there have been numerous attempts to design a soft robotic arm that can grasp and lift objects. OctArm is one of the most comprehensively researched continuum pneumatic arms and it operates using three groups of pneumatic artificial muscles in order to move and be able to execute whole-arm operations [6]. An interesting extension of the continuum PAM-driven robot concept is to add ossicles [7] serving as a backbone-like structure which decrease required pressure to move loads and increase the maximum angle of section's curve (Fig. 2). One of the first tasks in the design process is to develop a robot's kinematics model. For continuum robots, some of the constant curvature models are: Jones Kinematic Model, Godage Kinematic Model, Allen Kinematic Model and Walker-Frazelle Approximation Model. Jones', Allen's, Walker-Frazelle assume piece-wise constant curvature of the robotic arm whereas Godage model approximates constant curvature with modal shape functions which makes the model numerically stable at all configurations [1,4]. Non-constant curvature models also exist, like those based on the Cosserat Rods theory [10]. When designing a continuum robot for a given set of tasks, it is important to know what moves the robot can conduct. At the time of writing, the OctArm has been one of few PAM-driven arms that have undergone dexterity and workspace analysis [9] or perhaps the only one. In this paper, we look into workspaces of a specific type of continuum robot that composes multiple sections where three PAMs drive each section. A general idea of our PAM-driven multisection continuum arm with ossicles can be drawn from Fig. 2.

Figure 2: Overview of PAM driven multi-section robotic arm with ossicles

2 Kinematics

We developed a forward kinematic model for a multisection robotic arm. For one section the relationships for angles ϕ and θ as shown in Fig. 3 are:

$$\phi = \text{atan2} \left(\frac{\sin \frac{\pi}{3}}{\frac{L_3 - L_1}{L_2 - L_3} + \cos \frac{\pi}{3}} \right) \quad (1)$$

and

$$\theta = \frac{L_2 - L_3}{a \cdot \sin \phi} \quad (2)$$

where a is the distance between centers of the mounting points of actuators and L_1, L_2, L_3 are the active lengths of the PAMs. We can see that for the case when $L_2 = L_3$ there is a singularity in the expression for ϕ . We evade this by defining the angle at the point of singularity as $\phi = \frac{|L_1 - L_2|}{a \cdot \frac{\sqrt{3}}{2}}$. Identically to [5, 11], we get the transformation matrix for a point positioned on an arc of length L_i :

$$T = \begin{bmatrix} \cos(\phi) \cos(\theta) & -\sin(\phi) \cos(\phi) \sin(\theta) & \frac{L_i \cos(\phi) (1 - \cos(\theta))}{\theta} \\ \cos(\theta) \sin(\phi) & \cos(\phi) \sin(\phi) \sin(\theta) & \frac{L_i \sin(\phi) (1 - \cos(\theta))}{\theta} \\ -\sin(\theta) & 0 & \cos(\theta) \\ 0 & 0 & 1 \end{bmatrix} \quad (3)$$

Figure 3: Section geometry

To calculate orientation and position of each section we define rotations as quaternions and take into account what the distances are between the active lengths of PAMs representing the rigid plate and endfittings. With this approach we also avoid singularity limitations of Euler angles [2–4]. We create a

quaternion q_k combining the angle of rotation of the next start plate relative to the preceding end plate and the rotations by angles θ and ϕ . For the end plate mounting point of X_{k-1} of $(k-1)^{th}$ section and x_{0k-1} being the vector along the thickness of the mounting plates we get the position of the next mounting point:

$$X_k = X_{k-1} + q_{k-1}x_{0k-1}q_{k-1}^{-1} \quad (4)$$

The above equations may involve more terms in addition if we specify a larger number of intermediate translations and rotations between given sections. This framework allows us to easily change the expressions in order to be able to study different types of section setups such as when a robot that has multiple sections in parallel as in Fig. 4.

Figure 4: A graphic representation of kinematics model for continuum robot with multiple section in parallel which allows to use multiple tools using different distances and angles.

3 Workspace Analysis

3.1 Effective Workspace

Effective workspace is a volume created by all possible configurations of a robot in space. In this work, the approximation of a robot's workspace is obtained computationally. For our analysis, we assume that the extension ratio is defined as $ER = \frac{L_{press} - L_{rest}}{L_{rest}}$ and has a maximum value at 2 for our workspace analysis. L_{press} is the active length of the actuators in a section where each actuator is held at the same pressure. We assume that the maximum extension ratio is invariant of the robot's curvature. Fig. 5b presents data acquired for free extension of arm's section with ossicles.

(a) Pressure vs. Free-Extension relationship

(b) Continuum pneumatic arm's section.
Left: Resting; Right: Pressurized at 122 psi.

Figure 5: Pressure vs. Free-Extension relationship

We developed a computational algorithm that allows us to look at workspaces for different configurations of robots and assess their effective workspace shapes together with qualitative analysis of their workspace density. We define the workspace density as a measure of the quantity of points in an surrounding sphere weighted by function of their distance from the center of the sphere. We enclose the workspace in a cube of side length equal to twice the maximum absolute value of coordinates x, y, z defined as m . Then, an equal spaced 3D grid of n^3 points is created. For each point in the grid we look at the end-effector positions in its proximity which we defined as a sphere of radius r_{max} and compute the density score of the point. In this study we used $r_{max} = 10 \cdot m/n$. The density score for each point in the grid is a sum of gaussians defined as follows:

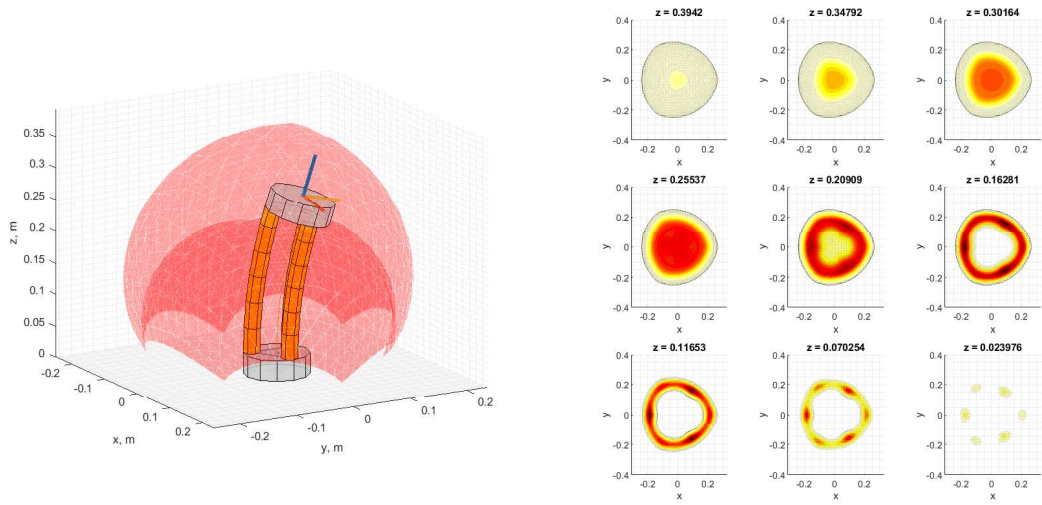

$$\rho_{score} = \sum_{i=1}^n \frac{1}{\sqrt{2 \cdot \pi \cdot r_{max}^2}} e^{-\frac{1}{2} \frac{r_i^2}{r_{max}^2}} \quad (5)$$

It allows us to create visual representation of the workspace shape and dexterity measure using density score. To generate a workspace approximation with points we compute a set of k configurations of the robotic arm by incrementally changing the actuators' lengths which gives us a set of points the end-effector can reach.

We decided not to use changes in pressure since our experimental robotic arm uses a new variant of extensible PAMs which has not been characterized extensively yet, hence, we use changes in actuator length to stay agnostic of the actuator characteristics. We also assume that the ossicles help in keeping

the robot shape close to the constant-curvature assumption and have minimal effect on the kinematics of a PAM-driven continuum robot.

For one section robotic arm, the workspace is characterized by the following shape and density score as the dexterity measure shown in Fig. 6. The light red surface is the boundary of the effective workspace of the section. Due to the fact that the workspace boundary is transparent, places where the surface overlaps are darker red. It can be observe that the workspace's shape resembles a closed tulip or Taj Mahal's dome. The workspace has been generated by computing 20^3 different configurations for a manipulator of one section with PAMs mounted at a distance of 6.7 cm from one another. The resting length for each PAM is 16.5 cm and the extension ratio is 2. The thicknesses of the plates (which include non-active elements: mounting plate and PAMs' endfittings) has been set to 3.2 cm.

(a) Effective workspace and an example of a one section robot's possible configuration.

(b) Slices of workspace volume characterized by p_{score} .

Figure 6: Effective workspace of a 1-section continuum robotic arm

For a two section robotic arm, the workspace is characterized by the shape and dexterity presented in Fig. 7. The Fig. 7a was computed for 13^6 possible configurations, whereas Fig. 7b used 7^6 possible configurations. The robotic arms composes of two sections which are identical to the one in the one-section example. An additional parameter in this case is the rotation of the second section relative to the first one. The second section start plate is rotated by 60° around the axis of symmetry of the first section end plate. The important thing is to note that there is a region inside the workspace where the arm cannot move. This can be observed in in the Fig. 7 where in the 3D the region is represented as the dark red area and in the dexterity plots where we can observe that the workspace resembles a an apple with some of its interior removed.

For three-section robotic arm, the workspace is characterized by the shape and dexterity presented in Fig. 8. The robotic arm composes of three sections which are identical to the one in the one-section example. An additional parameters in this case are the rotation of the second and third sections relative to the preceding ones. Both rotations are 60° around the axis of symmetry of the previous section end plate.

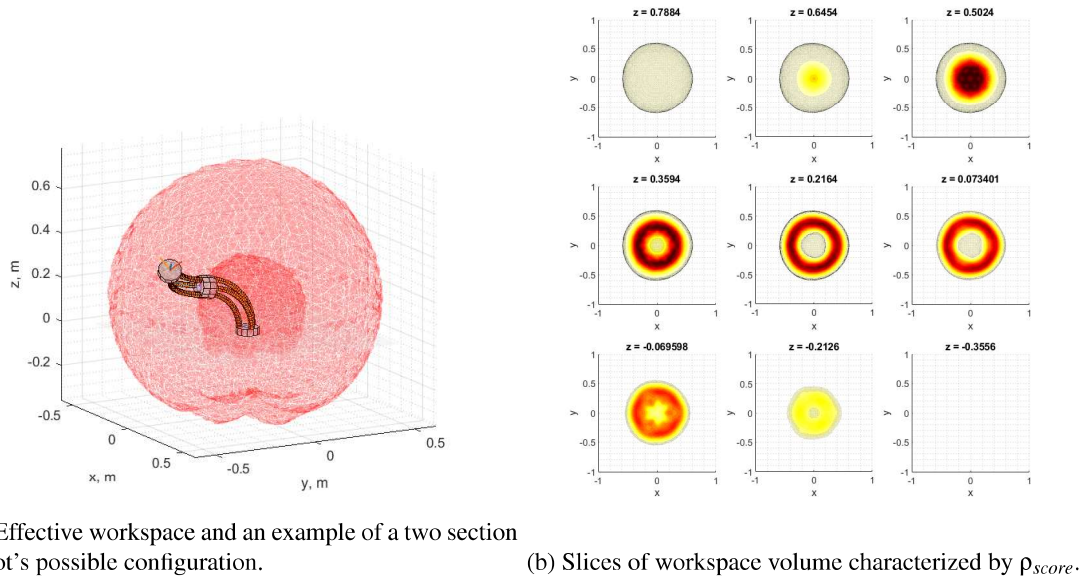

Figure 7: Effective workspace of a 2-section continuum robotic arm

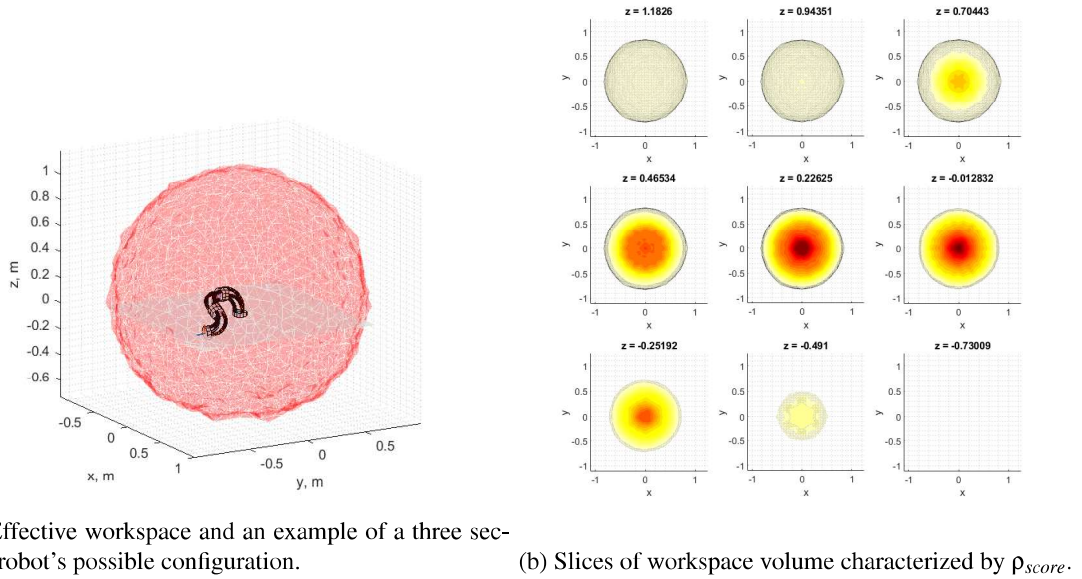

Figure 8: Effective workspace of a 3-section continuum robotic arm

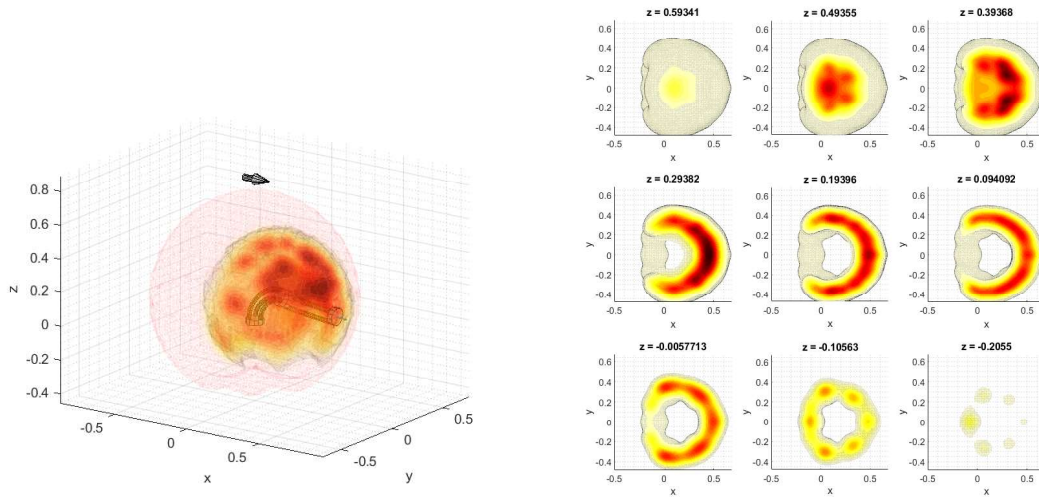

3.2 Fixed Orientation Workspace

As inherent to their flexible nature, continuum pneumatic arms (CPA) are superior for work in unstructured environments. Possible applications of CPAs are on-site maintenance including inspection

and repair of vehicles (reaching confined spaces), space robotics (high force-weight ratio), safer human-robot cooperation (compliance), crop harvesting and additive manufacturing of large structures (large and high-dexterity workspace). All of the applications mentioned above often involve tasks that require to move along lines or planes keeping the end-effector at a constant orientation. Those can be: pushing/pulling handles, spacecraft docking assistance, painting, serving food and drinks, fused filament fabrication or maintenance of surfaces. This is the reason why we aim to uncover qualitative trends for fixed-orientation arm configurations so that we have a better understanding of what are the capabilities of CPAs in terms of orienting its end effector.

The algorithm for fixed workspace generation is an extension of the algorithm we used for the effective workspaces. The only difference is that we constrain the end-effector to a subset of points where the orientation of the end-effector falls into a desired direction within some tolerance. In this paper the tolerance is defined as the apex angle of a cone created around the axis of a direction vector representing the fixed orientation. All the configurations for which the end-effector direction vector lands inside the cone belong to the workspace. Although for figures 9, 10 we chose an angle of 15° , it should be chosen taking into account the precision of a task a robot is to perform.

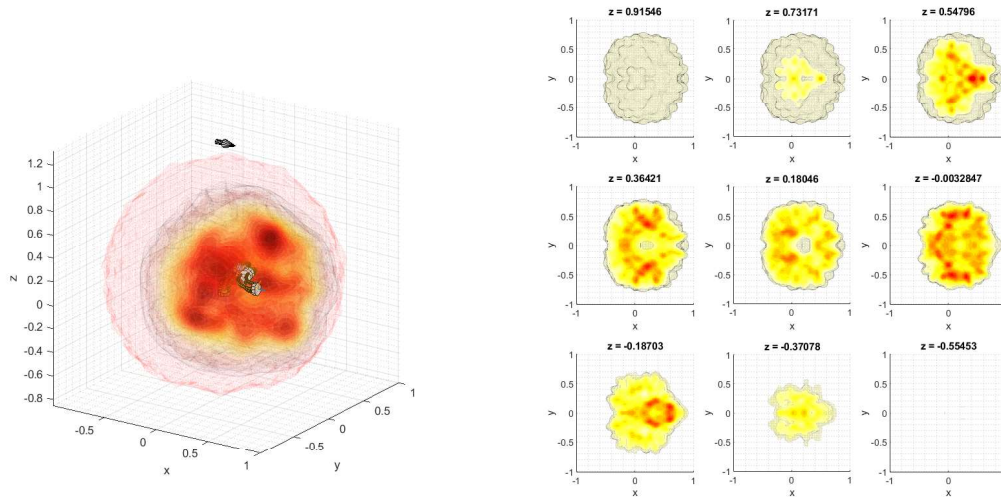

For two section robotic arm, the fixed orientation workspace in the gray arrow direction ($x = 1, y = 0, z = 0$) is characterized by the shape and dexterity presented in Fig. 9. The Fig. 9 was computed for 6^9 possible configurations and a grid of $50 \times 50 \times 50$ points for point density calculation. The arm used is the same as in the e.g. for the effective workspace of 2-section robotic arm. An additional parameter in this case is the rotation of the second section relative to the first.

4 Conclusion

Kinematics model of a multi-section continuum robotic arm has been developed. An algorithm for computing shape and dexterity measure have been proposed and implemented. The work gives insight about the shape of workspaces of 1, 2 and 3-section robotic arms in one arbitrarily chosen orientation and provides information about the dexterity of the arms for constraints of the orientation of the end-effector. Some of the future work may involve quantitative analysis of fixed orientation workspaces. Having the idealized model of kinematics, it is essential to find out what is the gap between reality and the model for a continuum pneumatic robot arm with ossicles. A load at the end-effector will undoubtedly change the workspace of the robot and pose an exciting topic for future work.

Key words: Statistical Analysis, Structural Reliability, Probability of Failure, Risk Analysis, Risk Based Maintenance, Bayesian Theorem

Abstract. This study outlines a method to numerically evaluate the probability of failure (PoF) and engineering risk using Bayesian theorem and the diagnostic results of real-time condition monitoring. Engineering risk is defined as the product of the PoF and consequences of failure. While a diagnostic result without any inspection error is ideal when conducting maintenance using real-time monitoring results. However, failure of structure is not caused even if the monitoring method overestimates to a few degree any small damage that can cause failure. Moreover, failure is not caused even if the method underestimates to a few degree any large damage., the inability to model failure dominates, Improving the accuracy of estimating specific damage levels is therefore important in reducing the PoF. Here a method for reducing the risk by improving the diagnostic accuracy of specific damage levels, which is achieved by controlling the sampling ratio of the training data with a weight function, is proposed. The consequences of the overestimation and underestimation of damage differ. The risk due to an underestimation is called failure risk and that due to an overestimation is called economic risk in this research. Here a numerical evaluation of the PoF using Bayesian theorem for each diagnostic result of real-time condition monitoring is proposed, and the effect of weighted regression on risk reduction is discussed. The proposed method is validated by employing it to identify delamination in a CFRP beam via the electric potential change method.

1 INTRODUCTION

The maintenance costs associated with aging infrastructure facilities has recently become an increasing concern. Temporary structures, such as the drainage plant at the Fukushima nuclear power plant, are of particular interest since there is a high degree of uncertainty in both the progression of corrosion and operating environment. Furthermore, inspection errors

are large since there is no established inspection method, and there are concerns regarding exposure during the inspection itself, highlighting the need to establish a risk evaluation method using remote monitoring data. Here we propose a method to evaluate the probability of failure (PoF) of structures using monitoring data and a Bayesian estimation.

It is possible to improve the damage evaluation method when the damage probability is quantitatively evaluated using a damage state evaluation and monitoring data, which reduces the damage probability. Here we consider a procedure that improves the damage evaluation method and also minimizes the risk. The engineering risk for infrastructure maintenance is expressed as the product of the PoF and consequence of failure (CoF). For example, risk-based maintenance [1,2], which takes the risks into account, has demonstrated that efficient facility maintenance can be achieved when considering the importance and urgency of the maintenance. It is possible to perform the appropriate degree of maintenance using damage identification estimation results if the damage is either significantly large or significantly smaller than the damage size determined by the distribution of the acting external force. Therefore, the method to reduce the risk by adjusting the estimation accuracy of a specific damage size is examined in this study.

Here the risk in the proposed method is reduced by using the weighting function, with the appropriate weighting function considered to be different for both the probability of occurrence of each damage size (PoO) and the assumed damage size that causes structural failure. The appropriate weighting functions for risk reduction under various conditions and the effectiveness of the risk reduction method using the weighting function are examined. The proposed method is validated by employing it to identify delamination in a CFRP beam via the electric potential change method [3–7].

2 FAILURE PROBABILITY EVALUATION PROCEDURE

2.1 Bayesian theorem

Bayesian theorem [8–11] is a simple mathematical theorem used for calculating conditional probabilities. In engineering, it is primarily used to assess the structural reliability of materials using small samples [12, 13] (e.g., RBM). Here the theorem is used to estimate the event probability of true damage due to an estimated damage size. Bayesian theorem is generally expressed as:

$$P(E_i | F) = \frac{P(E_i)P(F | E_i)}{\sum_j P(E_j)P(F | E_j)} \quad (i, j = 1, 2, \dots), \quad (1)$$

where $P(E_i)$ is the event probability of event E_i , $P(F | E_i)$ is the conditional probability that event F is caused by event E_i , and $P(E_i | F)$ is the “posterior probability” or the conditional probability that event E_i is caused by event F . When attempting to identify the damage sizes, the damage occurrence a_i is compared to the arbitrarily estimated results $EstA_k$, and the probability $P(EstA_k | a_i)$ that a_i leads to $EstA_k$ is determined. Eq. (1) can then be modified as follows:

$$P(a_i | EstA_k) = \frac{P(a_i)P(EstA_k | a_i)}{\sum_j P(a_j)P(EstA_k | a_j)} \quad (2)$$

where the left side is the posterior probability. Therefore, $P(a_i | EstA_k)$ is the event probability of $EstA_k$ for a true damage size a_i . The event probability distribution of a_i and $EstA_k$ can then be determined by estimating the event probability of each a_i value.

2.2 PoF Evaluation using an estimation of the true damage distribution

Figure 1 shows the PoF evaluation procedure. The learning data are first weighted, and a maximum likelihood estimation is performed using Gibbs sampling to estimate the damage parameter occurrence rate distribution, where the horizontal axis represents the estimated damage values, and the vertical axis represents the probability density function (PDF) (Figure 1; ①). Bayesian theorem is then employed to estimate the damage size event probability distribution and true damage parameter event probability, where the horizontal axis represents the true damage parameter value (Figure 1; ③). The residual strengths are estimated from the damage sizes, forming a residual strength distribution (Figure 1; ④), where the horizontal axis represents the residual strength. Finally, the PoF is evaluated (Figure 1; ⑤) since failure occurs when the external force exceeds the residual strength. Assumed external forces that could cause failure of structure at 15 (Chapter 3), 20, and 25 mm (Chapter 4) of damage in average are employed in this study.

The above-mentioned damage size occurrence distribution is the probability of occurrence of the damage sizes (PoO) that may occur in the target structure. An exponential distribution is used here, but Chapter 3 also examined cases with other distributions (chi-square, normal, Weibull, uniform).

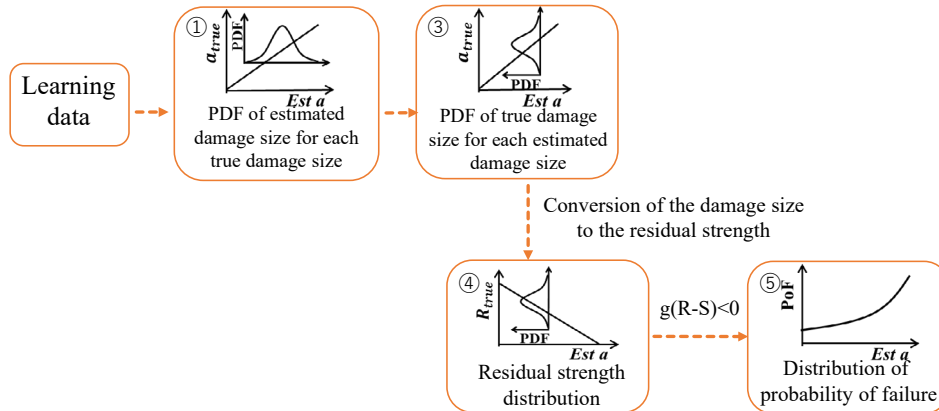

Figure 1: Procedure for estimating PoF.

2.2 Risk evaluation

Figure 2 shows the accidental and economic risks evaluated using the proposed method. Accidental risk is defined as the risk of failure due to an underestimation of the damage size, whereas the economic risk is defined as the risk of unnecessary maintenance costs due to an

overestimation of the damage size. The adjusted PoF (PDF of PoF versus PDF of PoO) is plotted on the vertical axis, and the estimated damage size is plotted on the horizontal axis. The accidental risk is evaluated as the area surrounded by the adjusted PoF and the maintenance threshold. The threshold is set as the accidental risk, and exhibits a constant value (0.03). The economic risk is evaluated as the area surrounded by the adjusted PoF, PoO, and maintenance threshold. This study aims to reduce the economic risk when the accidental risk is constant since the acceptable level of accidental risk is limited.

Figure 2: Accidental and economic risks from the estimated PoF.

3 EFFECTIVE WEIGHTED PEAK POSITION FOR RISK REDUCTION OF EACH PRIOR DISTRIBUTION

Figure 3 shows an example of the weighting function for a 5-mm peak position. The vertical axis is the probability density, and the horizontal axis is the damage size. This weighting function is used to evaluate the risk over the 3- to 15-mm peak position range. Figure 4 shows the results when an exponential distribution is used as the prior distribution. The vertical axis is the economic risk, and the horizontal axis is the peak position of the weight. The risk is reduced in both the small damage (4–5 mm) and increased PoF areas (10–11 mm).

The event probability of small damage is high and that of large damage decreases when an exponential distribution is used as the prior distribution. Risk evaluations were then conducted using a distribution with vertices (chi-square distribution ($k = 3$), normal distribution ($\mu = 5$, $\sigma^2 = 1.5$), and Weibull distribution (shape = 1.2, scale = 5)) as the prior distributions. Table 1 shows the appropriate weighting positions for risk reduction, with the chi-square distribution being the most effective. These risk evaluations indicate that it is possible to reduce the risk by locating a peak in either the small damage area or the increased PoF area.

Figure 3: Example weighting function (5-mm peak).

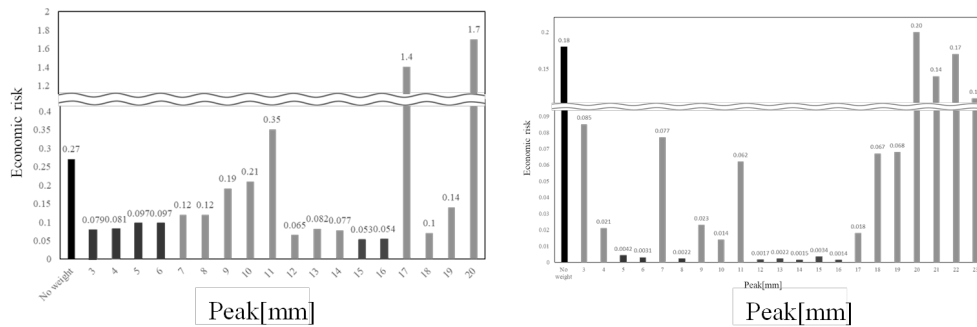

Figure 4: Economic risk at each peak location.

Table 1: Appropriate weighting positions for risk reduction.

	small damage size area	increasing PoF _{adj} area
Chi-square distribution	3	12
Normal distribution	5	11
Weibull distribution	3	11

4 INFLUENCE OF EXTERNAL FORCE ASSUMPTION

Figure 5 shows the results when the average failure size is increased to 20 and 25 mm. An exponential distribution is used as the prior distribution. The vertical and horizontal axes are the same as in Figure 4. The weighting in the small damage and increased PoF areas are effective for risk reduction in the tested damage size cases. Furthermore, the weighting in the increased PoF increase area becomes more effective as the average failure size increases.

(b) 25 mm

Figure 5: Economic risk at each peak location.

5 CONCLUSION

- A method to evaluate the PoF of structures using monitoring data and a Bayesian estimation is proposed. This method reduces the risk by improving the diagnostic accuracy of specific damage levels, which is achieved by controlling the sampling ratio of the training data with a weight function.
- The weighting near the vertices is the most effective approach for risk reduction in

each distribution. It is possible to reduce the risk by locating a peak in either the small damage area or the increased PoF area.

- The weighting in both the small damage and increased PoF areas is effective for risk reduction in the tested damage size cases. Furthermore, the weighting in the increased PoF area becomes more effective as the average failure size increases.

Damage localization using controllable inputs: an experimental study

BA Qadri¹, MD Ulriksen¹, LB Klockmann¹ and PH Veis¹

¹*Dept. of Civil Engineering, Aalborg University, Niels Bohrs Vej 8, Esbjerg, Denmark*

Abstract

The recently proposed Shaped Damage Locating Input Distribution (SDLID) method locates structural damage by active interrogation with controllable inputs. The methodological premise is to shape these inputs such that certain steady-state vibration features (depending on the type of damage to be located) are rendered dormant in one subdomain at a time. As such, damage is localized when the vibration response induced by the shaped inputs in the damaged state corresponds to that stored for the reference state. Previously, the SDLID method, which operates free of system identification, has been tested through numerical simulations and, in this context, demonstrated its merits; namely, a low demand on output sensors, robustness towards noise, and conceptual simplicity. This paper presents an experimental application study, in which the SDLID method is used to locate different mass perturbations in a frame structure investigated using two actuators delivering harmonic excitation. Based on steady-state acceleration measurements, it is shown how the method succeeds in locating all the added mass perturbations.

Keywords: Structural Health Monitoring, Damage localization, Input shaping, Experimental study.

1 Introduction

Structural damage localization is conventionally handled by mapping shifts in vibration features, such as transfer functions or modal parameters, from the reference and damaged states to the structural domain [1]. This mapping can be conducted either directly, in which case we refer to the approach as *data-driven*, or by use of a theoretical model of the structure in question, implying that the approach is *model-based* [2]. Here, the theoretical model is typically established on the basis of a finite element (FE) formulation.

Numerous studies document successful model-based damage localization under both laboratory conditions [3, 4, 5] and in-situ settings [6, 7, 8], but it is evident that damage localization has yet to find the applicability level required for industrial use. One of the major issues is that the sensitivity to structural damage of the employed vibration features is typically lower than the features' sensitivity to noise and other variabilities [9].

Two approaches to (attempt to) resolve the noted sensitivity issue is 1) reducing the impact of noise and other variabilities [4, 10, 11] and 2) designing closed-loop systems with enhanced sensitivity to damage [12, 13, 14]. In the present study, we focus on the former path and investigate the Shaped Damage Locating Input Distribution (SDLID) scheme proposed by Ulriksen et al. [11]. The SDLID scheme employs inputs that are shaped by use of a theoretical model to “deactivate” the damage for determining its location. The idea is to operate with the

shaped inputs in a forward interrogation for damage of one structural subdomains at a time; with damage revealing itself when, under ideal conditions, the vibration signatures prior and posterior to damage coincide. In this way, the impact of noise is reduced since the SDLID scheme operates without calling for system identification to extract the damage features.

Besides circumventing system identification, the merits of the SDLID scheme include a user-defined spatial localization resolution (as postulated damage areas are selected), a low demand on output sensors (in principle, one may suffice), and conceptual simplicity. These merits have been highlighted through numerical application examples with simple structural systems [11] and an offshore jacket structure [2]. The scope of the present paper is therefore to further test the applicability of the SDLID scheme by applying it in an experimental context with a frame structure, which is analyzed in its reference state and “damaged” states with different mass perturbations.

The rest of the paper is organized as follows: in section 2, the SDLID method is reviewed, section 3 outlines the experimental setup, and section 4 presents the obtained damage localization results. A brief conclusion in section 5 closes the paper.

2 The SDLID method

The SDLID method interrogates for damage in a structural subdomain by applying a set of controllable inputs, $u(t)$, which, for each structural subdomain, is shaped to render dormant certain kinematic quantities [11]. If the subdomain containing the damage is suppressed, the steady-state vibration output will, under ideal circumstances, be the same in the damaged state and in the healthy one; given, of course, that the set of inputs is identical in the two states. The task of shaping the inputs can be resolved by numerous approaches; of which two are proposed in [11]. One of these two takes its outset in the Laplace domain and is, as such, useful when shaping harmonic inputs, while the second one operates in the time domain. Since the experimental study in the present paper employs harmonic excitation, we focus on the Laplace domain-based approach and refer the reader to [11] for a tutorial on the time domain-based approach.

Consider a structural domain that is discretized to n degrees of freedom (DOF) and subjected to p inputs that are collected in $u(t) \in \mathbb{R}^p$ and distributed spatially through $B_2 \in \mathbb{R}^{n \times p}$. The governing temporal equation reads

$$M\ddot{x}(t) + C\dot{x}(t) + Kx(t) = B_2u(t), \quad (1)$$

where M, C and $K \in \mathbb{R}^{n \times n}$ are the mass, damping and stiffness matrices, while, $x(t)$, $\dot{x}(t)$ and $\ddot{x}(t) \in \mathbb{R}^n$ are the nodal displacement, velocity and acceleration vectors. Assuming steady state and zero initial conditions, equation (1), with p shaped inputs acting solely in the DOF indexed by τ , can be expressed in the Laplace domain as

$$X(s) = (Ms^2 + Cs + K)^{-1}B_2U(s) = G(s)B_2U(s) = G_{\bullet,\tau}(s)U(s), \quad (2)$$

where $G_{\bullet,\tau}(s)$ is the transfer matrix containing the columns in which the shaped inputs are applied and $X(s) = \mathcal{L}(x(t))$ and $U(s) = \mathcal{L}(u(t))$ are the Laplace transforms of the output and the input.

For simplicity we assume that the structure is only affected by the p shaped inputs, hence implying that any other exogenous loading is neglected. The task therefore becomes to shape the amplitude and the phase angle of the harmonic inputs, such that some linear transformation of $X(s) \in \mathbb{C}^n$, denoted $\Gamma(s) \in \mathbb{C}^q$, is suppressed. That is,

$$\Gamma(s) = LG_{\bullet,\tau}(s)U(s) = 0, \quad (3)$$

where $LG_{\bullet,\tau}(s) \in \mathbb{C}^{q \times p}$ and with L being the transformation matrix. Provided that $p > q$ (that is, the number of shaped inputs is greater than the number of suppressed kinematic quantities), there exists a null space

$$U(s) = \text{null}(LG_{\bullet,\tau}(s)), \quad (4)$$

from where relative values of the amplitudes and phase angles are directly computed as the moduli and arguments of the chosen vector within the span of $\text{null}(LG_{\bullet,\tau}(s)) \in \mathbb{C}^{p \times (p-q)}$.

One gathers that the inputs are most conveniently shaped using a model of the healthy structure. By applying the inputs to the structure prior and posterior to damage, we capture the steady-state response, $y(t)$ and $\tilde{y}(t)$, where $(\tilde{\bullet})$ denotes a quantity from the damaged state. On the premise that $y(t)$ can contain displacements, velocities, accelerations, and so forth, the Euclidean distance of the steady-state response shift in frequency domain, that is,

$$\Xi_i = \sqrt{\sum_j (|Y_j(\omega)| - |\tilde{Y}_j(\omega)|)^2}, \quad (5)$$

is used as damage metric with the index i indicating the i th subdomain being interrogated. In this way, damage is located in the subdomain that yields the lowest metric.

In the present study, we focus on locating mass perturbations, thus, as proved in [11], steady-state accelerations must be suppressed. If, on the other hand, stiffness-related damage was to be located, one would suppress the steady-state strains. A further elaboration on this can be found in [11].

3 Experimental setup

A frame structure with 5 floors is assembled and used as a damage localization test bed in a controlled laboratory environment, see figure 1. The structure is assembled using aluminium beam elements, all connected by corner cubes, screws and threaded rods, see table (1) for the structural properties of a single aluminum beam element.

The structure is instrumented with two actuators that generate a horizontal load. Two load cells are attached to the structure that measure the input force from the actuators. The structural response is captured by 9 piezo-electric accelerometers, distributed on the frame structure. The structure is mounted on a HEB260 profile, which is reinforced with steel braces and bolted to the ground.

Table 1: Material properties of a single aluminum beam element.

Description	Symbol	Value	Unit
Cross-sectional area	A	$49 \cdot 10^{-6}$	$[\text{m}^2]$
Density	ρ	2900	$[\text{kg}/\text{m}^3]$
Modulus of elasticity	E	$68 \cdot 10^9$	$[\text{Pa}]$
Poisson's ratio	ν	0.33	$[-]$
Shear modulus	G	$25 \cdot 10^9$	$[\text{Pa}]$
Second moment of inertia	I_y/I_z	$495 \cdot 10^{-12}$	$[\text{m}^4]$
Polar moment of inertia	I_x	$991 \cdot 10^{-12}$	$[\text{m}^4]$

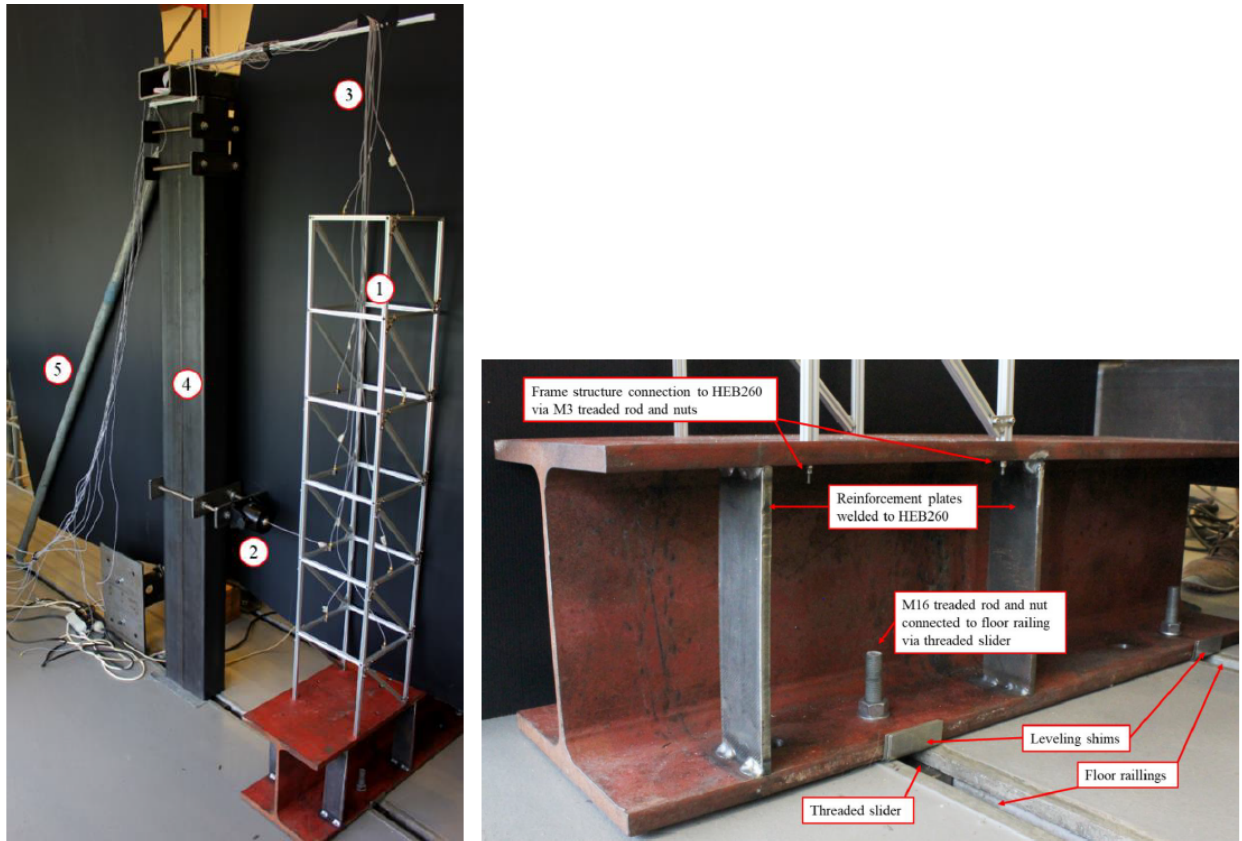

Figure 1: Experimental setup with indication of 1) frame structure, 2) actuator, 3) cables connecting the accelerometers, 4) steel column and 5) support cylinder for the steel column.

3.1 Damage emulation

The damage is introduced as a mass perturbation in different areas on the frame structure, see figure 2. The mass perturbation weighs 0.121 kg, which is approximately 6.31 % of the total mass of the frame structure. To appreciate the impact of adding the mass perturbation to the structure, we conduct an Experimental Modal Analysis (EMA) of the structure in its healthy configuration and with the mass perturbation added on the topmost level. The EMA is performed by use of a single actuator that delivers a sine sweep ranging from 0.1 Hz to 60 Hz, which ensures that the first three eigenmodes of the frame are excited. As observed from the resulting frequency response functions depicted in figure 3, the mass perturbation yields a clear damaged-induced shift in the eigenfrequencies.

Figure 2: Pictures of a) bolt and nuts serving as mass perturbation and b) the perturbation applied to the structure.

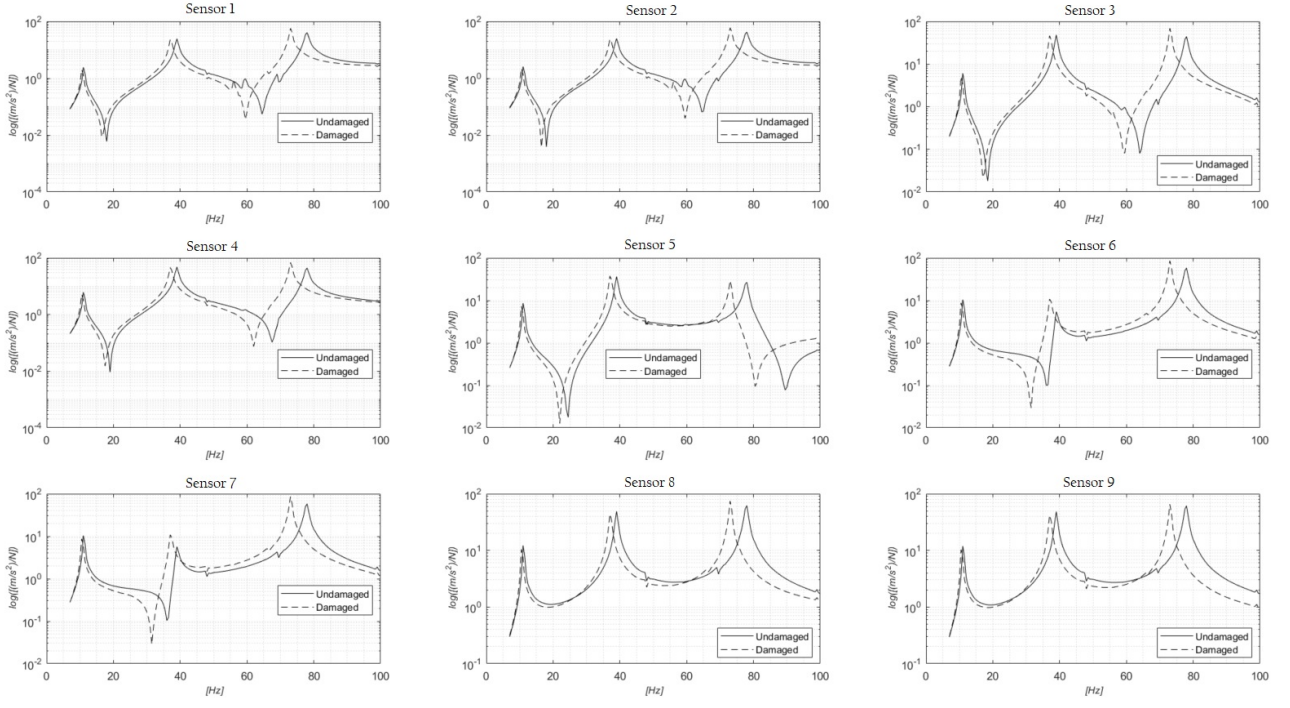

Figure 3: Frequency response functions for the structure in reference and damaged states.

4 Damage localization

As previously mentioned, the SDLID method is a model-based approach, meaning that a theoretical model must be used to shape the inputs. A finite element model consisting of 108

Figure 4: Finite element model of the frame structure and two highlighted beam elements, illustrated with the nodes and DOF.

Euler-Bernoulli elements has been established, see figure 4. The model has a total of 480 DOF of which 24 are fixed to represent the kinematic boundary conditions.

In the experimental study, two actuators are, as mentioned, attached to the frame structure to introduce a harmonic excitation; see figure 5, which also shows the positions of the accelerometers. The two harmonic inputs have a driving frequency of $\Omega = 0.7\omega_1$, where ω_1 is the first cyclic eigenfrequency, see figure 5 for the actuator positions. With two inputs, one gathers that the constraint of $p > q$ is violated if all six DOF in a node are to be suppressed. However, since the inputs only excite in one plane and the displacements and rotations are relatively small, suppressing just the translational DOF in the excitation direction is sufficient.

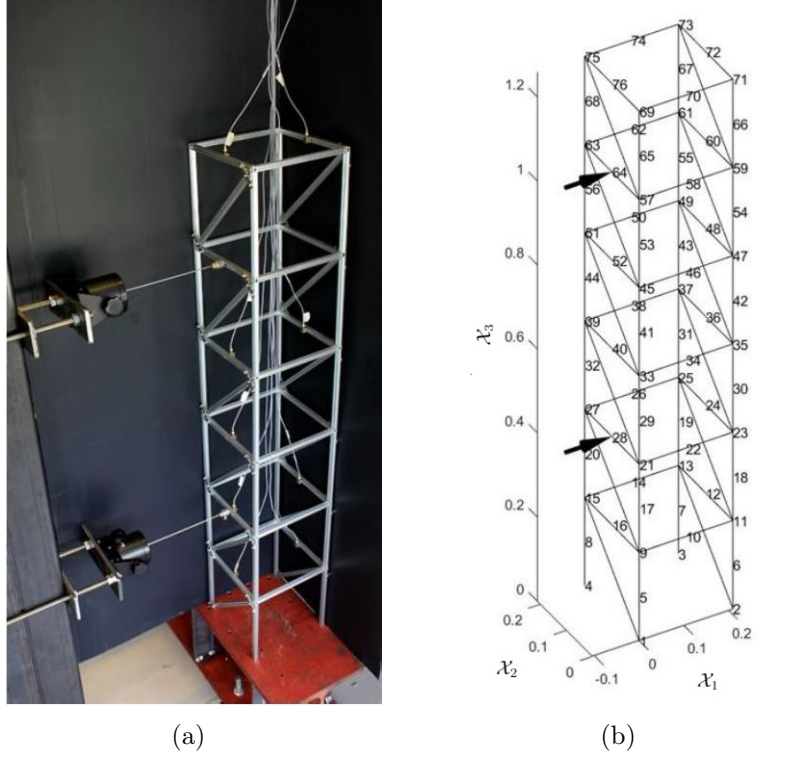

Figure 5: Frame structure in a) experimental setup with accelerometers and actuators and b) its numerical representation with the actuator positions.

The frame structure is tested in the healthy state and in five different damaged states, where the mass perturbation is located at node $\aleph = 12, 36, 52, 60$ or 76 . These nodes, which are indicated in figure 6, are also chosen as the subdomains to be interrogated consistently. The interrogations are conducted by suppressing steady-state accelerations in the excitation direction, and by doing so for each damaged state, we get the damage metrics—according to equation (4)—plotted in figure 6. As the red dot in each plot marks the damage location, it is evidenced how the SDLID method allows for successful localization of the mass perturbation in all damaged states.

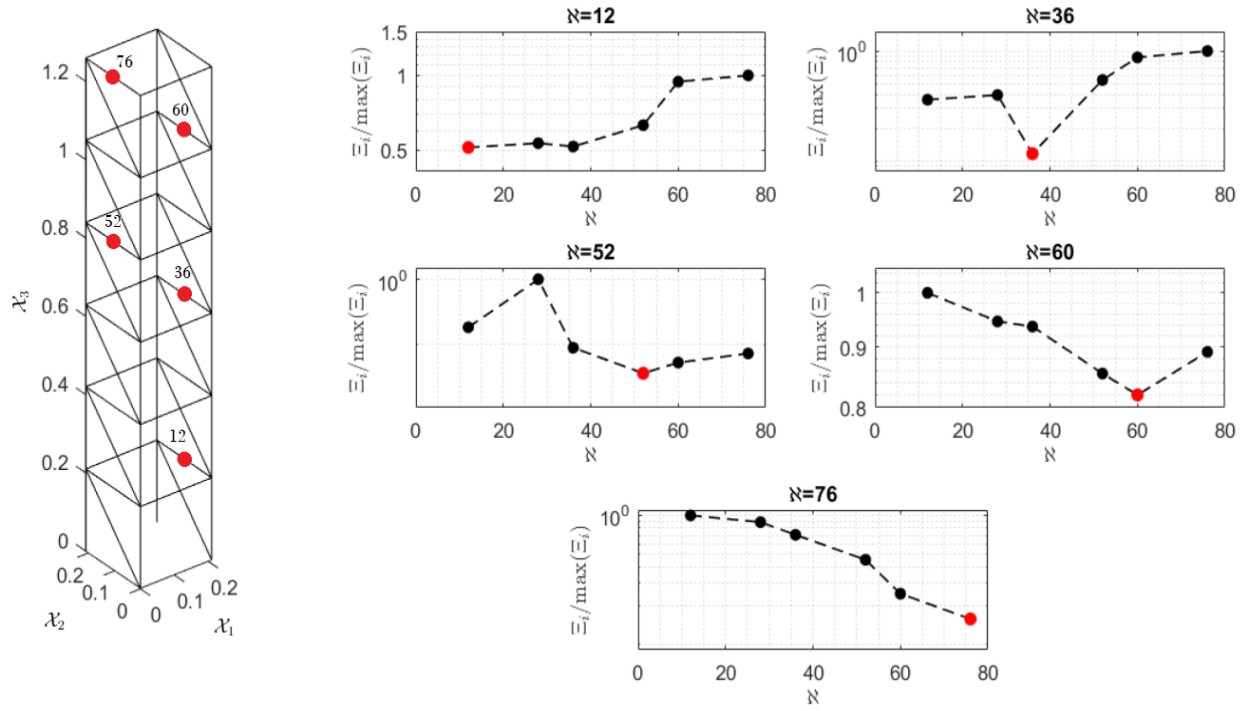

Figure 6: Damage localization results. The structure, depicted on the left side, illustrates the positions of the damage.

5 Conclusion

The principle of the SDLID method is to apply a set of inputs and then interrogate for damage by rendering dormant certain kinematic quantities (depending on the damage type to be located) in one structural subdomain at a time. Damage is, as such, located when the steady-state output governed by the shaped inputs is identical prior and posterior to the introduction of damage.

In the present paper, the SDLID method is tested in an experimental setup with a frame structure, which is subjected to two harmonic inputs and introduced to different mass perturbations. By shaping the available inputs to suppress steady-state accelerations in one subdomain at a time, it is found that the SDLID scheme succeeds in locating all the mass perturbations, albeit with rather poor resolution in some cases.

Key words: Vibration estimation, Modal expansion, Kalman Filter, Joint input-state estimation, Experimental testing

Abstract. State estimation is a well-established discipline within the field of modern control theory. In the context of vibration analysis, where application areas include damage prognosis and structural control with full state feedback, the topic has, however, emerged during the last couple of decades under the term *virtual sensing*. Here, the scope is to estimate physical quantities at both measured and unmeasured locations based on vibration signals captured in a limited set of sensors. This paper examines and compares three virtual sensing techniques, namely, modal expansion, direct Kalman filtering and a modified Kalman filter where the true value of the input is replaced by an optimal estimate. The performance of the three schemes is examined in an experimental setup with a cantilevered beam, which is subjected to different input types and installed with a limited set of accelerometers. Based on the experimental findings, some observations and particular recommendations on the use of the different schemes are provided.

1 INTRODUCTION

Within civil and mechanical engineering, it is common practice to use vibration measurements for structural monitoring and control purposes [1, 2, 3]. The vibrations are captured through an installed sensor network, which, in most applications, consists of a limited number of sensors due to the associated costs and the fact that there may be locations inaccessible for instrumentation. As such, virtual sensing can be utilized to estimate vibration responses at designated locations from response acquired by the installed sensor network [4].

The by far most applied virtual sensing approach within civil and mechanical engineering applications is to assume linearity and time invariance and then conduct modal expansion (ME). Here, an augmented basis consisting of measured and/or analytical mode shapes is used to solve an inverse problem resulting in vibration estimates in all the unmeasured degrees of freedom in the model of the structure in question [5, 6]. It follows directly that the inverse problem to be solved is underdetermined if the number of included modes exceeds the number of deployed sensors; a scenario that can easily occur in practice. Other virtual sensing methods include the direct Kalman filter (KF) algorithm [7] and a modified Kalman filter, namely, the joint input-state estimation (JISE) algorithm [8], which, in addition to estimating the full optimal state vector, also estimates the unknown input. In the present paper, the performance of these two schemes and ME is examined and compared in the context of an experimental setup with

a cantilevered beam, which is subjected to different input excitations, while a limited set of mounted accelerometers measure the output.

The paper is organized as follows: in Section 2, a brief overview of the prerequisite theory utilized in the three virtual sensing methods is provided, followed by the presentation of the methods in Section 3. Subsequently, in Section 4, the experimental setup is outlined and Section 5 provides a description of the required numerical model. In Section 6, the performance of the three schemes is examined and compared. Lastly, some concluding remarks are given in Section 7.

2 PREREQUISITE THEORY

Assuming linear, time-invariant (LTI) conditions for the structure of interest, which is spatially discretized with n degrees of freedom (DOF), the temporal equation of motion is given as

$$M\ddot{x}(t) + C\dot{x}(t) + Kx(t) = S_p f(t). \quad (1)$$

Here, $K, C, M \in \mathbb{R}^{n \times n}$ are the stiffness, damping and mass matrices, $x(t), \dot{x}(t), \ddot{x}(t) \in \mathbb{R}^n$ are the nodal displacements, velocities and accelerations, and $f(t) \in \mathbb{R}^p$ contains the p external inputs spatially distributed by $S_p \in \mathbb{R}^{n \times p}$. Assuming classical damping, Eq. (1) can be decoupled through the modal transformation

$$x(t) \approx \sum_{i \in \mathcal{A}} \phi_i q_i(t) = \Phi q(t) \quad (2)$$

where \mathcal{A} denotes a subset holding the indexes of the $m \leq n$ governing modes, $\Phi \in \mathbb{R}^{n \times m}$ is the truncated modal matrix containing mass-normalized mode shapes, and $q(t) \in \mathbb{R}^m$ is the truncated modal displacement vector. Let $(\tilde{\circ})$ denote a modal quantity, then it follows

$$\ddot{q}(t) + \tilde{C}\dot{q}(t) + \tilde{K}q(t) = \Phi^T S_p f(t) \quad (3)$$

where $\tilde{K} \in \mathbb{R}^{m \times m}$ is the spectral matrix and $\tilde{C} \in \mathbb{R}^{m \times m}$ is the modal damping matrix.

By defining the modal state vector, $\tilde{z}(t)^T = [q(t)^T \ \dot{q}(t)^T]^T \in \mathbb{R}^{1 \times 2m}$, and rewriting Eq. (3) into discrete state-space form, one has

$$\tilde{z}_{k+1} = \tilde{A}_d \tilde{z}_k + \tilde{B}_d f_k, \quad (4)$$

where $\tilde{z}_k = \tilde{z}(k\Delta t)$ and $f_k = f(k\Delta t)$ for $k \in [0, N-1]$, with N being the total number of samples and Δt the time increment. If the zero-order-hold rule is employed on the input, such that $\forall t \in [k\Delta t, (k+1)\Delta t] : f(t) = f_k$, the state-transition matrix, $\tilde{A}_d \in \mathbb{R}^{2m \times 2m}$, and the input matrix, $\tilde{B}_d \in \mathbb{R}^{2m \times p}$, are given as

$$\tilde{A}_d = \exp \left(\begin{bmatrix} 0 & I \\ -\tilde{K} & -\tilde{C} \end{bmatrix} \Delta t \right) \quad (5)$$

$$\tilde{B}_d = [\tilde{A}_d - I] \begin{bmatrix} 0 & I \\ -\tilde{K} & -\tilde{C} \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ \Phi^T S_p \end{bmatrix}. \quad (6)$$

The s measured outputs are gathered in $y_k \in \mathbb{R}^s$ and defined as

$$y_k = \tilde{C}_d \tilde{z}_k + \tilde{D}_d f_k, \quad (7)$$

where $\tilde{C}_d = [S_d \Phi - S_a \Phi \tilde{K} \quad S_v \Phi - S_a \Phi \tilde{C}] \in \mathbb{R}^{s \times 2m}$ is the output matrix, $\tilde{D}_d = [S_a \Phi \Phi^T S_p] \in \mathbb{R}^{s \times p}$ is the input-output transmission matrix and $S_d, S_v, S_a \in \mathbb{R}^{s \times n}$ relate measured displacements, velocities and accelerations to the corresponding DOF in the numerical model.

3 VIRTUAL SENSING METHODS

The discrete system output is divided into two subsets: the s measurands, $y_k \in \mathbb{R}^s$, and the α response quantities to be estimated, $\mu_k \in \mathbb{R}^\alpha$.

3.1 Modal expansion (ME)

Let $\eta_k \in \mathbb{R}^m$ be the general notation for a modal kinematic quantity (depending on the nature of y_k), then the modal formulation is partitioned into

$$\begin{bmatrix} y_k \\ \mu_k \end{bmatrix} = \begin{bmatrix} \Phi_s \\ \Phi_\alpha \end{bmatrix} \eta_k \quad (8)$$

with $\Phi_s \in \mathbb{R}^{s \times m}$ and $\Phi_\alpha \in \mathbb{R}^{\alpha \times m}$ being the truncated modal matrices containing the corresponding s and α DOF, respectively. In this paper, it is chosen to use mode shapes from a finite element (FE) model, which is calibrated against modal parameters obtained from experimental modal analysis (EMA). From the first partition of Eq. (8),

$$y_k = \Phi_s \eta_k, \quad (9)$$

it is evident that a unique solution can only exist if the number of installed sensors, s , is no less than the number of considered modes, m . In cases where $s < m$, the measured output histories, y , should, if possible, be truncated or low-pass filtered such that at most s modes govern the signals.

The modal kinematics can be computed as

$$\eta_k = \Phi_s^\dagger y_k, \quad (10)$$

where $(\circ)^\dagger$ denotes the Moore-Penrose pseudo-inverse, which, in this case, minimizes $\|y_k - \Phi_s \eta_k\|_2$. When the modal kinematics are obtained, the physical response at the α desired locations can be readily estimated as

$$\mu_k = \Phi_\alpha \eta_k. \quad (11)$$

3.2 Kalman filter (KF) algorithm

The KF algorithm is a recursive algorithm, which estimates the full optimal state vector [7]. In the KF algorithm, the input is unknown and included in the process noise, $w_k \in \mathbb{R}^{2m}$ (and, as such, \tilde{w}_k), and measurement noise, $v_k \in \mathbb{R}^s$, such that Eqs. (4) and (7) become

$$\tilde{z}_{k+1} = \tilde{A}_d \tilde{z}_k + \tilde{w}_k \quad (12)$$

$$y_k = \tilde{C}_d \tilde{z}_k + v_k. \quad (13)$$

When accelerations are measured, a correlation between w_k and v_k is present [9]. Hence, to accommodate a general framework, w_k and v_k are assumed to be mutually correlated, zero mean, white signals with known covariance matrices, $Q \in \mathbb{R}^{2m \times 2m}$, $R \in \mathbb{R}^{s \times s}$ and $S \in \mathbb{R}^{2m \times s}$, given as

$$Q = \mathbb{E}[w_k w_k^T], \quad R = \mathbb{E}[v_k v_k^T], \quad S = \mathbb{E}[w_k v_k^T]. \quad (14)$$

The process noise covariance matrix, Q , indicates how accurate the algorithm considers the model to be, whereas the measurement noise covariance matrix, R , indicates the confidence put into the measured data. It is chosen to employ the approach outlined in [10], such that the triplet $\{Q, R, S\}$ is estimated as

$$\begin{bmatrix} Q & S \\ S^T & R \end{bmatrix} = \begin{bmatrix} \tilde{B}'_d \\ \tilde{D}'_d \end{bmatrix} U_{\text{in}} \begin{bmatrix} \tilde{B}'_d{}^T & \tilde{D}'_d{}^T \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & U_{\text{out}} \end{bmatrix}, \quad (15)$$

Algorithm 1: The KF algorithm.

```

for  $k = 0$  to  $k = N - 1$  do
    Measurement update:
    (1)  $K_k = P_{k|k-1}^z \tilde{C}_d^T (\tilde{C}_d P_{k|k-1}^z \tilde{C}_d^T + R)^{-1}$ 
    (2)  $\hat{z}_{k|k} = \hat{z}_{k|k-1} + K_k (y_k - \tilde{C}_d \hat{z}_{k|k-1})$ 
    (3)  $P_{k|k}^z = P_{k|k-1}^z - K_k \tilde{C}_d P_{k|k-1}^z$ 
    Time update:
    (4)  $\hat{z}_{k+1|k} = \tilde{A}_d \hat{z}_{k|k}$ 
    (5)  $P_{k+1|k}^z = \tilde{A}_d P_{k|k}^z \tilde{A}_d^T + Q - \tilde{A}_d K_k S^T - S K_k^T \tilde{A}_d^T$ 
end
    
```

where $U_{\text{out}} = \sigma_{\text{out}}^2 I$ with σ_{out}^2 defined from known sensor characteristics or utilized as a tuning parameter, and $U_{\text{in}} = \sigma_{\text{in}}^2 I$ with σ_{in}^2 being the variance of the known input. If more than one input acts on the structure, σ_{in}^2 can, for example, be taken as the mean variance of the inputs. In Eq. (15), $\tilde{B}'_d \in \mathbb{R}^{2m \times n}$ and $\tilde{D}'_d \in \mathbb{R}^{s \times n}$ differ from $\tilde{B}_d \in \mathbb{R}^{2m \times p}$ and $\tilde{D}_d \in \mathbb{R}^{s \times p}$ as excitation in all DOF are assumed in the FE model; that is, $p = n$.

The KF algorithm is presented in Algorithm 1 according to [10], where $(\hat{\cdot})$ denotes an estimated quantity and $K_k \in \mathbb{R}^{2m \times s}$ is the Kalman gain, which is calculated such that the state estimate is minimum-variance and unbiased. Algorithm 1 is initialized using an initial state estimate vector, $\hat{z}_{0|-1}$, assumed independent of w_k and v_k , and its associated error covariance matrix, $P_{0|-1}^z$, defined as

$$P_{k|k}^z = \mathbb{E}[(\tilde{z}_k - \hat{z}_k)(\tilde{z}_k - \hat{z}_k)^T] \in \mathbb{R}^{2m \times 2m}. \quad (16)$$

After $\hat{z}_{k|k}$ is computed, the response can be estimated at desired locations using

$$\mu_{k|k} = \tilde{C}_{d,e} \hat{z}_{k|k}, \quad (17)$$

where the output matrix is redefined as

$$\tilde{C}_{d,e} = [S_{d,e} \Phi - S_{a,e} \Phi \tilde{K} \quad S_{v,e} \Phi - S_{a,e} \Phi \tilde{C}] \in \mathbb{R}^{\alpha \times 2m} \quad (18)$$

with subscript e referring to estimation and the distribution matrices, $S_{d,e}, S_{v,e}, S_{a,e} \in \mathbb{R}^{\alpha \times n}$, relating the estimated quantities to the designated locations.

3.3 Joint input-state estimation (JISE) algorithm

The JISE algorithm is an extension of the KF algorithm, as it jointly estimates both the input(s) and states from a limited number of sensor measurements [8]. Therefore, Eqs. (12) and (13) are extended to

$$\tilde{z}_{k+1} = \tilde{A}_d \tilde{z}_k + \tilde{B}_d f_k + \tilde{w}_k \quad (19)$$

$$y_k = \tilde{C}_d \tilde{z}_k + \tilde{D}_d f_k + v_k \quad (20)$$

in which it is assumed that w_k and v_k are correlated, zero mean and white noise signals. As such, Eqs. (14) and (15) still hold.

Algorithm 2: The JISE algorithm.

```

for  $k = 0$  to  $k = N - 1$  do
    Input estimation:
    (1)  $\hat{R}_k = \tilde{C}_d P_{k|k-1}^z \tilde{C}_d^T + R$ 
    (2)  $M_k = (\tilde{D}_d^T \hat{R}_k^{-1} \tilde{D}_d)^{-1} \tilde{D}_d^T \hat{R}_k^{-1}$ 
    (3)  $\hat{f}_{k|k} = M_k (y_k - \tilde{C}_d \hat{z}_{k|k-1})$ 
    (4)  $P_{k|k}^f = (\tilde{D}_d^T \hat{R}_k^{-1} \tilde{D}_d)^{-1}$ 

    Measurement update:
    (5)  $K_k = P_{k|k-1}^z \tilde{C}_d^T \hat{R}_k^{-1}$ 
    (6)  $\hat{z}_{k|k} = \hat{z}_{k|k-1} + K_k (y_k - \tilde{C}_d \hat{z}_{k|k-1} - \tilde{D}_d \hat{f}_{k|k})$ 
    (7)  $P_{k|k}^z = P_{k|k-1}^z - K_k (\hat{R}_k - \tilde{D}_d P_{k|k}^f \tilde{D}_d^T) K_k^T$ 
    (8)  $P_{k|k}^{zf} = (P_{k|k}^{fz})^T = -K_k \tilde{D}_d P_{k|k}^f$ 

    Time update:
    (9)  $\hat{z}_{k+1|k} = \tilde{A}_d \hat{z}_{k|k} + \tilde{B}_d \hat{f}_{k|k}$ 
    (10)  $N_k = \tilde{A}_d K_k (I - \tilde{D}_d M_k) + \tilde{B}_d M_k$ 
    (11)  $P_{k+1|k}^z = [\tilde{A}_d \quad \tilde{B}_d] \begin{bmatrix} P_{k|k}^z & P_{k|k}^{zf} \\ P_{k|k}^{fz} & P_{k|k}^f \end{bmatrix} \begin{bmatrix} \tilde{A}_d^T \\ \tilde{B}_d^T \end{bmatrix} + Q - N_k S^T - S N_k^T$ 
end
    
```

The JISE algorithm, presented in Algorithm 2 according to [10], is a three-step recursive filter, where $\hat{f}_{k|k}$ is the estimated input vector, $M_k \in \mathbb{R}^{p \times s}$ is the gain related to the input estimate and I is the identity matrix of appropriate size. The algorithm is, just like in the KF, initialized using an initial state vector, $\hat{z}_{0|-1}$, and its associated error covariance matrix, $P_{0|-1}^z$, defined in Eq. (16). After initialization, the algorithm recursively estimates the input and state vector. When the estimated state vector, $\hat{z}_{k|k}$, is computed, the response can be estimated at α desired locations by

$$\mu_{k|k} = \tilde{C}_{d,e} \hat{z}_{k|k} + \tilde{D}_{d,e} \hat{f}_{k|k}, \quad (21)$$

where $\tilde{C}_{d,e} \in \mathbb{R}^{\alpha \times 2m}$ is defined in Eq. (18) and $\tilde{D}_{d,e} = [S_{a,e} \Phi \Phi^T S_p] \in \mathbb{R}^{\alpha \times p}$ is the input-output transmission matrix.

Worth of explicit note regarding Algorithm 2 is that \hat{R}_k becomes rank deficient if $s > m$, while $\tilde{D}_d^T \hat{R}_k^{-1} \tilde{D}_d$ becomes rank deficient if $s > m$, $p > s$ or $p > m$. To prevent conditioning issues, the matrices can, as outlined in [11], be truncated using a singular value decomposition (SVD) procedure.

4 EXPERIMENTAL SETUP

The performance of the three virtual sensing methods is examined in an experimental context with a cantilevered beam, which is installed with nine uniaxial Brüel & Kjær (B&K) type 4507 piezoelectric accelerometers, see Fig. 1. The beam is treated in two different input settings; the first being an impulse

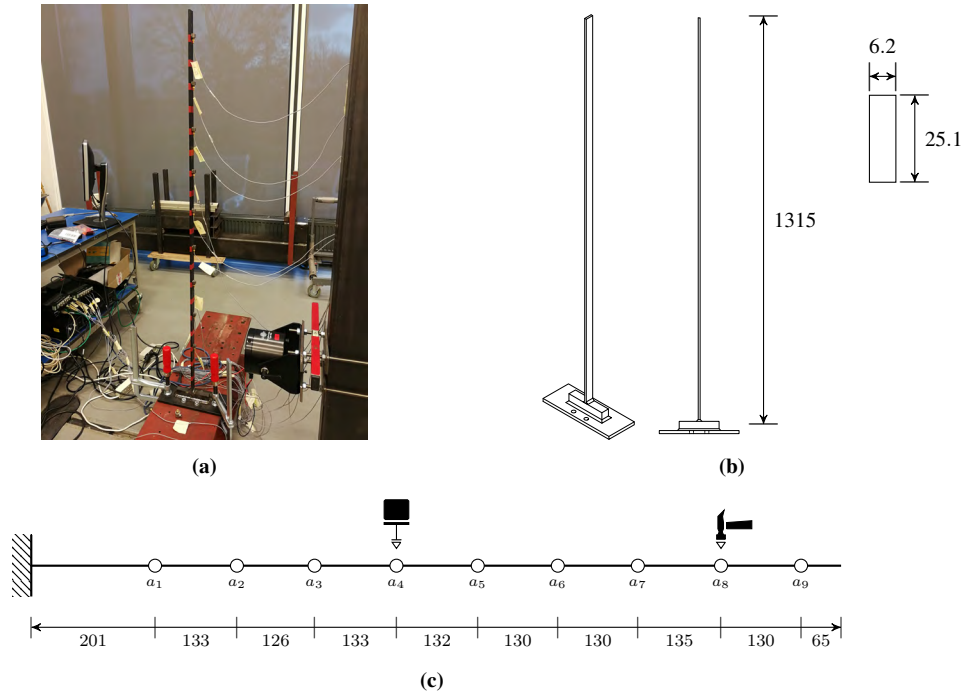

Figure 1: (a) Picture of the experimental setup with installed accelerometers on the cantilever beam, (b) illustration of the beam and its cross-section with dimensions and (c) spatial distribution of the accelerometers (denoted a_{1-9}), the pseudo-random input acting at a_4 and the impulse input applied at a_8 . All dimensions are in mm.

excitation with a B&K type 8206 impact hammer and the second being a pseudo-random excitation with a B&K type 4809 shaker. In Fig. 1c, the spatial distribution of the accelerometers is shown along with the input locations. The accelerations captured from the impulse excitation are low-pass filtered with a cut-off frequency of 250 Hz to include the first six in-plane bending modes, while the pseudo-random input acts within a frequency span of $[0, 100]$ Hz to include the first four in-plane bending modes.

5 NUMERICAL MODEL

The modal parameters of the first six in-plane bending modes are identified using a deterministic subspace state-space system identification algorithm [12]. Furthermore, the modulus of elasticity and mass density are from preliminary non-destructive tests found to be $E = 201$ GPa and $\rho = 7770$ kg/m³,

Table 1: Comparison of the identified and model-predicted eigenfrequencies and mode shapes. Furthermore, the identified modal damping ratios are shown.

Mode	$\bar{\omega}_{FE}$ [Hz]	$\bar{\omega}_{ID}$ [Hz]	$\frac{\bar{\omega}_{FE} - \bar{\omega}_{ID}}{\bar{\omega}_{ID}} 100$ [%]	ζ_{ID} [%]	MAC [–]
1	2.82	2.82	0.00	1.33	1.00
2	17.58	17.48	0.57	0.38	1.00
3	48.69	48.68	0.02	0.27	1.00
4	96.13	97.17	–1.08	0.33	0.99
5	161.21	161.77	–0.35	0.28	0.99
6	240.13	237.02	1.30	0.30	0.99

respectively. From the identified modal and material parameters, a FE model, discretized using 20 2D Euler-Bernoulli beams, is established. Subsequently, the FE model is calibrated against the identified undamped eigenfrequencies and mode shapes, where the percentage-wise eigenfrequency error and the modal assurance criterion (MAC) [13] are, respectively, minimized and maximized by adding point masses (from the equipment) and a rotational spring at the kinematic boundary condition. In Table 1, the identified modal parameters are compared with those of the calibrated FE model. As can be seen, the identified and numerical mode shapes are almost fully correlated with MAC values ≥ 0.99 for all modes, while the undamped eigenfrequencies deviate $\leq 1.30\%$.

6 COMPARATIVE ANALYSIS OF VIRTUAL SENSING METHODS

6.1 Assessment criteria for vibration estimation

To assess and compare the performance of the methods outlined in Section 3, the time response criterion (TRAC) [14] and the mean absolute error (MAE) are utilized. In this application, the former expresses the correlation at one DOF, i , between an estimated and a measured output signal, thus

$$\text{TRAC}_i = \frac{\left(\sum_{k=1}^N y_k^{(i)} \mu_k^{(i)}\right)^2}{\sum_{k=1}^N y_k^{(i)} y_k^{(i)} \sum_{k=1}^N \mu_k^{(i)} \mu_k^{(i)}} \in [0, 1]. \quad (22)$$

Here, a value of one implies full correlation, while a value of zero corresponds to no correlation. As the TRAC does not account for magnitude errors in the estimated signal, the MAE is introduced as the mean average error magnitude between an estimated and a measured signal at one DOF, i . As such,

$$\text{MAE}_i = \frac{1}{N} \sum_{k=1}^N |y_k^{(i)} - \mu_k^{(i)}| \in [0, \infty], \quad (23)$$

hence implying that $\text{MAE} = 0$ and $\text{TRAC} = 1$ indicate a perfect estimation.

6.2 Sensor configurations

From the nine installed accelerometers, see Fig. 1c, it is chosen to analyze 11 different subset of sensor configurations for both input types. In Fig. 2, an example of a sensor configuration—consisting of three accelerometers, namely, a_5 , a_7 and a_8 —is depicted along with the assumed virtual sensor, a_6 (marked with \bullet).

6.3 Impulse excitation

In Table 2, TRAC and MAE values for the 11 sensor configurations are presented for the case of a virtual sensor deployed instead of a_6 . The KF and JISE algorithms are initialized using $\hat{z}_{0|-1} = 0$ and $P_{0|-1}^z = 0$, as the initial state is known exactly. For the presented sensor configurations, the KF yields $\text{TRAC} \in [0.89, 0.99]$ and $\text{MAE} \in [0.09, 0.41] \text{ m/s}^2$ and JISE yields $\text{TRAC} \in [0.96, 1.00]$ and $\text{MAE} \in [0.09, 0.28] \text{ m/s}^2$. The ME scheme yields $\text{TRAC} \in [0.27, 1.00]$ and $\text{MAE} \in [0.08, 1.97] \text{ m/s}^2$, where

Figure 2: A sensor configuration with physical accelerometers (\circ) and a virtual sensor (\bullet).

Table 2: TRAC and MAE values for 11 sensor configurations. The beam is illustrated in the top with the chosen virtual sensor (●) and all the physical accelerometers (○). The impulse input is applied at a_8 and the first six bending modes are utilized in all configurations.

Config. no.	Considered accelerometers, a_i	TRAC [–]			MAE [m/s ²]		
		ME	KF	JISE	ME	KF	JISE
1	1,2,3,4,5,7,8,9	1.00	0.98	0.99	0.08	0.09	0.09
2	1,8,9	0.55	0.89	0.99	1.90	0.24	0.15
3	1,8	0.52	0.96	0.98	1.97	0.29	0.16
4	8,9	0.64	0.91	0.99	1.86	0.18	0.13
5	5,7,8	0.95	0.99	1.00	0.69	0.11	0.08
6	7,8	0.57	0.97	0.98	1.38	0.23	0.15
7	5,8	0.27	0.95	0.98	1.65	0.29	0.16
8	2,4,8	0.82	0.97	0.98	1.81	0.32	0.23
9	2,8	0.81	0.96	0.96	1.83	0.27	0.23
10	4,8	0.80	0.97	0.99	1.88	0.27	0.12
11	8	0.63	0.93	0.97	1.92	0.41	0.28

we note that the inconsistent performance is a consequence of having more modes than sensors in all configurations except no. 1.

To examine the performance when estimating at other locations than a_6 , virtual sensors are now deployed at the unmeasured locations for sensor configurations no. 5 and 8, see Figs. 3 and 4. It is observed that the KF and JISE schemes perform well for both configurations compared to ME, which—

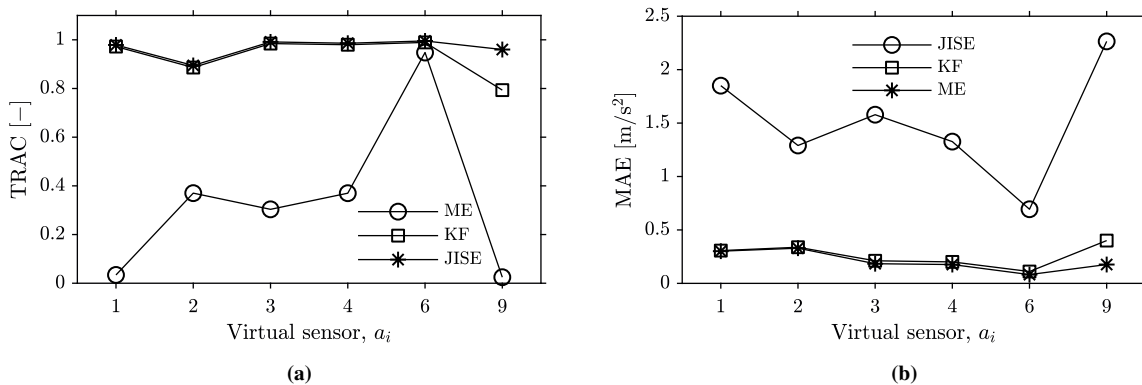

Figure 3: (a) TRAC and (b) MAE values for different virtual sensors using configuration no. 5 from Table 2.

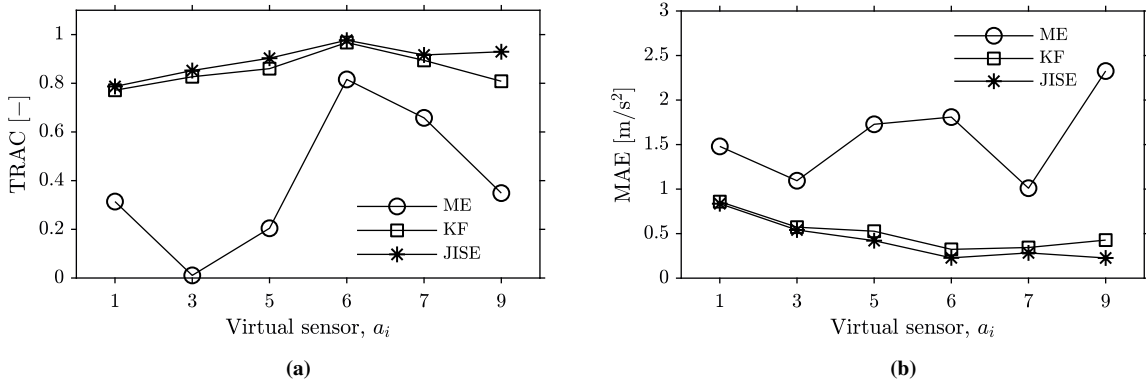

Figure 4: (a) TRAC and (b) MAE values for different virtual sensors using configuration no. 8 from Table 2.

Figure 5: (a) TRAC and (b) MAE values for sensor configuration no. 8 from Table 2 using truncated data. Note that the interval on the second axis has changed from $[0, 3]$ to $[0, 0.25]$ m/s^2 compared to Fig. 4b.

in the underdetermined case where $s < m$ —is particularly sensitive to the placement of virtual sensors with respect to the specific physical sensor configuration. For instance, when utilizing configuration no. 5 for ME, the virtual sensor at a_6 yields $\text{TRAC} = 0.95$ and $\text{MAE} = 0.69 \text{ m/s}^2$, while a virtual sensor at a_9 yields $\text{TRAC} = 0.02$ and $\text{MAE} = 2.26 \text{ m/s}^2$, see Fig. 3. To exemplify the importance of having more sensors than modes in the ME scheme, some of the measured time histories for configuration no. 8 are removed such that $s \geq m$ is fulfilled. Hereby, we obtain the results depicted in Fig. 5, where it is seen that the performance of ME improves considerably when compared to Fig. 4. It is noted that ME improves for all configurations when $s \geq m$ is fulfilled.

6.4 Pseudo-random excitation

In Table 3, TRAC and MAE values for 11 sensor configurations are shown for the case of pseudo-random input and a virtual sensor deployed instead of a_6 . The KF and JISE algorithms are initialized with $\hat{z}_{0|-1} = 0$ and $P_{0|-1}^z = 0$, where JISE yields $\text{TRAC} \in [0.62, 0.98]$ and $\text{MAE} \in [0.40, 1.93]$, while the KF yields $\text{TRAC} \in [0.19, 0.87]$ and $\text{MAE} \in [1.15, 3.45]$. Correspondingly, ME provides $\text{TRAC} \in [0.01, 1.00]$ and $\text{MAE} \in [0.09, 3.84]$.

Configurations no. 7 and 10, which both fulfil $s \geq m$, are used to examine the performance when

Table 3: TRAC and MAE values for 11 sensor configurations. The beam is illustrated in the top with the chosen virtual sensor (●) and all the physical accelerometers (○). The pseudo-random input is applied at a_4 and the first four bending modes are utilized in all configurations.

virtual sensors are deployed at all unmeasured locations, see Figs. 6 and 7. Here, ME performs better than the KF and JISE at all locations for sensor configuration no. 7, while ME performs poorly when using sensor configuration no. 10. The latter is due to poor sensor placement, as a_1 and a_2 capture low modal amplitudes. When comparing configuration no. 10 with 4, where a_2 is changed with a_8 , one observes a considerable improvement in the performance of ME, see Fig. 8. The importance of

well-placed sensors is elaborated by the authors in [15].

7 CONCLUSIONS

In the present paper, experimentally obtained vibration measurements are used to compare the performance of three vibration estimation schemes, namely, ME, KF and JISE. The comparative analysis is based on a cantilevered beam subjected to an impulse and a pseudo-random input. The findings suggest that if the number of installed sensors is no less than the number of considered modes, that is, $s \geq m$, ME is the preferable method. If $s \geq m$ is not fulfilled, JISE is the preferable method, as it generally outperforms ME and KF and demonstrates the lowest sensitivity to the sensor distribution.

Key words: Optimal sensor distribution, Vibration estimation, Effective independence, Driving point residue, Kinetic energy.

Abstract. The general outset in vibration analysis is that a sensor distribution is optimal if the utility of the deployed system is maximized; with system referring to, for example, an identification system if the sensors are deployed to facilitate modal parameter estimation or a monitoring system if damage detection is the target. While numerous studies have been presented in the context of system identification and structural health monitoring, few studies have addressed the sensor placement task for vibration estimation (also known as virtual sensing). Therefore, the present paper offers an examination of this by adapting four schemes—developed and widely used for optimal sensor placement in system identification and structural health monitoring—for placing sensors to estimate unmeasured vibrations from a limited number of output sensors. More specifically, we test the performance of the effective independence (EI) method, the driving point residue (DPR) method, a combination of the two (the EI-DPR method), and the kinetic energy (KE) method in the context of estimating unmeasured vibrations of a structural system of engineering interest.

1 INTRODUCTION

Within civil and mechanical engineering, it is common practice to use vibration measurements for structural monitoring and control purposes [1, 2, 3]. The vibrations are captured through an installed sensor network, which, in most applications, consists of a limited number of sensors due to the associated costs and the fact that there may be locations inaccessible for instrumentation. As such, virtual sensing can be utilized to estimate vibration responses at designated locations from response acquired by the installed sensor network [4, 5].

In [6], an experimental comparison study is conducted to assess the performance of three well-established virtual sensing methods, namely, modal expansion (ME) [7, 8], Kalman filtering [9] and a joint input-state estimation (JISE) algorithm [10], which, in addition to estimating the full optimal state vector, also estimates the unknown input. The findings reported in [6] aid to the general proposition that the performance of the virtual sensing methods is greatly affected by the number and distribution of sensors. While only a few studies have been put forth for optimal sensor placement for virtual sensing [11], the topic has been explored extensively in the context of system identification [12, 13, 14] and structural health monitoring [15, 16, 17]. Within both these application areas, a widely adopted approach is to, a

priori, select the type and number of sensors to install and then proceed by treating the task as a discrete optimization problem in which the sensor locations are the variables. What distinguishes each method is, as such, the cost function that must be minimized/maximized.

In this paper, we offer an examination of the virtual sensing applicability of four well-established sensor distribution schemes, which, albeit proposed for either system identification or structural health monitoring, all have cost functions with expected merit in the context of vibration estimation. Specifically, we test (1) the effective independence (EI) method [12], which places sensors to maximize the linear independence of the mode shapes, (2) the driving point residue (DPR) method [18], which places sensors to maximize the average modal amplitudes, (3) the EI-DPR method [19], which directly combines the EI and DPR methods, and (4) the kinetic energy (KE) method [20], which places sensors to maximize the kinetic energy. The methods are tested in a numerical framework with a finite element (FE) frame structure, where the ME technique and the JISE algorithm are utilized to estimate vibrations from the sensor networks deployed based on the four distribution schemes.

The paper is organized as follows: in Section 2, we present the prerequisite vibration theory that forms the basis for the vibration estimation techniques and sensor distribution methods outlined in Sections 3 and 4. Section 5 presents the numerical example in which the performance of the sensor distribution methods is examined and compared. Lastly, some concluding remarks are given in Section 6.

2 PREREQUISITE THEORY

Assuming the structure of interest is classically damped, can be adequately described with n degrees of freedom (DOF) and linear, time invariant (LTI) conditions hold, the temporal equation of motion is given as

$$M\ddot{x}(t) + C\dot{x}(t) + Kx(t) = S_p f(t). \quad (1)$$

Here, $K, C, M \in \mathbb{R}^{n \times n}$ are the stiffness, damping and mass matrices, $x(t), \dot{x}(t), \ddot{x}(t) \in \mathbb{R}^n$ are the nodal displacements, velocities and accelerations, and $f(t) \in \mathbb{R}^p$ contains the p external inputs distributed by $S_p \in \mathbb{R}^{n \times p}$. By introducing the modal transformation

$$x(t) \approx \sum_{i \in \mathcal{A}} \phi_i q_i(t) = \Phi q(t), \quad (2)$$

where \mathcal{A} denotes a subset holding the indexes of the $m \leq n$ governing modes and $\Phi = [\phi_1 \ \phi_2 \ \dots \ \phi_m] \in \mathbb{R}^{n \times m}$ is the truncated modal matrix containing mass-normalized mode shapes, Eq. (1) is transformed to modal coordinates as

$$\ddot{q}(t) + \tilde{C}\dot{q}(t) + \tilde{K}q(t) = \Phi^T S_p f(t), \quad (3)$$

with \tilde{C} being the modal damping matrix and \tilde{K} the spectral matrix.

By defining the modal state vector, $\tilde{z}(t)^T = [q(t)^T \ \dot{q}(t)^T]^T \in \mathbb{R}^{1 \times 2m}$, and rewriting Eq. (3) into discrete state-space form, one has

$$\tilde{z}_{k+1} = \tilde{A}_d \tilde{z}_k + \tilde{B}_d f_k, \quad (4)$$

where $\tilde{z}_k = \tilde{z}(k\Delta t)$ and $f_k = f(k\Delta t)$ for $k \in [0, N-1]$, with N being the total number of samples and Δt the time increment. Accepting a zero-order-hold, the state-transition matrix, $\tilde{A}_d \in \mathbb{R}^{2m \times 2m}$, and the input matrix, $\tilde{B}_d \in \mathbb{R}^{2m \times p}$, are given as

$$\tilde{A}_d = \exp \left(\begin{bmatrix} 0 & I \\ -\tilde{K} & -\tilde{C} \end{bmatrix} \Delta t \right) \quad (5)$$

$$\tilde{B}_d = [\tilde{A}_d - I] \begin{bmatrix} 0 & I \\ -\tilde{K} & -\tilde{C} \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ \Phi^T S_p \end{bmatrix}. \quad (6)$$

The s measured outputs are gathered in $y_k \in \mathbb{R}^s$ and defined as

$$y_k = \tilde{C}_d \tilde{z}_k + \tilde{D}_d f_k, \quad (7)$$

where $\tilde{C}_d = [S_d \Phi - S_a \Phi \tilde{K} \quad S_v \Phi - S_a \Phi \tilde{C}] \in \mathbb{R}^{s \times 2m}$ is the output matrix, $\tilde{D}_d = [S_a \Phi \Phi^T S_p] \in \mathbb{R}^{s \times p}$ is the input-output transmission matrix and $S_d, S_v, S_a \in \mathbb{R}^{s \times n}$ relate measured displacements, velocities and accelerations to the corresponding DOF in the numerical model.

3 VIBRATION ESTIMATION TECHNIQUES

The discrete system output is partitioned into two subsets: the s measured vibration quantities, $y_k \in \mathbb{R}^s$, and the α vibrations quantities to be estimated, $\mu_k \in \mathbb{R}^\alpha$.

3.1 Modal expansion (ME)

Let $\eta_k \in \mathbb{R}^m$ be the general notation for a modal kinematic quantity (depending on the nature of y_k), then the modal formulation is rewritten as

$$\begin{bmatrix} y_k \\ \mu_k \end{bmatrix} = \begin{bmatrix} \Phi_s \\ \Phi_\alpha \end{bmatrix} \eta_k \quad (8)$$

with $\Phi_s \in \mathbb{R}^{s \times m}$ and $\Phi_\alpha \in \mathbb{R}^{\alpha \times m}$ being the truncated modal matrices containing the corresponding s and α DOF, respectively. From the first partition of Eq. (8),

$$y_k = \Phi_s \eta_k, \quad (9)$$

it is evident that a unique solution can only exist if the number of installed sensors, s , is no less than the number of considered modes, m . In cases where $s < m$, the measured output histories, y , should, if possible, be truncated or low-pass filtered such that at most s modes govern the signals.

The modal kinematics can be computed as

$$\eta_k = \Phi_s^\dagger y_k, \quad (10)$$

where $(\circ)^\dagger$ denotes the Moore-Penrose pseudo-inverse, which, in this case, minimizes $\|y_k - \Phi_s \eta_k\|_2$. When the modal kinematics are obtained, the physical response at the α desired locations can be readily estimated as

$$\mu_k = \Phi_\alpha \eta_k. \quad (11)$$

3.2 Joint input-state estimation (JISE)

The JISE algorithm [10] is a modified Kalman filter [9] where the input(s) and states are recursively estimated at each time step k from sensor measurements. Eqs. (4) and (7) are extended to

$$\tilde{z}_{k+1} = \tilde{A}_d \tilde{z}_k + \tilde{B}_d f_k + \tilde{w}_k \quad (12)$$

$$y_k = \tilde{C}_d \tilde{z}_k + \tilde{D}_d f_k + v_k, \quad (13)$$

where w_k (and, as such, \tilde{w}_k) and v_k are assumed mutually correlated, zero mean and white signals with covariance matrices, $Q \in \mathbb{R}^{2m \times 2m}$, $R \in \mathbb{R}^{s \times s}$ and $S \in \mathbb{R}^{2m \times s}$, given as

$$Q = \mathbb{E}[w_k w_k^T], \quad R = \mathbb{E}[v_k v_k^T], \quad S = \mathbb{E}[w_k v_k^T]. \quad (14)$$

The process noise covariance matrix, Q , indicates how accurate the algorithm considers the model to be, whereas the measurement noise covariance matrix, R , indicates the confidence put into the measured data.

The JISE algorithm is presented in Algorithm 1 according to [21], where $(\hat{\cdot})$ denotes an estimated quantity, $K_k \in \mathbb{R}^{2m \times s}$ is the Kalman gain, which is calculated such that the state estimate is minimum variance and unbiased, and $M_k \in \mathbb{R}^{p \times s}$ is the gain related to the input estimate. Algorithm 1 is initialized using an initial state vector, $\hat{z}_{0|-1}$, assumed independent of w_k and v_k , and its associated error covariance matrix, $P_{0|-1}^z$, defined as

$$P_{k|k}^z = \mathbb{E}[(\tilde{z}_k - \hat{z}_k)(\tilde{z}_k - \hat{z}_k)^T] \in \mathbb{R}^{2m \times 2m}. \quad (15)$$

When the estimated state vector, $\hat{z}_{k|k}$, is computed, the unmeasured response can be estimated by

$$\mu_{k|k} = \tilde{C}_{d,e} \hat{z}_{k|k} + \tilde{D}_{d,e} \hat{f}_{k|k}, \quad (16)$$

where $\tilde{C}_{d,e} = [S_{d,e}\Phi - S_{a,e}\Phi\tilde{K} \quad S_{v,e}\Phi - S_{a,e}\Phi\tilde{C}] \in \mathbb{R}^{\alpha \times 2m}$ is the redefined output matrix and $\tilde{D}_{d,e} = [S_{a,e}\Phi\Phi^T S_p] \in \mathbb{R}^{\alpha \times p}$ is the redefined input-output transmission matrix, with subscript e referring to estimation and the distribution matrices, $S_{d,e}$, $S_{v,e}$, $S_{a,e} \in \mathbb{R}^{\alpha \times n}$, relating the estimated quantities to the designated locations.

    (10)  $N_k = \tilde{A}_d K_k (I - \tilde{D}_d M_k) + \tilde{B}_d M_k$ 
    (11)  $P_{k+1|k}^z = [\tilde{A}_d \quad \tilde{B}_d] \begin{bmatrix} P_{k|k}^z & P_{k|k}^{zf} \\ P_{k|k}^{fz} & P_{k|k}^f \end{bmatrix} \begin{bmatrix} \tilde{A}_d^T \\ \tilde{B}_d^T \end{bmatrix} + Q - N_k S^T - S N_k^T$ 
end
    
```

Worth of explicit note regarding Algorithm 1 is that \hat{R}_k becomes rank deficient if $s > m$, while $\tilde{D}_d^T \hat{R}_k^{-1} \tilde{D}_d$ becomes rank deficient if $s > m$, $p > s$ or $p > m$. To prevent conditioning issues, the matrices can, as outlined in [22], be truncated using a singular value decomposition (SVD) procedure.

4 SENSOR DISTRIBUTION METHODS

In the presentation of the four sensor distribution schemes, we distinguish between candidate sensor locations, l , and the final sensor locations, $s \subset l$. In this way, the former represents the set of all potential sensor locations, while the latter is the particular subset selected through the optimization.

4.1 The effective independence (EI) method

The EI method maximizes the linear independence of the considered mode shapes through an iterative process, where l candidate sensor locations are reduced to s locations. By defining the modal matrix, $\Phi_{\mathcal{B}} \in \mathbb{R}^{l \times m}$, adding white Gaussian noise, $u_k \in \mathbb{R}^l \sim \mathcal{N}(0, I\sigma)$, and rewriting Eq. (2) into discrete form, one has

$$x_k \approx \Phi_{\mathcal{B}} q_k + u_k. \quad (17)$$

The optimal estimate of q_k , denoted \hat{q}_k , is realized when the covariance matrix of the estimate errors, $J = \mathbb{E}[(q_k - \hat{q}_k)(q_k - \hat{q}_k)^T] \in \mathbb{R}^{m \times m}$, is minimized. In [12], it is shown that J can be written as

$$J = \left(\left(\frac{\partial x_k}{\partial q_k} \right)^T (\sigma^2)^{-1} \left(\frac{\partial x_k}{\partial q_k} \right) \right)^{-1} = \sigma^2 (\Phi_{\mathcal{B}}^T \Phi_{\mathcal{B}})^{-1} = \mathcal{F}^{-1}, \quad (18)$$

where $\mathcal{F} \in \mathbb{R}^{m \times m}$ is the Fisher information matrix (FIM). From Eq. (18), it is, given that $u_k \in \mathbb{R}^l \sim \mathcal{N}(0, I\sigma)$, seen how maximizing some suitable norm of the FIM, and, as such, $\Phi_{\mathcal{B}}^T \Phi_{\mathcal{B}}$, is tantamount to minimizing the covariance matrix of the estimate errors.

To determine which candidate sensor location to discard, one starts by solving the eigenvalue problem

$$(\Phi_{\mathcal{B}}^T \Phi_{\mathcal{B}} - \lambda I) \Psi = 0, \quad (19)$$

where $\Psi \in \mathbb{R}^{m \times m}$ contains the orthogonal eigenvectors and $\lambda \in \mathbb{R}^{m \times m}$ the associated eigenvalues. Worth of explicit note is that λ becomes rank deficient when $m > s$, which means that the amount of sensors utilized in the EI method can be no less than the number of considered modes. From the eigencharacteristics of $\Phi_{\mathcal{B}}^T \Phi_{\mathcal{B}}$, the EI coefficients at the l DOF are computed as

$$\mathcal{E} = (\Phi_{\mathcal{B}} \Psi) \otimes (\Phi_{\mathcal{B}} \Psi) \lambda^{-1} \mathcal{J} \in \mathbb{R}^l, \quad (20)$$

with \otimes denoting the Hadamard product (that is, term-by-term matrix multiplication) and $\mathcal{J} \in \mathbb{R}^m$ a vector with only ones. The procedure is to iteratively exclude the candidate sensor location associated with $\min\{\mathcal{E}\}$ and subsequently update Eqs. (19) and (20) until $l = s$.

4.2 The driving point residue (DPR) method

The DPR method selects a sensor distribution that yields the highest average modal amplitudes for the considered modes; that is, the s DOF with the largest DPR coefficients. The i th DPR coefficient is defined as

$$\mathcal{D}_i = \sum_{j=1}^m \frac{\phi_{ij}^2}{\bar{\omega}_j}, \quad (21)$$

where $\bar{\omega}_j$ and ϕ_{ij} are the undamped eigenfrequency and the i th eigenvector component of the j th mode.

By multiplying the i th EI coefficient, \mathcal{E}_i , with \mathcal{D}_i for $i \in [1, l]$, one can couple the two methods to the EI-DPR method and iteratively exclude $\min\{\mathcal{E}_i \mathcal{D}_i\}$ until $l = s$. Hence, it is possible to avoid placing sensors in DOF with low energy content.

4.3 The kinetic energy (KE) method

The KE method provides a measure of the average kinetic energy at the l candidate sensor locations for all considered modes. By defining

$$C = \Phi_B \otimes M_B \Phi_B \in \mathbb{R}^{l \times m}, \quad (22)$$

where $M_B \in \mathbb{R}^{l \times l}$ is the mass matrix truncated to l DOF, the i th KE coefficient is given as

$$\mathcal{K}_i = \frac{1}{m} \sum_{j=1}^m C_{ij}, \quad (23)$$

from which the s highest coefficients are chosen as sensor locations.

5 NUMERICAL EXAMPLE

The sensor distribution methods are tested on the FE frame model depicted in Fig. 1a. The model is discretized using 75 2D Euler-Bernoulli beam elements, with a uniform cross-section of 10×10 mm. The modulus of elasticity, mass density and Poisson's ratio are set to $E = 205$ GPa, $\rho = 7750$ kg/m³ and $\nu = 0.3$, and classical damping is assumed with damping ratios $\zeta_i = 0.02$. A pseudo-random input, which excites the first four bending modes, is applied, and acceleration outputs are captured with a sampling frequency of 2 kHz for a time duration of 20 s.

5.1 Assessment criteria for evaluating sensor distributions

To assess and compare the performance of the sensor distribution methods, the time response criterion (TRAC) [23] and the mean absolute error (MAE) are utilized. In this application, the former expresses

Figure 1: (a) FE frame model excited with a pseudo-random input at the top right corner (illustrated with an arrow). All dimensions are in mm. (b) The first four bending modes of the FE model.

the correlation between a measured and an estimated output signal, thus

$$\text{TRAC}_i = \frac{\left(\sum_{k=1}^N y_k^{(i)} \mu_k^{(i)} \right)^2}{\sum_{k=1}^N y_k^{(i)} y_k^{(i)} \sum_{k=1}^N \mu_k^{(i)} \mu_k^{(i)}} \in [0, 1] \quad (24)$$

for the i th DOF. Here, a value of one implies full correlation, while a value of zero corresponds to no correlation. As the TRAC does not account for magnitude errors in the estimated signal, the MAE is introduced as the mean average error magnitude between a measured and an estimated acceleration signal. As such,

$$\text{MAE}_i = \frac{1}{N} \sum_{k=1}^N |y_k^{(i)} - \mu_k^{(i)}| \in [0, \infty], \quad (25)$$

hence implying that $\text{MAE} = 0$ and $\text{TRAC} = 1$ indicate a perfect estimation.

5.2 Results of the sensor distribution methods

The sensor networks selected by the sensor distribution methods are exemplified with six sensors in Fig. 2. As seen, the DPR and KE approaches cluster the sensors at the top floor, while the EI and EI-DPR approaches select DOF at multiple levels. In Table 1, the TRAC and MAE values provided by the different sensor distributions from Fig. 2 are presented. Here, JISE yields $\text{TRAC} \in [0.96, 1.00]$ and $\text{MAE} \in [0.16, 1.13] \text{ m/s}^2$, while ME yields $\text{TRAC} \in [0.00, 1.00]$ and $\text{MAE} \in [0.17, 547] \text{ m/s}^2$. As expected, ME performs best when using the sensor network suggested by the EI approach, as the scheme maximizes the linear independence between the eigenvectors.

The performance of the sensor distribution methods are assessed for $s \in [1, 30]$, see Fig. 3. Here, it is seen that the ME technique is more sensitive towards the number and placement of sensors than the JISE algorithm. For ME, the sensor networks selected by the EI and EI-DPR approaches yield similar results when $s \geq 7$. By visual inspection of Figs. 3a and 3b, it is further noted that the KE scheme and the DPR scheme require, respectively, 19 and 27 sensors in the ME technique to achieve similar results as the EI scheme provides with four sensors. When using the JISE algorithm, it is seen in Figs. 3c and 3d how the sensor networks suggested by the EI, EI-DPR and KE approaches yield similar results when $s \geq 7$,

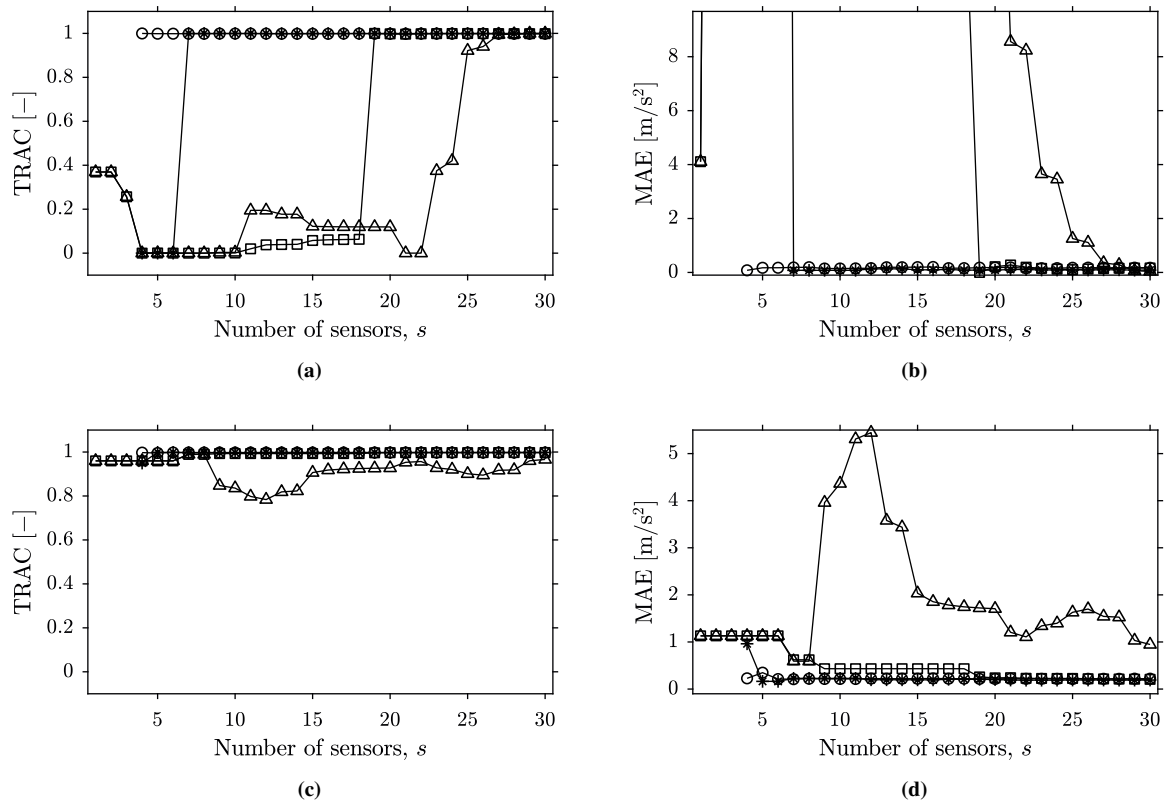

Figure 2: Distribution of six sensors when utilizing (a) the EI approach, (b) the DPR approach, (c) the EI-DPR approach and (d) the KE approach. The deployed virtual sensor is marked as (•) and the arrows indicate measurement in the horizontal direction.

Table 1: TRAC and MAE values for ME and JISE when utilizing six sensors distributed using the EI, DPR, EI-DPR and KE approaches, see Fig. 2.

Estimation method	TRAC [–]				MAE [m/s ²]			
	EI	DPR	EI-DPR	KE	EI	DPR	EI-DPR	KE
ME	1.00	0.00	0.00	0.00	0.17	547	129	547
JISE	1.00	0.96	1.00	0.96	0.21	1.13	0.16	1.13

while the MAE values are, more or less, equally good for the three methods. The best estimations are, in general, obtained utilizing the EI approach. It should, however, be recalled that the EI method (and, as such, the EI-DPR method) can only operate when $s \geq m$.

As the results in Fig. 3 are from ideal circumstances—that is, no model errors or measurement noise—a more realistic analysis setup is established. Here, model errors are introduced by assigning each element random perturbations such that eigenfrequency deviations up to 3.18 % and modal assurance criterion values ≥ 0.96 are observed. Furthermore, the outputs are polluted with 5 % white Gaussian noise. Hereby, the results depicted in Fig. 4 are obtained, where one observes the same tendencies as in

Figure 3: TRAC and MAE values for $s \in [1, 30]$ for (a, b) ME and (c, d) JISE. Note that the second axis in (b) is limited to 50 % of the maximum acceleration captured at the virtual sensor. The markers are assigned as follows: (O) EI, (Δ) DPR, (□) KE and (*) EI-DPR.

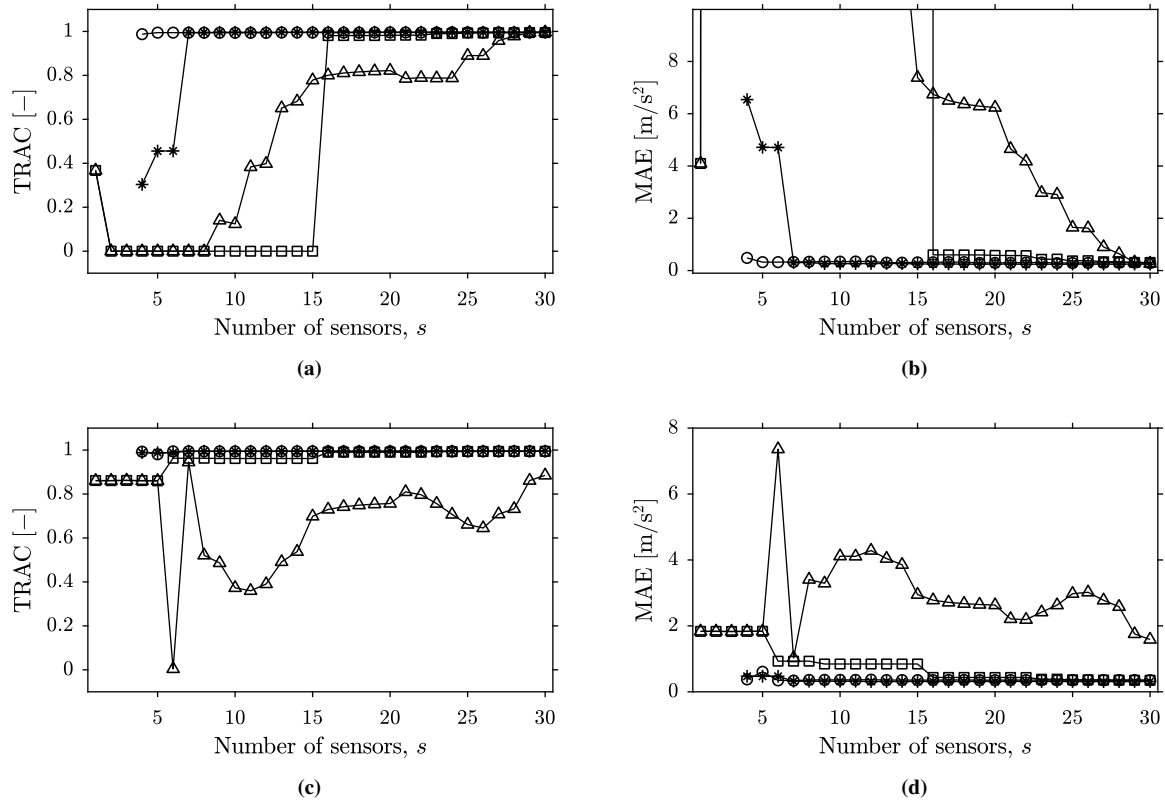

Figure 4: TRAC and MAE values for $s \in [1, 30]$ for (a, b) ME and (c, d) JISE. Note that the second axis in (b) is limited to 50 % of the maximum acceleration captured at the virtual sensor. The markers are assigned as follows: (○) EI, (△) DPR, (□) KE and (*) EI-DPR.

Fig. 3. It is worth of explicit note that, as seen in Figs. 4c and 4d, the performance of the DPR approach is impaired the most by model errors and noisy outputs.

6 CONCLUSIONS

In the present paper, the performance of different sensor distribution schemes, namely, EI, DPR, EI-DPR and KE is examined. The comparative analysis is based on a FE frame model subjected to a pseudo-random input, where accelerations at a designated location are estimated by means of the ME technique and JISE algorithm. The findings suggest in this particular application that when utilizing either ME or JISE for virtual sensing, the EI scheme is preferable for sensor placement, as it yields good results for all distributions when $s \geq m$. If utilizing JISE when $s < m$, the DPR and KE approach yield the exact same results for this particular application.

Key words: Ring Type, Nonlinear Fault, Damage Indicator, Fault Localization.

Abstract. In order to localize nonlinear faults in ring type structures, a novel second-order output spectrum (SOOS) based method is proposed in this paper. Along the vibration transmission paths in complex structures, the ring type structures are found and labeled by the sensor chains. The ring type multiple degree-of-freedom (MDOF) model and Volterra series are utilized to describe the nonlinear behavior of these ring type structures with nonlinear faults and inherent nonlinearity. With harmonic excitation analysis and local tuning approach (LTA), the properties of the SOOS of nonlinear ring type structure are derived and analyzed. Based on these properties, a novel SOOS based method with a local damage index is proposed for nonlinear fault localization. In the numerical study, the results of comparison between previous and novel methods demonstrate that the proposed local damage index can provide more correct information of fault positions, and hence the novel method can be used for multiple fault diagnosis in ring type structure with inherent nonlinearity.

1 INTRODUCTION

Bolt self-loosening frequently exists in complex structures like offshore platforms and bridges since these engineering structures are often subjected to various dynamic loads in their service process [1]. Some results in the literature demonstrate that structural failure caused by bolt-loosening will affect the smooth operation of structures and even cause some catastrophic accidents [2,3]. Therefore, evaluating the integrity of structures is a very important objective to minimize the downtime of structures and save maintenance costs. For this purpose, numerous fault diagnosis methods have been proposed [4-6]. Compared with others, vibration-based approaches provide more theoretical and operational simplicity [4]. The basic principle of this indirect method is that faults will change the structural properties (mass, damping and stiffness), which in turn will alter the vibration characteristics of the structure. Thus, the changes in vibration features can be used to evaluate the durability of structures [6]. Moreover, many structures with loose bolts behave in a nonlinear way [1,7]. For example, joint structures with loose bolts have nonlinear stiffness and damping [1]. Therefore, vibration-based methods utilizing the nonlinearity caused by bolt-loosening faults have been proposed and provide high sensitive damage indicators for fault diagnosis in complex structures [8].

Nonlinearity-based transmissibility (TF), defined as the ratio of output spectra between two

different response points of structures, is more available for the diagnosis of localized nonlinear damages since it considers nonlinearity due to faults and depends on structural zeros solely [9]. Considering the cubic nonlinear internal forces caused by loosen bolts, the properties of TF of multi-degree-of-freedom (MDOF) system were derived and then were applied for a rotorcraft fuselage [10]. Based on an efficient n th-order output spectrum estimation (n th-OSE) algorithm [11,12], the second order output spectrum (SOOS) was calculated through measured data directly, and the more sensitive SOOS based TF was defined to diagnose crack flaw in a beam-like structure [13], and then was applied to a satellite-like structure with bolt-loosening faults and inherent nonlinearity later [14]. The novel SOOS based methods provide higher sensitivity for local nonlinear faults in complex structures with inherent nonlinearity, while some problems should be further studied such as the MDOF model used to describe the behaviour of complex structures. In most previous fault diagnosis methods, the open chain type MDOF model with nonlinear connections is used for cantilever beams [15] and suspension systems of vehicle [16]. However, this MDOF model may not be suitable for other complex structures like pipelines [17] and steel frames [18].

To consider this issue, the nonlinear fault localization in ring type structures is studied in this paper. The main novelty of this paper is summarized below. (1) a more general ring type MDOF model with nonlinear restoring forces is built to describe the nonlinear behaviour of ring type structures. (2) Harmonic excitation analysis and local tuning approach (LTA) are utilized to derive the properties of the SOOS of nonlinear ring type structures. (3) A novel method with a local damage index, which is proposed based on the properties of the SOOS, can provide more position information of nonlinear faults in ring type structures even with inherent nonlinearity.

The rest of this paper is organized below. Section 2 introduces some basic theory about the model of ring type structures. Section 3 derives the properties of the SOOS of nonlinear ring type structure. In Section 4, a novel method based on the properties of the SOOS is proposed and is verified by numerical study. Conclusions and discussions are given in Section 5.

2 NONLINEAR MODEL OF RING TYPE STRUCTURES

2.1 Ring type structures

The vibration transmission paths in some complex structures such as pipeline and frame structures can form a closed loop. Thus, the closed ring type sensor chains should be targeted for exploring effective methods for fault localization.

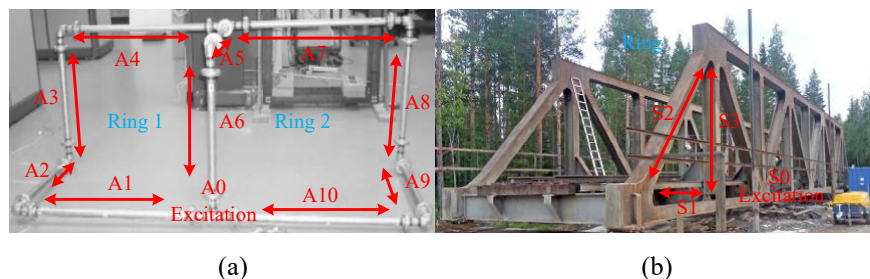

Figure 1: Ring type structures: (a) In a pipeline [17]; (b) In a steel frame [18]

Two typical examples of ring type structures are illustrated in Figure 1. When the pipeline structure (Figure 1(a)) is excited at A0, the closed vibration transmission paths (A0-A1-A2-A3-A4-A5-A6-A0 and A0-A6-A5-A7-A8-A9-A10-A0) can be regarded as two ring type structures, and can be used to detect and localize damaged bolted joints between pipes. Figure 1(b) shows a V-type planar truss which is formed by a series of triangles [18]. The nonlinear faults in beam members can be diagnosed through the dynamic output responses along the closed vibration transmission path labeled by a triangular sensor chain (S1-S2-S3-S1).

Overall, some pipeline and frame structures can be decomposed into some ring type structures, and the fault diagnosis of them can be performed by utilizing dynamic responses of these ring type structures.

2.2 Nonlinear MDOF model

According to the analysis above, a more general closed ring type MDOF model with nonlinear connections (Figure 2) is considered to describe the structural dynamic response of the ring type structure.

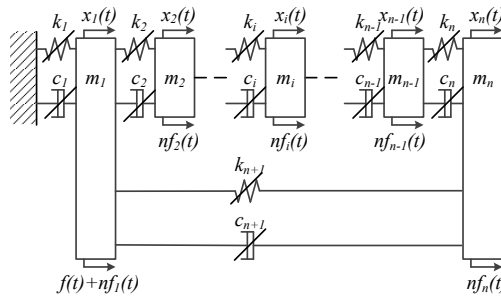

Figure 2: Ring type discretized MDOF model

The differential equation of motion can be written [8], as

$$[M]\{\ddot{x}\} + [C]\{\dot{x}\} + [K]\{x\} = \{f\} + \{nf\} \quad (1)$$

where $[M]$, $[C]$ and $[K]$ are mass, damping and stiffness matrices respectively. $\{\ddot{x}\}$, $\{\dot{x}\}$, $\{x\}$, $\{f\}$ and $\{nf\}$ are vectors of accelerations, velocities, displacements, external excitation forces and nonlinear restoring forces respectively.

To simulate the effects of inherent nonlinearity and nonlinear faults, the nonlinear restoring force vector $\{nf\}$, which is mainly a polynomial function of displacement and velocity responses [10], can be expressed, as

$$\{nf\} = \begin{Bmatrix} nf_1 \\ nf_2 \\ \vdots \\ nf_n \end{Bmatrix} = \begin{Bmatrix} nf_{-in-1} \\ nf_{-in-2} \\ \vdots \\ nf_{-in-n} \end{Bmatrix} + \begin{Bmatrix} nf_{-fa-1} \\ nf_{-fa-2} \\ \vdots \\ nf_{-fa-n} \end{Bmatrix}, i = 1, 2, \dots, n \quad (2a)$$

$$\begin{aligned}
 nf_{in_i} &= -\sum_{l=2}^{n^*} (c_{in_i,l} \dot{x}_i^l + k_{in_i,l} x_i^l); \\
 nf_{fa_i} &= \sum_{l=2}^{n^*} (c_{fa_i,l} \dot{S}_{i-1,i}^l + k_{fa_i,l} S_{i-1,i}^l) - \sum_{l=2}^{n^*} (c_{fa_i+1,l} \dot{S}_{i,i+1}^l + k_{fa_i+1,l} S_{i,i+1}^l); \\
 (\dot{S}_{i-1,i} &= \dot{x}_{i-1} - \dot{x}_i, S_{i-1,i} = x_{i-1} - x_i, \dot{x}_0 = \dot{x}_n, x_0 = x_n, \dot{x}_{n+1} = \dot{x}_1, x_{n+1} = x_1, c_{fa_1,l} = c_{fa_n+1,l}, k_{fa_1,l} = k_{fa_n+1,l})
 \end{aligned} \tag{2b}$$

where the term nf_{in_i} with nonlinear damping and stiffness parameters ($c_{in_i,l}$ and $k_{in_i,l}$) represents the nonlinear restoring force due to inherent nonlinearity, and the other term nf_{fa_i} with nonlinear damping and stiffness parameters ($c_{fa_i,l}$ and $k_{fa_i,l}$) represents the nonlinear restoring force caused by the i^{th} and/or the $(i+1)^{th}$ damaged damper-spring connections (nonlinear faults).

2.3 The Volterra model

The input-output relationship of above nonlinear MDOF structure can be expressed by the Volterra series up to order N^* [19-22], as

$$x_i(t) = \sum_{N=1}^{N^*} x_{i,N}(t) = \sum_{N=1}^{N^*} \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} h_{i,N}(\tau_1, \dots, \tau_N) \prod_{l=1}^N f(t - \tau_l) d\tau_l \tag{3}$$

where N^* is the maximum order of structure nonlinearity; $f(t)$ is the input; $h_{i,N}(\tau_1, \dots, \tau_N)$ and $x_i(t)$ are the N^{th} order Volterra kernel and output response of the i^{th} mass respectively.

Defining the N^{th} order generalized frequency response function (GFRF) as the multi-dimensional Fourier transform of the N^{th} order Volterra kernel gives [23]

$$H_{i,N}(j\omega_1, \dots, j\omega_N) = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} h_{i,N}(\tau_1, \dots, \tau_N) e^{-j(\omega_1\tau_1 + \dots + \omega_N\tau_N)} d\tau_1 \dots d\tau_N \tag{4}$$

Then, (4) could be rewritten with the inverse Fourier transform of the N^{th} order GFRF [22], as

$$x_i(t) = \sum_{N=1}^{N^*} x_{i,N}(t) = \sum_{N=1}^{N^*} \frac{1}{2\pi} \int_{-\infty}^{\infty} \left[\frac{1}{(2\pi)^{N-1}} \underbrace{\int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} \Xi_{i,N} d\omega_1 \dots d\omega_{N-1}}_{N-1} \right] e^{j\omega t} d\omega \tag{5}$$

where $\Xi_{i,N} = H_{i,N}(j\omega_1, \dots, j\omega_{N-1}, j(\omega - \omega_1 - \dots - \omega_{N-1})) F(j\omega_1) \dots F(j\omega_{N-1}) F(j(\omega - \omega_1 - \dots - \omega_{N-1}))$

Therefore, the nonlinear output spectrum of the MDOF structure can be expressed [22], as

$$X_i(j\omega) = \sum_{N=1}^{N^*} X_{i,N}(j\omega) = \sum_{N=1}^{N^*} \frac{1}{(2\pi)^{N-1}} \underbrace{\int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} \Xi_{i,N} d\omega_1 \dots d\omega_{N-1}}_{N-1} \tag{6}$$

where $X_{i,N}(j\omega)$ is the N^{th} order output spectrum of the i^{th} mass.

3 ANALYSIS OF NONLINEAR RING TYPE STRUCTURES

3.1 Harmonic excitation with single frequency

If the structure (Figure 1) is excited by

$$f(t) = e^{j\omega_1 t} \quad (7)$$

The corresponding output response is

$$x_i(t) = Y_{i,1}(j\omega_1)e^{j\omega_1 t} + \text{other higher order terms} \quad (8)$$

Substituting (7) and (8) into (1), and equating the coefficients of $e^{j\omega_1 t}$ yields the equation of motion of the i^{th} mass in the frequency domain, as

$$A_i(j\omega_1)Y_{i,1}(j\omega_1) - B_i(j\omega_1)Y_{i-1,1}(j\omega_1) - B_{i+1}(j\omega_1)Y_{i+1,1}(j\omega_1) = 0 \quad (9)$$

where $A_i(j\omega_1) = -m_i\omega_1^2 + j\omega_1 c_i + k_i + j\omega_1 c_{i+1} + k_{i+1}$ and $B_i(j\omega_1) = j\omega_1 c_i + k_i$

Both sides of (9) divided by $Y_{i,1}(j\omega_1)$ gives

$$A_i(j\omega_1) = B_i(j\omega_1) \frac{Y_{i-1,1}(j\omega_1)}{Y_{i,1}(j\omega_1)} + B_{i+1}(j\omega_1) \frac{Y_{i+1,1}(j\omega_1)}{Y_{i,1}(j\omega_1)} \quad (10)$$

Define

$$\chi_{i-1,i}^1(j\omega_1) = \frac{Y_{i-1,1}(j\omega_1)}{Y_{i,1}(j\omega_1)}; \quad \chi_{i+1,i}^1(j\omega_1) = \frac{Y_{i+1,1}(j\omega_1)}{Y_{i,1}(j\omega_1)} \quad (11)$$

Equation (10) can be rewritten, as

$$A_i(j\omega) = B_i(j\omega)\chi_{i-1,i}^1(j\omega) + B_{i+1}(j\omega)\chi_{i+1,i}^1(j\omega), (\omega = \omega_1) \quad (12)$$

It is shown that parameters $B_i(j\omega)$ and $B_{i+1}(j\omega)$ are functions of the linear physical properties between mass m_{i-1} and m_{i+1} , and they will remain constant even though there are nonlinear faults and inherent nonlinearity in the structure. If an additional equation, which has the same form as (12) but different values of $\chi_{i-1,i}^1(j\omega)$ and $\chi_{i+1,i}^1(j\omega)$, exists, the left term in (12) can be eliminated and thus the ratio of $B_i(j\omega)$ to $B_{i+1}(j\omega)$ can be calculated to indicate the connection state between mass m_{i-1} and m_{i+1} in the structure.

To find a satisfactory equation, a local tuning approach (LTA), described in Appendix A, can be applied. The ring type MDOF structure is excited by excitation (7) again, new equation which is similar to (9) can be obtained, as

$$A_i(j\omega_1)Y'_{i,1}(j\omega_1) - B_i(j\omega_1)Y'_{i-1,1}(j\omega_1) - B_{i+1}(j\omega_1)Y'_{i+1,1}(j\omega_1) = 0 \quad (13)$$

where $Y'_{i,1}(j\omega_1)$ is the first order output spectra (FOOS) of the i^{th} mass when the LTA has been implemented.

Define

$$\chi_{i-1,i}^{\prime 1}(j\omega_1) = \frac{Y'_{i-1,1}(j\omega_1)}{Y'_{i,1}(j\omega_1)}; \quad \chi_{i+1,i}^{\prime 1}(j\omega_1) = \frac{Y'_{i+1,1}(j\omega_1)}{Y'_{i,1}(j\omega_1)} \quad (14)$$

Equation (13) can be expressed, as

$$A_i(j\omega) = B_i(j\omega)\chi_{i-1,i}^{r1}(j\omega) + B_{i+1}(j\omega)\chi_{i+1,i}^{r1}(j\omega), (\omega = \omega_1) \quad (15)$$

It can be seen that (15) and (12) have the same form but different values of $\chi_{i-1,i}^1(j\omega)$ and $\chi_{i+1,i}^1(j\omega)$. Therefore, the left term in (15) and (12) can be eliminated and one ratio $\gamma_i^{1,r}(j\omega)$ can be deduced, as

$$\gamma_i^{1,r}(j\omega) = \frac{\chi_{i+1,i}^{r1}(j\omega) - \chi_{i-1,i}^1(j\omega)}{\chi_{i-1,i}^{r1}(j\omega) - \chi_{i-1,i}^1(j\omega)} = -\frac{B_i(j\omega)}{B_{i+1}(j\omega)} \quad (16)$$

The ratio $\gamma_i^{1,r}(j\omega)$ is a function of the physical properties $B_i(j\omega)$ and $B_{i+1}(j\omega)$.

3.2 Harmonic excitation with dual frequencies

Exciting the structure (1) by the following input force.

$$f(t) = e^{j\omega_1 t} + e^{j\omega_2 t} \quad (17)$$

The obtained output response of the i^{th} mass is

$$x_i(t) = Y_{i,2}(j\omega_1, j\omega_2)e^{j(\omega_1 + \omega_2)t} + \text{other higher order terms} \quad (18)$$

Substituting (17) and (18) into (1) and equating the coefficients of $e^{j(\omega_1 + \omega_2)t}$, the equation of motion of the i^{th} mass can be written, as

$$A_i(j\omega_1 + j\omega_2)Y_{i,2}(j\omega_1, j\omega_2) = B_i(j\omega_1 + j\omega_2)Y_{i-1,2}(j\omega_1, j\omega_2) + B_{i+1}(j\omega_1 + j\omega_2)Y_{i+1,2}(j\omega_1, j\omega_2) + NF_{i,2}(j\omega_1, j\omega_2) \quad (19)$$

where $NF_{i,2}(j\omega_1, j\omega_2) = NF_{in_i,2}(j\omega_1, j\omega_2) + NF_{fa_i,2}(j\omega_1, j\omega_2)$ is the second-order nonlinear restoring force vector caused by inherent nonlinearity and nonlinear connections (nonlinear faults) between mass m_{i-1} and m_{i+1} .

Assuming that there is only inherent nonlinearity in the benchmark structure (i.e., structure is in reference state), (19) can be expressed, as

$$A_i(j\omega_1 + j\omega_2)Y_{i,2}^r(j\omega_1, j\omega_2) = B_i(j\omega_1 + j\omega_2)Y_{i-1,2}^r(j\omega_1, j\omega_2) + B_{i+1}(j\omega_1 + j\omega_2)Y_{i+1,2}^r(j\omega_1, j\omega_2) + NF_{in_i,2}(j\omega_1, j\omega_2) \quad (20)$$

Subtracting (20) from (19), a new equation can be obtained, as

$$A_i(j\omega_1 + j\omega_2)Y_{i,2}^{d-r}(j\omega_1, j\omega_2) = A_i(j\omega_1 + j\omega_2)(Y_{i,2}(j\omega_1, j\omega_2) - Y_{i,2}^r(j\omega_1, j\omega_2)) \\ = B_i(j\omega_1 + j\omega_2)Y_{i-1,2}^{d-r}(j\omega_1, j\omega_2) + B_{i+1}(j\omega_1 + j\omega_2)Y_{i+1,2}^{d-r}(j\omega_1, j\omega_2) + NF_{fa_i,2}(j\omega_1, j\omega_2) \quad (21)$$

Both sides of (21) divided by $Y_{i,2}^{d-r}(j\omega_1, j\omega_2)$ gives

$$A_i(j\omega_1 + j\omega_2) = B_i(j\omega_1 + j\omega_2)\frac{Y_{i-1,2}^{d-r}(j\omega_1, j\omega_2)}{Y_{i,2}^{d-r}(j\omega_1, j\omega_2)} + B_{i+1}(j\omega_1 + j\omega_2)\frac{Y_{i+1,2}^{d-r}(j\omega_1, j\omega_2)}{Y_{i,2}^{d-r}(j\omega_1, j\omega_2)} + \frac{NF_{fa_i,2}(j\omega_1, j\omega_2)}{Y_{i,2}^{d-r}(j\omega_1, j\omega_2)} \quad (22)$$

Define

$$\begin{aligned}\chi_{i-1,i}^{2,d-r}(j\omega_1, j\omega_2) &= \frac{Y_{i-1,2}^{d-r}(j\omega_1, j\omega_2)}{Y_{i,2}^{d-r}(j\omega_1, j\omega_2)}; \chi_{i+1,i}^{2,d-r}(j\omega_1, j\omega_2) = \frac{Y_{i+1,2}^{d-r}(j\omega_1, j\omega_2)}{Y_{i,2}^{d-r}(j\omega_1, j\omega_2)}; \\ n\chi_i^{2,d-r}(j\omega_1, j\omega_2) &= \frac{NF_{-fa-i,2}(j\omega_1, j\omega_2)}{Y_{i,2}^{d-r}(j\omega_1, j\omega_2)}\end{aligned}\quad (23)$$

Equation (22) can be rewritten, as

$$A_i(j\omega) = B_i(j\omega)\chi_{i-1,i}^{2,d-r}(j\omega) + B_{i+1}(j\omega)\chi_{i+1,i}^{2,d-r}(j\omega) + n\chi_i^{2,d-r}(j\omega), (\omega = \omega_1 + \omega_2) \quad (24)$$

Substituting (12) into (24) gives

$$0 = B_i(j\omega)(\chi_{i-1,i}^{2,d-r}(j\omega) - \chi_{i-1,i}^1(j\omega)) + B_{i+1}(j\omega)(\chi_{i+1,i}^{2,d-r}(j\omega) - \chi_{i+1,i}^1(j\omega)) + n\chi_i^{2,d-r}(j\omega) \quad (25)$$

Then, one ratio $\gamma_i^{2,d-r}(j\omega)$ can be defined, as

$$\begin{aligned}\gamma_i^{2,d-r}(j\omega) &= \frac{\chi_{i+1,i}^{2,d-r}(j\omega) - \chi_{i+1,i}^1(j\omega)}{\chi_{i-1,i}^{2,d-r}(j\omega) - \chi_{i-1,i}^1(j\omega)} = -\frac{B_i(j\omega)}{B_{i+1}(j\omega)} - \frac{n\chi_i^{2,d-r}(j\omega)}{B_{i+1}(j\omega)(\chi_{i-1,i}^{2,d-r}(j\omega) - \chi_{i-1,i}^1(j\omega))} \\ &= \gamma_i^{1,r}(j\omega) - \frac{n\chi_i^{2,d-r}(j\omega)}{B_{i+1}(j\omega)(\chi_{i-1,i}^{2,d-r}(j\omega) - \chi_{i-1,i}^1(j\omega))}\end{aligned}\quad (26)$$

The ratio $\gamma_i^{2,d-r}(j\omega)$ consists of the referenced ratio $\gamma_i^{1,r}(j\omega)$ and the second-order nonlinear restoring force term $n\chi_i^{2,d-r}(j\omega)$.

3.3 Properties of the SOOS

From (26), the properties of the SOOS among coordinates $x_{i-1}(t)$, $x_i(t)$ and $x_{i+1}(t)$ are summarized as follows.

Table 1: The properties

Coordinate	$1 < i < n$	
	Without nonlinear faults $n\chi_i^{2,d-r}(j\omega) = 0$	With nonlinear faults $n\chi_i^{2,d-r}(j\omega) \neq 0$
Relationship	$\gamma_i^{2,d-r}(j\omega) = \gamma_i^{1,r}(j\omega)$	$\gamma_i^{2,d-r}(j\omega) \neq \gamma_i^{1,r}(j\omega)$

The properties in Table 1 reveals that how the nonlinear faults between mass m_{i-1} and m_{i+1} affect the relationship between $\gamma_i^{2,d-r}(j\omega)$ and $\gamma_i^{1,r}(j\omega)$ in the nonlinear ring type structure. If the area between mass m_{i-1} and m_{i+1} is free from nonlinear faults (nonlinear connections), the nonlinear restoring force term $n\chi_i^{2,d-r}(j\omega)$ in (26) will be zero, and then $\gamma_i^{2,d-r}(j\omega)$ equals to $\gamma_i^{1,r}(j\omega)$.

4 APPLICATION TO NONLINEAR FAULTS DIAGNOSIS

4.1 A novel method

According to the properties of the SOOS of the ring type structure with nonlinear faults and inherent nonlinearity, a local damage index can be defined as the relative change between parameters $\gamma_i^{1,r}(j\omega)$ and $\gamma_i^{2,d-r}(j\omega)$, as

$$DI_i^{d-r}(j\omega) = \left| \frac{\gamma_i^{2,d-r}(j\omega) - \gamma_i^{1,r}(j\omega)}{\gamma_i^{1,r}(j\omega)} \right|, (1 < i < n) \quad (27)$$

Large value of $DI_i^{d-r}(j\omega)$ indicates that there are one or more nonlinear faults between mass m_{i-1} and m_{i+1} . Moreover, parameters $\gamma_i^{2,d-r}(j\omega)$ and $\gamma_i^{1,r}(j\omega)$ are just functions of the linear parameters $B_i(j\omega)$ and $B_{i+1}(j\omega)$. This means that $DI_i^{d-r}(j\omega)$ is a local fault indicator and can provide higher sensitivity for the positions of faults between mass m_{i-1} and m_{i+1} .

Based on the local damage index, a novel method can be proposed for nonlinear faults localization in ring type structures with inherent nonlinearity. The main merits of this method are summarized as follows:

- (1) A more general ring type MDOF model with nonlinear connections is used to describe the nonlinear behaviour of ring type structures;
- (2) This method considers the effect of nonlinearity caused by faults and inherent material or boundary nonlinearity;
- (3) The local damage index is decided only by the linear and nonlinear parameters in damaged area.

4.2 Procedures

The detailed procedures of this novel method are summarized here.

Step 1: The structure is in reference state

- (1) Choose the area to be investigated in the ring type structure and install sensors (S_{i-1} , S_i and S_{i+1});
- (2) Excite the structure with harmonic input at frequency ω_1 and $\omega_2 = 2\omega_1$ respectively. For each frequency, use the nth-OSE algorithm [11,12] to calculate the output spectra $\{Y_2^r(j2\omega_1)\}$ and $\{Y_1^r(j\omega_2)\}$ respectively.

Step 2: The structure is in reference state

- (1) Apply LTA to other parts of structure, which are away from the area between sensors S_{i-1} and S_{i+1} ;
- (2) Excite the structure with harmonic input at frequency $\omega_2 = 2\omega_1$ again. Use the nth-OSE algorithm [11,12] to calculate the output spectrum $\{Y_1^{rr}(j\omega_2)\}$;
- (3) Calculate the referenced ratio $\gamma_i^{1,r}(j2\omega_1)$ by (16) with $\{Y_1^r(j\omega_2)\}$ and $\{Y_1^{rr}(j\omega_2)\}$.

Step 3: The structure is in damaged state

(1) Excite the structure with harmonic input at frequency ω_1 . Use the nth-OSE algorithm [11,12] to calculate the output spectrum $\{Y_2^d(j2\omega_1)\}$;

(2) Calculate the diagnostic ratio $\gamma_i^{2,d-r}(j2\omega_1)$ by (26) with $\{Y_1^r(j\omega_2)\}$ and $\{Y_2^{d-r}(j2\omega_1)\} = \{Y_2^d(j2\omega_1)\} - \{Y_2^r(j2\omega_1)\}$.

Step 4: Fault diagnosis

(1) Calculate the damage index $DI_i^{d-r}(j2\omega_1)$ by (27) with $\gamma_i^{l,r}(j2\omega_1)$ and $\gamma_i^{2,d-r}(j2\omega_1)$;

(2) Decide where there are nonlinear faults between sensors S_{i-1} and S_{i+1} or not.

4.3 Numerical study

In this section, numerical case will be studied to verify the validity of proposed SOOS based method. As shown in Figure 3, a six DOF ring type structure with two nonlinear faults and inherent nonlinearity is considered. Mass m_1 is connected to the fixed boundary and is excited by harmonic excitation f . LTA will be applied to coordinate six (m_6). One fault is between mass m_1 and m_2 , and the other one is between mass m_5 and m_6 .

Figure 3: Schematic diagram of numerical case

The values of linear and nonlinear parameters used for simulation are shown in Table 2.

Table 2: Values of parameters

Parameters		i=1	i=2	i=3	i=4	i=5	i=6	i=7
Linear	m_i	1	1	1	1	1	1/20.5 ^a	
	c_i (1e2)	0.72	1.08	1.44	1.26	0.864	1.332	1.44
	k_i (1e4)	0.864	1.62	3.456	1.386	1.3824	2.9304	3.312
Inherent nonlinearity	$k_{in_i,2}$ (1e6)	1.296	2.592	3.888	5.184	6.48	7.776	-
Nonlinear faults	$k_{fa_i,2}$ (1e6)	0	2.592	0	0	0	6.48	0

^a An extra mass is applied to m_6 in LTA such that the value of m_6 is changed from 1 to 20.5.

For simplicity, only second-order stiffness nonlinearity in (2) is considered. Linear parameters are utilized to represent the structural model properties (mass, damping and stiffness). Nonlinear parameters ($k_{in_i,2}$) are used to simulate the inherent nonlinearity, and nonlinear parameters ($k_{fa_i,2}$) represent the nonlinear faults.

Following the procedures in section 4.2, data are proceed to calculate the local damage index. The results of the novel SOOS based method and previous SOOS transmissibility based method are shown below.

Table 3. The results of previous method [14]

Previous Method	i=1	i=2	i=3	i=4	i=5	i=6
$ \beta_{i,i+1}^{1,r}(j2\omega_1) $	0.94268	0.66408	0.84635	1.36967	1.44824	0.95147
$ \beta_{i,i+1}^{2,d}(j2\omega_1) $	0.77047	1.02797	1.06857	1.20290	1.04333	0.94145
$DI_{i,i+1}^d(j2\omega_1)^a$	0.18268	0.54794	0.26256	0.12175	0.27958	0.01052

$$^a DI_{i,i+1}^d(j2\omega_1) = \left| \left(\beta_{i,i+1}^{2,d}(j2\omega_1) - \beta_{i,i+1}^{1,r}(j2\omega_1) \right) / \beta_{i,i+1}^{1,r}(j2\omega_1) \right|$$

Table 4. The results of proposed method

Proposed Method	i=2	i=3	i=4	i=5
$ \gamma_i^{1,r}(j2\omega_1) $	0.52047	1.99557	1.15006	0.50673
$ \gamma_i^{2,d-r}(j2\omega_1) $	0.64944	1.99557	1.15006	0.44321
$DI_i^{d-r}(j2\omega_1)$	0.24780	2.28e-14	1.47e-14	0.12534

From the results in Table 3, it can be seen that the values of damage indexes for all coordinate pairs are larger than zero. Relatively large values of $DI_{i,i+1}^d(j2\omega_1)$ for $(i=1,2,...,5)$ indicate that faults may locate between m_1 and m_6 . Thus, the previous method can only give rough position information of faults, the reason is that this method, proposed based on open chain type MODF model, is not applicable for closed ring type structure. For the results of proposed method, the values of damage indexes $DI_3^{d-r}(j2\omega_1)$ and $DI_4^{d-r}(j2\omega_1)$ are about zero meaning that there is no fault between m_2 and m_5 , and that of damage indexes $DI_2^{d-r}(j2\omega_1)$ and $DI_5^{d-r}(j2\omega_1)$ are larger than zero indicate that one fault is located between mass m_1 and m_2 , and the other one fault is located between m_5 and m_6 . This diagnostic result is closer to the real situation of case setup. Therefore, the validity of proposed SOOS based method is proved by this numerical study.

5 CONCLUSIONS AND DISCUSSIONS

In this study, a new SOOS based method is proposed for the localization of nonlinear faults in a ring type structure. Some conclusions and discussions are outlined below.

(1) In some complex structures like pipeline and frame structures, closed sensor chains (i.e., the ring type structure) along the vibration transmission paths are found, and a more general closed ring type MDOF model is used to describe these structures' dynamic behavior.

(2) With the harmonic excitation analysis and LTA, the properties of the SOOS of the ring type structure with nonlinear faults and inherent nonlinearity are derived to reflect the relationship between nonlinear output spectra and nonlinear faults.

(3) Based on these properties, a novel fault localization method with local damage index is proposed to provide more local characteristics of faults in ring type structures. The results of

numerical study demonstrate that the novel method can localize the faults more precisely.

Furthermore, more local and sensitive damage indicator, which can provide more information of faults like the severity of faults, should be studied in the future.

APPENDIX A. LOCAL TUNING APPROACH

The main idea of LTA is that the local tuning operation on structure will only change the physical properties and/or boundary conditions away from the area between mass m_{i-1} and m_{i+1} . Then, the values of $\chi_{i-1,i}^1(j\omega)$ and $\chi_{i+1,i}^1(j\omega)$ in (12) are changed while the linear model parameters $B_i(j\omega)$ and $B_{i+1}(j\omega)$ between mass m_{i-1} and m_{i+1} remain constant.

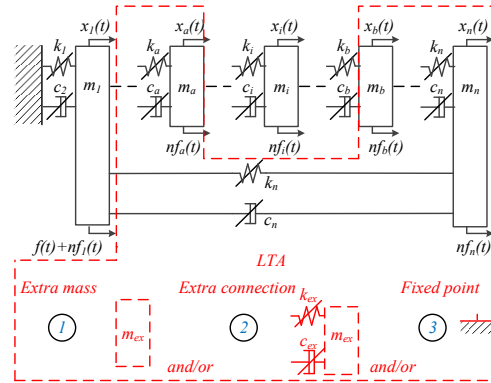

Figure 4: The local tuning approach

In practice, this LTA (Figure 4) can be performed by adding extra masse, damper and spring connection or fixed boundary condition to mass m_c ($c \neq i, i$). Moreover, to make a significant change of $\chi_{i-1,i}^1(j\omega)$ and $\chi_{i+1,i}^1(j\omega)$, more than one ways in Figure 4 can be applied to mass m_c and/or more than one masses can be applied the LTA.

Key words: Structural health monitoring, Lamb waves, Pulse-echo, Piezo-electric arrays, High Frequency Power Amplifier

Abstract. Required improvements of piezoelectric elements actuation and measurement system efficiency and robustness are introduced as a critical feature for structural health monitoring (SHM) applications. An electronic module (Lamb wave detection system: LWDS) allowing to use each piezoelectric element in an array either in emission or reception mode is presented. The high commutation rate between these two states, for each transducer separately, is a key enhancement for SHM methods. The robustness of the sensor integration is also studied considering the patches size and bonding method. Coupled dispersion curve are introduced. Comparison of FEM simulation and experiments of the piezo-electric coupling are presented. This work takes part of the H2020 REMAP project about adaptive aircraft maintenance planning.

1 INTRODUCTION

Ultrasonic waves generated by piezo-electric patches offer a very promising way to perform Structural Health Monitoring (SHM) of composite aeronautic structures. Permanently bonded sensor arrays are interesting for on-demand interrogation of the structure in order to detect and localize damages (pits, disbonds), or to follow damage progression (cracks, delaminations). At the opposite of NDT techniques, SHM is independent from the operators.

Many applications have been reported for space applications [1], aircrafts [2] or civil engineering [3]. One can divide the piezoelectric elements applications between passive and active methods [4]. In passive methods piezoelectric elements array can be used to monitor acoustic emissions [5]. Active methods use signal generation on piezoelectric transducer to interact with the structure. Usual piezoelectric elements array are generally used to generate Lamb waves in plates [6]. The transmitted Lamb waves are received by another piezoelectric element in a pitch-catch mode, or by the same piezoelectric element in pulse-echo mode. The

wave generation can be controlled by phased array of various forms and distribution [4], [7]–[10]. Diverse signal processing methods can be used for damage monitoring with the signal measured with piezoelectric elements, such as transfer functions, time of flight analysis with cross correlation envelope [4], instantaneous baseline [11], time reversal [12], [13]. This can lead to an efficient damage localization mapping of the structure. However the positioning of the emitting and receiving piezoelectric elements, or the management of the commutation between these two states are of prior importance to ensure the covering of the whole structure as well as optimal signal quality.

Recently, Lamb waves detection techniques have been enhanced by developing a dedicated electronic system called Lamb Wave Detection System (LWDS) [8]. This module allows to use each piezoelectric element in an array either in emission or reception mode. Each sensor can not only be used in the usual pitch-catch method, (i.e. one sensor is emitting and the other sensors are receiving the propagated wave information), but also in pulse-echo (i.e. emitting a lamb wave and listening to the echo simultaneously on the same patch). This feature can drastically improve PZT network efficiency for SHM purposes as one additional information source (the signal received back by the exciter) is made available. All transducers can be used simultaneously to scan the structure, and directly listen to the structure response. It facilitates the use of advanced methods such as instantaneous baseline, beamforming in emission and reception, time reversal or other advanced algorithms.

Moreover the quality of signals is also highly impacted by the robustness of the sensor integration [14], [15]. Complex contributions such as the effects of temperature [16], or also adhesive nonlinearities [17] have been highlighted. The durability of sensor is also crucial for the proper application of SHM algorithms [18].

In order to overcome these difficulties and to improve SHM detection techniques, this paper presents a combination of an advanced electronic system with a robust piezo wafer integration within the host structure.

First, the electronics detection system is presented in detail. Commutation rates against capacitive loads of piezo patches is discussed, as well as Signal to Noise Ratio (SNR) improvement. Second, a focus is made on a fine study of coupling efficiency between the piezoelectric patches and Lamb wave propagation through so-called tuning curves. This feature helps in selecting the correct frequency range for ultrasonic SHM interrogation. These results are compared to FEM simulation on ATILA/GiD software. In the last part an experimental study is performed and the correlation with theory and simulation is discussed.

2 LAMB WAVE DETECTION SYSTEM & ELECTRONICS

The LWDS electronics is made for multi-channel Lamb wave excitation and measurement of thin structures.

From the hardware point of view, a channel suited for piezoelectric patches is described on Figure 1. This channel is typically composed of three analog functions:

- A power amplifier to drive the piezoelectric patches in order to emit the acoustic waves on the structure.
- A conditioner to be able to read the acoustic waves incoming on the piezoelectric

patches.

- A commutation function to be able to switch each piezoelectric patch between emission and reception modes.

The power amplifiers offer an unloaded wide bandwidth of 2.5 MHz with a current limit of 0.5 A peak, in order to reach the ultrasonic range and feature a high SNR (more than 70 dB). They are specifically designed to drive capacitive loads, since the piezo elements have a capacitive behavior.

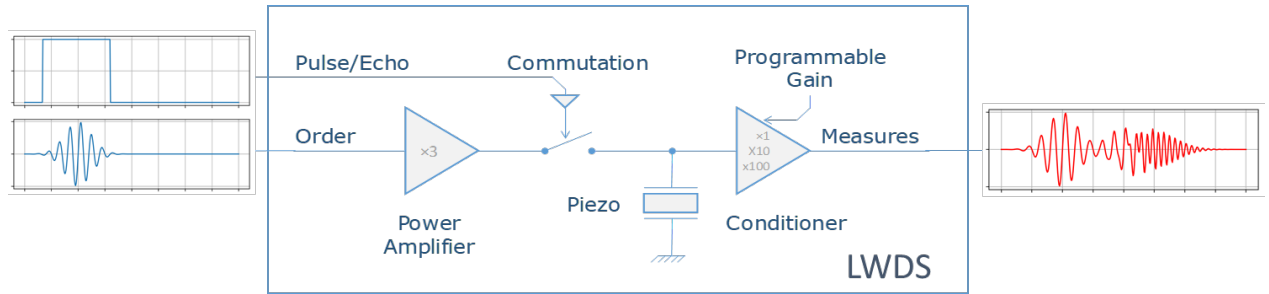

Figure 1 : High frequency commutation with LWDS

The conditioners offer a wide bandwidth to match the amplifier bandwidth and a very high SNR to be able to receive acoustic waves of low amplitude. If required, the conditioners can feature a variable amplifier gain up to 100, which is particularly interesting for laboratory setups. A picture of the LWDS module is presented on Figure 2 with 36 channels.

The switching function, allowing pulse-echo technique, offers the possibility to switch the patch between the two modes (emission or reception). This enables to emit a signal with a patch and to monitor the echo of the signal on the same patch, maximizing the detection ability for a given quantity of patches, cables and boards. It is thus a cost effective solution that reduces the complexity of the system. In order to take advantage of this function, the commutation time has to be short enough to be able to catch the echo. As an example a burst of 5 cycles at 1 MHz lead to a commutation time of 5 μ s. The LWDS allows commuting between emission and detection within 1 μ s. The echo can be caught even if the damage is very close from the patch.

Figure 2 : Up to 36 PZT channels simultaneously emitting or receiving signals with 1 μ s selective commutation

An example of emitted, reflected, and transmitted signals is shown on Figure 3. The upper

part of the figure shows the pulse signal applied by the emitting patch. The commutation signals enables the recording of the same patch for the reflected wave analysis. The center graph is a zoom on y-axis to observe reflected waves with around 20% of the emitted wave amplitude. The lower graph shows the signals measured by a second patch at the same order of magnitude as the echo signal.

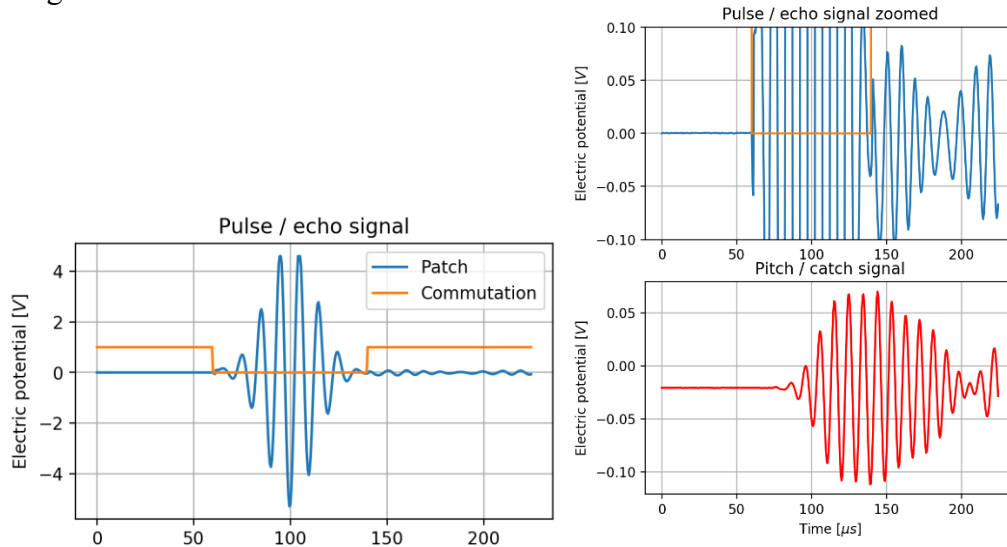

Figure 3- Pulse/echo and Pitch/catch signals

In addition to the previous functions, some generation and sampling functions are required to send the orders, and to record the received signals for analysis. This could be done with regular generators and with oscilloscopes or acquisition platforms. However, SHM applications often require specific equipment since multiple channels are required, as well as very high refresh rates. In order to reduce the time for acquisition and the complexity of the setup, dedicated generation and acquisition platforms are recommended. These platforms feature:

- Several synchronized input or output channels with refresh rates up to 10 MSps.
- High resolution to comply with the high SNR requirements of the SHM applications.
- Arbitrary generator channels so that the user can generate any waveform, to fit with his application.
- Interface with computers and dedicated GUI for loading the signals to be generated and recovering the recorded data

A picture of a full setup is presented on Figure 4.

The simultaneous excitation of all the piezo array with appropriate phase shifts allows beamforming for excitation [10] in excitation mode, as well as retro-propagation beamforming for acoustic wave field reconstruction [12] in listening mode.

The high frequency of commutation allows as correct patch selection to get closer to a defect and rapidly converge toward the spatial position of a damage.

Figure 4 : Test bench of Lamb wave emission and acquisition with LWDS

3 PIEZO ELECTRIC PATCHES COUPLING MODELLING

In this part a focus is made on the definition of the piezo patches array, based on coupling efficiency, patch size, & material in order to get an efficient, reliable and robust SHM solution.

3.1 Dispersion curves

The detection of structural damages using Lamb Waves detection methods require some particular attention about the choice and the positioning of the piezo patches, and the frequency range to study. The dispersion curves are a useful tool to predict and understand the behavior of the sensorized structure and the patches signal output. These curves are based on analytical equations of waves propagation in frequency-wave number domain. They are function of the material and thickness of the structure. The material is considered as homogeneous and edge effects are not taken into account.

Figure 5 : Coupled dispersion curves of Lamb waves for a patch diameter 20 mm. Good coupling shown in green, low coupling in red

In ReMAP application the structure of the plate is defined: material is a multi-layer composite made of graphite-epoxy Hexcel IM7/8552 with 1.7mm thick. The computation of the equivalent homogeneous properties allows to plot the dispersion curves. Figure 5 shows the first symmetric and antisymmetric modes S0 and A0. A first criteria in SHM is to work in a frequency range where there is only the firsts mode to simplify the signal output analysis.

One cleverness of ReMAP approach is to add the information about the coupling between the piezo patches and the structure, in order to help in defining an efficient SHM solution.

Considering the diameter D_{PZT} of the piezo patch and λ the wave length of the considered mode, the coupled dispersion curve takes into account the facts that:

- If $D_{PZT} = n \cdot \lambda$, the patch cannot couple (excite or detect) the considered mode.
- If $D_{PZT} = (2n+1) \cdot \lambda/2$, the patch maximally couples (excites or detects) the considered mode.

Because the wave lengths of A0 and S0 modes are different for a given frequency, both modes are not equally coupled in general. So the coupled dispersion curve is a tool for choosing how to couple S0 or A0 modes by selecting the frequency and exhibits one role of the coupling.

The coupling aspect also manages the choice of the patch diameter with respect to the damage. The last point to study is to compare the size of the damage D_{Damage} with the wavelength. A damage will be better detected if its diameter is half of the wavelength, giving another design criteria

- If $D_{Damage} = \lambda/2$, the damage is optimally detected.

But this criteria is a more qualitative one than very predictive because of the different kinds and shapes of damages that the wave can encounter.

Besides, the material of the patches is selected to have a high value of d_{31} coefficient. This means that the voltage difference applied on the patch electrodes, implies a high in-plane deformation to the board, the polarization of the patch being orthogonal. Additionally, a low Q factor, a low aging and a thermally stable behavior are requested.

3.2 Finite element modelling

3.2.1 Wave propagation on a plate

A sample of composite plate $200 \times 40 \text{ mm}^2$ is modelled using finite element method. The modelling is performed on ATILA/GiD which enables to run transient analysis with piezoelectric coupling.

Figure 6 - Burst excitation at 100 kHz used in simulation

The plate is modelled in 3D with tetrahedral elements. It is sensorized with two Ø20mm

piezo-patches. A voltage is applied between the two faces of one patch. The voltage signal applied to the patch is a burst of a given frequency. The temporal signal is shown on Figure 6. The other patch has one electrode at 0V and the other free and is used in order to measure the voltage generated by the plate deformation. The plate is clamped at its two edges.

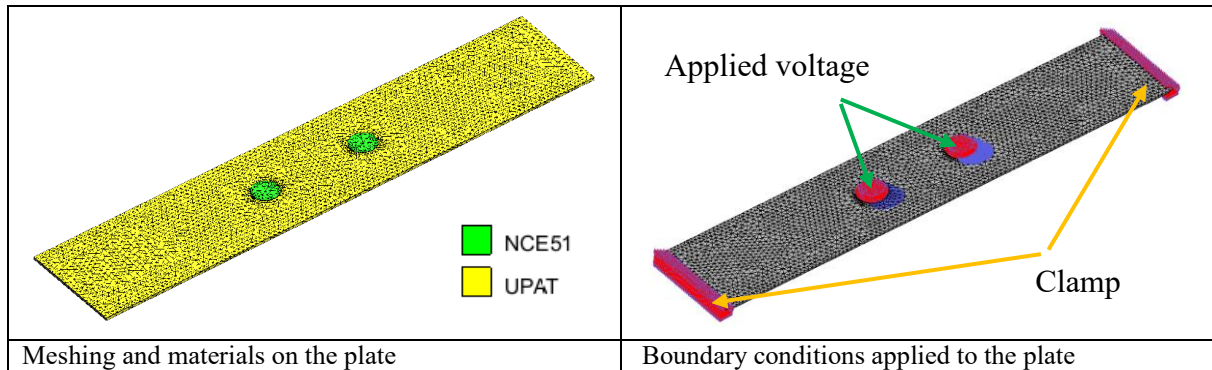

Figure 7 – FEM Simulation conditions in ATILA/GiD

A first modelling is performed with a coarse meshing (element size=4mm). For each frequency of the burst signal input, the convergence as a function of the mesh have to be carefully studied, particularly at high frequencies (>200 kHz). The meshing, materials and boundary conditions can be seen on Figure 7.

The transient displacement calculated for a burst at 100 kHz is given on Figure 8. The wave length is clearly visible and the displacement shape follow a cross repartition. That cross is representative of the fact that the material is orthotropic: the wave velocity is not the same in all directions.

Figure 8 - Wave propagation in composite plate, 100 kHz

The same simulation is then performed considering an aluminum plate. In this case the distribution of the displacement is square. Close to the piezo patch the distribution is more circular like the patch shape. Then the square aspect can be explained by the edge effect.

Figure 9 - Wave propagation in aluminum plate, 100 kHz

Using the plate made of composite material, the frequency of the burst is changed from 100 kHz to 200 kHz. For each signal the maximum displacement in the plate under the piezo patch is measured. The amplitude is plot in function of the frequency in Figure 10.

Figure 10 - Amplitude under the patch used in detection mode

We can see that the maximum of amplitude varies with the frequency of the signal. The amplitude is higher at 200 kHz than at 100 kHz which can be related to the coupling effect.

3.2.2 Damage detection

The finite element modelling is then performed using an aluminum plate with a local damage. The choice is made to represent the damage as a forced zero displacement in the damage zone. The goal of this computation is to study the wave propagation in the case which the wave encountered a damage. The material and boundary conditions are the same as previously described, we just changed the damage condition.

Figure 11 – Displacement clamping to simulate a damage

A MATLAB program is written to enable the comparison between two result distributions. Particularly, it's used to plot the displacement distribution difference between a perfect structure with homogeneous material and the structure with the damage. The displacement distribution into the two healthy and damaged structures, and the distribution difference, are shown on Figure 12.

Figure 12 - Localization of the damage using Lamb Waves

The difference on displacement distribution clearly allows to establish the position of the damage. By varying the frequency on the signal we could study the quality of the detection, and compare these results with the dispersion curves and study the coupling. The transducer array could compute the difference in time with the emitting sensor synchronization. The fast commutation of the LWDS in this configuration is relevant for scanning the full structure quickly while keeping one additional measurement for virtual back-propagation.

4 EXPERIMENTAL VERIFICATIONS

In this part the LWDS electronics is used to compare coupling efficiency between pitch-catch mode and pulse-echo mode. Two samples are tested, equipped with two patches.

4.1 Gluing process

In the modelling we consider a perfect interface between the patches and the plate. In reality, the piezo patches are fixed on the plate by gluing. To ensure a good coupling between the patches and the plate another important point is the glue choice. In the frame of needs about reliability, the glue have to respect several criteria:

- Low thickness
- High shear modulus
- High thermal range
- High chemical resistance

Easy gluing process (cure at ambient temperature in aim at equipping large structures) According to these criteria, an epoxy glue have been chosen for the application. Then an accurate gluing process have been written to control the glue thickness and make the gluing as reproducible as possible. An overview of the gluing is available on Figure 13.

Figure 13- Overview of the patches gluing

4.2 Frequency tuning curve

In this section the comparison of the pulse echo and pitch catch modes are presented while varying the frequency of the burst excitation.

The Figure 14 shows two examples at 150 kHz and 250 kHz. One can notice a qualitative significant decrease in received signal amplitude.

Figure 14- Comparison of different frequency for time signals

The amplitude ratio between excitation burst and reflected wave (coupling efficiency, in %) is compared between echo mode and catch mode in Figure 15. This picture shows relevant correlation between both transducers. It can be also correlated with coupled dispersion curves. The frequency 150 kHz shows a high coupling coefficient for the tested aluminum plate.

Figure 15- Comparison of pulse/echo and pitch/catch coupling coefficient

4.3 Toward robustness of SHM

In this section, four configuration are compared using two board samples and switching the emitting patch, and accordingly the pulse-echo mode and pitch catch mode. Figure 16 shows the results for the 2x2 configurations.

One can notice that the permutation of emitting and receiving patch in pitch catch mode shows very close results. For the pulse-echo mode, each transducer has its own coupling, but the trends are comparable for the 4 sensors. The variations between two different plates may be due to various factors such as gluing or piezo ceramics. These variations should be managed by software processing, for example by calibrations. The most important will be the time stability in order to clearly see any damage birth and growth.

So the future works should consider aging versus temperature cycles and time.

Figure 16- Reproducibility testing on patch coupling with two plates with two patches. Pulse/echo is represented by continuous lines, Pitch/catch by dotted lines

5 CONCLUSION

The baseline for the study of the robustness of SHM system has been detailed. The concept of coupled dispersion curves is introduced; Analytical, FEM simulation and experiments have been presented through examples to recall the notion of tuning and coupling in SHM systems. Different structural material have been tested including composites in the simulation campaign, illustrating the analytical results with spatial propagation analysis.

Experimental results showed good correlation with the well-known tuning curves. Apparent coupling coefficient is exposed for pulse-echo mode and pitch catch mode. The pulse echo mode shows an interesting behavior compared to pitch catch, showing that the commutation of sensor is relevant as an additional information to enhance the performance of SHM algorithm. The configuration discrepancy is analyzed on the coupling coefficient.

The synchronous difference of signals between a plain plate and a damaged plate has been illustrated through a 3D example and displacement mapping. Pulse-echo method can be relevant for increasing the efficiency of instantaneous baseline algorithm, or to decrease the number of patches to cover a whole structure.

As presented in the literature review there are many other algorithms such as time reversal and beamforming that are being develop to map structures and identify damages. The use of pulse echo method and the proper handling of transducer integration is likely to be key in future improvements.

Key words: Fatigue; image processing; non-destructive testing; SteBLife; structural health monitoring; thermography

Abstract. Engineering structures are prone to damage when being under operation and under the process of ageing. Damage usually occurs locally such as in notches and/or material inhomogeneities and may then spread gradually around from those. A way on how to understand and model the phenomenon of damage is to transfer the material behaviour in the damage critical area onto a smooth specimen used for materials testing. This of course also requires the material behaviour itself to be understood, such as it is described in terms of fatigue behaviour as the material's related S-N curve. A way on how to get such a curve in a most efficient way has been proposed with the SteBLife approach, where a single close to unnotched specimen is divided into five sections with different gauge length diameters and through this each of the sections represents a source of the material's information being related to fatigue at different stress levels. This information is retrieved on the basis of parameters conventionally known from non-destructive testing (NDT) being related to temperature and magnetics at present, monitored with the respective sensors. This information, which can be even more sensitive than plastic strain being often used as a damage parameter for elastic-plastic materials, can be recorded along the life cycle of a material's fatigue test or even a component. Furthermore this information can virtually even be broken down to a pixel level with respect to the structure to be monitored, where histograms can be generated for each of the pixels. This may allow an ageing process of a material as well as the scattering of material properties to be described, all being an additional important information to reliably predict the residual life of a component in the end. Such a way of smart monitoring easily generates a large amount of data that has to be managed accordingly, using adequate data management

procedures. As a result techniques and technologies developed in the wider context of NDT including acoustics can be arranged in a ‘toolbox’ in a way that they can be combined to structural health monitoring (SHM) systems for smart monitoring in the longer term. The way on how to determine a material’s fatigue data on the basis of NDT-based parameters to configure an SHM-system on a possibly non-conventional but systematic way is indicated.

1 INTRODUCTION

SHM has now been around for at least a quarter of a century if not even more. It has been considered as the integration of sensors and possibly also actuators into structures to monitor changes in the structures’ condition using advanced signal processing. Much of the ideas and concepts for SHM have been explored and summarised in books (i.e. [1]). A vision has been around during that whole period, that a structure should become like a human body, monitored by billions of renewable sensors and controlled by a central ‘brain’, hence a computer or something similar. However, this more turns out to be an illusion since sensing in engineering is completely different to nature, as can be easily proven, not saying that bio-inspiration would not trigger new ideas in engineering. If SHM is ever to come into true application, then more pragmatic approaches need to be taken than the illusion described before.

A prerequisite for SHM is that a change in a structure’s condition has to be tolerated. This is provided through the damage tolerance design (DTD) principle where damage is allowed to exist in a structure as long as it does not become critical. This principle has now been applied for more than 70 years within aeronautics with success for designing structures becoming lighter weight. Recently civil engineering has also discovered the DTD principle, however, mainly in view of extending a structure’s operational life without compromising safety.

Damage in structures does principally not accumulate to become critical anywhere on a structure but rather at locations being specifically exposed to extreme loading, would the damage either be of a mechanical or corrosive nature. In the case of mechanical loading and its resulting impact, fatigue is possibly the most representative phenomenon currently represented in terms of crack propagation. Initiation and progression of fatigue cracking from a phenomenological point of view is a stochastic process. It is therefore difficult to predict when it occurs rather than where, because the latter is mainly driven by local stresses and strains distributed in an irregularly shaped structure, which can be determined numerically. Together with a damage accumulation rule, which in the case of the linearized Palmgren-Miner rule is rather incorrect, at least the damage critical locations can be determined. An additional numerical assessment has then to be made in which the allowable critical damage has to be configured in terms of shape and size. This preliminary work becomes the onset from where SHM starts and how an SHM system may have to be designed.

However, before getting an SHM system realised the material being considered needs to be understood. In the case of fatigue this can become rather laborious because S-N curves have to be generated, which traditionally require 15 fatigue experiments or even more. This is specifically true in the case of ageing infrastructure, where material conditions may have changed when compared to their pristine state and a structure’s residual life assessment may be ex-

posed to large uncertainties. To come around this problem so called Short Term Evaluation Procedures (STEP) [2], which in the ideal case require a single fatigue test to be performed only, can be of significant help. Another important aspect is the detection of the incubation of damage. Classical DTD is based on crack propagation only. Combined with an acoustics wave approach monitoring in the sense of SHM has become rather popular. However, the crack propagation life of a structure may be short when compared to the structure's pre-crack and crack initiation life and as such other parameters would have to hold in excess to the plastic strain being considered traditionally. Such alternative parameters can be found through techniques applied in NDT where electromagnetism and thermography are two techniques described in excess to the acoustic techniques used traditionally.

Finally, it needs to be mentioned that with the significant cost reduction and miniaturisation of sensors today the importance of the number of sensors used can become rather marginal. However, large amounts of data are to be easily generated when the number of sensors increases, of which the signals then need to be processed. Different of the emerging signal processing and visualisation tools may therefore be of invaluable help.

This article will first address STEP as a means to generate an S-N curve for fatigue life evaluation including the application of thermography and magnetism as NDT techniques from which micro-mechanic phenomena such as damage initiation and propagation patterns can be retrieved. Elements of those techniques can then be implemented into a 'toolbox' allowing appropriate SHM systems to be generated in the longer term.

2 SHORT TIME EVALUATION PROCEDURES (STEP)

Traditional testing of materials is based on the principle that a single result is retrieved from a single experiment. This makes it rather laborious in the case of a material's fatigue and the evaluation of S-N curves being required to assess a structure's residual fatigue life in the end. STEPs have therefore been around since a decade or slightly more as a means of enhanced determination of S-N curves reducing the effort to get those curves determined easily by a factor of 10 or more. The first approach considered was PhyBaL (physically based fatigue life calculation) [3], for which the logic is shown in Fig. 1 and which requires a load increase test (LIT) and two traditional constant amplitude tests (CAT) to be performed. The LIT starts at a load level usually below the so called fatigue limit (up to 2×10^6 cycles), where a decent number of fatigue cycles, often around 9000, is applied such that the material stabilizes cyclically, before the loading is then moved to a next higher level and the procedure of fatigue cycling is repeated again. This procedure is applied up to fracture of the specimen and generates the relationship between the controlling parameter (here the load) and a possible fatigue damage relevant but non-controlled parameter called the material response such as plastic strain as shown in the upper left of Fig. 1. This relationship between the controlled (stress) and the uncontrolled (material response) parameter obtained from the LIT is related to conventional CATs where one experiment is now performed close to the fatigue limit and another around the loading level where the LIT failed respectively. It is assumed that the well known Morrow equation

$$\sigma_a = K'_M(M)^{n'_M} \quad (1)$$

can be applied, where σ_a represents the stress applied and M the plastic strain measured respectively while K'_M and n'_M represent a coefficient and an exponent respectively. From the exponent n'_M the fatigue strength exponent b_M

$$b_M = \frac{-n'_M}{5 \cdot n'_M + 1} \quad (2)$$

is determined, describing the slope of the S-N curve in accordance to the Basquin equation

$$\sigma_a = \sigma'_f \cdot (2N_f)^{b_M} \quad (3)$$

where N_f represents the number of cycles to failure and σ'_f the fatigue strength coefficient describing the S-N curve respectively. With this an S-N curve of the material considered is determined on the basis of simply three experiments.

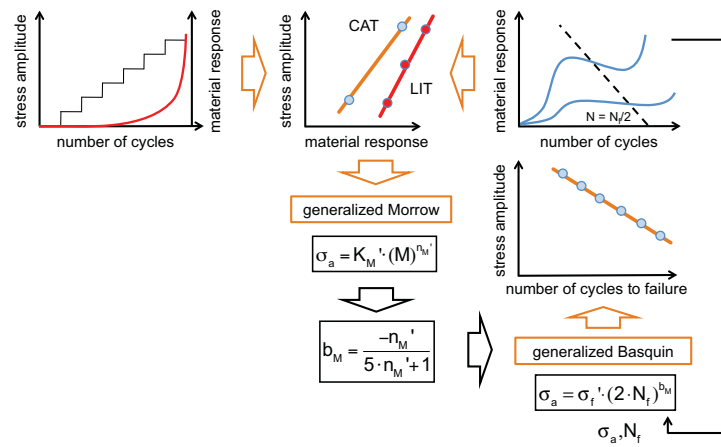

Figure 1: STEP for the evaluation of S-N curves

It is important to know that the above parameter M is by far not limited to plastic strain only but can be rather extended to any parameter describing a material's fatigue behaviour. Such parameters can be derived from NDT such as acoustics, temperature or electromagnetics driven parameters, to just name a few.

In the recently developed STEP StebLife [4] the evaluation of an S-N curve has been reduced to a single fatigue test only. This is achieved through a newly designed fairly smooth specimen, which is symmetric with regard to its minimum cross-section and consists of five sections of three different diameters \emptyset_1 , \emptyset_2 and \emptyset_3 respectively as can be seen from Fig. 2. Each of the sections represents a materials volume onto which a different stress depending on the diameter applies. As can be seen from Fig. 2 no LIT is now required and the material response is determined from a single CAT only. This CAT delivers the material response at the give loading including the fatigue life for the middle section with the minimum diameter only. The sections above and below the middle section only provide the material response up to the fatigue life of the middle section. However, the material response information retrieved from the sections other than the middle section can be well used for further evaluations in case the material response can be considered mainly stabilized which is true for most cases. Principal-

ly five data points are therefore made available that allow the loading versus material response relationship to be described in accordance to Eq. (1). The remaining procedure on how to determine the S-N curve is then identical to what has been explained before with regard to PhyBaL. Running more than one of those fatigue tests and this possibly at different load levels with respect to the fatigue life of the specimen immediately enhances the breadth of data sampling leading to the possibility to generate S-N data including their scatter bands possessing a remarkable level of confidence.

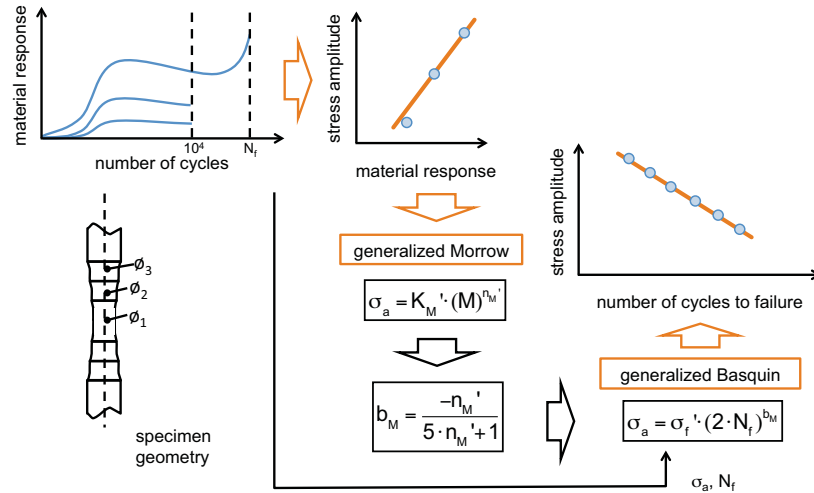

Figure 2: SteBLife as a STEP for the evaluation of S-N curves based on a single experiment

3 TEMPERATURE AS A MEANS FOR FATIGUE DAMAGE ASSESSMENT

As mentioned before the material response parameter M can be also chosen from an NDT technique where M should be sensitive to fatigue. In [4] results have been reported where thermographic data have been recorded in each of the sections of a SteBLife specimen using a commercial Micro-Epsilon type thermoIMAGER TIM 450 infrared camera. For temperature measurements, seven measurement fields with a size of 5×5 pixels were defined along the specimen within the infrared camera software, one in each gauge length (T_1 , $T_{2o/u}$, $T_{3o/u}$, ϕ : upper, u: lower), and two at each shaft ($T_{4o/u}$). The changes in temperature ΔT in the different specimen sections were calculated in accordance to Eq. (4) to Eq. (6):

$$\Delta T_1 = T_1 - 0.5 \times (T_{4o} + T_{4u}) \quad (4)$$

$$\Delta T_{2o/u} = T_{2o/u} - T_{4o/u} \quad (5)$$

$$\Delta T_{3o/u} = T_{3o/u} - T_{4o/u} \quad (6)$$

The diameter of the shafts is bigger than the diameters of the gauge lengths such that $T_{4o/u}$ can be considered as the elastic portion of the change in temperature as well as the environment. It is therefore subtracted from T_1 , $T_{2o/u}$, $T_{3o/u}$, which leads to the changes in temperature (ΔT_1 , $\Delta T_{2o/u}$, $\Delta T_{3o/u}$). ΔT_1 , $\Delta T_{2o/u}$, $\Delta T_{3o/u}$ are proportional to the plastic strain amplitude $\epsilon_{a,p}$ and are dedicated to the plastic deformations in the different gauge length sections. This temperature compensation allowed the elimination of external temperature effects to be maximised,

allowing thermal effects originating from the fatigue damaging process to be made available only. Fig. 3 shows the data recorded in terms of temperature based cyclic deformation curves and the material's response versus loading applied for a SAE 1045 (German designation C45E) medium carbon steel described in terms of Eq. (1). The resulting S-N curve added by the results of another four of those SteBLife fatigue tests can be seen in Fig. 4 which shows that even a statistical process having been applied to the five input values has allowed scatter bands to be described appropriately as can be seen from the different independent CAT results shown in Fig. 4. Those results as well as many others published can be considered as a proof that STEPs have become a most efficient means to assess a material's fatigue properties at a fraction of effort, time and cost making it ideal for the assessment of ageing infrastructure.

Figure 3: Temperature based cyclic deformation curves recorded from a constant amplitude loaded SteBLife specimen (left) and determined resulting Morrow function (right) for normalized SAE 1045

Figure 4: S-N curve and scatter band evaluated from five SteBLife experiments and compared to conventional determined S-N data for normalized SAE 1045

4 VISUALIZATION AND ANALYSIS OF RECORDED THERMOGRAPHIC DATA

Data can be recorded today with an increasing ease. This applies to most of the NDT tech-

niques applied would those be based on an acoustical/vibro-mechanical or electromagnetic/electro-mechanical basis. This easily leads to an interesting application in terms of digitized monitoring and visualization possibly followed by big data handling, advanced signal processing and deep learning. Many of the NDT techniques have been digitized the one way or the other would this be with digital radiography, phased array acoustics, laser vibrometry, laser speckle photometry or digital thermography, to just name a few. Such techniques allow data to be taken on a near to continuous basis and this over larger areas leading to histograms to be generated at virtually every location observed. Hence developments over the lifetime of a material and component can be visualized on a dynamic basis. Such a trend may lead to a material and component to be fully ‘pixelized’ and ‘digitized’ in the end.

A fatigue loaded SteBLife specimen as described under Fig. 2 made from SAE 4140QT and run at a loading frequency of 5 Hz has been fully recorded with a digital thermography camera, where Fig. 5 shows five stages along the fatigue life of the CAT performed. The displays show the topography of inertly generated accumulated energy appearing on the specimen’s surface. In the early phase within the fatigue process up to around 1000 s a fairly homogeneous and flat distribution is to be seen showing that fatigue accumulation has been rather constant up to that stage. At 1663 s or 67 % of the specimen’s fatigue life the rather homogeneous distribution of the accumulated thermal energy has been abandoned and some maxima have emerged indicating internal heat ‘generators’ resulting from some weakest links within the material not having appeared as cracks as such. It is then where it becomes clearly apparent where the final fracture is expected to occur and that the ‘heat generators’ identified earlier are indeed precursors of cracks to be initiated. A deeper look into these topographies and their development may be a source for further damage accumulation retrieval.

5 VISUALIZATION AND ANALYSIS OF OTHER RECORDED NDT DATA

What has been briefly performed and shown for thermography based data before can be principally also performed with electromagnetic measurements. However, here the digital image has been generated on measurements having been taken on a point to point basis although matrix sensors are gradually getting available in the meantime providing an additional option in this field. Principally scanning with a single sensor is possible as long as the sensor can be repeatedly positioned at the same position in a 3D space. With such an approach interesting first observations have been made such as the transformation to stress induced martensite and a relationship of magnetic measurement to plastic strain, which is shown for the example of a metastable austenitic steel AISI 347 in Fig. 6 and 7 respectively. In the case of martensite transformation a specifically designed magnetic force sensor (patent application pending) has been used in combination with a scanning device to scan the surface of a specimen having been fatigue loaded. This procedure could be done on a repetitive basis either by installing the sensor at the location of interest or scanning the specimen (i.e. component) at defined intervals. The information retrieved could be clearly localized and stored allowing some advanced signal processing to be performed in a next step. Fig. 6 shows a scanned image where locations of martensite generation, partially generated through hardness indentations, can be well recognized and this at a fairly high resolution [5].

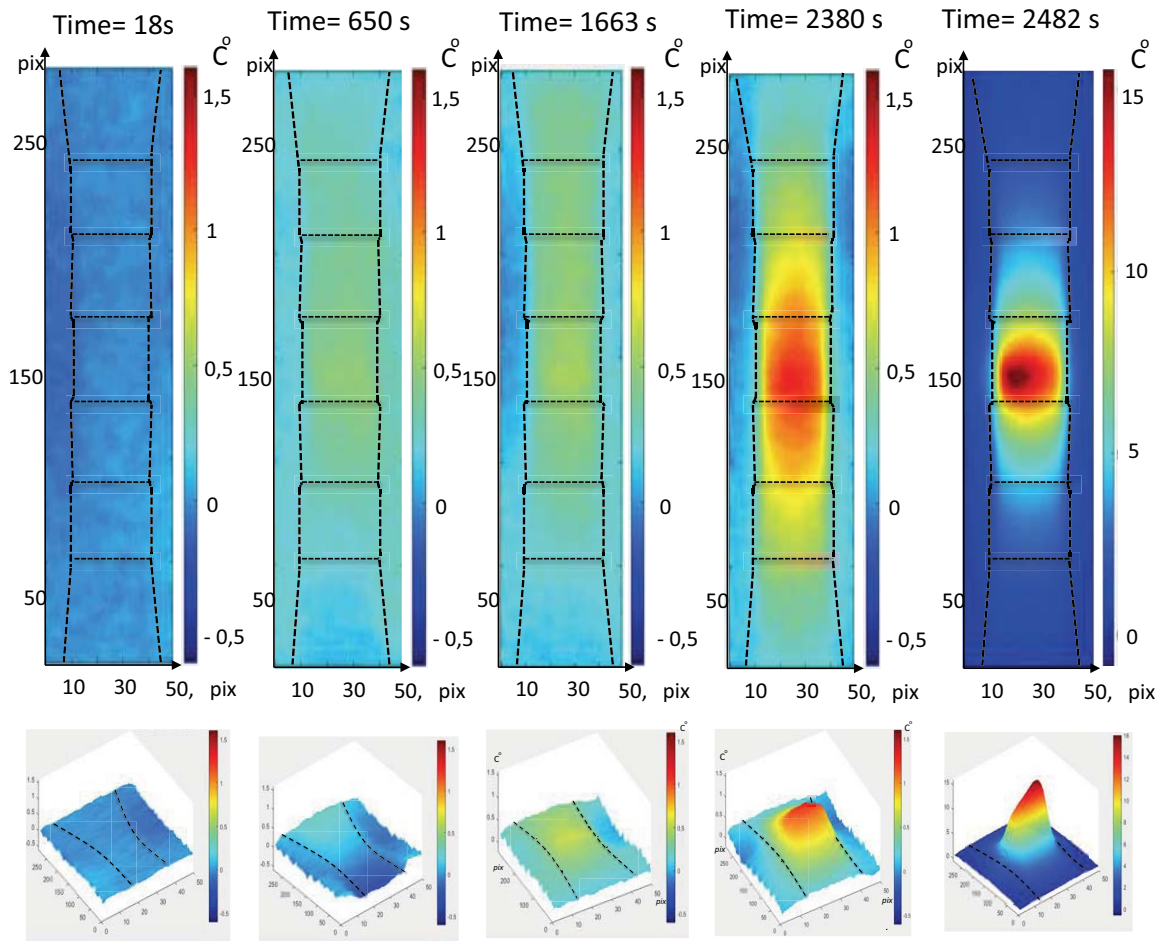

Figure 5: Topography of accumulated heat generation recorded along a constant amplitude fatigue test on a SteBLife specimen made of medium alloyed SAE 4140 QT

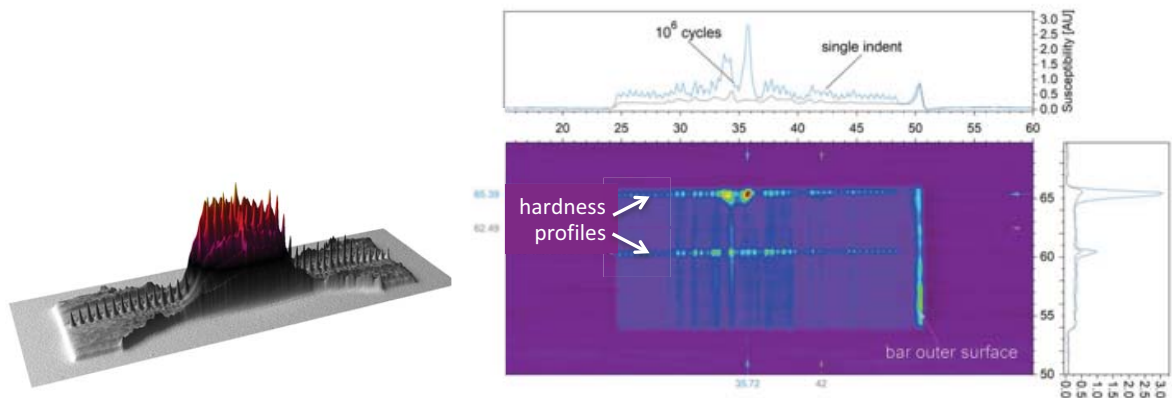

Figure 6: Distribution of stress induced martensite obtained through a scanning procedure for a metastable austenitic steel AISI 347

Magnetic sensors do also have the potential to identify other fatigue damage inducing phenomena such as plasticity as can be seen from the results shown in Fig. 7 below also for the

AISI 347 mentioned before [6]. Here a specimen has been magnetized and the normal and tangential magnetic field has been recorded with a Hall element based sensor in a test at ambient temperature. Although automation of this way of monitoring has still not been shown, the technique has all the potential to be done so in the longer term. This does also include the option in placing the sensing option in line with a strategy being based on continuous monitoring in the sense of SHM.

Figure 7: Experimental setup with magnetic sensor applied (left) and change in magnetic field obtained during a strain increase fatigue test (right) for a metastable austenitic steel AISI 347

One of the possibly most advanced techniques in NDT is ultrasonics, where sensing, signal and data processing as well as visualization is widely discussed when looking at the phased array developments including ray tracing and full matrix capture development. As can be schematically seen from Fig. 8 a phased array transducer with 16 elements is sending acoustic signals into a squared solid body of an either isotropic or even anisotropic material, which has been sectioned into individual elements (i.e. pixels), that can be considered as discrete data stocks of those elements. These elements can be considered as the elements of a 2D or even

Figure 8: Ultrasonic phased array monitoring using ray tracing, SAFT and FMC for optimized monitoring

3D matrix of a structure. From each of the time domain signals recorded an allocation is made to each of those elements applying a ray tracing algorithm that identifies the relevant information then to be stored for each of those elements. The fact that specific features in the signal dominate allows an adaptation of the signals in terms of velocity, phase and even anisotropy to be made which has been known under the name of Synthetic Aperture Focusing Technique (SAFT) [7], Full Matrix Capture (FMC) [8] and Sampling Phased Array (SPA) [9]. The frame of such segmentations does allow NDT data to be managed and an ‘adaptive digital twin’ of the structure considered to be established that in the context of SHM could serve as an extension to improve an SHM system’s efficiency.

6 SMARTER SHM THROUGH NDT INHERITANCE

SHM has to be seen as an element within the frame of an engineering structure’s operational life. It is part of a process chain starting from the structure’s design expressed in terms of loads, geometry and material and is further broken down into strength, durability, integrity and inspection. Such a process has been drawn and discussed in further detail [10] and is shown in Fig. 9 below.

Figure 9: Design process chain for structural integrity assessment leading to SHM system generation

Structural integrity is directly associated with the expression of DTD which allows damage to be present in a structure as long as it does not become critical. DTD is a prerequisite for SHM. As such, a tolerable damage has to be defined, which needs to be detected by the SHM system reliably. To get this achieved, numerical simulation can be of invaluable help since it can allow locations to be identified where the tolerable damage would be monitored best. Much of the developments made in NDT are worth to be considered in the context of SHM. Acoustics has been the NDT technique most elaborated on in this regard over the past. To get those developments somehow placed in a logic order a trial has been made, which has been described in more detail in [11]. This trial is based on the fact that SHM requires simulation, data handling and a resulting hardware respectively. Fig. 10 shows how this can be configured in view of the design process chain shown in Fig. 9. Such a configuration has to be considered as a type of ‘toolbox’ for which a part of the scheme of the box is shown in Fig. 10 but the tools still need to be filled in. Filling such a toolbox is not a task to be done ‘overnight’ but rather a process to be continuously done and possibly never ending. However, it may provide some clarification and some new ideas with respect to SHM in view of a certain NDT inheritance. What is therefore tried is to fill the toolbox with some tools from the acoustics field point of view where more can be found in [11].

Fig. 11 shows the toolbox in terms of acoustics filled with some of the ‘tools’ made available. The scheme shown in Fig. 10 is now added by a fourth column, which makes reference to the various acoustics based NDT techniques available and serving as an input. All of those techniques may contain options with regard to simulation, data handling and hardware, which are worth to be broken up into the toolbox since they may be valuable tools in terms of gener-

ating new SHM solutions beyond the scope of what has been developed so far. This procedure of breaking up tools into the toolbox becomes specifically interesting when it comes to techniques other than acoustics and which have been considered less in the context of SHM. Electromagnetics looks to be one in that regard.

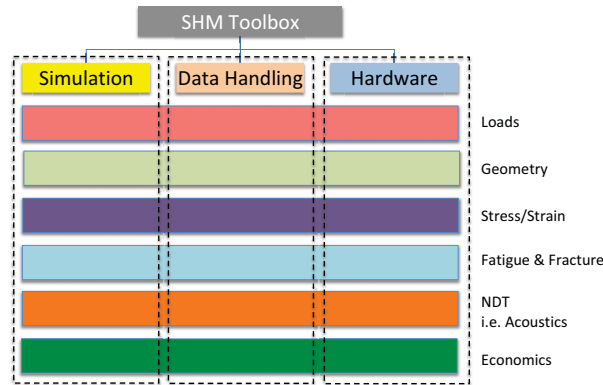

Figure 10: Upper level of a toolbox to configure SHM systems

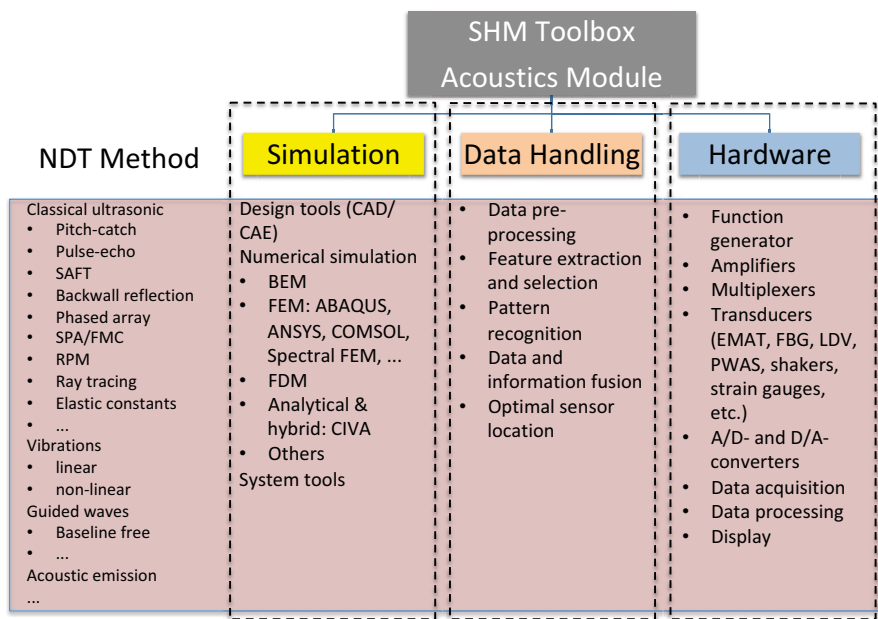

Figure 11: Acoustics based SHM systems design toolbox

7 CONCLUSIONS

SHM is a system's approach serving a structure's lighter weight design or longer operational life or possibly both of them. The longer operational life aspect requires a holistic view of a structure to be obtained including the design, operational and maintenance principles being applied. In many of those cases the SHM system's solution has to be specific and with this various input parameters have to be provided. This concerns the structural material's fatigue properties after ageing, which may have significantly changed and therefore may have to be

reassessed. Here STEPs are of an invaluable help since they allow a material's appropriate fatigue data to be determined at a reasonable effort. Along this assessment process damage relevant parameters can be recorded with sensing and possibly actuation options being beyond traditional strain measurement. Understanding the signal patterns of those sensors in view of structural damage can help to understand the measurement technique to be applied and as such build the basis to develop an SHM system being based on the respective technique and its parameters. This may not be an easy task as has been trying to be shown with regard to thermographic measurements, where influences not originating from the damaging phenomenon have to be eliminated. This may require an understanding of such phenomena that can be obtained through numerical simulation and may be further understood when imaging a measurement result. Such a process easily leads to a digital model of the structure considered if not to say to a 'digital twin' to be established already. This demonstrates the necessity of numerical simulation when efficiently designing an SHM system being an indispensable help to design an appropriate sensor network that reliably detects a damage considered to be tolerable. Getting the various NDT techniques being around broken down into a 'toolbox' can further serve to widen the scope of SHM and to make SHM further smart.

Abstract. An iterative algorithm for refinement of elastic constant of composite laminates is offered. It comprises solution of the inverse problems in accordance with the data received from the fiber Bragg grating (FBG) sensors embedded into composite structure to ensure a match with a given precision of numerical and experimental results for strain values at the control points. The adjusted values of the constants allow to deliver more accurate simulation results using numerical models of mechanical behavior of the structures.

1 INTRODUCTION

The idea of creating materials that together with the basic functions allow to collect information about their condition is very relevant for polymeric composite laminates. The application fields of these materials are developing so rapidly that the current state of numerical and experimental methods for assessing their performance, strength and durability does not always meet the desired requirements. Therefore, it is important to enhance traditional methods for analysis of the mechanical state of composite laminates with new reliable approaches based on non-destructive solutions. One of the self-diagnostics concepts that can be implemented with regard to laminated composite structures involves optical fiber strain sensors [1–3]. The capabilities of such sensors to measure the mechanical state of the surrounding area are derived by using fiber Bragg gratings (FBGs), which provide periodic change in the refractive index of the core of an optical fiber subjected to external influence [4–6]. The operation principle of these sensors is based on a comparison of the wavelength of the light transmitted to and reflected from the Bragg grating.

There are many works devoted to the measurement of strains in composite materials with

the help of embedded or attached optical fiber sensors, with broad description of technical and methodological issues [6–12]. Embedded into composite laminates, optical fiber sensors have a wide range of advantages in comparison with the other structural health monitoring instruments. In particular, they are able to withstand strains comparable with strains of composite structures; are immune to electrical interference; are being integrated during the manufacturing process of the materials and allow to monitor the composite structure during both manufacturing and exploitation.

One of the specifics of composites is that, due to influence of manufacturing parameters, mechanical properties of the structure may not correspond exactly to the properties of the reference samples, even if they made of the same material. Increasing difference between final properties implemented in the structure and properties of testing samples sometimes makes it difficult to find correspondence between experimental and modelled behavior of composite structures.

This work is aimed at creating methods for evaluation of the mechanical state and prediction of mechanical properties of laminated composite structures using mathematical models which parameters are underpinned by the real-time monitoring data from the optical fiber strain sensors with Bragg gratings, integrated into the structures.

2 DEFINITION OF THE OPTIMIZATION PROBLEM

The principle of the proposed method is based on the comparison of the data of FBG sensors, placed in the predetermined control points in the composite structure, with the data of numerical finite element modelling of the same structure. The values of strains obtained from the sensors depend on the relative value of the resonance wave of the spectrum reflected by the Bragg grating, changes in the temperature of the optical fiber at location of the grating, strain and temperature coefficients. In the process of deformation of the sample, dependence of relative value of the resonance wavelength of the reflected spectrum of the optical fiber in the FBG location on the applied load is recorded at the control points. At the constant temperature, it is connected with strain tensor components ε_{ij} of the Bragg grating as follows [13]:

$$k = \Delta\lambda/\lambda = -\frac{n^2}{2}(p_{11} + p_{12})\varepsilon_{22} + \left(1 - \frac{n^2}{2}p_{12}\right)\varepsilon_{11}, \quad (1)$$

where n is refractive index of the optical fiber, p_{11} and p_{12} are the Pokkels coefficients of the strain-optical tensor.

Similar data, in terms of strain values later converted into the k coefficient, as in (1), is extracted from the simulation results. By the difference between the experimentally measured values $\Delta\lambda/\lambda$ and calculated values of k at the control points, a functional is constructed, which should be minimized:

$$M = \sum_{i=1}^N \left(k_i^{FBG}(F_i) - k_i^{FEM}(\mathbf{p}, \sigma_{ij}) \right)^2 \quad (2)$$

where $k_i^{FBG}(F_i)$ is relative value of the resonance wavelength of the reflected spectrum, obtained at the sample load F_i , $k_i^{FEM}(\mathbf{p}, \sigma_{ij})$ is computed with the same applied load F_i values of the coefficient k .

The optimization parameters are the elastic effective constants of the composite ply. Under plane stress conditions, only the values of $E_1, E_2, \nu_{12}, G_{12}$ and G_{13} are required to define an orthotropic material. Let's presume that the optical fiber is directed along the axis 1. The relations between strains and stress in the ply can be written in the following form:

$$\varepsilon_{11}^{FEM}(\mathbf{p}, \sigma_{ij}) = \frac{\sigma_{11}}{E_1} - \frac{\nu_{12}\sigma_{22}}{E_1} \quad (3)$$

$$\varepsilon_{22}^{FEM}(\mathbf{p}, \sigma_{ij}) = -\frac{\nu_{12}\sigma_{11}}{E_1} + \frac{\sigma_{22}}{E_2} \quad (4)$$

The regression function takes the form of Eq. (1) and is written using the constitutive relation for orthotropic media under conditions of plane stress state:

$$k^{FEM}(\mathbf{p}, \sigma_{ij}) = -\frac{n^2}{2}(p_{11} + p_{12})\left(-\frac{\nu_{12}\sigma_{11}}{E_1} + \frac{\sigma_{22}}{E_2}\right) + \left(1 - \frac{n^2}{2}p_{12}\right)\left(\frac{\sigma_{11}}{E_1} - \frac{\nu_{12}\sigma_{22}}{E_1}\right). \quad (5)$$

The stress values σ_{ij} depend on the applied sample load. Thus, the task is to find such values of the constants vector $\mathbf{p} = (E_1, E_2, \nu_{12})$, that will minimize the functional (2) and bring the results of the calculation $k_i^{FEM}(\mathbf{p}, \sigma_{ij})$ into conformity with the experimentally monitored values at a given load.

In the case of several control points, the multi-objective optimization problem is transformed into a single equation problem using the weighting coefficients w_i . Then the error estimation function is written as a sum:

$$G = \sum_{j=1}^N w_j M_j, \quad (6)$$

where N is the number of control points, M_j is the functional (2) for the control point j , the weighting factors w_j are chosen based on the parameters and initial conditions of the specific problems (for example, they can be related to the location of control points and closure of the critical zones).

The Levenberg-Marquardt (L-M) algorithm is used for the optimization, which presumes successive approximation of the given initial values of the parameters to the sought local optimum [14,15]. The initial value of the parameters vector $\mathbf{p} = (E_1, E_2, \nu_{12})$ corresponds to known or initially proposed values of the elastic constants of the ply. It is important, that if the

properties are unknown, zero initial vector of parameters can also lead to correct results with larger number of optimization steps required.

According to the Levenberg-Marquardt algorithm, the following formula is used to estimate the increment of the parameters vector $\Delta \mathbf{p}$:

$$\Delta \mathbf{p} = \left(J^T J + \lambda \text{diag}[J^T J] \right)^{-1} J^T \left(k_i^{FBG}(F_i) - k_i^{FEM}(\mathbf{p}, \sigma_{ij}) \right), \quad (7)$$

where parameter λ controls approximation speed, J is a Jacobian of $k^{FEM}(\mathbf{p}, \sigma_{ij})$ represented as a function of the current parameters values:

$$J = \begin{bmatrix} \frac{\partial k_1^{FEM}(\mathbf{p}, \sigma_{ij}(F_1))}{\partial p_1} & \dots & \frac{\partial k_1^{FEM}(\mathbf{p}, \sigma_{ij}(F_1))}{\partial p_3} \\ \dots & \dots & \dots \\ \frac{\partial k_n^{FEM}(\mathbf{p}, \sigma_{ij}(F_n))}{\partial p_1} & \dots & \frac{\partial k_n^{FEM}(\mathbf{p}, \sigma_{ij}(F_n))}{\partial p_3} \end{bmatrix} \quad (8)$$

Thus, as a result of the optimization problem solution, an optimal set of elastic constants can be found.

3 EXAMPLE OF IMPLEMENTATION

A test problem was considered in which optical fiber sensors were embedded in a composite sample with cutouts on the sides. The sample consisted of 14 0-oriented plies of fiberglass. The FBG sensors were placed in 4 control points on one optical fiber which was embedded between the 7th and 8th layer along axis 1 (coaxially with the direction of the applied load).

Figure 1: The numerical result of the calculation of the strain field ε_{11} and the location of control points (large red dots)

The calculated strain values ε_{11} obtained with (i) the finite-element model employing initial ply constants, (ii) FBG strain sensors and (iii) the finite-element model using optimized ply constants are presented in Fig. 2 for all control points located along axis 1. In the given example, using the proposed optimization algorithm, it was possible to achieve almost complete correspondence between the calculated and experimentally determined strain values. The

comparison of the values of the initial and optimized elastic constants for the lamina ply is presented in Table 1.

The Fig. 3 demonstrates the change in the values of the constants during implementation of the Levenberg-Marquardt optimization algorithm.

Figure 2: Comparison of strain values ε_{11} obtained using the model with initial constants (◆), FBG sensors (■) and model with optimized constants (■) depending on the distance from the center of the sample along its length

Figure 3: The values of the constants depending on a step of the optimization algorithm

Table 1: Initial and optimized properties of a fiberglass ply

	Young modulus E_1 , GPa	Young modulus E_2 , GPa	Poisson's ratio ν_{12}
Initial value	26,0	8,0	0,15
Adjusted value	22,05	10,81	0,137

The proposed method can be generalized for materials with higher anisotropy of properties or generalized strain-stress conditions. In such a case, it is necessary to experimentally measure several components of the strain tensor at the control points. To achieve this, the arrangement of optical fibers in the form of rosettes can be introduced, allowing to obtain measurements in different directions [16–18].

It should be noted that within the framework of this methodology, the measurements from FBG sensors should be considered reliable with the necessary precision. Since this area of research is actively developing at the moment, it is undoubtedly that recent advances will contribute to the development of FBG sensors as reliable tool for independent non-destructive monitoring of the state of composite structures.

4 CONCLUSIONS

- The method of assessment of the elastic constants of composite laminates is proposed based on the comparison of experimental measurements from the optical fiber sensors with Bragg gratings with the numerical results of finite element modelling.
- Numerical part of the proposed scheme is connected with finite element modelling of composite structures under quasi-static loading conditions. Experimental part is based on real-time measurement of strain values at the predetermined control points using FBG sensors.
- The regression function was constructed using constitutive relations for orthotropic media under conditions of plane stress state.
- The Levenberg-Marquardt algorithm is used for optimization of the effective elastic constants' values and their consequent application for validation of numerical modelling results.
- The proposed technique allows to estimate the elastic constants even if their initial values are unknown.
- Implementation of the proposed scheme is demonstrated on the test example.

Key words: piezoelectric actuators, delamination, Lamb waves, hybrid approach, mode conversion

Abstract. This paper presents the results of theoretical and experimental investigations of Lamb wave propagation and scattering by a horizontal delamination in a layered elastic waveguide induced by a piezoelectric wafer active sensor (PWAS). The boundary integral equation method is used to simulate wave propagation and diffraction by a delamination. It is coupled with the frequency domain spectral element method, which is employed to model the dynamic behaviour of the PWAS considering possible debonding of the contact between the transducer and the multilayered waveguide. Experimental investigations of the debonded PWAS dynamic interaction with the layered plate, containing a horizontal delamination, conducted for several damage scenarios, are used to verify the obtained mathematical model. A good agreement between experimental and theoretical results is demonstrated. The developed mathematical model is employed to analyse alteration of the piezo-induced Lamb waves including modes' decomposition due to degradation of the contact conditions. The conversion and/or conservation of the Lamb waves due to delamination is investigated.

1 INTRODUCTION

Structural health monitoring (SHM) methods are of increasing importance since they enable the user to inspect the structure in an automated way in order to perform condition-based maintenance and prevent failure of the investigated system. A considerable amount of SHM techniques rely on elastic guided waves (GWs) as a physical principle for structural inspection [1]. Frequently, they employ a distributed network of surface-mounted piezoelectric wafer active sensors (PWAS) for GW excitation and detection. Since GWs are altered by all kinds of structural damages, the corresponding PWAS-recorded signals

after certain postprocessing are used for the estimation of the defect presence and might allow its localization and extent evaluation. To enhance these capabilities of SHM systems, preliminary numerical analysis of the corresponding wave phenomena is essential. Here, along with the investigation of single pure GW mode interaction with various defect types, studies of multimode PWAS-induced signal scattering are also important. Moreover, the PWAS itself might become a source of imperfections during the structure life-cycle, i.e., its cracking or partial debonding could have a non-negligible effect on the performance of the SHM system [2]. The latter should be also properly addressed in simulations. Thus, a reliable mathematical model simulating piezo-induced Lamb waves propagating and scattering from the delamination as well as PWAS' dynamic interaction with the structure is to be developed.

A combination of the boundary integral equation method (BIEM) and the frequency domain spectral element method (FDSEM), addressed as hybrid approach, is presented in the paper. The semi-analytical BIEM is an efficient tool for simulation of wave propagation in an elongated structure with an internal delamination [3, 4]. Moreover, this method allows investigating single pure Lamb wave mode propagation and scattering by the delamination and quantifying its conversion into other modes. The frequency domain spectral element method [5] is employed to discretize the complex-shaped PWAS in order to simulate its dynamic behaviour considering possible degradation of the contact between the transducer and the waveguide. These two methods are coupled in the contact area between the PWAS and the host structure on the basis of the continuity of the corresponding stresses and displacements. The proposed hybrid approach allows for a detailed parametric analysis of wave phenomena in an elongated structure due to partially debonded PWAS and in the presence of delamination.

2 STATEMENT OF THE PROBLEM

Let us consider an elastic layered structure with Lamé constants μ, λ and mass density ρ occupying the domain $\Omega_1 = \{|x_1| < \infty, -H \leq x_2 \leq 0\}$ with the surface bonded PWAS $\Omega_a = \{0 \leq x_1 \leq w_a, 0 \leq x_2 \leq h_a\}$ where h_a stands for the PWAS height and w_a denotes its width. The lower boundary of the PWAS is composed of the contact area S_c and the debonded area S_d . The horizontal delamination occupies the domain $\Omega_c = \{|x_1 - x_c| \leq l_c, x_2 = -d_c\}$, see Figure ??.

Figure 1: Statement for the mathematical problem

Governing equations defining time-harmonic vibrations of the PWAS Ω_a with angular frequency ω in the two-dimensional case (consider plane strain assumption) are written as follows:

$$C_{ijkl}u_{k,lj} + e_{kij}\phi_{,kj} + \rho\omega^2 u_i = 0, \quad (1)$$

$$e_{ikl}u_{k,li} - \epsilon_{ik}\phi_{,ki} = 0. \quad (2)$$

Here u_i are the components of the displacement vector, ϕ is electric potential; $u_{k,l}$ denotes differentiation $\frac{\partial u_k}{\partial x_l}$, while C_{ijkl} , e_{kij} and ϵ_{ij} are matrices of the elastic constants, piezoelectric constants and dielectric constants measured with zero strain respectively ($i, j, k, l = \overline{1, 2}$).

The electric potential $p(t)$ with the voltage $V = V_0$ is applied on the lower (S^+) surface of the PWAS:

$$\phi(\mathbf{x}, t) = p(t)V_0, \quad (\mathbf{x}) \in S^-, \quad (3)$$

while the upper (S^-) surface of the PWAS is grounded ($\phi(\mathbf{x}, t) = 0, (\mathbf{x}) \in S^+$) and the side boundaries of the PWAS are considered free of charge.

All boundaries of the piezoelectric structure Ω_a are stress-free except for the contact area S_c :

$$\sigma_{ij}\eta_j = 0, \quad \mathbf{x} \in \partial\Omega_a \setminus S_c, \quad (4)$$

here σ_{ij} – are components of the stress tensor and $\boldsymbol{\eta}$ is the normal vector.

The continuity of the stresses and displacements are assumed at the contact area S_c :

$$\boldsymbol{\tau}^a = \boldsymbol{\tau}^1, \quad (5)$$

$$\mathbf{u}^a = \mathbf{u}^1. \quad (6)$$

Components of the stress tensor hereinafter are expressed in terms of the traction vector $\boldsymbol{\tau} = \{\sigma_{12}, \sigma_{22}\}$.

Delamination boundaries are assumed being stress-free:

$$\boldsymbol{\tau} = 0, \quad \mathbf{x} \in \Omega_c. \quad (7)$$

3 HYBRID APPROACH

Application of the hybrid approach scheme is explained in detail in [9] for the case of the PWAS attached to a layered structure without delamination. The proposed method suggests solution of the problem in the frequency domain first and employment of the inverse Laplace transform to obtain a time domain solution afterwards. According to the FDSEM [6] the solution in the PWAS $\mathbf{y} = \{u_1, u_2, \phi\}$ can be approximated using Lagrange interpolation polynomials $C^I(x_1, x_2)$ at Gauss-Legendre-Lobatto points for each spectral element via a special index I :

$$\mathbf{y} = \sum_I y_I C^I(x_1, x_2). \quad (8)$$

In order to couple the PWAS with the waveguide at the contact area S_c , the unknown traction vector $\mathbf{q}(x_1)$ is introduced so that:

$$\mathbf{q} = \boldsymbol{\tau}^a = \boldsymbol{\tau}^1, \quad \mathbf{x} \in S_c. \quad (9)$$

The crack opening displacements (COD) $\mathbf{w}(x_1)$ for the delamination Ω_c are expanded via Chebyshev polynomials of the second kind with square root weight $p_n(x_1)$, see more details in [3]:

$$\mathbf{w}_k(x_1) = \sum_{n=0}^N \gamma_{kn} p_n(x_1). \quad (10)$$

The total wavefield in the elastic structure Ω_1 is obtained as sum of the wavefields excited by the PWAS \mathbf{u}^{in} and wavefields scattered by the crack \mathbf{u}^{sc} :

$$\mathbf{u}^1 = \mathbf{u}^{(in)} + \mathbf{u}^{(sc)}. \quad (11)$$

According to the BIEM [7, 8] displacements vector can be expressed as:

$$\mathbf{u}^{(in)}(\mathbf{x}) = \frac{1}{2\pi} \int_{\Gamma} \mathbf{K}(\alpha, x_2) \mathbf{Q}(\alpha) e^{-i\alpha x_1} d\alpha. \quad (12)$$

Here $\mathbf{K}(\alpha, x_2)$ is the Fourier transform of Green's matrix of the waveguide, $\mathbf{Q}(\alpha)$ is the Fourier transform of the surface load function $\mathbf{q}(x_1)$ with respect to x_1 coordinate, while Γ is the contour in the complex plane of the variable α along real axis surrounding poles of the integrand. Similar, the traction vector is expressed as:

$$\boldsymbol{\tau}^{(\text{in})}(\mathbf{x}) = \frac{1}{2\pi} \int_{\Gamma} \mathbf{T}(\alpha, x_2) \mathbf{Q}(\alpha) e^{-i\alpha x_1} d\alpha. \quad (13)$$

Here \mathbf{T} is matrix obtained after differential stress operator has been applied to representation (12). The scattered displacements vector is obtained in the same way:

$$\mathbf{u}^{(\text{sc})}(\mathbf{x}) = \frac{1}{2\pi} \int_{\Gamma} \mathbf{K}^{(c)}(\alpha, x_2) \mathbf{W}(\alpha) e^{-i\alpha x_1} d\alpha, \quad (14)$$

where $\mathbf{K}^{(c)}(\alpha, x_2)$ is the Fourier transform of Green's matrix and $\mathbf{W}(\alpha)$ is the Fourier transform of the unknown crack opening displacement $\mathbf{w}(x_1)$ for delamination Ω_c . Similar integral representations can be written for the traction vector:

$$\boldsymbol{\tau}^{(\text{sc})}(\mathbf{x}) = \frac{1}{2\pi} \int_{\Gamma} \mathbf{T}^{(c)}(\alpha, x_2) \mathbf{W}(\alpha) e^{-i\alpha x_1} d\alpha, \quad (15)$$

again, $\mathbf{T}^{(c)}$ is the matrix obtained after differential stress operator has been applied to representation (14).

The traction vector (9) is interpolated with the first order splines based on the nodal points χ_J at the contact area S_c . Employing the special index J , $\mathbf{q}(x_1)$ is expanded as follows

$$\mathbf{q}(x_1) = \sum_J \mathbf{q}^J s_J(x_1), \quad (16)$$

where $s_J(x_1)$ are the combinations of the first order splines.

Thus, a system of the linear algebraic equations with respect to the vector of unknowns

$$\mathbf{g} = \{y_1^J, y_2^J, y_3^J, q_1^J, q_2^J, \gamma_{1l}, \gamma_{2l}\}$$

can be written as follows

$$\begin{pmatrix} \mathbf{A}_{ij} & \mathbf{B}_{ik} & \mathbf{0} \\ \mathbf{C}_{lj} & \mathbf{D}_{lk} & \mathbf{F}_{lk} \\ \mathbf{0} & \mathbf{G}_{lk} & \mathbf{H}_{lk} \end{pmatrix} \cdot \begin{pmatrix} \mathbf{y} \\ \mathbf{q} \\ \boldsymbol{\gamma} \end{pmatrix} = \begin{pmatrix} \mathbf{V} \\ \mathbf{0} \\ \mathbf{0} \end{pmatrix}. \quad (17)$$

Matrices \mathbf{A}_{ij} and \mathbf{B}_{ik} are composed in accordance with the FDSEM, see more details in [9]. In order to satisfy boundary conditions (6) taking into account (11), the equations (12), (14) are substituted to (11) and afterwards the collocation method is applied to the solution at the nodal points. Thus matrices \mathbf{C}_{lj} , \mathbf{D}_{lk} , \mathbf{F}_{lk} are obtained:

$$C_{J'I;nj} = \delta_{J'I} \delta_{nj}, \quad (18)$$

$$D_{J'J;lk} = -\frac{1}{2\pi} \int_{\Gamma} K_{lk}(\alpha, 0) S_J(\alpha) e^{-i\alpha \chi_{J'}} d\alpha, \quad (19)$$

$$F_{J'n;lk} = -\frac{1}{2\pi} \int_{\Gamma} K_{lk}^{(c)}(\alpha, 0) P_n(\alpha) e^{-i\alpha \chi_{J'}} d\alpha. \quad (20)$$

Substitution of the representations (13), (15) to boundary conditions (7) and Bubnov-Galerkin scheme application results in the following expressions for the matrices G_{lk} , H_{lk} :

$$G_{n'J;lk} = -\frac{1}{2\pi} \int_{\Gamma} T_{lk}^{(0)}(\alpha, -d_c) S_J(\alpha) P_n^*(\alpha^*) d\alpha, \quad (21)$$

$$H_{n'n;lk} = -\frac{1}{2\pi} \int_{\Gamma} T_{lk}^{(c)}(\alpha, -d_c) P_n(\alpha) P_{n'}^*(\alpha^*) d\alpha. \quad (22)$$

The inverse Laplace transform is applied to the obtained time-harmonic solution $\mathbf{u}(\mathbf{x}, \omega)$ in order to calculate the time dependent solution.

The hybrid mathematical model can be used to investigate the elastic wave energy transfer from the PWAS into the waveguide and the amount of the wave energy carried by each Lamb wave. The application of the Cauchy's residue theorem and Jordan lemma allows to substitute integral representations (11)–(15) by sums of residues in the poles, which corresponds to propagating and attenuating Lamb waves [3]. Such analysis is based on the time-averaged power density vector $\mathbf{e}(\mathbf{x})$ or Umov-Poynting vector:

$$e_j = \frac{\omega}{2} \text{Im}(\sigma_{1j} u_1^* + \sigma_{2j} u_2^*). \quad (23)$$

The presence of the delamination in the waveguide results in a partial reflection of the GWs and, therefore, it is convenient to calculate transmission and reflection coefficients, which is also possible within the developed model. The wave energy distribution coefficients η_m^{\pm} (m corresponds to Lamb wave) are introduced via the integration of the horizontal component e_1 of the time-averaged power density vector along a certain cross-section of the waveguide in a far-field zone. The energy distribution coefficients $\eta_m^{\pm} = E_m^{\pm}/E^0$ are the ratios between the wave energy E_m^{\pm} carried by m -th Lamb wave in directions $x_1 \rightarrow \pm\infty$ and the wave energy transmitted by a PWAS:

$$E^0 = \frac{1}{2\pi} \int_{\Gamma} \mathbf{K}(\alpha, 0) \mathbf{Q}(\alpha) \mathbf{Q}^*(\alpha^*) d\alpha$$

or by a certain incoming Lamb wave

$$E^0 = \int_{-H}^0 e_1^{(\text{in})}(x_1, x_2) dx_2.$$

4 EXPERIMENT

Experimental investigations of the debonded PWAS dynamic interaction with the layered plate, containing a horizontal delamination, have been conducted for several damage scenarios. The scheme of the experiment specimen is shown in figure 2. Two rectangular piezoelectric transducers with sizes 10 mm×30 mm×1 mm have been glued one after another to the surface of the two-layered aluminum plate of dimensions 600 mm×100 mm with the thicknesses of the layers 1 mm and 2 mm. The interface horizontal delamination with the length $l_c = 10$ mm and center in $x_c = 155$ mm is located between the layers at the depth $d_c = 1$ mm. The Lamé constants $\lambda = 51.1$ GPa, $\mu = 26.3$ GPa and mass density $\rho = 2640$ kg/m³ are used in mathematical model for aluminum and the material of the PWAS is PIC 155 PI Ceramics production. Four different damage scenarios have been investigated, see Table 1. Within

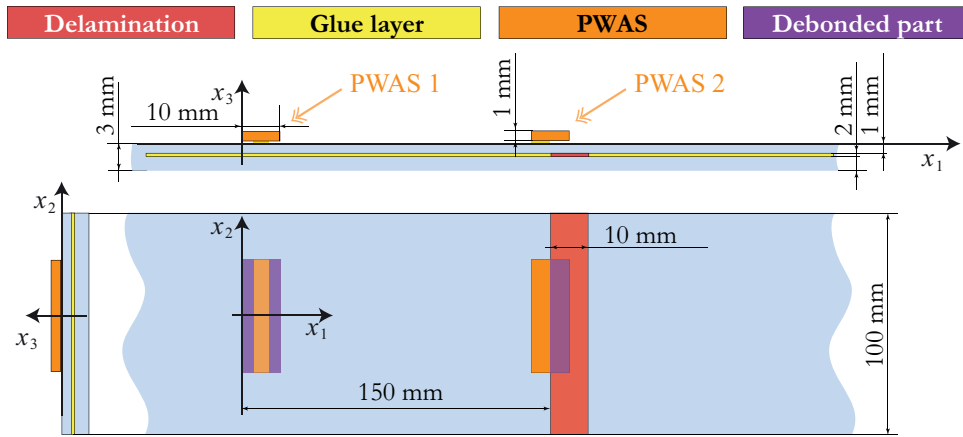

Figure 2: Design of the specimen

Table 1: Damage scenarios

Damage scenario	Transducer	Contact area S_c	PWAS x_1 coordinate
1	PWAS 1	$[0, 10]$	$[0, 10]$
2	PWAS 1	$[3, 7]$	$[0, 10]$
3	PWAS 2	$[0, 10]$	$[145, 155]$
4	PWAS 2	$[0, 5]$	$[145, 155]$

each damage scenario, only one transducer has been glued to the plate with the contact area S_c and particular distance to the crack. In that way, experimental results were obtained firstly for different bonding conditions and secondly for different mutual location between the PWAS and the delamination.

As input voltage signal $p(t)$ with the amplitude $V_0 = 40$ V is applied to the PWAS, Lamb waves are excited in the plate. The signal $p(t)$ has been used the same as was introduced in formula 53 in [9]. The velocities of the out-of-plane motion \dot{u}_2 have been measured at both sides of the plate $x_2 = 0$, $x_2 = -H$ with a 1D Laser Doppler vibrometer from OptoMET using a compact optical head with an infrared measurement laser of 1550 nm wavelength. In order to perform a comparison with the 2D mathematical model measurements have been taken along the line $x_2 = 0$, see Figure 2.

4.1 Verification of the model

In order to verify the developed mathematical model a comparison with the experimental signals and a standard FEM model has been performed. Comsol Multiphysics software has been used to calculate velocities of the piezo-induced motion at the surface of the plate with the standard finite element method. For the Comsol calculation 7921 (figures 3a, 3b) or 9176 (figures 3c, 3d) quadrilateral elements with quartic Lagrange interpolation polynomials have been used.

The results of the comparison for the damage scenario No 3 are shown in the figures 3a and 3b. The left plot presents velocities of the motion calculated and measured in the point $x_1 = 125$ mm which is located 20 mm from PWAS 2 on the left. The same data is shown in the right plot, but for the point $x_1 = 175$ mm, which is also located 20 mm from the PWAS 2 but on the right – where the delamination takes place (see Figure 2). All three methods provide similar results, though amplitudes of the calculated signals are slightly higher than the experimental data in the point $x_1 = 175$ mm. Additionally, it is

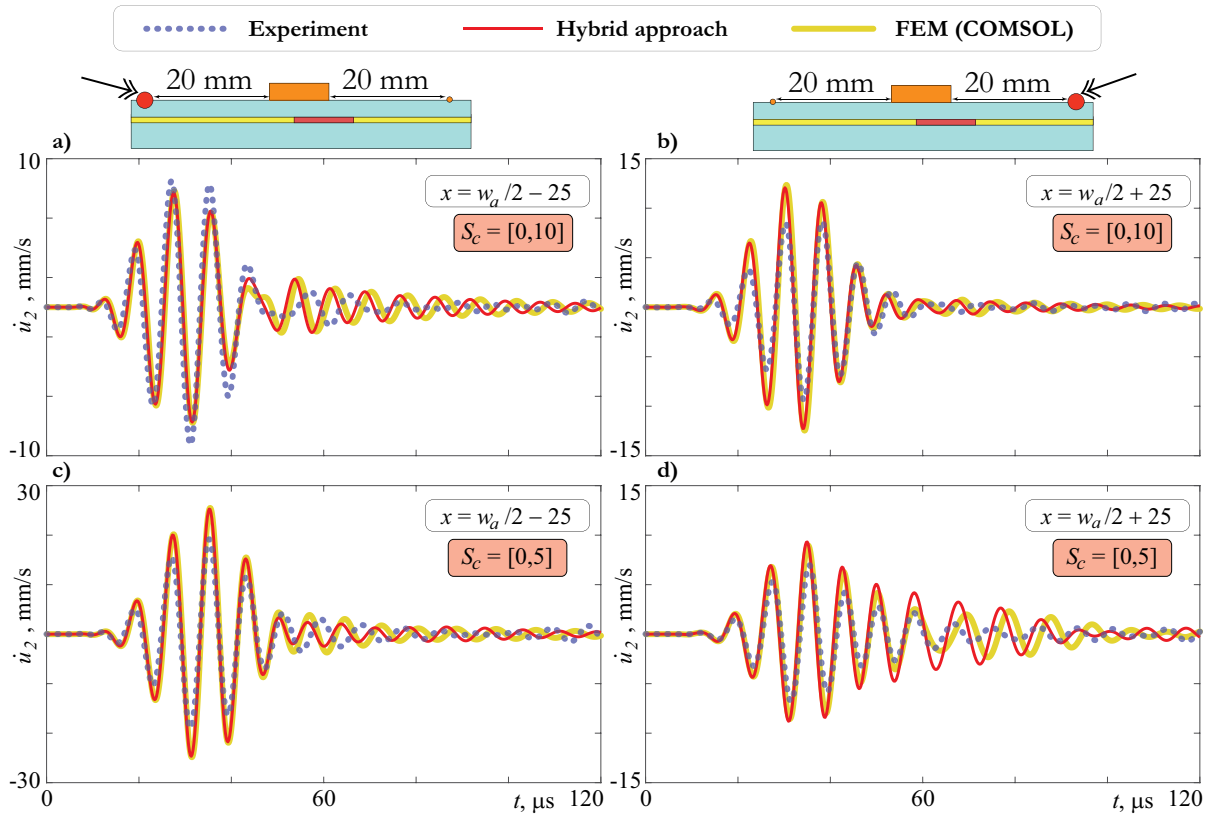

Figure 3: Velocities of the motion on the surface of the plate $u_2(125, 0, 0, t)$ (a,c) and $u_2(175, 0, 0, t)$ (b,d) measured and calculated with the central frequency $f = 120$ kHz for the perfectly bonded $S_c = [0, 10]$ (a,b) and partly debonded $S_c = [0, 5]$ (c,d) PWAS

observed that the amplitudes of the signal propagating over the delamination are slightly higher than the amplitudes of the signal propagating in the opposite of the delamination direction. The detailed analysis of transmission and reflection characteristics is provided in the section 4.2.

Figures 3c and 3d present results of the comparison at the same points measured and calculated with the partly debonded PWAS (damage scenario No 4). Again, agreement between the calculated and measured signals is very good. It is evident that in case of debonding, amplitudes of the signal propagating in the direction opposite to the delamination (figure 3c) are 2.8 times higher than the amplitudes measured at the point after the delamination (figure 3d). The proposed mathematical model predicts this effect accurately. Moreover, comparing figures 3b and 3d one can observe additional wave package, which is excited due to debonding.

4.2 Experimental investigation and analysis

The susceptance spectrum of the PWAS being the imaginary part of the admittance can be used to estimate PWAS structural health, including bonding conditions between the transducer and the waveguide [2]. It has been shown [2, 10] that the electro-mechanical impedance (EMI) spectrum is dependent on the contact conditions and various defects of the transducer. Electrical and mechanical parameters influence the EMI spectrum and therefore any structural alteration of the PWAS due to defect leads to an EMI spectrum change. The measurements of the EMI spectrum have been performed for four damage

scenarios with a Cypher C60 using 1024 points over a frequency range of 1kHz to 1MHz.

Figure 4 presents the measured susceptance spectrum for four PWAS conditions in dependence on frequency. The measured spectrum includes four eigenfrequencies leading to maxima in the susceptance spectrum in the following frequency ranges: 100kHz–260kHz; 410kHz–520kHz; 650kHz–780kHz and 910kHz–990kHz. Outside these frequency ranges susceptance spectrum does not depend neither on contact conditions nor on delamination existence and location. Two phenomena, which are explained in [2, 10] are visible here. The debonding leads to an elevated resonance phenomenon, as visible for the blue dotted line corresponding to the most debonded PWAS ($S_c = [3, 7]$, $w_a = 10\text{mm}$). Moreover there is a shift of the resonance to lower frequencies for the first resonance, which is highly influenced by the bonding conditions. To analyse the influence of the delamination it is proper to compare the yellow and red lines corresponding to the perfectly glued transducers, while the first one is far from the delamination (150 mm distanced) and the second one is located directly above the delamination. The difference in peaks is observed in the second and fourth frequency ranges, which leads to a conclusion that a delamination might influence susceptance spectrum as well. Though, more repetitions of similar experiments are needed to make a statistically proved resume.

Figure 4: Susceptance spectrum

5 WAVE PHENOMENA ANALYSIS

The developed mathematical model allows to simulate distribution of the piezo-induced energy and quantify the conserved and/or converted energy due to delamination. Figure 5 presents the dependance of the energy E^0 on the excitation frequency for 4 damage scenarios and for the pristine PWAS glued to the waveguide with no delamination. It is visible, that the blue dotted and yellow solid lines oscillate, while the green dashed, red solid and brown solid lines are smooth. The reason for this effect lies in the method used to obtain E^0 – in the harmonic solution, the mutual influence between the delamination and the PWAS has no time dependence. And as long as the distance between the PWAS and delamination is rather big (145mm), the harmonic wavefields from both domains superimpose and the resulting E^0 plot oscillate. It is worthy to note, that E^0 excited in the waveguide with no delamination by the healthy PWAS (brown solid line) coincides with the same data, but with the delamination presence (yellow solid line). Thus, it can be concluded that the delamination has minor influence on the PWAS-excited energy if it is located in the far field.

Figure 5: Wave energy E^0 excited by the PWAS in the plate with delamination $d_c = 1$ mm, $l_c = 5$ mm and $x_c = 155$ mm

It is observed that all maxima of the excited energy are located inside the same frequency diapasons determined during susceptance analysis. Moreover, all the peaks at the susceptance plot are in coincidence with peaks in the E^0 plot. For example the green dashed line indicating fourth damage scenario has two peaks at the susceptance plot ($f_1^B = 429\text{kHz}$ and $f_2^B = 489\text{kHz}$) and two similar peaks at the E^0 plot ($f_1^{E^0} = 464\text{kHz}$, $f_2^{E^0} = 502\text{kHz}$). The yellow solid line indicating the first damage scenario has no visible maximum in the third frequency range $650\text{kHz} - 780\text{kHz}$ at the susceptance plot and there is also no maxima at the E^0 plot in the same diapason. Such close correlation between the susceptance and elastic waves energy is due to both physical quantities are highly dependent on the eigen frequencies of the PWAS attached to waveguide. Nevertheless, there are additional maxima at the E^0 plot, in the additional frequency diapason $570\text{kHz} - 585\text{kHz}$, which have no counterpart at the susceptance plot. The nature of those peaks lies in the eigen characteristics of the coupled waveguide and PWAS.

A detailed analysis of the different modes of piezo-induced Lamb waves propagating in the waveguide with delamination has been performed. Figure 6 illustrates the modes' distribution over the excitation frequency for perfectly bonded (a) and debonded (b) PWAS located directly above the delamination (damage scenarios 3 and 4). Here parameter η_M^\pm indicates the share of the M mode in E^\pm , which is part of the PWAS-excited energy E^0 propagating in directions $x_1 \rightarrow \pm\infty$. It is observed that at lower frequencies (up to 250kHz) partial debonding results in increasing of the reflected energy. Thus, at frequency $f = 120\text{kHz}$ with the perfectly glued PWAS 44% of the energy is distributed to the right (33% A_0^+ , 11% S_0^+) and 56% of the energy is distributed to the left (20% A_0^- , 36% S_0^-). At the same time, with the half debonded PWAS only 26% of the energy is distributed to the right (2% A_0^+ , 24% S_0^+) and 74% of the energy is distributed to the left (25% A_0^- , 49% S_0^-). The same results are visible in the figure 3 – amplitudes of the velocities measured to the right and to the left from the PWAS are almost the same for the healthy PWAS (figures 3a and 3b) and differ in 2.8 times for the debonded PWAS (figures 3c and 3d).

In order to distinguish modes excited by the PWAS from converted modes due to delamination, the investigation of the modes' excitation in the waveguide without delamination has been performed. Figure 7 presents distribution of the modes in the excited wavefield by perfectly bonded (a) and partly debonded (b) PWASs. The contact conditions are chosen the same like in damage scenarios 1 and 2.

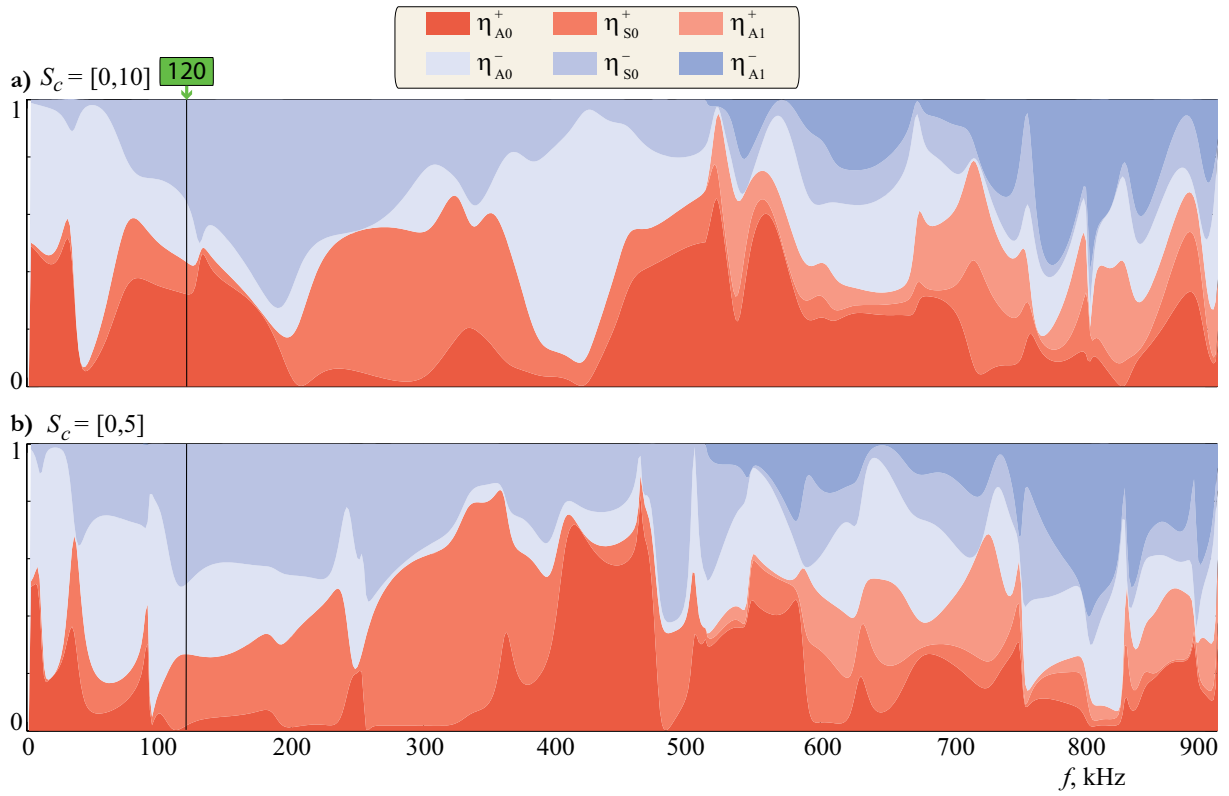

Figure 6: Wave energy modes distribution over frequency for (a) perfectly bonded ($S_c = [0, 10]$) and (b) debonded ($S_c = [0, 5]$) PWAS; $x_1 \in [145, 155]$

Figure 7: Decomposition of the piezo-induced Lamb waves over frequency for (a) perfectly bonded ($S_c = [0, 10]$) and (b) debonded ($S_c = [3, 7]$) PWAS in case of plate with no delamination

As the problem is symmetric, only the positive direction is shown. It is evident that even without the delamination, modes' distribution is strongly influenced by the PWAS debonding. For example, the healthy PWAS excites only the S_0 mode at the frequency $f = 260$ kHz and mostly A_1 mode (82%) at the frequency $f = 615$ kHz, but neither of these effects are visible if the PWAS is debonded. In that case, at $f = 260$ kHz share of the S_0 mode is only 38% and at $f = 615$ kHz share of A_1 mode is 18%. However, if one assumes that PWAS is healthy, such analysis might be quite useful for the practical applications. It is

possible to calculate modes' distribution for the PWAS of any size and choose appropriate combination of the PWAS size and frequency in order to select a so called sweet spot frequency to excite mainly the desired Lamb wave mode, interacting best with the presumed damage type.

In order to improve damage detection techniques, it is necessary to analyse how each Lamb wave interacts with every kind of defect. As illustrated in figure 7, either A_0 or S_0 are excited in the waveguide at frequencies up to 500kHz. Therefore, an analysis of the incident A_0 and S_0 modes interaction with the delamination is provided. Figure 8a presents Lamb waves energy distribution transmitted and scattered from the delamination. It is observed, that incident A_0 mode is reflected by the crack (A_0^-) and ratio between the transmitted and reflected waves depends on the frequency. Moreover, up to a frequency $f = 520\text{kHz}$ almost no mode conversion is visible; starting from $f = 520\text{kHz}$ firstly part of the A_0^+ is converted to A_1^+ and then to S_0^+ . The most interesting effect is observed at frequency $f = 440\text{kHz}$, where almost all incident A_0 wave is transmitted through the delamination without any reflection or conversion. Figure 8b demonstrates the same modes' distribution but for incident S_0 mode. It is evident, that the S_0 mode practically does not interact with delamination at the frequencies up to 580kHz. Starting from $f = 580\text{kHz}$, a small part of incident S_0 is converted to A_0 , the conversion-to-conservation ratio increases with the highest frequencies. But over the whole frequency range even at the higher frequencies, ratio of the reflected waves is insignificant. Thus, if a PWAS is used to induce Lamb waves at the frequency for example $f = 260\text{kHz}$, where only S_0 is excited, those GW most likely will not interact with the delamination and therefore the defect will not be detected. Evidently, such mode analysis is needed during development of the SHM system for the particular structure.

Figure 8: Wave energy distribution coefficients for A_0 and S_0 scattering by a delamination $l_c = 5\text{mm}$, $d_c = 1\text{mm}$

6 CONCLUSIONS

A mathematical model based on the combination of the BIEM and the FDSEM simulating piezo-induced Lamb waves propagation and scattering in a waveguide with a horizontal delamination has been obtained. Experiments with healthy and partially debonded PWASs glued to the layered waveguide with a delamination have been conducted. A good agreement between the calculated and measured signals has been demonstrated. A correlation between the susceptance value and energy of elastic waves induced in the waveguide has been revealed. It was shown that delamination does not influence the PWAS-induced energy, if the distance between the transducer and the delamination is considerable large. A detailed analysis of the Lamb waves transmission and/or reflection due to delamination including modal analysis has been performed. It was revealed that debonding of the PWAS leads to the significant changes in the modes' distribution in the excited wavefield. Incident A_0 and S_0 modes interaction with the delamination has been analysed. It was revealed that the A_0 mode is partly reflected by the delamination, while the S_0 interaction with the delamination is insignificant.

The work is supported by the Ministry of Science and Higher Education of the Russian Federation (Project No 9.1022.2017/4.6) and by the Deutscher Akademischer Austauschdienst (DAAD).

Abstract. This paper presents comparison between two excitation solutions for tubular ultrasonic transducer. The axial excitation is widespread in conventional ultrasonic transducer. The radial excitation is proposed in order to have an uniform acoustic energy all along the tube. This excitation approach is also proposed to allow the modularity by adding several tubes.

1 INTRODUCTION

Ultrasonic transducers are commonly used for transmitting mechanical energy to several kinds of media: fluid, polymers. . . . in order to impact its properties.

Ultrasonic transducers are usually used for converting electrical energy to mechanical vibration. The Langevin solution is widely used for this conversion. This solution is based on two different masses at the ends of active material (typically piezoelectric material). Both masses are mechanically connected by a screw in order to preload and ensure the compression of the piezoelectric material during the vibration. The weight of both masses is different in order to favour the vibration in one direction. In order to increase the emitting surface, the ultrasonic transducers are connected to a large surface structure with adapted impedance in order to fit with the frequency resonance of the ultrasonic transducer. The most common cases are flat surfaces or tubular surface. For the flat surface, several ultrasonic transducers are required and the number of transducers is directly linked to the active power. The technological limitation for the tubular solution is the tube length. Tubes are convenient for some coating application if width is limited to typically less than 1 m. A new need addressed in H2020 PROTECT Eu project is to coat large textiles width using sonochemistry [<http://protect-h2020.eu/>]. For such a need, it is required to produce a uniform acoustic energy all along the textile widths. Similar acoustic uniformity requirements are also met in ultrasonic unclogging of cylindrical filters.

In order to overcome this technological limitation, several research activities have been performed. The wasted vibration issued from the Langevin ultrasonic transducer is recovered by connecting two tubes in both sides of the ultrasonic transducer [1]. The proposed solution is called wing type ultrasonic transducer. This architecture enables to increase the emitting surface through two tubes. Nevertheless, a non-vibration area remains at the piezoelectric stack location which means a non-uniform treatment all along the tube. So, another architecture is

proposed [2] by the by using two ultrasonic transducers at the two ends of the tube. This option enables to increase the length of the tube by 25 to 30 %. In the same way, the length of the tube is limited at 2 to 2.5 m. For longer tube, the attenuation of the vibration occurs in the middle of the tube. Such a solution is called a push-pull, ultrasonic transducer. This solution allows for increasing the length of the tube. Nevertheless, the modular approach seems more suitable for a longer tube. The modular approach is proposed [3] using the ultrasonic transducer connected in axial excitation. In this case, the diameter of the tube is higher compared to the diameter of the ultrasonic transducer. This approach allows connecting several tubes in serial from the mechanical point of view. So the ultrasonic transducer is located in the hollowed part of the previous tube. The entire tube is constituted by several tubes connected together by a welding process at the external diameters of the tube. In this case, the vibration is uniform all along the tube. This architecture allows having a longer tube with less dissipation of the vibration at the tube level. However, the ratio between the axial displacement of the ultrasonic transducer and the radial displacement at the tube lever is not favourable due to the difference between the diameter of the ultrasonic transducer and the diameter of the tube. Instead of using the ultrasonic transducer in the axial vibration, the approach of [4] is to use the strain generated in the radial direction of the ultrasonic transducer and transmitted to the tube through the internal diameter. This architecture is proposed to allow to pass the fluid (or the media) to treat inside the tube (instead of outside).

The approach proposed in this paper is to use a radial excitation in order to install the ultrasonic transducer within the tube. This configuration named MUST standing for Modular UltraSonic Transducer and patented by CTEC [5] is preferred in the perspective of providing a uniform acoustic energy along the transducer. It also offers a good potential for using the ultrasonic transducer in a modular approach, by stacking them to get a length of several meters.

2 CONVENTIONAL AXIAL EXCITATION

Tubular ultrasonic transducers are based on ultrasonic transducer (for the mechanical vibration generation) connected to one end of the tube. The second end of the tube is connected to an heavy mass (see Figure 1). The ultrasonic transducer is based typically on Langevin transducer. The aim of the tube is to increase the emitting surface through its external surface which is immersed in the media to treat.

Figure 1: Tubular ultrasonic transducer approach

2.1 The transducer solution

The Langevin transducer which is typically made up of rear mass, head mass (emitter) and active material (stack of piezoelectric material) is depicted in Figure 2. The screw is used to preload the stack of the all the components constituting the ultrasonic transducer. In this way, the screw ensures that all the components stay connected during the vibration of the ultrasonic transducer.

Figure 2: Typical Langevin, ultrasonic transducer (axisymmetric view)

The resonance frequency of such a system depends on the dimension and the material properties of the ultrasonic transducer components. The simplified formulation depicting this relation is given by the formulation given hereafter.

$$\text{wavelength } (\lambda) = \frac{1}{f} \times \sqrt{\frac{E}{\rho}} \quad (1)$$

With:

E: Young modulus [N/mm²]

ρ : Density of the material [Kg/m³]

f: Considered frequency [Hz]

Finite Element Method gives a more accurate prediction. The shape and the mapping of the axial and radial displacement are given the pictures below (Figure 3).

Figure 3: The axial and the radial displacement on the ultrasonic transducer

The displacement is considered in free-free consideration. The resonance frequency of the transducer is about 24.3 kHz with a coupling coefficient of 24 % at this frequency. The displacement depicted is given for 1 volt supply. The density of the rear mass is chosen in such a way to favour the emitting energy in the head mass side. The displacement of the transducer in the axial and radial all along the transducer is given in the curves below.

Figure 4: The axial and the radial displacement on the UST

In order to increase the emitting surface, the ultrasonic transducer is connected to the tube. The design of the tube is done in order to fit with the resonance frequency of the ultrasonic transducer. In such a configuration, the system is called ‘Tubular ultrasonic transducer’. This design is based on the previous equation above (equation 1).

2.2 The resonator behaviour

The assembly of the tube on the ultrasonic transducer is described below (Figure 5). The tubular part is designed in order to allow the maximum radial displacement while being compliant with the material fatigue.

Figure 5: Tubular ultrasonic transducer with simple excitation

The analyses of the Eigen shape of the tube show two different shapes of deformation. The cylindrical shape corresponds to the increase of the tube diameter at a given position (Figure 6). The black lines correspond to the initial diameter of the tube, the red lines to the maximum position of the tube and the green line to the minimum position of the tube. For the elliptic shape, the diameter of the tube increases in one direction and decreases in the other direction at the given position (Figure 7). In the same approach, the black lines correspond to the initial diameter of the tube, the red lines to the maximum position of the tube and the green line to the minimum position of the tube.

Figure 6: Tubular with the cylindrical deformation

Figure 7: Tubular with the elliptic deformation

The cylindrical deformation of the tube occurs at 24.1 kHz 500 mm length of the hollowed part of the tube. The radial and the axial displacements all along the tube are given by Figure 8. The radial displacement at the hollowed part is lower by 50 % compare to the axial displacement.

Figure 8: Tubular with the elliptic deformation

The impact of the vibration issued by the tube on the fluid has been studied. The mapping of the pressure generated by the transducer on the fluid (water in this case) is given below (Figure 9). The pressure is non-uniform all along the tube. The pressure is higher in the closer part of the tube to the generator and the pressure is attenuated at the farther part of the tube. This attenuation is due to the damping effect of the fluid. The maximum pressure is about 778 Pascal.

Figure 9: The generated pressure in the fluid (water) by the tubular ultrasonic transducer.

3 MUST WITH RADIAL EXCITATION

3.1 The transducer solution

For the MUST, the radial excitation ultrasonic transducer has been developed by Cedrat Technologies (Figure 10). The approach of this transducer is to install the head mass between both stacks of piezoelectric material and both rear masses on the other side of both piezoelectric stacks. Finally, a bolt connects the both rear masses. The activation piezoelectric material will compress the head mass of the ultrasonic transducer this will increase the diameter of the head mass.

Figure 10: The ultrasonic transducer for radial excitation configuration (axisymmetric view)

The shape of the deformation of the radial excitation ultrasonic transducer is given below (Figure 11). The frequency resonance of the ultrasonic transducer is equal to 25.7 kHz with a coupling coefficient of 44.5 %. The displacement in the radial and axial displacement all along is also compared. The displacement in the radial direction is lower by 41 % compares to the axial direction. In the case of a hollowed preload screw, the amplification ratio decrease to 38 %.

Figure 11: The ultrasonic transducer for radial excitation configuration

In the same way, the ultrasonic transducer is connected to the tube in order to increase the emitting surface of the transducer. The attachment isn't done with the same approach compare to the axial excitation solution.

3.2 The resonator behaviour

The mechanical connection between the ultrasonic transducer and the tube is obtained directly due to the shape of the monolithic part of the head mass (Figure 12).

Figure 12: The head mass geometry for axial excitation configuration.

Once the ultrasonic transducer assembled (piezoelectric stack, rear mass and bolt) to the head mass, both tubular ends are connected mechanically to tubes.

Figure 13: Tubular ultrasonic with the radial excitation

The frequency resonance of the ultrasonic transducer installed in the tube is equal to 25.0 kHz. The shape of deformation at the tube level corresponds to the cylindrical one (Figure 14). At both ends of the transducer, the geometry of the tube is changed in order to avoid the propagation of the vibration issued from the tube to the structure of the tank.

The wiring of both piezoelectric stacks comes out of the tube from the same side. (right side - Figure 13). The cable located in the left side goes through the hollowed preloading from the left to the right side of the tube.

Figure 14: The tube deformation on the MUST transducer

The impact of the vibration issued by the tube on the fluid has been studied. The mapping of the pressure on the fluid (water in this case) is given below (Figure 15, to compare with figure 9). The pressure is uniform all along the tube, which is the main advantage of this transducer technology. The maximum pressure is about 6195 Pascal. The pressure level is

obtained at the same level of voltage as for ultrasonic transducer in axial excitation configuration.

Figure 15: The generated pressure in the fluid (water) by MUST ultrasonic transducer

4 PROTOTYPING

An ultrasonic transducer with radial excitation prototype (Figure 16) has been manufactured in order to evaluate and compare the simulation and the experimental results. The stack of piezoelectric material and rear mass have been assembled.

Figure 16: The ultrasonic transducer for radial excitation assembly

A preliminary measurement has been performed in order to evaluate and compare the results to the simulation. The test has been done in two steps, the first one to measure the resonance frequency of the system (Figure 17 - a) and the second to measure the amplitude of displacement generated at the ultrasonic transducer level (Figure 17 – b).

Figure 17: The ultrasonic transducer for radial excitation on test bench

The preliminary measurement on the prototype for the first test a variation of the frequency resonance from 25.7 kHz (simulation) to 22.1 kHz (measurement). The first analysis of such a variation of frequency could be generated due to the boundary condition which is not the same between the simulation and the test bench. For the second test, the displacement ratio as measured is about 45 % between the axial and the radial direction (for both cases of screws). The simulation shows a ratio of 41 % for standard screws and 38 for the hollowed screws. In the case of the standard screw, the coupling coefficient is about 37 % and 22 % in the case of the hollowed screw.

Two tubular ultrasonic transducers, one with axial and one with radial excitation approach have been manufactured (Figure 18) in order to evaluate their performances and to compare between both solutions. Further measurement and experimentation are planned in the near future. This test will include the performance measurement on immersed and also connected several MUST in order to increase the length of the tube (so the emitting surface) without losing vibration at the ends of the tube.

Figure 18: The MUST and conventional ultrasonic tube transducer

5 CONCLUSIONS

The comparison study between the axial and the radial excitation on the tubular ultrasonic transducers has been done in this paper. The radial excitation approach has been studied in order to improve the capability of such a solution for getting a homogeneous acoustic energy generation and higher tube length by staking. This has lead to a new Modular Ultra Sonic Transducer (MUST). Based on FEM simulation, its results show a higher coupling coefficient for the radial excitation with the same amplification ratio than conventional tube transducer using axial excitation. The pressure generated by the MUST is uniform all along the tube as wanted.

The experimental campaign is still in progress in order to have deeper information about the performance of MUST solution especial in the immersed configuration.

This activity takes parts on H2020 PROTECT project (GA 720851) targeting the textile sono-chemical treatment to get anti-bacteriologic property.

Key words: Offshore Wind Turbine, Structural Health Monitoring, Damage Detection, Damage Classification, Data Driven

Abstract. A structural health monitoring (SHM) system verifies the mechanical state of a structure to ensure its proper functioning and determines whether it needs some kind of maintenance. Thus, SHM for wind turbines (WT) in remote locations, as offshore, is crucial. Offshore wind farms are increasingly realized in water depths beyond 30 meters, where lattice support structures are an interesting option to withstand the severe environmental actions. In particular jackets appear to be a highly competitive substructure type with a wide range of applicability, from approximately 25 to 70 meters water depth. With no doubt, structural damage is a significant issue in these structures. Unlike on-shore structures or even shallow water structures, the access for regular monitoring and repair is not an easy option, in terms of both the cost and the accessibility. In this work, a methodology for the detection and classification of structural damages in offshore jacket-type WT is stated. The proposed method relies on the paradigm that any damage in the structure produces changes in the vibrational response. However, it is assumed that the only available excitation of the WT is the wind turbulence, so the input excitation is assumed to be unknown. Therefore, using only accelerometer information, a data driven approach for damage detection is developed. The scheme of the proposed method can be summarized in the following steps: (i) the wind excitation is simulated as a Gaussian white noise and the data coming from the WT is collected using a set of accelerometers; (ii) the raw data is arranged in matrix form and pre-processed using mean-centered group-scaling; (iii) principal component analysis (PCA) is selected as a technique to reduce the dimensionality of the data and the computing time of the next step; finally, (iv) the quadratic-kernel support vector machine (SVM) is used as a classifier. The 5-fold cross-validation technique is employed to estimate the overall accuracy and to avoid overfitting. In order to experimentally validate the proposed approach, the damage detection strategy is applied to different types of predefined damage in a small-scale structure—an experimental laboratory tower modeling an offshore-fixed jacked-type wind turbine—. The results that have been obtained for these predefined damages are included and discussed to demonstrate the reliability of the proposed approach.

1 INTRODUCTION

Offshore wind farms are seen as a key ingredient in renewable energy, and an important element in the battle against climate change. In the last ten years, the average offshore wind farm has increased in

size from 79.6 MW in 2007 to 561 MW in 2018, see [1]. Accordingly, the size of offshore wind turbines has also increased. Since 2014 the average rated capacity of newly installed wind turbines has grown at an annual rate of 16%. As an example, the largest turbine in the world to date was installed offshore in the United Kingdom in 2018: two V164-8.8 MW from MHI Vestas Offshore Wind, with a rotor diameter of 164 m, that were connected at the European Offshore Wind Development Centre (EOWDC) wind farm, see [2]. The extreme size of nowadays offshore wind turbines leads to the demand for structural health monitoring (SHM) solutions on its overall structure. However, the foundation of fixed offshore wind turbines, in particular, are subject to harsh conditions including environmental loadings (wave and current), a corrosive environment, and shifts in the seabed as scouring and water depth erosion. Besides, inspection of the submerged foundation is expensive due to the difficult access and sometimes impossible due to the environmental conditions. In this case, SHM is the crux of the matter to provide an early warning of degradation and diminish operation and maintenance costs.

SHM for offshore wind turbines remains a research topic which is slowly getting into the field deployment stage, see [5]. This is due to the early stage of the technology's deployment, the additional challenge that offshore environments pose to these technologies, and associated costs to operators for hardware installation and data processing.

There are different types of foundations, according to the depth at which the wind turbine will be installed. In general, monopiles are used in installations at depths below 15 meters, gravity foundations are preferred when depth is less than 30 meters, and jackets are the used option for greater depths. This work focuses on the jacket type. These are foundations with a lattice framework that feature three or four sea bed anchoring points, which increases the levels of safety when anchoring the towers. The top of the jackets features a transition piece that is connected to the turbine shaft, while the legs are anchored to the sea bed with piles. This work proposes a complete methodology for damage detection and classification in a laboratory jacket-type offshore-fixed wind turbine model. As in [3], it is supposed that the only available excitation of the WT is the wind turbulence, so the input excitation is assumed to be unknown. Therefore, the scheme of the proposed method can be summarized in the following steps: (i) the wind excitation is simulated as a Gaussian white noise and the data coming from the WT is collected using a set of accelerometers. It is worth remarking that only output data will be used to detect damage; (ii) the raw data is pre-processed using group-scaling to simplify the computation of the principal components; (iii) PCA is selected as a technique to reduce the dimensionality of the data and the computing time of the next step; finally, (iv) the quadratic SVM classifier is used. In the end, 5-fold cross-validation technique is employed to estimate the overall accuracy and to avoid overfitting. In order to validate the proposed approach in this work, the damage detection strategy is applied to different types of predefined damage in a small-scale structure—an experimental laboratory tower modeling an offshore-fixed jacked-type wind turbine—. The results that have been obtained for these predefined damages are included and discussed to demonstrate the reliability of the proposed approach.

2 LABORATORY TOWER MODEL

The real structure used in this work is a tower model, similar to those of a wind turbine. From Figure 1 it can be seen the components of the structure: jacket, tower and nacelle. As a whole, this structure is 2.7 m high. The tower is composed of three sections joined with bolts, while the jacket is composed with several sections, all of them joined with bolts, with a torque of 12 Nm. The different studied damages are introduced in one of these sections, see Fig. 1. The top piece is 1 m long and 0.6 m width. There a modal shaker is located that simulates the nacelle mass and the environmental effects of the wind over the whole structure. Applying an electrical signal to the shaker (white noise), the vibration needed to

excite the structure is created. The simulation of different wind speeds is also simulated with this shaker, by changing the amplitude of the input electrical signal, in particular multiplying it by the factor 0.5, 1, 2, and 3.

Figure 1: WT scaled tower model used in the experimental tests (off-shore fixed jacked-type platform).

Two types of damage are introduced at the jacket support: a 5 mm crack in one of the bars; and

loosening one of the bolts in the jacket. Also a healthy replica of the studied bar has been considered, as the proposed strategy should be able to detect and classify the studied faults, but also be robust to the replacement of one bar by a new healthy one (avoiding false alarms).

To analyze the structural response, eight triaxial accelerometers are placed in the tower and jacket. The method used to find the optimum location and amount of these sensors is given in [4]. Thus, data from 24 sensors is collected. The nomenclature used for each sensor is given in Table 1.

Table 1: Nomenclature used to refer to each available sensor. Note that $i = 1, \dots, 8$, as there are eight accelerometers.

Sensor	
A_i^x	Acceleration in x -direction for accelerometer number i
A_i^y	Acceleration in y -direction for accelerometer number i
A_i^z	Acceleration in z -direction for accelerometer number i

3 DAMAGE DETECTION AND CLASSIFICATION METHODOLOGY

3.1 Data collection

The time window for each experimental test is 60 seconds with a sampling frequency of 1651.6129 Hz. Thus, each experiment obtains $1651.6129 \times 60 = 99097$ data measurements from each of the 24 sensors.

In this work, a total of 25 experimental tests are conducted for each different white noise amplitude. In particular:

- (i) 10 tests with the original healthy bar.
- (ii) 5 tests with the replica bar.
- (iii) 5 tests with the 5 mm crack damaged bar.
- (iv) 5 tests with an unlocked bolt in the jacket.

That is 100 experiments in total, as there are 25 experiments for each one of the 4 different considered white noise amplitudes.

Given the k -th experimental test, the data is initially stored in a matrix $\mathbf{Y}^{(k)} \in \mathcal{M}_{99097 \times 24}(\mathbb{R})$ such that

$$\mathbf{Y}^{(k)} = \begin{pmatrix} y_{1,1}^{(k)} & y_{1,2}^{(k)} & \cdots & y_{1,24}^{(k)} \\ y_{2,1}^{(k)} & y_{2,2}^{(k)} & \cdots & y_{2,24}^{(k)} \\ \vdots & \vdots & \ddots & \vdots \\ y_{99097,1}^{(k)} & y_{99097,2}^{(k)} & \cdots & y_{99097,24}^{(k)} \end{pmatrix}, \quad (1)$$

where the number of rows is given by the number of time stamps in each experimental test and the number of columns is equal to the number of sensors. Note that data in the first column is related to sensor A_1^x , data in the second column is related to sensor A_1^y , third column is related to A_1^z , fourth column to A_2^x , and so on and so forth.

The data from the k -th experimental test stored initially in matrix $\mathbf{Y}^{(k)}$, see eq. (1), is reshaped into the matrix $\mathbf{Z}^{(k)} \in \mathcal{M}_{41 \times 2417 \cdot 24}$,

$$\mathbf{Z}^{(k)} = \begin{pmatrix} y_{1,1}^{(k)} & \cdots & y_{2417,1}^{(k)} & \cdots & y_{1,24}^{(k)} & \cdots & y_{2417,24}^{(k)} \\ y_{2418,1}^{(k)} & \cdots & y_{4834,1}^{(k)} & \cdots & y_{2418,24}^{(k)} & \cdots & y_{4834,24}^{(k)} \\ \vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\ y_{96681,1}^{(k)} & \cdots & y_{99097,1}^{(k)} & \cdots & y_{96681,24}^{(k)} & \cdots & y_{99097,24}^{(k)} \end{pmatrix}, \quad (2)$$

where each row (each sample) contains 2417 time stamps from each sensor.

Finally, the data matrix $\mathbf{X} \in \mathcal{M}_{(41 \cdot 100) \times (2417 \cdot 24)}(\mathbb{R})$ that contains the data from all the experiments is defined by:

$$\mathbf{X} = \begin{pmatrix} \mathbf{Z}^{(1)} \\ \vdots \\ \mathbf{Z}^{(k)} \\ \vdots \\ \mathbf{Z}^{(100)} \end{pmatrix} \quad (3)$$

that is, concatenating the data matrices coming from the 100 experiments.

3.2 Autoscaling

The main reason to autoscale the raw data is to simplify the computations for the multiway PCA decomposition. Autoscaling uses column-wise mean-centering followed by division of each column by the standard deviation of that column of matrix \mathbf{X} . The result is that each column of the new autoscaled matrix, $\tilde{\mathbf{X}}$, has a mean of zero and a standard deviation of one. The fact that $\tilde{\mathbf{X}}$ is a mean-centered matrix simplifies the empirical covariance matrix computation, needed for the PCA decomposition.

3.3 Principal component analysis

Recall that, before using a classifier, the data must be processed to obtain the most suitable features. In this work, after the autoscaling step, multiway PCA is selected as the main objective is to reduce computing time for the quadratic discriminant analysis classifier. In this work, the first 400 components of the PCA decomposition are used as they account for 85% of the variance. Thus, the transformed coordinates of the $\tilde{\mathbf{X}}$ data in the new basis given by the first 400 principal components are used as features by the quadratic SVM strategy. Thus, 400 features are used instead of 58008 variables, that is 0.69% of the data retains 85% of the variance.

3.4 Quadratic SVM

The scatter plots shown in Fig. 2 of the first feature versus the second and tenth features reveal a quadratic relationship. Therefore, the quadratic SVM classifier is adopted. For a detailed review on the SVM classifier see references [6], [7], and [8]. In this work the kernel scale is set to 10 and the box constraint level to 2.

Finally, in this work, the 5-fold cross-validation technique has been employed to estimate the overall accuracy and to avoid overfitting.

4 RESULTS

A comprehensive decomposition of the error between the true classes and the predicted classes is shown by means of the so-called confusion matrix, see Fig. 3 (an empty blank square means 0%). In this matrix, each row represents the instances in a true class while each column represents the instances in a predicted class (by the classifier). In particular, the first row (and first column) is labeled as 1 and corresponds to the healthy and replica bar. The next labels (for rows and columns) correspond to each fault (label 2 corresponds to crack damage, and label 3 to unlocked bolt type of damage).

As shown in Fig. 3 the true positive rate (TPR) for the healthy case is 99% and the false negative rate (FNR) only 1%. For the crack damaged bar a TPR of 96% is accomplished and for the unlocked bolt type of damage a TPR of 99% is obtained. The overall accuracy is 98.6%. The training time was 1080 seconds in a 3GHz Intel Core i7 with 16GB RAM computer. Finally, note that the proposed strategy can be deployed in real time as the prediction speed is 2100 observations per second.

5 CONCLUSIONS

In this work, using only accelerometer information, a data driven approach for damage detection in offshore jacket-type WT is developed. The proposed approach has been experimentally validated for different types of predefined damages in a small-scale structure—an experimental laboratory tower modelling an offshore-fixed jacked-type wind turbine—. The obtained results, with an overall accuracy of 98.6%, demonstrate the reliability of the proposed approach.

Abstract

This paper focuses on the use of wireless sensors networks (WSN) on cultural heritage buildings for long-term monitoring purposes. This technology is highly attractive because of both the reduced dimensions of the sensors and the absence of cables, that ensures a small visual impact. In this way, the need of a long-term monitoring is addressed without significant impact on the features of the cultural heritage. Nevertheless, this technology is still growing, and several issues still need to be addressed: wireless connection of signals is not even simple because of the thickness of the structural elements, size of the transmitted packages could not be too large, thus implying low frequency resolution and small length signals, etc.[1] [2]. In this emerging scenario, this paper discusses and reports on an automated procedure setting-up for the Modal Tracking (MT) of the Modal Parameters (MP) obtained from long-term monitoring data. The considered data were recorded through a WSN recently installed on a representative historic structure: an ancient masonry tower [3]. The monitoring system has been built with cheap devices, ensuring a wide applicability to the cultural heritage. As shown by several authors [4] [5], the tracking of the frequency across a suitable time span allows to identify possible structural anomalies and/or checking the effectiveness of a specific retrofitting. The results of the first six months are discussed in detail, showing performances and criticism of the monitoring system.

INTRODUCTION

The preservation of the Cultural Heritage (CH) is one of the biggest challenges for our generation to avoid the loss of priceless objects. The recent cases of partial or total collapses renewed the attention on that, topic showing how that structures that are exposed to hazardous events.

The Structural Health Monitoring (SHM) framework gives a powerful tool to analyze the evolution in time of the selected damage sensitive features. That operation, usually known as Modal Tracking (MT), is based on extraction of the Modal Parameters (MP) through an automated procedure. The major part of the automated procedure proposed in the last years are based on the Stochastic Subspace Identification algorithm [6], fed both with the data or with the covariance matrix. The capability of the technique in the modal identification under unknown input in operative conditions led to an increasing interest among the scientific community. The main issue was the high number of setting parameters needed for perform the modal identification. Indeed, in several works the Authors [7–10] proposed several semi or fully automated procedures based on the clustering analysis techniques.

Then the identified modes are tracked [11,12] over the time based on the distance in terms of frequency and Modal Assurance Criterion (MAC) index.

The most investigated damage sensitive feature is the frequency because of its numerical stability and for the limited number of accelerometers required for the identification. Even if the frequency is sensitive to the environmental effects such as temperature and humidity [13–15] that can be of the same measure of that produced by a damage. Then the environmental effects are compensated by ARX model, Multiple Linear Regression (MLR), the Principal Component Analysis (PCA) and the non linear models as the kernel PCA. The damage detection is then finalized through statistical tools called control charts [16].

In the recent years, many Authors [4,17] developed monitoring systems for the CH site, showing how the detection of damage can be successfully achieved with a limited number of accelerometers.

In the present paper is introduced an algorithm for the features extraction in the continuous dynamic monitoring system installed on a historic masonry tower from the recorded signals. The entire monitoring system is wireless, and the accelerometers are Micro Electro Mechanical Systems (MEMS) devices. Not so many cases of application of wireless long-term monitoring system to the CH, despite the advantages in terms of low invasiveness.

The results of the first six months of monitoring of an ancient masonry tower through a continuous (ten minutes of record every hour) wireless monitoring system and the features extraction algorithm are showed.

THE FEATURES EXTRACTION ALGORITHM

The Modal Parameter Identification (MPI) through automated procedures is still an open issue. The parametric techniques in the time allows the implementation of codes based on the identification of the system properties managing the data collected by the sensors. The calibration of the procedure allowing to distinguish among the real modes and the mathematical or spurious modes minimizing the variance of the identified modal parameters is one of the biggest issues that usually is underestimated.

Nevertheless, in the operative conditions the source of excitation is sometimes a colored noise

or a harmonic excitation and the hypothesis of a broadband process decays. In many cases the signals exhibit a low power respect to the ground noise leading to difficult modal identification. Considering all these problems the automated procedure should replace the judgment of an expertise selecting the recorded signals which lead to a higher accuracy in the identification of the MP. This procedure is effective if the monitoring system collect a high number of records for each day, enabling the Continuous Vibration-Based Structural Health Monitoring (CVB-SHM). Ceravolo [18] applied the CVB-SHM technique to a complex elliptical dome by selecting the input of the identification procedures exhibiting higher levels of root mean square. Then the Subspace-Stochastic Identification based on the data (SSI-data) is set guaranteeing the identification of a higher number of modes.

The algorithm herein proposed is based on the definition of statistical threshold through the analysis over a limited period (Calibration Phase) that affect all the phases of the automated procedure. Starting from the selection of the inputs, the setup of the modal order and the number of rows in the Henkel matrix and the definition of the threshold for each mode for the MT are set.

The input selection is based on the quality of the signals measured through the kurtosis and the rms and on the level of signal respect to noise measured as the signal to noise ratio [19] (SNR). The setup of the SSI based on the covariance matrix of the signal (SSI-cov) is made by means of a sensitivity analysis and then by the analysis of the obtained standard deviations of each mode in terms of frequency and damping ratio. Then the distance in terms of MAC and frequency is evaluated for each mode.

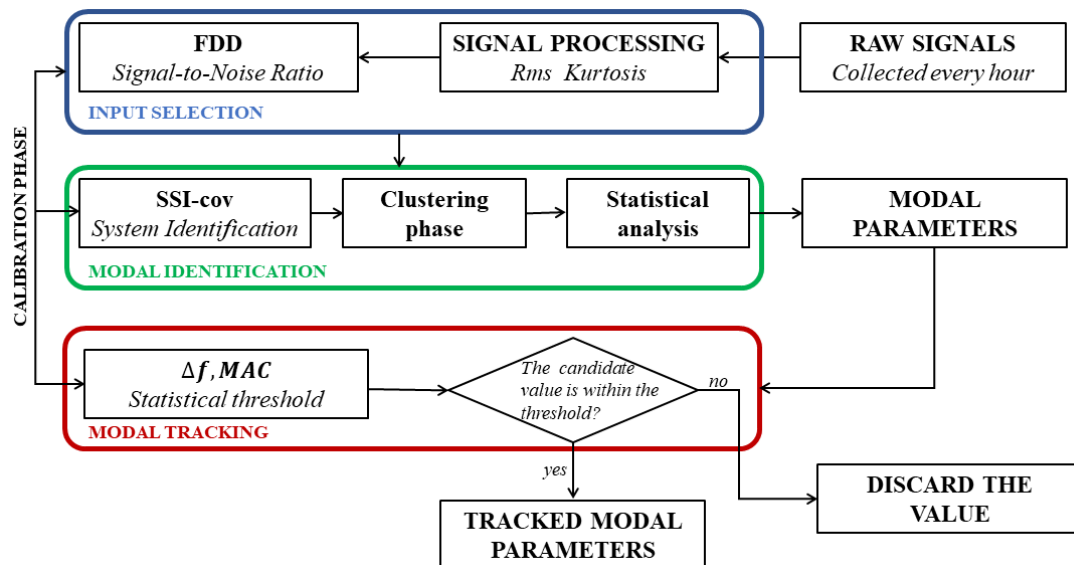

Figure 1: Block scheme of the proposed automated modal identification algorithm.

APPLICATION TO THE MATILDA'S TOWER

The Matilde Tower in the Livorno's harbor, is a round plan tower with a height of about 29 m and an external diameter of about 12 m. The masonry walls have a thickness of about 2,5 m with a spiral staircase embedded to connect the level zero with the upper two levels. The tower

has four levels mainly built by vaults that were reinforced with steel bars in the past centuries. In the upper level there is a round terrace with at the center another small round area with a flat slab.

The tower was erected as a free-standing structure probably in the late XII century with the purpose of ensuring a clear observation of the sea and the possibility of repelling the enemy attacks from all directions. With the passing of centuries, the structure was surrounded by the walls, becoming a complex fortress (the Old Fortress). The whole architectural complex shows a severe cracking pattern, probably due to several causes (foundation settlements, sea erosion, bombing of the second world war).

Within the MOSCARDO project, a research project funded by Tuscany Regional Administration in 2015-2018, the tower was listed in the relevant cases of study to analyze to develop a wireless monitoring system and a reliable post-processing algorithm. Indeed, the modal properties of the structure were extracted from preliminary dynamic tests [3]. The results of the preliminary dynamic tests campaign were also very useful to understand the characteristics of the dynamic excitations and their intensity levels. In the preliminary experimental campaign, the most relevant dynamic loads were the wind and the harmonic forces probably generated by the engines of the boats operating in the harbor.

The monitoring system and the calibration of the MP extraction algorithm

The wireless sensor network installed on the tower is composed by seven MEMS accelerometers (three at the level 0 and four at the terrace level), two meteorological stations measuring the temperature and humidity (one inside the level 0 and one outside at the terrace level), one anemometer (at the top of the highest level) and two strain gauges on the steel chains of the level 0. The acquisition last for ten minutes for every daily hour with a frequency of acquisition of 50 Hz, the data are then sent to a server and the results can be visualized on the website (<http://www.moscardo.it/>).

Figure 3 The sensor positions for the long-term monitoring of the Matilde Tower. The red arrows represent the direction of the accelerometers. In blue are represented the two meteorological stations (temperature and humidity). In yellow the anemometer measuring the wind speed and direction.

Figure 4 (a) The biaxial accelerometer at the node 1007. (b) The node 1037 with the anemometer and the meteorological station. (c) A node of the network at the level zero with the meteorological station a monoaxial accelerometer and the gateway.

The calibration of the algorithm is made over two distinct periods of one week. The first period #P1 (3/12/2018-7/12/2018) is when the tower is excited by the highest wind level and the second #P2 (15/02/2019-22/02/2019).

Figure 5 The results of the first calibration period (#P1) in terms of rms and average wind speed.

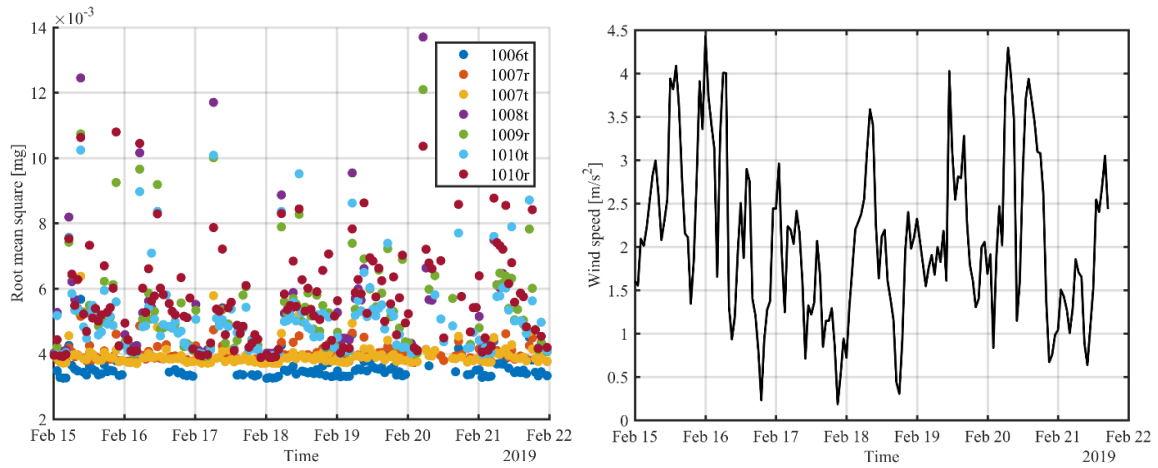

Figure 6 The results of the second calibration period (#P2) in terms of rms and average wind speed.

From the analysis of these two extreme events the threshold for the input selection are defined by means of an outlier analysis excluding the values outside 1,5 times the interquartile range. Then the minimum values evaluated from the two periods is selected in terms of rms and SNR and the maximum for the Kurtosis. Indeed, the first two thresholds guarantee a minimum input quality even if the external excitation is very low. Instead the Kurtosis gives a refined information about the tails of the pdf that can from anomalies in the signals or from non-gaussian process.

Table 1: Threshold values for the input selection

	SNR [dB]	RMS [mg]	Kurtosis
#P1	39,06	0,0075	118,67
#P2	34,72	0,0040	24,49
Threshold	34,72	0,0040	118,67

In the analysed case of study in the band of interest (0-10 Hz) are available the first three modes, that in many cases are not excited at the same time. The automated procedure for the modal identification based on the *SSI-cov* algorithm is set by means of a sensitivity analysis and a minimum number of elements for each cluster is chosen to avoid the selection of spurious and mathematical modes. In the calibration period it is evaluated the complexity of the mode shapes by means of the Mean Phase Deviation (MPD) and Mean Phase Collinearity (MPC) [20]. Both these indicators are normalized to give a result equal to one for perfect real modes and equal to zero for modes with the highest degree of complexity. Usually the physical modes exhibit a low degree of complexity, but in some cases some degree of complexity can arise from the structural non-linear behaviour [21]. For these reasons a statistical threshold is built for each mode in terms of MPC and MPD as the minimum value of the mean across the two calibration periods.

Table 2: Threshold values for the modal identification phase.

	MPC	MPD
#P1	0,90	0,77
#P2	0,73	0,78
Threshold	0,73	0,77

The MT of the identified modal parameters is made starting from a reference value for each mode in terms of frequency and mode shapes. During the calibration phase a hierarchical clustering algorithm is performed with two initial fixed threshold 5 % for the frequency and 0,7 for the MAC index. Then for each identified mode is computed the MAC distance for each value and the threshold value is obtained as the lower bound of the interquartile range. Then the maximum value among the two calibration periods is chosen for the MT of each mode during the whole monitoring period.

Table 3: Threshold values for the MT of the MP

	1st Mode	2nd Mode	3rd Mode
#P1	0,78	0,79	0,84
#P2	0,73	0,79	-
Threshold	0,78	0,79	0,84

This conservative choice is made to avoid the selection of some harmonic response of the structure near to the band of interest of each modal frequency.

The results of the first six months

The early results from the first six months (from the 19th of September 2018 to the 20th of March 2019) of long-term monitoring of the Matilda's tower obtained with the algorithm introduced in the previous section are described herein.

Despite some disconnections of instruments due to the initial trial period, the results can furnish some preliminary information on the working activity of the package WSN monitoring system and the feature extraction algorithm. The MT of the first three modes is successfully achieved, even if some offline periods (mid-November and mid-January) of some sensors cannot allow a continuous tracking over the monitoring period.

The first two modes seem to be less scattered than the third, implying a lower accuracy in the

modal identification. Moreover, the third mode cannot be identified in every session, probably requiring higher energy levels in the input.

Figure 7 The variation of the environmental parameters in the first six months of monitoring period.

Figure 8 The modal tracking of the first three modes: The bending (B_1 , B_2) and the torsional (T).

CONCLUSIVE REMARKS

The presented monitoring system is based on a wireless network of sensors developed during the MOSCARDO project shows how it is possible to satisfying the requirements of low visual impact and low costs that are fundamental in the CH application.

The feature extraction algorithm for a CVB-SHM monitoring system is presented focusing on the calibration of the entire automated procedure to obtain good quality identification results that is crucial for the systems based on the tracking of the frequency. Enabling the damage detection (level 1 in the Rytter's scale [22]) for the monitored CH building.

Despite the presented algorithm is suitable for every kind of CH building, the preliminary dynamic identification and the calibration phase should be adopted to the operative conditions and to the dynamics of the monitored structure.

In the case of study presented herein the main dynamic excitation source was the wind, and the

calibration phases furnishes the input selection parameters in order to avoid outliers or low excited modes. In the modal identification phase through an automated *SSI-cov* procedure with the initial values are set by means of a sensitivity analysis. Then for the MT the MAC thresholds are defined for each mode by the results obtained in the calibration period. Instead the distance in terms of frequency is fixed relatively high to group together the MP represented the same mode with different environmental conditions.

To make further analysis, more data are required with different environmental conditions to understand the relationships among these values and the tracked modes.

Key words: Corrosion Detection, Solitary waves, Structural Health Monitoring, Smart Structures.

Abstract. Structural health monitoring methods based on the generation and detection of highly nonlinear solitary waves are emerging as a potential cost-effective technique for a variety of structures and materials. Meanwhile, outlier analysis is a statistic tool able to identify anomalies in data that diverge from a set of baseline data. In this paper the use of outlier analysis was explored to detect damage in metallic plates using the propagation and detection of highly nonlinear solitary waves. A thick steel plate was monitored with a solitary wave transducer placed above the plate, and damage was simulated in terms of a foreign object attached to the bottom of the plate. Three different masses located at an increasing distance from the transducer were considered. A few features were extracted from the experimental time waveforms, and then fed to a multivariate analysis that compared the testing data to a set of baseline data. The experimental results show that the outlier analysis significantly enhances the ability to detect damage using solitary waves.

1 INTRODUCTION

Structural health monitoring (SHM) and nondestructive evaluation (NDE) play a consolidate role in a wide range of industrial activities and are considered a vital component for the development and deployment of smart structures. In recent years, a novel SHM / NDE approach based on the propagation of highly nonlinear solitary waves (HNSWs) has emerged [1-5]. The overall principle of this novel method is rather straightforward: a chain made of spherical particles is in dry point-contact with the material or structure to be evaluated. An incident solitary wave (ISW) is induced at one end of the chain, which is in contact with the structure of interest. This compact non-dispersive compressive wave propagates along the chain and reaches the opposite end. Here, owing to principles discussed in several papers, including some by the authors, the single pulse gives rise to one or two reflected waves that are typically referred to as the primary and the secondary reflected solitary waves (PSW and SSW). Most of the studies reported in the scientific literature demonstrated that the amplitude and time-of-

flight (ToF) of these reflected pulses are dependent on some characteristics of the material/structure to be monitored/inspected.

Statistical approaches have been proven effective in SHM [6-10]; generally, these methods are based on the evaluation of certain damage-sensitive features which are measured on the structure of interest. One of these statistical approaches is based on outlier analysis (OA), which is a novelty detection method that establishes whether a new configuration of the system is discordant or inconsistent from the baseline configuration that consists of an existing set of data (or patterns) that describe the normal operative conditions.

The work presented in this article combines HNSWs and outlier analysis. A HNSW *transducer* is placed in contact with the structure of interest, in this case a metallic plate. To mimic damage a magnet is attached to the plate to simulate the change in local impedance. The solitary wave signals are stored and processed in order to extract a few features that are assumed to be damage-sensitive. The features are clustered into a vector to perform a multivariate analysis in order to determine whether a current feature is representative of damage or it is simply within the baseline, undamaged distribution.

It is noted here that the article presented here is a short version of an extended article currently under revision [11].

2 BACKGROUND

In monodisperse chains of spherical particles, the interaction among weakly compressed beads supports the generation and propagation of HNSWS [12-13]. The nonlinearity derives from the Hertzian contact law $F=k\delta^{3/2}$ between two adjacent beads. In this relationship, the force F is proportional to the deformation δ of the diameter connecting the centers of the interacting beads through the stiffness constant k equal to $E\sqrt{2R}/3(1-\nu^2)$. This stiffness contains the particles radius R , the Poisson's ratio ν , and the elastic modulus E of the particles material. As mentioned in the Introduction, several authors found that the acoustic energy distribution between the PSW and the SSW depends on the elastic modulus and geometry of the object in contact with the chain, and this can be used for SHM and NDE applications.

The OA is an unsupervised learning algorithm based on novelty detection. It establishes whether a new configuration of the system is discordant or inconsistent from the baseline configuration which consists of an existing set of data (or patterns) that describes the normal operative conditions. OA can be performed by using one or more parameters. In the analysis of one-dimensional elements, the detection of outliers is a straightforward process based on the determination of the discordancy between the one-dimensional datum and the baseline.

In the analysis of multi-dimensional elements (multivariate data), the Mahalanobis squared distance (MSD) D_ζ is often computed. This distance is a scalar defined as:

$$D_\zeta = \left(\{x_\zeta\} - \{\bar{x}\} \right)^T \cdot [K]^{-1} \cdot \left(\{x_\zeta\} - \{\bar{x}\} \right) \quad (1)$$

where $\{x_\zeta\}$ is the potential outlier vector, $\{\bar{x}\}$ is the mean vector of the baseline, $[K]$ is the covariance matrix of the baseline and T is the transpose symbol.

In order to determine whether a new datum is an outlier, the corresponding value of D_ζ has to be compared to a threshold computed from the baseline.

3 EXPERIMENTS

3.1 Setup

A straight HNSW transducer was assembled: it consisted of a chain of eight spheres 19.05 mm in diameter, a commercial electromagnet able to lift and release the first particle of the chain (typically indicated with the term *striker*), a sensor, and a frame. The sensing system consisted of a wafer transducer (PZT), embedded between two 6.05 mm thick, 19.05 mm diameter disks. The *transducer* was connected to and driven by a National Instruments PXI running in LabVIEW using a graphical user interface created *ad hoc* for the experiments. The waveforms were sampled at 4 MHz and stored for post-processing.

A $610 \times 610 \times 6.35$ mm³ simply-supported steel plate was monitored. The *transducer* sit at the center of the plate face (Fig. 1a). Defect was mimicked by attaching one of the magnets displayed in Fig. 1b below the plate. The magnets were labeled as small, medium and large and their mass was 20.0 g, 52.1 g and 199 g. Each object was attached to the plate at eight different locations, 10 mm apart, according to the scheme of Fig. 1c.

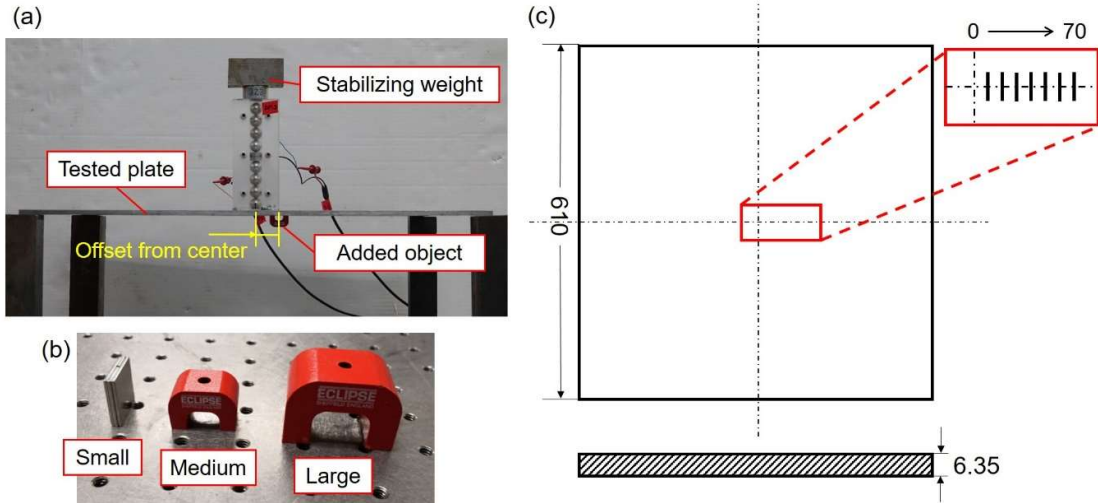

Figure 1: Test setup. (a) Photo of the sample with the transducer above the plate and a foreign object magnetically attached. (b) Photo of the small, medium, and large magnets used as foreign objects. (c) Scheme of the tested thick steel plate including the offset between the magnet and the *transducer*. (Dimensions in mm).

For convenience of discussion, the measurements taken with the *transducer* were grouped into five clusters. The first cluster includes two measurements of 15 waveforms each, taken with the pristine plate. Group 2 comprised the experiments with the small object, whose mass was only 0.09% of the total mass of the plate-transducer system. In this cluster, measurement numbers 3 through 10 identify the positions 0 through 7 shown in Fig. 1c, respectively. Position 0 indicates the object located right below the *transducer* whereas position 7 represents the magnet attached 70 mm away. For each measurement number, 15 recordings of the solitary waves were taken. Groups 3 and 4 follow the same scheme of Group 2, but represent the cases with the medium and the large magnet, respectively. The last group represents two sets of 15

measurements collected with the pristine plate after monitoring the plate with the large object. Based on the above, a total of 420 time waveforms were recorded and post-processed.

3.2 Results

Figure 2 shows one of the waveforms recorded when the small magnet was attached 40 mm away from the contact point. The ISW, PSW, and SSW are visible.

Figure 2: Experimental waveform recorded during the experiment.

The following features were extracted from the waveforms: (1) amplitude ratios A_P/A_I and A_S/A_I of the primary and secondary reflected waves; (2) time-of-flight ToF_{P-I} and ToF_{S-I} of the two reflected waves. Figures 3a to 3d show these features for the 28 sets of measurements.

The data in Fig. 3(a) represent the A_P/A_I feature, i.e. the amplitude of the PSW normalized with respect to the amplitude of the ISW. Here, the ratio remains between 0.45 and 0.50 for the pristine plate and the small magnet. An evident step-up is visible when the medium and the large masses were located close to the *transducer*. The region of influence, i.e. the distance from the *transducer* within which the foreign object was detected, was about 40 mm. Figure 3b shows that the amplitude of the secondary wave does not complement the primary reflection. Typically, when the PSW increases, the SSW is expected to decrease and vice versa. In the experimental data shown in Figs. 3a and 3b, both amplitudes increase when the medium and the large mass were added. The motivation of such behavior is related to the “local” increase of the thickness but also to local vibrations of the plate. Finally, both time-of-flights do not show uniform trend, and at the moment seems not effective at detecting any anomaly.

To validate the research hypothesis that the OA can enhance the ability to detect structural anomalies using solitary waves, the four features were the inputs of a multivariate analysis. The calculation of the confidence threshold values was based on measurement #1 and #2. The MSD was computed by considering all four solitary wave features. In the present study, since the potential outliers are always known *a priori*, both z_ζ and D_ζ were calculated exclusively without contaminating the statistics of the baseline data.

Figure 3: Solitary wave features associated with the PSW and SSW calculated at the 28 measurement points. The data are the average of the 15 measurement and the vertical bars are twice the corresponding standard deviation. The numbers on top of the figure refer to the offset distance in millimeter. (a) amplitude ratio A_p/A_1 ; (b) amplitude ratio A_s/A_1 ; (c) time flight of the primary wave; (d) time of flight of the secondary wave.

The results are presented in Fig. 4 where the MSD is plotted for all 420 measurements. The results show that the multivariate analysis properly classified most of the data. Only a few testing data were classified as false negatives.

All but one of these false negatives referred to the small mass. Surprisingly, the data associated with the last cluster, i.e. no mass, were labeled as outliers. These false positives confirm the existence of the aforementioned “hysteretic” behavior, and warrants an improvement of the *transducer* design for the future.

Fig. 4. Health monitoring of a thick plate. Mahalanobis squared distance (MSD) of a four-dimensional vector that contains the four features A_p/A_t , A_s/A_t , ToF_{P-I} , and ToF_{S-I} . The horizontal line is the value of 17.49 representing the 99.73% confidence threshold.

4 CONCLUSIONS

In this study, a HNSW-based defect detection strategy with the assistance of OA was established. The strategy consists of the use of a special transducer designed to trigger, sustain, and sense nonlinear solitary waves that interact dynamically with the structure to be monitored. The recorded waveforms are then processed with a multivariate statistics to label data that diverge significantly from a set of baseline data. The experiment presented in this article consisted of a transducer located at the center of a thick plate and damage simulated by adding magnetically a mass significantly smaller than the overall weight of the structure-transducer system. The results demonstrated that the proposed monitoring system was effective at detecting the presence of a defect as small as 0.25% of the mass of the structure. Although the sensitivity may not be as good as the one provided by an ultrasonic-based thickness gauge device, the proposed HNSW-based system may be suitable to be deployed when the structure to be monitored operates at high temperature and the use of piezoelectric transducers may not be feasible due to the Curie temperature of the piezoelectric crystal. Future studies should attempt to test the monitoring system at high-temperature and in presence of real corrosion.

Key words: helium airship, control of vertical mobility, reduced energy consumption, optimal ascending and descending paths

Abstract. In this article we propose a new concept of adaptive telescopic high-altitude aerostat designed in a modular form which allows for sequential changes of volume during the flight. The proposed telescopic aerostat can be easily enlarged or contracted due to application of multi-segmented construction, controllable segments' couplings and precise adjustment of internal pressure obtained using additional gas tank, valve and compressor. Conducted changes of aerostat volume allow to precisely control generated lift force and to obtain desired paths of ascending and descending. The paper briefly presents development of control strategies aimed at: i) reaching the subsequent altitudes in the shortest period of time, ii) reaching these altitudes at the smallest cost defined as total work done by the compressor. The obtained results show high potential of the proposed innovative concept of the aerostat.

1 INTRODUCTION

Over the last 30 years, there have been a few projects conducted in different parts of the world, the purpose of which was to build numerous objects operating in the stratosphere in order to carry communications and monitoring equipment for intelligence, surveillance and reconnaissance missions (so-called HAPS - High Altitude Pseudo Satellites). Currently, more and more companies, mainly specializing in telecommunications or remote monitoring are working on development of technologies enabling applications of flying objects located 20-30 km above the sea level [1]. Ultimately, they are intended to be unmanned aircrafts powered by solar energy, having the ability to move both in the vertical and horizontal directions and which may persist in space for several months to 1-2 years without landing on the ground. In parallel to development of stratospheric airplanes, many countries are working on new generation of airships filled with hydrogen or helium, also with electric drive.

Such airships are usually built as classical systems in which the external volume of the airship is constant and does not change during its ascent from the ground to the level of the stratosphere. Examples of such solutions are, for example, US constructions HiSentinel and ISIS (see Fig. 1a and 1b), or French Stratobus (see Fig. 2).

As a rule, these are objects with very large dimensions - length from approx. 100 m to approx. 300 m and diameters from approx. 30 m to approx. 50 m. In this type of construction the required flight altitude is obtained by changing the mass and pressure of the gas (helium hydrogen or air) inside additional storage tanks located inside the airship. Another solution, where the external volume of the airship is changing during increasing of the altitude is, for example, the Russian proposal of the HAA Berkut airship (Fig. 3a), in which at the low altitude the airship has a small volume Fig. 3b, and in the stratosphere its volume is about 12 times larger - Fig. 3c. In this case, the elevation control is carried out by changing the gas pressure inside the airship

Figure 1: (a) – Airship HiSentinel 80 [2], (b) – Lockheed Martin's ISIS airship ISIS [3]

Figure 2: The airship of Thales Alenia Space – Stratobus [4]

Despite the large number of programs currently implemented in the world and huge expenses related to the construction of stratospheric airships, a number of technical problems still rise and some of them remain unresolved. Many research papers are dedicated to particular ultralight materials, technical solutions or development of airships design in which various solutions are used in order to reduce weight and to obtain required payload. In the case of airship with the electric propulsion one of the heaviest components reducing significantly available payload are electric batteries and solar panels which are needed to provide the airship the enough amount of energy. Therefore, the objective of our research is to show that proper control of aerostat's volume during the flight allows to noticeably decrease the amount of energy required for its operation and thus to reduce the total weight of the applied power system.

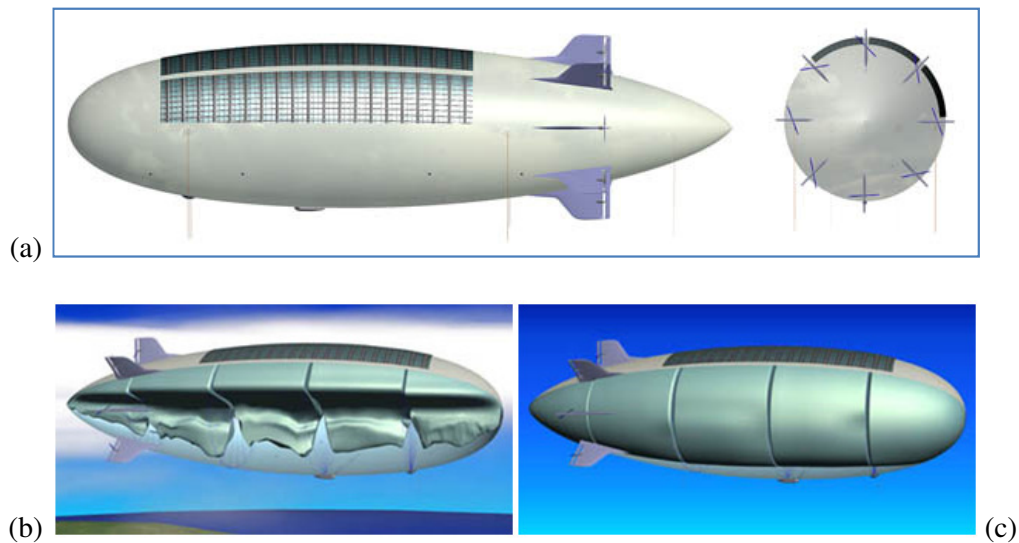

Figure 3: The concept of the Russian airship HAA Berkut [5]

In this paper we briefly present numerical analyses of vertical motion of the aerostat of innovative telescopic design. Conducted simulations, even though regarding the medium-altitude aerostat, reveal key problems and indicate factors that play crucial role in design and control of telescopic aerostats with reasonable payload. The first issue to be addressed is the requirement of obtaining maximal efficiency of the aerostat, understood as minimal time of ascending and descending. In turn, the second issue is minimization of the total cost required for controlling vertical mobility, understood as total amount of energy required for transfer of helium between storage tank and aerostat and vice versa. The corresponding control problems are formulated basing on previous research works [6,7]. The conducted numerical simulations show that both the time of ascending / descending and the amount of energy needed for the flight can be significantly reduced by proper control of HAPS volume and helium flow. In the latter case, the applied control strategy allows to reduce the mass of external energy sources, such as electric batteries or solar panels.

2 GENERAL IDEA OF TELESCOPIC HAPS

The proposed concept for vertical mobility is based the reversible, telescopic option for the aerostat volume modifications, in which the crucial feature is system composed of structural sections connected via controllable actuators fixing or releasing their relative movement and additional helium container (pressure tank) allowing controllable release or absorption of gas [8]. The design concept of the small HAPS module applied in further analyses of its mobility and load-carrying capacity is illustrated in Fig. 4. The construction consists of a cylindrical housing reinforced by axial and circumferential ribs. The HAPS offers a possibility of volume modification by changing the length of the cylindrical section from initial dimension of D to the maximal dimension of $2D$. It is possible due to the construction consisting of the inner (1) and outer segments (2), which are sliding along linear guideways (7). Relative motion of these guideways can be blocked by actuator (3), which creates the clamping mechanism providing control of the aerostat volume.

Figure 4: Scheme of the HAPS design: a) aerostat in initial form: 1 – inner segment, 2 – outer segment, 3 – piezoelectric actuator, 4 – additional helium tank, 5 – valve controlling helium flow, 6 – compressor, 7 – linear guideways; b) aerostat in extended form

In order to achieve a proper mobility the aerostat is equipped with an additional gas storage tank (4) with an additional amount of pressurised helium. This additional tank serves for the purpose of generating the pressure difference between aerostat and its environment. The created overpressure or underpressure is used to generate forces needed to fold and unfold the aerostat. In order to reduce helium losses caused by its release to atmosphere, the aerostat is equipped with a compressor (6) and a valve (5), which control the flow of helium from the aerostat back to the additional gas tank.

Application of the above described system composed of additional pressure tank, the compressor and the valve enables precise control the gas flow and actual pressure difference between the aerostat and the atmosphere during the ascending and descending process. This allows to control the process of folding and unfolding of the aerostat, to generate the required value of the lift force resulting from buoyancy and to obtain equilibrium position of the aerostat at desired altitude.

3 STRATEGY AIMED AT MAXIMIZATION OF VERTICAL MOBILITY EFFICIENCY

In the considered control problem we will analyze the process of aerostat ascending and descending of total duration of 12000 s. During the first part of the process, the aerostat should ascend from the ground level to initial equilibrium position located at $h_1=350$ m, next it should float to the target altitude $h_3=5000$ m with an intermediate stop at the altitude $h_2=3000$ m. Further, in the second part of the process, the aerostat should descend from the altitude $h_3=5000$ m back to altitude $h_5=350$ m, with the intermediate stop at the altitude of $h_4=3000$ m.

The first control problem is to find change of aerostat volume $V(t)$ and the corresponding required change of pressure difference between the aerostat and the atmosphere $\Delta p_{HAPS-atm}(t)$, which enable realization of the above defined aerostat ascending and descending sequence, simultaneously providing the shortest time of aerostat motion between the assume altitudes. Mathematically, the above problem of maximization of vertical mobility efficiency takes the form:

Find $V(t)$ and $\Delta p_{HAPS-atm}(t)$ such that:

1. $\{(h_1, 0), (h_2, 0), (h_3, 0), (h_4, 0), (h_5, 0)\} \subset \{x(t), \dot{x}(t)\}, t \in \langle 0, T \rangle$
2. $\Delta t_{h_1-h_2} + \Delta t_{h_2-h_3} + \Delta t_{h_3-h_4} + \Delta t_{h_4-h_5}$ is minimal
subject to condition of compressor maximal mass flow rate: $\dot{m}_h \leq q_{max}$

The first condition describes successful realization of the assumed flight scenario, which includes reaching the subsequent altitudes h_1 - h_5 with intermediate brief stops. The second condition defines the objective function, which is a sum of subsequent times of transfer between the altitudes. The intuitive solution of the above control problem is maximally fast change of pressure difference and step-wise change of aerostat volume at the beginning of each stage of ascending and descending. The corresponding plots of HAPS altitude and work done by compressor are presented in Fig. 5 and Fig. 6.

Figure 5: Strategy maximizing vertical mobility efficiency: change of aerostat altitude

Figure 6: Strategy maximizing vertical mobility efficiency: work done during gas transfer

The conducted simulations indicate that for the assumed parameters of the aerostat the required altitudes can be achieved in time periods substantially shorter than initially assumed (Fig. 5). However, each stage of ascending and descending process is associated with large amount of work done by the compressor. In particular, large power consumption is required at the beginning of the descending stages, when large mass of helium has to be transferred back to storage tank (Fig. 6).

4 STRATEGY AIMED AT MINIMIZATION OF VERTICAL MOBILITY ENERGETIC COST

The second control problem is to find change of aerostat volume $V(t)$ and the corresponding required change of pressure difference between the aerostat and the atmosphere $\Delta p_{\text{HAPS-atm}}$, which enable realization of the above defined aerostat ascending and descending sequence, simultaneously providing minimization of the energy used for gas transfer between additional gas tank and aerostat. Mathematically, the above problem of minimization of vertical mobility energetic cost takes the form:

Find $V(t)$ and $\Delta p_{\text{HAPS-atm}}(t)$ such that:

1. $\{(h_1, 0), (h_2, 0), (h_3, 0), (h_4, 0), (h_5, 0)\} \subset \{x(t), \dot{x}(t)\}, t \in \langle 0, T \rangle$
2. $E_{\text{comp}} = \int_0^t \frac{\dot{m}_h}{\rho_h} (\Delta p_{\text{HAPS-tank}}) dt$ is minimal

subject to condition of compressor maximal mass flow rate: $\dot{m}_h \leq q_{\text{max}}$

Now, the second condition defines the objective function, which is work done by compressor during helium transfer and is a function of required mass flow rate of helium, its actual density and pressure difference between the additional storage tank and the aerostat. The intuitive solution of the above control problem is realization of the entire process in possibly slow manner, with minimal pressure difference between the aerostat and the storage tank. The corresponding plots of aerostat altitude and work by compressor are presented in Fig. 7 and Fig. 8.

Figure 7: Strategy for minimization of vertical mobility energetic cost: change of aerostat altitude

Figure 8: Strategy for minimization of vertical mobility energetic cost: work done during gas transfer

In the conducted simulations the change of aerostat volume during each stage of the process is not instantaneous but gradual and subsequent time periods of volume change are equal to the corresponding predefined time periods of ascending or descending (Fig. 7). In this strategy each stage of the process is associated with significantly smaller work done by compressor and, in particular, initial part of descending stages does not require excessive power consumption (Fig. 8). As a result, the total work done by compressor is almost ten times smaller than in previous control strategy (note the scale difference in Fig. 6 and Fig. 8).

5 CONCLUSIONS

The paper provides preliminary positive verification of the concept of adaptive telescopic stratospheric aerostats based on mechanism of volume change, application of additional pressure tank and compressor. The conducted simulations prove that adaptive telescopic HAPS can be adjusted to various operational conditions. Control of internal pressure can be used to achieve desired altitudes possibly fast or to operate in a slow mode providing significant reduction of energy consumption. It can be concluded that adaptive telescopic aerostats offer exceptional vertical mobility and thus they seem to be promising solution in many practical applications in the coming years.

Key words: Flapping Wing Micro Air Vehicle, Fluid Structure Interaction, Four Bar Mechanism.

Abstract. In this paper, it is introduced to find net aerodynamic lift capacity of proposed flapping-wing micro air vehicle (FWMAV) by performing dynamical calculation and FSI (Fluid Structure Interaction) analysis of a flapping wing test system. In the flapping system, a single degree of freedom type four-bar mechanism which was used as a piezo-driven flapping wing mechanism in previous literature studies is implemented to create beating motion of the wings. For the wing structure, Calliphora Erythrocephala's wing is used which is presented by Konkuk University [1]. The flapping wing mechanism and wing structure are fabricated by 1 mm of plexiglass. In FWMAV applications, in order to produce enough force to levitate the flapping structure, the inertial forces are created by flapping wing mechanism should not dominate on aerodynamic lift capacity of the wings. In this framework, the real-time flapping test is performed by six degrees of freedom force transducer for a specific flapping frequency (11.2 Hz) to understand inertial and aerodynamic characteristics of the proposed mechanism and test results are presented. The theoretical approach is put forward by obtaining the dynamic model of the proposed flapping structure. The initial angular position, mass, and radius of rotation values of the major linkages of the flapping wing mechanism are presented. Tangential and centrifugal forces acting on major linkages of the four-bar flapping wing mechanism are found and total inertial characteristics of the proposed mechanism are obtained in different axes. FSI analysis of the proposed flapping wing mechanism is performed to understand how the elasticity of the wing effects of the aerodynamic lift capacity of the structure. The aeroelastic analysis is modelled based on the conditions are performed in the test phase. The Fluid-structure interaction model is created in two different domain using ABAQUS CAE and STARCCM+. ABAQUS CAE is used to create the

structural dynamics finite element model of the proposed flapping wing structure. A time-dependent dynamic implicit analysis step is created in finite element analysis (FEA) model and sinusoidal input is defined to the corresponding linkage and inertial results are shared. In this framework, the wing is modelled in STARCCM+ interface. The inertial force results belonging to FSI analysis is presented and compared with the theoretical model and experimental test results.

1 INTRODUCTION

In recent years, there has been growing interest in micro air vehicles (MAV) in military and civilian applications using the state of art technology of developed micro-sized mechanical and electronic devices. In literature, MAVs are categorized with respect to their wing types as fixed, rotary and flapping wing. Flapping wing micro air vehicles (FWMAV) have gained great attention in MAV category for their high maneuver capability, especially for indoor activities. Researchers are in this field still trying to enlighten how to use low Reynold flyer's such as birds and bats features in their design.

In FWMAV applications, some preliminary items emerge as aerodynamic and inertial forces for producing enough aerodynamic lift force to levitate the flapping wing structure. Flapping wing mechanisms are used to obtain beating motion of wings. During flapping motion, the flapping mechanism creates inertial forces in different axes. In this framework, the inertial forces created by the flapping wing mechanism must be investigated deeply. In literature, some preliminary real-time tests have been performed to find the generated inertial forces by four-bar flapping wing mechanisms [1]. However, this study is an experimental based study and does not present an inertial analysis. Senol et al. ([2]-[3]) presented inertial force analysis and compared with test results. But, in this study, the inertial analysis is carried out only based on the proposed wing, the inertial forces created by linkages and rotating parts are neglected.

To understand the inertial characteristic of the flapping wing based structures, the flapping test is performed using 6 DOF force/moment transducer. Flapping wing test bed gives extensive information about the aerodynamic characteristics of flapping wing structure. Khan et al. [4] performed force and moment measurements by use of 6 DOF force/moment transducer and correlate the measured force and moment values with the proposed dynamical flapping model. Jang et al. [5] improved a passive control mechanism for adjusting the mean angle of attack in hovering using 6 DOF transducer. Phan et al. [6] proved that clap and fling mechanism has a positive impact on aerodynamic lift capacity using a force sensor.

In FWMAV applications, the net lift capacity which is the combination of aerodynamic lift force and inertial force created by flapping wing mechanism determines whether the proposed FWMAV structure produce just enough lift to levitate the model or not. There are great numbers of computational studies are performed to understand the lift capacity of the presented FWMAV structure, mostly using computational fluid dynamics (CFD) technique for rigid bodies ([7], [8]). However, using CFD model for the rigid structures neglects the elasticity of the wing structure and does not take account into the inertial forces created by flapping wing mechanism and wing structure during beating motion.

Fluid-structure interaction analyses solve fluid and dynamic equations simultaneously for an elastic body and give a net force result in the desired direction. Some preliminary works are performed to understand aerodynamic characteristic using FSI technique. Cetraro et al. [9] implemented electro-active material on a wing membrane and used FSI analysis to show generating oscillations on wing membrane at a resonance frequency and an angle of attack increases aerodynamic lift force. Nakata et al. [10] performed FSI analysis to investigate the flexibility effect of the wings to the aerodynamic efficiency based on Hawkmoth *Agrius Convolvuli* insect wing. Nakata et al. [10] reported that using flexible wing enhances the aerodynamic efficiency in terms of the lift capacity, in contrast flexible wings require more power for flapping and creates more drag force since the deformation of the wings.

The goal of this study is to validate the test results using theoretical and computational approach and offer a design methodology for the proposed FWMAV structure. In this framework, a flapping wing mechanism is presented and a flapping test is performed. Based on the proposed mechanism and flapping conditions, dynamical calculations and some preliminary computational studies (FSI) are performed and compared with test results.

2 FLAPPING WING MECHANISM DESIGN

The flapping wing mechanism is responsible for transferring the actuation force to wings and creating flapping motion. For this study, a four-bar mechanism is designed based on the piezo-driven four bar mechanism designed in Ref. [1]. The position analysis is carried out and an amplification ratio is found between the input angle and the flapping angle. With the lengths of the four-bar mechanism selected as $l_0=38$ mm, $l_1=30$ mm, $l_2=8$ mm and $l_3=7.5$ mm, the maximum flapping angle (θ_3) is achieved as 24.9° whereas the minimum angle is -16.6° . The four-bar flapping wing mechanism flapping angle response is given in Figure 1.

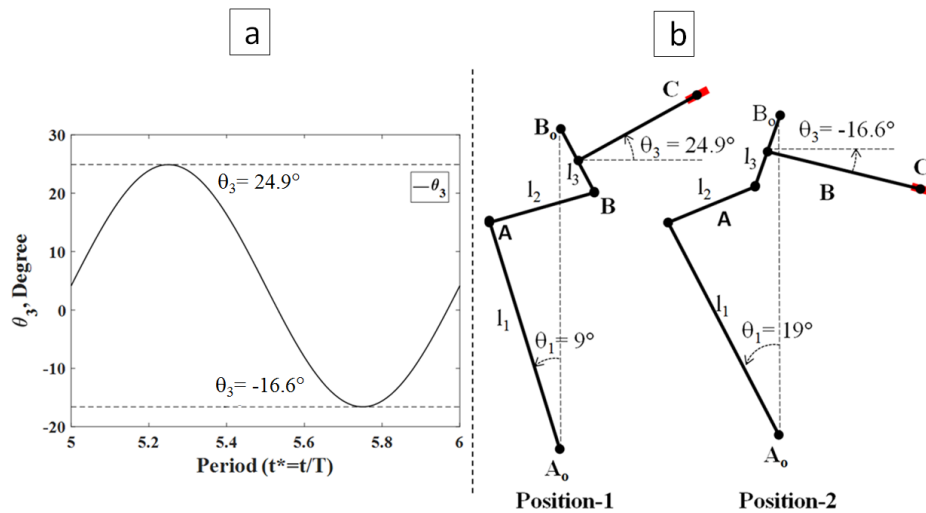

Figure 1: Kinematic relations a) Instantaneous flapping angle b) Position of the mechanism at the maximum up-stroke (position-1) and at the minimum down-stroke (position-2) during the flapping motion

3 EXPERIMENTAL SETUP

Experimental test is performed to measure total forces created by the designed and manufactured flapping wing mechanism in non-vacuum condition using ATI Nano17 6 DOF F/T (Force/Torque) transducer. The resolution of the ATI Nano F/T card is 3 mN of force and 16 μ Nm of moment. The flapping wing mechanism is driven by a servo motor. A sinusoidal input is defined in microcontroller as to run the servo motor. Its oscillation amplitude is 10° and its frequency is 11.2 Hz. The measured force data is transferred to DAQ/FT and its amplifier and the gathered data is visualized in Lab-View program in PC. The schematic view of the experimental setup is given in Figure 2.

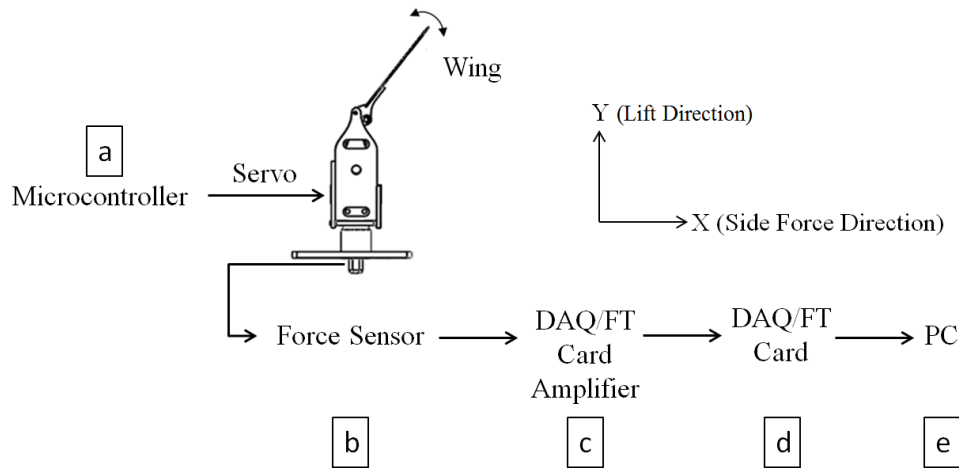

Figure 2 : Experimental Setup a) Microcontroller b) Force Sensor c) Data Acquisition Board (DAQ) Amplifier d) Data Acquisition Board e) Computer

The flapping test is performed with flapping frequency of 11.2 Hz and a flapping angle of 41.5° . Using acquired data, Fast-Fourier Transformation is performed using MATLAB and to eliminate white noise, 5th order Butterworth filter with a cut-off frequency of 33.54 Hz is used. In this study, since the lift capacity of the proposed flapping wing mechanism is investigated the forces in lift direction (y-axis) is studied in detail.

4 RIGID-BODY DYNAMICS CALCULATIONS

In this section, the inertial forces created by flapping wing mechanism are investigated. The majority of the inertial forces are created by linkages of the four-bar flapping mechanism and the Calliphora Erythrocephala's wing. In this framework, the forces acting on the major four-bar linkages and wing are found and inertial forces are presented in different directions. The proposed flapping wing mechanism and the obtained free-body diagram are given in Figure 3.

Figure 3: Schematic and exploded view of the proposed flapping wing mechanism a) Sections of the proposed flapping wing mechanism b) Forces acting on proposed flapping wing mechanism

The link-1 rotates around C_1 with R_1 (6.72 mm) radius of rotation whereas the wing and link-3 rotates about C_2 with R_w (6.72 mm) and R_3 (52.56 mm) radius of rotations respectively as given in Fig.3b. The mass, initial angular position of the center of mass and derived instantaneous angular position of the major linkages and wing are given in Table 1. The maximum angle obtained for the Link-1 is 19° with respect to y-axis whereas for the wing and link-3, the maximum angle is 20.75° with respect to x-axis. In Table 1, $\bar{\theta}_i$ (as shown in Fig.3b) represents instantaneous angle, $\bar{\theta}_{i-initial}$ represents the initial angular position of the center of mass, $\bar{\theta}_{i-max}$ represent the reached maximum angle of the corresponding part for $i=w, 1, 3$. In dynamical calculations, the link-2 is neglected since it has a small mass or 0.1 gram.

Table 1: The masses and radius of rotations of each part of the proposed flapping wing mechanism

Part name	Mass [gram]	Initial Angle, (Relevant axis) ($\bar{\theta}_{i-initial}$)	Maximum angle ($\bar{\theta}_{i-max}$)	Instantaneous Angular Positions
Wing	1.5	3.55 (x-axis)	3.55 (x-axis)	$\bar{\theta}_w = \bar{\theta}_{w-initial} + \bar{\theta}_{w-max} \sin(2\pi ft)$
Link-1	1.9	14 (y-axis)	14 (y-axis)	$\bar{\theta}_l = \bar{\theta}_{l-initial} + \bar{\theta}_{l-max} \sin(2\pi ft)$
Link-2	0.1	-	-	-
Link-3	0.3	-28.42 (x-axis)	-28.42 (x-axis)	$\bar{\theta}_3 = \bar{\theta}_{3-initial} + \bar{\theta}_{3-max} \sin(2\pi ft)$

After obtaining the instantaneous angular positions of the wing, link-1 and link-3, the instantaneous angular velocities and angular accelerations of the corresponding parts are obtained using Eq. (1) and Eq. (2) respectively.

$$w(t) = \frac{\partial \theta_i}{\partial t} \quad (1)$$

$$\alpha(t) = \frac{\partial w}{\partial t} \quad (2)$$

The obtained angular acceleration values are plugged into the centrifugal and tangential force terms in Eq. (3) and Eq. (4). Then the inertial forces generated in the x-axis and the y-axis are found using Eq. (5) and Eq. (6).

$$F_{i\text{-centrifugal}} = m_i w_i^2 R_i \quad (3)$$

$$F_{i\text{-tangential}} = m_i \alpha_i R_i \quad (4)$$

$$\Sigma F_{i-x} = \Sigma F_{i\text{-centrifugal}} + \Sigma F_{i\text{-tangential}} \quad (5)$$

$$\Sigma F_{i-y} = \Sigma F_{i\text{-centrifugal}} + \Sigma F_{i\text{-tangential}} \quad (6)$$

For $i = 1, 3, w$

Based on the dynamical calculations, the instantaneous angles of the center of mass of the each corresponding parts and total inertial forces in the x-axis and y-axis are given in Figure 4.

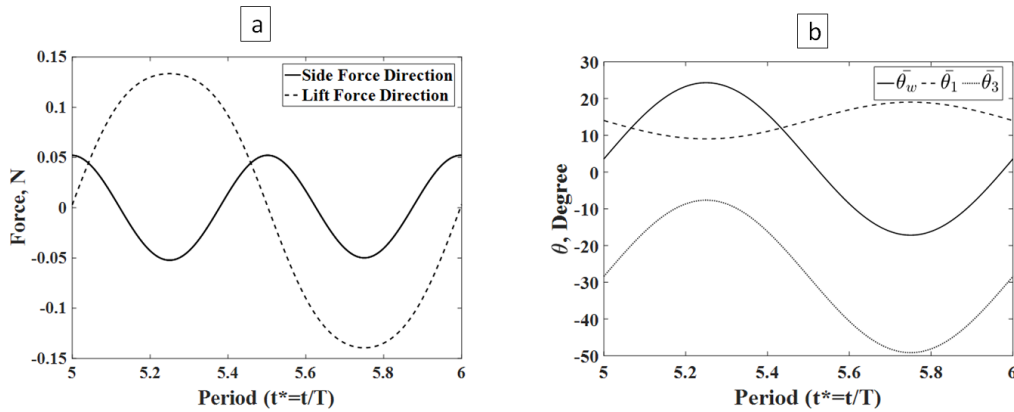

Figure 4 Dynamic calculations a) Forces during the 5th period in lift and side force directions b) Instantaneous angular positions for the wing, link-1 and link-3

5 COMPUTATIONAL METHOD

Fluid-structure interaction analysis (FSI) is performed to understand the inertial and aerodynamic lift characteristic of the proposed flapping wing mechanism. FSI analysis gives extensive results about how dynamically moving body is affected by fluid surround it. In FSI analysis, two types of computational domains work simultaneously and communicate with each other as the structural and fluid domain. Essentially, in this study, ABAQUS CAE 14.0 is used for the structural domain and STARCCM+ is used for the fluid domain. The simulation is ran with 5×10^{-4} seconds time increment.

A dynamic implicit analysis step is defined as the finite element analysis model. The linear-hexagonal element type is used for the created FEA model. The total node number of the FEA model is 7375, the total element number of the FEA model is 4830. The created finite element analysis (FEA) model of the proposed flapping wing mechanism is given in Fig. 5. Sinusoidal angular displacement rotation is defined from point C_1 in z-axis whereas fixed-type boundary condition is defined from point C_2 and the flapping wing mechanism is fixed from point C_1 (Figure 3).

The plexiglass material is defined for the whole parts of the proposed flapping wing mechanism. The modulus of elasticity, Poisson's ratio and density of the Plexiglass are defined as 3100 MPa, 0.3 and 1.4 kg/m³ respectively.

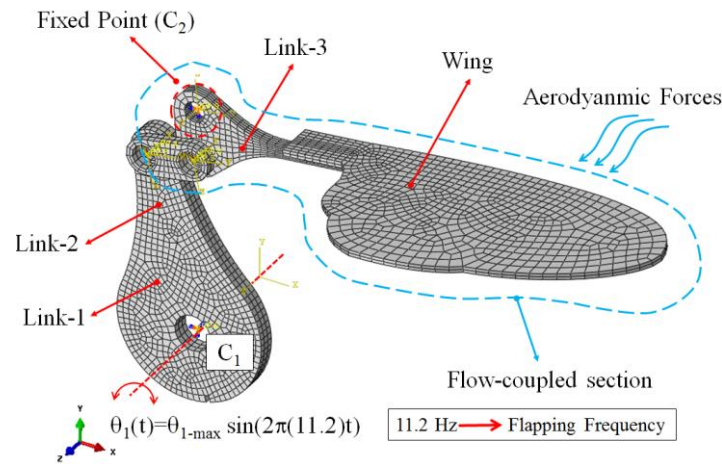

Figure 5 Finite element analysis model of the proposed flapping wing mechanism

CFD analysis only covers the flow coupled section as shown in Fig.5 and Fig. 6. The fluid domain and its dimensions are given in Figure 6. The property of air is defined for the fluid domain as 1.18 kg/m³. The section view of the fluid domain is also given in Figure 7.

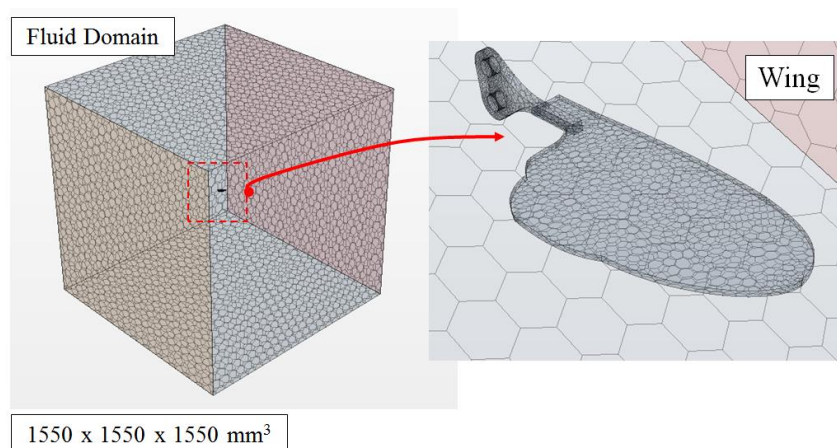

Figure 6: Fluid domain for the CFD analysis

Figure 7 Mesh in the fluid domain

5 RESULTS

In this section, the theoretical, experimental, FSI (Fluid-structure interaction) and dynamic FEA (Finite element analysis) results of the proposed flapping wing mechanism are compared and the effect of the aero-elasticity is addressed. In the FSI analysis, the proposed flapping wing mechanism undergoes the body inertial force and aerodynamic effects simultaneously. However, in the FEA analysis, the effect of aerodynamics is not included and it simulates as the proposed flapping wing mechanism is in vacuum condition. As a result of this, different load and wing tip deflections occur between FSI and FEA results. Figure 8a, illustrates the wing tip deflection difference between the FSI and dynamic FEA for the proposed flapping wing mechanism. According to the Figure 8b, performing FSI analysis causes maximum 0.135 mm difference in the y-axis.

Figure 8: Tip displacement difference between FSI and dynamic FEA analysis in the y-axis

An experimental study is also conducted and compared with the theoretical, FEA and FSI results during the second period as it is given in Fig. 9.

Figure 9: Comparison of the forces in y direction

The maximum and minimum inertial forces for the introduced methods are pin-pointed and given in Table 2.

Table 2: Inertial values at the end of the up-stroke and down-stroke

Method	End of the Up-stroke ($t^*=2.24$)	End of the Down-stroke ($t^*=2.74$)
Experiment	0.143	-0.186
FSI	0.142	-0.182
FEA	0.138	-0.177
Theory	0.133	-0.139

According to Table 2, the maximum and minimum inertial forces obtained in the experiment at the end of the up-stroke ($t^*=2.24$) and down-stroke ($t^*=2.74$) are 0.143 N and -0.186 N, respectively. From Fig. 9, it is evident that the FSI and FEA give the closest result to the experiment compared to the theoretical result. However, since FSI analysis result includes elastodynamics and aerodynamic effects in contradiction of the FEA result which only includes elastodynamics effect, the FSI analysis gives more realistic result to the experimental study as 0.142 N and -0.182 N at the end of the up and down-strokes respectively. During flapping motion, the wing sweeps different angles with respect to the x-axis between 24.9° and -16.6° (Fig. 9b). Thus, the introduced flapping wing mechanism is subject to instantaneous inertial loads. Based on the theoretical study results, the proposed flapping wing mechanism experiences more inertial load at the end of the down-stroke compared to the up-stroke as it is given in Table 2. As a result of this, different wing tip deflection occurs at the end of each stroke phase. In this study, the proposed theoretical formulation is derived based on rigid body dynamics and does not cover the inertial forces created by the elastic effects. It is also noted that, a significant difference is inspected in inertial forces between the theoretical

and experimental result as 7% and 25% for the end of the up-stroke and down-stroke, respectively.

6 CONCLUSIONS

- In this study, a single degree of freedom type four-bar flapping mechanism is introduced and the performed experimental force results are compared with the theoretical, FSI and FEA results. To find the inertial loads created by the proposed flapping wing mechanism theoretical, FEA and FSI analysis studies are conducted. In the theoretical approach, a rigid-body dynamics formulation is derived by finding out the tangential and centripetal forces on the Calliphora Erythrocephala's wing and linkages. Then the lift contribution of the corresponding force is investigated. For FEA, dynamic implicit step is defined and the total inertial forces are found in the lift direction. In FSI analysis, the dynamic structural analysis and CFD domain are created and performed together to find the inertial forces in the lift direction. 0.135 mm tip deflection difference is obtained between performed FSI analysis and FEA for the introduced flapping wing mechanism.
- According to the results obtained, each calculation method used to find the inertial loads in lift direction, the FSI analysis gives the closest result to the experiment result with 0.7% and 2.15% difference at the end of the upstroke and downstroke phases respectively whereas the theoretical result gives the worst result since it does not include elastic effect in its formulation.
- As a future work, the current mechanism is intended to be actuated by use of piezoelectric materials [11] instead of a servo motor to perform sinusoidal flapping motion.

Key words: Deployable bridge, Scissors-type of robotic bridge, Seismic performance.

Abstract. This paper presents a dynamic characteristics of robotic emergency bridge, called Mobile Bridge, which can be quickly constructed to recovery the damage after a natural disaster. The concept of the bridge is based on the application of a scissor mechanism, which enables its rapid deployment. From the point of to use the Mobile Bridge in disaster area, it is needed to investigate the dynamic behavior by the numerical simulation included both eigenvalue and seismic response analysis. From these results, it was possible to estimate basic mechanical characteristics of dynamic properties of the bridge including reduction of vibration by reinforcement technique. The conducted research allows for better and safer design of the structure of the Mobile Bridge.

1 INTRODUCTION

In recent years, the world has seen several types of natural disasters that have caused many critical situations in the lives of people by damage of an infrastructure. It is important to rebuild the damaged traffic routes immediately in such serious situations in order to facilitate quick relief and restoration activities. An emergency bridge is a specialized bridge designed for short time construction. Typical emergency bridges, for example, the Bailey bridge proposed by D. Bailey in 1943, are modularized truss bridges. It is possible to design different types of bridge configurations by the combination of modularized bridge panels [1]. However, prefabricated truss block type bridges require construction yards and heavy machinery on site. Even some erectable bridges which are possible to build up manually, require a number of

considerable skilled human resources, sometimes over a hundred workers.

Therefore the authors have proposed a rapidly and easily constructible emergency bridge using a deployable system, called Mobile Bridge (herein called MB). It is based on the concept of the Origami skill [2] and Multi-Folding Micro structures (MFM) theory [3]. The original structural form of the MB, in its patent [4], is similar to a scissor system [5] for its structural form. The design concept of the MB enables the reduction of construction time on site by deploying the structural frame directly over a damaged bridge or road. Research development of the MB began with a small footbridge as a prototype [6] which used patented technology. The expansion time depended on the person performing operation, and was approximately 2 mins. After the successful development of the footbridge, research focused on the live loading both pedestrian and vehicle. A prototype of the full-scaled MB was created, MB version 1.0 [7], The MB1.0 demonstrated its potential for the live loading of the traffic weight using a vehicle. Based on this experimental demonstration using the MB1.0, the current model, the MB4.0 with a length of approximately 20m and height of approximately 2m was created [8]. The expansion process can be easily controlled and it looks only 5 mins for the bridge to be fully deployed.

This presented research reviews fundamental dynamic analysis of the pedestrian type of the MB (herein called prototype). In the case of deployable structures, as well as the static analysis of different configurations, it is important to investigate dynamic behaviour of the system. The high compliance and flexibility of the scissors-type bridge may influence the comfort and safety of users in case of heavy dynamic loads such as human induced impacts, wind gusts, or earthquakes. Therefore, numerical simulation included both eigenvalue and seismic response analysis was performed. From these considerations, it was possible to estimate basic mechanical characteristics of dynamic properties of the bridge. The conducted research allows for better and safer design of the structure of the MB.

2 NUMERICAL MODEL

In case of the deployable structures which have completely different configurations by change of their structural forms, investigation of the dynamic behavior is so important due to their flexibility. Hence, we carried out numerical simulation and experimental testing for the prototype to find out the fundamental dynamics of the MB, that is natural frequency and vibration mode. Besides, the seismic response analysis is performed by assuming the use of the MB in the disaster area.

2.1 FE model

The prototype used in this research has a span of approximately 6.1m and a height of 0.5m. The main structural members of the bridge are fabricated using extruded aluminum alloy A6063. The material of the shafts connecting main frame is assumed to be same with scissors member, and the total mass of the bridge is less than 100kg. The FE numerical model is created using MSC Marc 2016 which is one of the major nonlinear finite element software. The model is represented in 3D by use of beam elements. The pivot part which is connecting two components is allowed to rotate without any friction. Besides, the damping of the bridge dynamics is assumed as Rayleigh damping model. Detail modeling method can be found

Figure 1: Change of boundary condition according to deployable action

Figure 2: Acceleration response on time of Kobe earthquake

in our previous paper [7].

2.2 Boundary condition

This research examined the basic dynamic characteristics of the MB under two sets of boundary conditions. During the deployment phase, the bridge is supported only at one end resulting in cantilever boundary conditions (see **Figure 1** (a)). Once deployed, the bridge has two supports hence the deployed, second condition is the simply supported beam case, where the supports have horizontal and vertical displacement constraint (see **Figure 1** (b)). After finishing construction, the pedestrian bridge is set on the upper decks aligned at the line of top hinges (see **Figure 1** (c)).

2.3 Seismic load

The dynamic data from the Kobe earthquake (1995) observed by the Japan Metrological Agency (JMA) was utilized to model the ground acceleration acting on the bridge as shown in **Figure 2**. In this research three directions, that is North-South (NS), East-West (EW) and Up-Down (UD) direction, are considered. A relatively high acceleration which resulted in severe damage to structures was observed in the North-South (NS) direction at approximately 5 sec., and it was equal to 8.2m/s^2 . These accelerations were applied to the considered FE model as seismic excitation.

3 NUMERICAL RESULT

Primary numerical results in cantilever and both-ends supported conditions without decks are described.

3.1 Eigenvalue analysis for natural frequency

The considered problem was the eigenvalue analysis aimed at finding the frequencies of free vibrations and the corresponding vibration modes. Although the MB has geometric

nonlinearity which affect to the stiffness of the bridge according to its expansion angle, in this paper, we present the results of the eigenvalue analysis for particular expanding angle as local linearization problem.

The numerical result for the prototype under cantilever condition showed that the frequencies for the 1st modes for the vertical direction, horizontal direction and expanding direction were 2.6Hz, 2.6Hz and 4.6Hz as shown in **Figure 3**. Similarly, the 1st modes under both-ends supported condition were 12.0Hz in the vertical direction, 12.6Hz in the horizontal direction and 19.0Hz in the vertical direction as shown in **Figure 4**. These results indicate that in the case of the prototype, the vibrations in the horizontal direction are stronger than those in the vertical and expanding direction. Besides, we can see that the vibration modes of the scissor bridge are generally similar to the beam structure. Therefore, special attention has to be paid to the in-plane vibrations when a pedestrian type of the MB is installed on-site.

3.2 Seismic response analysis

The numerical results of time-displacement relationship under the earthquake are shown in **Figure 5** and **Figure 6**. **Figure 5** shows the result in fully deployment focused on the bottom hinge of the edge member. In this case, the vibration in horizontal direction has high response in comparison with the vertical and expansion direction. The maximum amplitude of the vibration for the horizontal direction is approximately 145mm, and this result is over 3 times higher than vertical direction and 4 times higher than expanding direction. **Figure 6** shows the result after finishing construction focused on the bottom hinge at the middle of the bridge. The central displacement is not so large value during the earthquake compared with the cantilever condition. The maximum amplitude of the vibration for the horizontal direction is approximately 2mm, and the value become less than 1/30 times than that of cantilever condition. Therefore the bridge should be careful during expanding case in design stage.

Further results including seismic behavior with decks and live load are presented in the conference.

4 CONCLUSIONS

This paper reviewed the dynamic characteristics of the MB based on the experimental

pedestrian bridge. The eigenvalue analysis revealed the basic vibration modes of the prototype and indicated that major vibration of the scissoring bridge was dependent on its boundary conditions.

Thus, it is more susceptible to vibration in the horizontal direction than in the vertical direction after installation. Besides, we found that the vibration modes of the longer scissor bridge are generally similar to the discreted beam structure. This tendency was also found from the seismic response analysis. The horizontal vibration of the prototype was dominant in both cantilever and both-ends supported conditions, and maximum vibration amplitude was 3 - 4 times higher than another direction. Therefore, special attention has to be paid for the in-plane vibrations when a pedestrian type of the MB is installed on-site, especially in fully deployment state. The conducted research allows for better and safer design of the MB. We would like to tackle to reduction and/or control of this flexible bridge by optimal reinforcement or using traditional mass damper in the future studies.

ACKNOWLEDGEMENT

This research has been partially supported by Grant-in-Aid for Early-Career Scientists JP18K13818 in 2018 – 2020 and Grant-in-Aid for Challenging Exploratory Research JP18K18888 in 2018 – 2020. The author wishes to thank my undergraduate students, Mr. Hayashi and Mr. Minami, for their continuous supports.

Key words: Shape Memory Alloy, Drilling, Drill-string Joints, Uncertainties Quantification

Abstract. For decades, several researches with shape memory alloys focused on pipe coupling by taking advantage of shape memory effect in assembly. This application can avoid problems such as loosening on traditional threaded tool joints, but an added benefit on its dynamics was never discussed. This paper investigates the use of shape memory alloys as pipe joints on drill-string dynamics. The idea is to evaluate the hysteretic behavior's influence of the superelastic effect and the attenuation of severe torsional vibration, especially stick-slip oscillations. A simplified lumped parameter model is used to model the torsional dynamics of the drill-string, with imposed angular speed at the top and a nonlinear bit-rock interaction at the bottom. This simplified model is validated through finite element analysis. Thermomechanical behavior of SMA is described using a constitutive model proposed by Lagoudas. The numerical results show strong dependence of the system torsional oscillations on temperature and austenitic elastic modulus of the selected material in some drilling conditions as weight on bit and top angular speed. In order to evaluate the impact of SMA uncertainties on the system dynamic response, the material parameters are modeled as random variables, and Monte Carlo simulations are performed to estimate the statistics of permanent response. The random stability map is obtained for different values of weight on bit and top angular velocity. The stick-slip severity factor, which is a measure of the amplitude of the torsional vibration, is computed for this purpose. Overall, this work stands that the main variables in drilling operation can be improved by the introduction of an admissible length of SMA connection, and it brings new perspectives to smart material adoption in a very significant mechanical system.

1 INTRODUCTION

Over this century, mechanical systems have incorporated special materials capable of *smart* behavior. Among such metals, Ni-Ti and others shape memory alloys (SMAs) have close interest to the offshore industry such in applications as pipe joints¹ and actuators.² Particularly, the tubing solution also presented by Schlumberger® have not been completely studied for their impact on the dynamics.

For the SMA, this work is interested on the pseudoelastic effect, or also called superelasticity, which is a phenomenological effect that occurs above the austenitic temperature and comes from the transformation cycle between austenite - detwinned martensite - austenite.³ Fig. 1 illustrate this phenomenon by showing an experimental result where the hysteresis loop can be seen in force-displacement diagram of load-unload history.

Based on this matter, we focused on the application to drilling operation, where force and torque are transmitted from a drilling rig to the drill bit through a drill-string. In this system, torsional oscillations, such as stick-slip phenomenon caused by the bit-rock interaction⁴, may occur frequently and causes several damages to its tools. This can be catastrophic to the operation and must be avoided.

This work aims to combine the use of SMAs as a pipe joints¹ and the application in tubes⁵ which brought notice to SMA as torque tubes with high energy density and low mass density. As certain parameters could have huge impact in the system's response, uncertainties quantification of the drilling operation and the material characterization are explored by a stochastic evaluation.

Figure 1: Experimental results for training via isothermal cycling of stress (Source: Hartl and Lagoudas³).

2 MATHEMATICAL MODEL

This work considers a lumped parameter approach of a drill-string and the obtained results are validated by a finite element analysis performed with ABAQUS. As for the shape memory alloy, we use a constitutive model to account for the pseudoelastic effect. Again, we validate it using the pseudoelasticity model present in ABAQUS, which is based in an alternative constitutive model.

2.1 SMA constitutive model

In 2012, Lagoudas et al.⁶ proposed a phenomenological model to describe the shape memory effect and the pseudoelasticity that has been used in several mechanical models including the previous

application analysis designed by UFRJ workgroup^{7,8}. In 2016, Enemark et al.⁹ presented a reduction for one dimensional shearing, so that the Lagoudas constitutive model can be expressed in terms of the stress-strain relationship as

$$\tau = G_{SMA} (\gamma - \gamma_t) \quad (1)$$

where τ is the shear stress; G_{SMA} is the shear modulus; γ is the engineering shear strain; and γ_t is the phase transformation strain. Fig. 2 depicts Eq. 1. Moreover, G and γ_t , which are time dependents, can be written as

$$G_{SMA} = (G_A + (G_M - G_A) \xi) \quad (2a)$$

$$\dot{\gamma}_t = \dot{\xi} \Lambda, \quad \Lambda = \begin{cases} \Lambda_f = \sqrt{3} \text{sgn}(\tau) H & , \dot{\xi} > 0 \\ \Lambda_r = \frac{1}{\tilde{\xi}} \tilde{\gamma}_t & , \dot{\xi} < 0 \end{cases} \quad (2b)$$

with G being the shear modulus and the subscript A and M standing for austenite and martensite phase, respectively; ξ is the martensite volume fraction (belonging to interval $0 \leq \xi \leq 1$); Λ is the phase transformation direction, with the subscripts, Λ_f and Λ_r , standing for the forward and reverse direction; $\text{sgn}(\tau)$ is the sign of τ ; H is the maximum transformation strain, considered constant in this investigation; and the dot notation, $\dot{\gamma}_t$ and $\dot{\xi}$, stands for evolution while the tilde notation, $\tilde{\gamma}_t$ and $\tilde{\xi}$, indicates that the value should be taken at change in phase transformation direction.

For the evolution equations, there are transformation functions for the forward and reverse transformation, that together with the Kuhn-Tucker conditions control whether phase transformations take place.

Figure 2: Stress-strain relationship for SMA pseudoelasticity effect in pure torsion.

2.2 Drill-string equations

The drill-string can be modeled as a linear torsional pendulum using lumped parameters.^{10,11} This simplification offers a low computational cost with great agreements to the continuum model. To include the nonlinear effect of the shape memory alloy, small modifications were made by adding the SMA stiffness in the joint. Figure 3 shows a schematic representation of the proposed model. The governing equations here presented in Eq. 3(a-h) were adapted from Navarro and Lopez¹² formulation and used for the case of constant angular velocity applied in the rotary table, at the top

$$\ddot{\phi}_r = 0 \quad (3a)$$

$$\ddot{\phi}_1 = \frac{c_{SMA} + c_{tc}}{I_c}(\dot{\phi}_r - \dot{\phi}_1) + \frac{k_{SMA} + k_{tc}}{I_c}(\phi_r - \phi_1) - \frac{c_t}{I_c}(\dot{\phi}_1 - \dot{\phi}_2) - \frac{k_t}{I_c}(\phi_1 - \phi_2) \quad (3b)$$

$$\ddot{\phi}_2 = \frac{c_t}{I_p}(\dot{\phi}_1 - \dot{\phi}_2) + \frac{k_t}{I_p}(\phi_1 - \phi_2) - \frac{c_{SMA} + c_{tc}}{I_p}(\dot{\phi}_2 - \dot{\phi}_3) - \frac{k_{SMA} + k_{tc}}{I_p}(\phi_2 - \phi_3) \quad (3c)$$

$$\vdots$$

$$\ddot{\phi}_{j-1} = \frac{c_{SMA} + c_{tc}}{I_c}(\dot{\phi}_{j-2} - \dot{\phi}_{j-1}) + \frac{k_{SMA} + k_{tc}}{I_c}(\phi_{j-2} - \phi_{j-1}) - \frac{c_t}{I_c}(\dot{\phi}_j - \dot{\phi}_{j-1}) - \frac{k_t}{I_c}(\phi_j - \phi_{j-1}) \quad (3d)$$

$$\ddot{\phi}_j = \frac{c_t}{I_p}(\dot{\phi}_{j-1} - \dot{\phi}_j) + \frac{k_t}{I_p}(\phi_{j-1} - \phi_j) - \frac{c_{SMA} + c_{tc}}{I_p}(\dot{\phi}_j - \dot{\phi}_{j+1}) - \frac{k_{SMA} + k_{tc}}{I_p}(\phi_j - \phi_{j+1}) \quad (3e)$$

$$\vdots$$

$$\ddot{\phi}_n = \frac{c_{tc} + c_{SMA}}{I_p}(\dot{\phi}_{n-1} - \dot{\phi}_n) + \frac{k_{tc} + k_{SMA}}{I_p}(\phi_{n-1} - \phi_n) - \frac{c_{tl}}{I_p}(\dot{\phi}_n - \dot{\phi}_l) - \frac{k_{tl}}{I_p}(\phi_n - \phi_l) \quad (3f)$$

$$\ddot{\phi}_l = \frac{c_{tl}}{I_l}(\dot{\phi}_n - \dot{\phi}_l) + \frac{k_{tl}}{I_l}(\phi_n - \phi_l) - \frac{c_{tb}}{I_l}(\dot{\phi}_l - \dot{\phi}_b) - \frac{k_{tb}}{I_l}(\phi_l - \phi_b) \quad (3g)$$

$$\ddot{\phi}_b = \frac{c_{tb}}{I_b}(\dot{\phi}_l - \dot{\phi}_b) + \frac{k_{tb}}{I_b}(\phi_l - \phi_b) - \frac{T_{ob}}{I_b} \quad (3h)$$

Figure 3: Drillstring schematics. SMA joint added to original Navarro-Lopez and Cortes¹² formulation.

where φ_i , $\dot{\varphi}_i$, $\ddot{\varphi}_i$ ($i \in \{r, 1, 2, \dots, j-1, j, \dots, n, l, b\}$) are the angular position, velocity and accelerations with the subscripts standing for: r , the top-rotary system; 1 to n , the drill-pipes parts; l , the drill collars; and, b , the bit. The inertias, I_i ($i \in \{c, p, l, b\}$), are in agreement with the locations of the drill-pipes, p , coupling components, c , the drill-collars, l , and the bit, b . These inertias are connected by linear torsional springs (k_t , k_{tl} and k_{tb}), nonlinear torsional springs (k_{SMA}) and viscous torsional dampers (c_t , c_{tl} , c_{tb} and c_{SMA}) in order to represent the dynamics as a mass-spring-damper of this rotating system.

For the nonlinear torsional stiffness, representing the SMA's pseudoelasticity, we can define the expression as

$$k_{SMA} = \frac{G_{SMA} J_c}{L_c} = \frac{J_c}{2L_c(1+\nu)} (E_A + (E_M - E_A)\xi) \quad (4)$$

where J_c is the polar moment of inertia of the cross-sectional area; and L_c is the length of the coupling. Again, the dependencies of G_{SMA} to the current temperature and phase transformation are implicit.

Additionally, n is an even number and, in this case, the system of $n + 3$ Degrees of Freedom (DOF), can be represented as a $2n + 6$ DOF set of first-order Ordinary Differential Equation (ODE) in the state-space representation. Moreover, by integration over time, using a MATLAB integrator, they can be solved for positions and velocities.

2.3 Bit-rock interaction

The bit-rock interaction is the second source of nonlinearity presented in the governing equations. In order to estimate it, several authors have tried to capture their essential dynamic properties of interest.^{11, 13} This work uses a simplified model based in a regularization on the classical Coulomb's dry friction model (as presented by Lin and Wang¹⁴, with regularization near to zero angular velocity) expressed in Eq. 5 which is a non-smooth but simple and continuous torque on bit model.

$$T_{ob} = W_{ob} r_b \begin{cases} \mu_s \frac{\dot{\varphi}_b}{\omega_{reg}} & , \dot{\varphi}_b \leq \omega_{reg} \\ \mu_c + (\mu_s - \mu_c) \exp(-d_c (\dot{\varphi}_b - \omega_{reg})) & , \dot{\varphi}_b > \omega_{reg} \end{cases} \quad (5)$$

where W_{ob} is the Weight on bit; ω_{reg} is the transition velocity between the regularized *stick* and *slip* zone r_b is the bit radius; μ_s is the static friction coefficient for the *stick* zone; μ_c is the kinetic friction coefficient for the *slip* zone; d_c is the exponential decay of transition between static and kinetic friction; and ω_{reg} is the regularization and defines the *stick* zone. All parameters must be calibrated from experimental or field data.

2.4 Stochastic evaluation

The stochastic evaluation of the deterministic results here presented tries to determine which parameters uncertainties could cause significant changes in the drill-string oscillatory dynamics. Preliminary results have showed that the martensite and austenite modulus of elasticity needed further investigation due to their uncertainties effect in the stick-slip mitigation.

For the elastic modulus, we can state that the support must be positive and nonzero, so $E_A, E_M \in (0, \infty)$. In addition, it's a usual procedure for stiffness to guarantee that its expectation must be positive and not infinity. Thus, we avoid the indetermination on the compliance tensor of division by zero.

Finally, we can address the probability distribution function (PDF), by means of the maximum entropy principle, as follows in Eq. 6(a-c).

$$E_A \sim \text{GAMMA}(100, 0.7) \quad (6a)$$

$$E_M \sim \text{GAMMA}(100, 0.3) \quad (6b)$$

These PDFs are used to perform a Monte Carlo's simulation for the parametric evaluation varying the weight on bit (W_{OB}) and Angular velocity at the top rotary table (Ω). Similar analysis was previously done by Nogueira and Ritto¹⁶, which presented the probability map we are interest in.

3 DETERMINISTIC RESULTS

The drill-string here considered is based on the same analyzed by Ritto et al.¹¹ The geometry and material properties are described in Tab. 1- 2. This choice was made due to the experimental data provided so the bit-rock interaction could be calibrated to match those data.

The system behavior is illustrated in Fig. 4 for three values of W_{ob} , with the same top angular velocity being prescribed constant, i.e., $\dot{\phi}_r = 100 \text{ rpm}$. At these three pairs, we can see that at $W_{ob} = 100 \text{ kN}$ we have an condition of great drilling operation from its torsional dynamics. However, at $W_{ob} = 150, 200 \text{ kN}$ we can observe torsional oscillations that are recurrent over time. This behavior is unwanted during operation because can cause failure over drill-string tools, resulting in a catastrophic rupture of pipes. To quantify it, authors have used an indicator of torsional vibration severity, also named as stick-slip severity, Eq. 7.

$$S_{SS} = \frac{\max(\dot{\phi}_b) - \min(\dot{\phi}_b)}{2\Omega} \cdot 100\% \quad (7)$$

Table 1: Drill-string geometry and drilling parameters

$J_r = 134 \text{ kg m}^2$	$J_c = 13 \text{ kg m}^2$	$J_p = 134 \text{ kg m}^2$	$J_l = 235 \text{ kg m}^2$
$J_b = 471.9698 \text{ kg m}^2$	$\omega_{reg} = 3 \text{ RPM}$	$W_{ob} = 120 \text{ kN}$	$\Omega = 100 \text{ RPM}$
$k_t = 3.08 \text{ kN m/rad}$	$k_{tc} = 0.31 \text{ kN m/rad}$	$k_{tl} = 38.55 \text{ kN m/rad}$	$k_{tb} = 687.41 \text{ kN m/rad}$
$c_t = 1.24 \text{ kN m s/rad}$	$c_{tc} = 0.12 \text{ kN m s/rad}$	$c_{tl} = 15.42 \text{ kN m s/rad}$	$c_{tb} = 274.87 \text{ kN m s/rad}$
$\mu_c = 0.65$	$\mu_s = 1.5$	$d_c = 0.5$	$r_b = 0.4 \text{ m}$

Table 2: Steel and shape memory alloy material parameters

$E_{steel} = 206.8 \text{ GPa}$	$\nu_{steel} = 0.28$	$\alpha = 0.05$	$\beta = 0.4$
$H = 0.04$	$E_A = 30 \text{ GPa}$	$E_M = 70 \text{ GPa}$	$\nu = 0.3$
$C_A = 6 \text{ MPa/K}$	$C_M = 7 \text{ MPa/K}$	$A_s = 30^\circ \text{ C}$	$A_f = 43^\circ \text{ C}$
$M_s = 30^\circ \text{ C}$	$M_f = 20^\circ \text{ C}$	$n_s = \{.1 \ .1 \ .2 \ .2\}^T$	

To compare the effect on drill-string dynamics of the SMA tool joint, we use the same pairs of W_{OB} and $\dot{\phi}_r$ presented earlier and the new results are presented in Fig. 5. We can see that the angular velocity amplitudes were decreased in each W_{ob} compared. In fact, for $W_{ob} = 150 \text{ kN}$, it attenuates torsional vibrations. These results were compared with a finite element analysis, modeled in ABAQUS.

For the SMA joint, we present in Fig. 6 the evolution of the martensite volume fraction and the stress-strain relationship for three positions in the drillpipes: one close to the top rotary table, one in middle and another one close to the BHA. Also, the results are shown for two conditions, one with large torsional amplitude vibration and other with stable velocity at the bit.

Figure 4: Deterministic results for drill-string angular velocities, ϕ_b and ϕ_r , without SMA joint. From left to right: $W_{ob} = 100, 150$ and 200 kN.

Figure 5: Deterministic results for a drill-string angular velocities, ϕ_b and ϕ_r , with SMA joint. From left to right: $W_{ob} = 150$ and 200 kN.

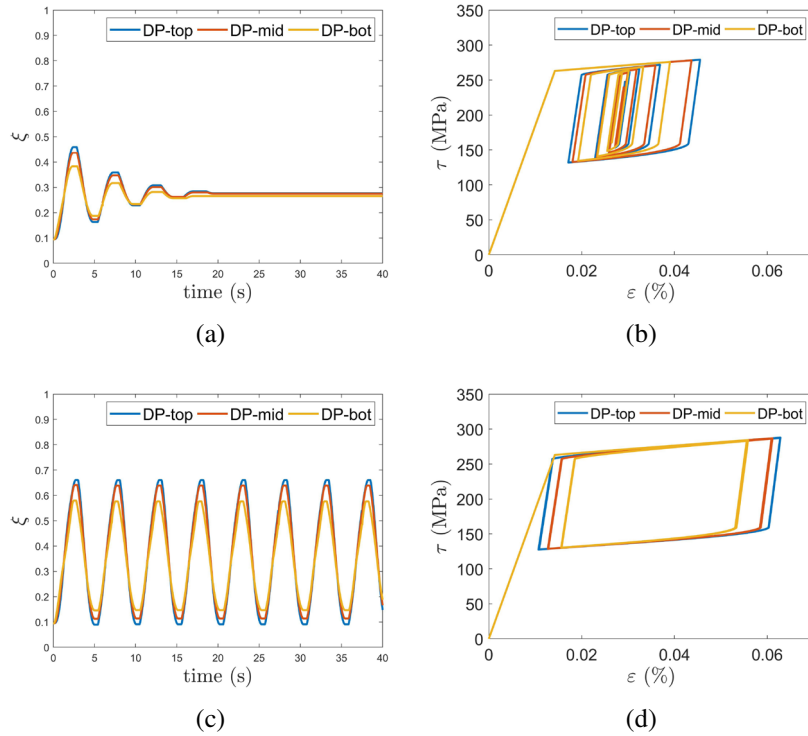

Figure 6: Deterministic results of the SMA joint, martensite volume fraction over time, $\xi(t)$, and stress-strain relationship, $\tau - \epsilon$, with SMA joint. For (a) and (b), $W_{ob} = 150$; and, for (c) and (d), $W_{ob} = 200$ kN.

The outcomes from Figs. 4-5 also led to a parametric investigation of SMA joint effect in different pairs of $(\dot{\phi}_r, W_{ob})$. This evaluation was done in Matlab due to lower computational cost when compared with ABAQUS. Fig. 7 presents the results for different parameters of drilling operation.

Figure 7: Parametric evaluation of torsional stability (a) without and (b) with SMA joint. Colors indicate the torsional vibration severity factor, S_{SS} .

4 STOCHASTIC RESULTS

For the stochastic evaluation, we run a Monte Carlo's simulations in a 40 by 40 grid of $(\dot{\phi}_r, W_{ob})$ pairs. We consider the uncertainties separately so we could assess the effects of austenite and martensite elastic modulus into the stability map. To determine the agreement of these simulations in the system response, for each point, we observe the convergence in quadratic mean for the angular velocity at the bit. For 50 simulations, we could see it converging. Therefore, Fig. 8 presents the probability of each point in the map to have stick-slip, i.e. $S_{SS} > 80$.

Figure 8: Stochastic parametric evaluation of drill-string's torsional vibrations with SMA joint. Analysis for (a) E_A and (b) E_M . Colors indicate the occurrence probability of large torsional oscillations.

From Fig. 8 we can see that occurrence zone of stick-slip, on this map in red, is the most altered zone in both stochastic analysis.

5 CONCLUSIONS

It follows from the deterministic and stochastic analyses here presented:

- The introduction of the SMA joint gives a broader spectrum of safe operation due to damping introduced by the SMA coupling. Fig. 7 shows that the effect into this verge varies different for each W_{ob} and $\dot{\phi}_r$.
- The choice of the shape memory alloy is important to the drilling system because the new drill-string dynamics depends on it. In this work, we chose the SMA as experimental data was available at our laboratory. Optimal material parameters could be determined in order to maximize the attenuation behavior introduced by hysteresis.
- The stochastic analysis presented the response dependency of SMA material parameters, by showing changes in the parametric evaluation of two random gamma distributions with coefficients of variation of only 15%. It suggests that, for different values of E_A or E_M , the verge dividing stability and stick-slip could be different, but, luckily, the effect could be to increase the safe region of torsional vibrations.

Key words: celt, friction, stability

Abstract. The problem of the motion of a celt on a fixed horizontal plane with viscous friction is considered. On the plane of the parameters of the problem, regions of stability of uniform rotations about the vertical are constructed. The dynamics of transient processes from unstable motions to stable ones is studied.

1 INTRODUCTION

The Celt is a convex solid body, one of its principal central axis of inertia being perpendicular to the surface of the body, and the directions of the principal curvatures of the surface at the point of intersection with this axis are not parallel to the other two principal axes. It is well known that the stability of the rotations of this body around the vertical axis depends from the direction of rotation. In most of the papers devoted to this property, the non-holonomic formulation of the problem is considered; it is assumed that the velocity of the point of contact between the body and the plane is zero (see, for example, [1], [2]). In the paper [4] the motion of the celt on a plane with friction is considered, and the consistency of this formulation of the problem with full-scale experiments is confirmed.

In the present paper, the investigation of [1] is continuing, in which it is assumed that the viscous friction force acts on the stone from the side of the plane. This model of friction allows us to carry out not only numerical, but also analytical studies in the problem. In addition, when the coefficient of viscous friction strives for infinity, the force of viscous friction is realized the non-holonomic constraint [3].

2 STATEMENT OF THE PROBLEM

We will introduce the following variables: \mathbf{v} is the velocity of the mass centre of the celt, ω is its angular velocity and γ is the unit vector of the rising vertical. The slipping velocity is given by the relation $\mathbf{u} = \mathbf{v} + [\omega, \mathbf{r}]$, where \mathbf{r} is the radius vector of the point of contact of the body with the plane, defined by the equation $\gamma = -\text{grad} f(\mathbf{r})/|\text{grad} f(\mathbf{r})|$.

A gravitational force $\mathbf{P} = -mg\gamma$, the normal component of the reaction of the support plane $\mathbf{N} = N\gamma$ and the friction force $\mathbf{F} = -mk\mathbf{u}$ (k is the coefficient of viscous friction) act on the celt. The equations of

Figure 1: $A_1 = 3 \text{ kg} \cdot \text{m}^2$, $A_2 = 4 \text{ kg} \cdot \text{m}^2$, $A_3 = 5 \text{ kg} \cdot \text{m}^2$, $a_1 = 5 \text{ m}$, $a_2 = 4 \text{ m}$, $a_3 = 3 \text{ m}$, $m = 1 \text{ kg}$, $\delta = 0.75$; $J = 7 \text{ kg} \cdot \text{m}^2$, $\omega_* = -0.97 \text{ s}^{-1}$

its motion in the moving coordinates have the form

$$m\dot{\mathbf{v}} + [\boldsymbol{\omega}, m\mathbf{v}] = (N - mg)\boldsymbol{\gamma} + \mathbf{F} \quad (1)$$

$$\mathbf{J}\dot{\boldsymbol{\omega}} + [\boldsymbol{\omega}, \mathbf{J}\boldsymbol{\omega}] = [\mathbf{r}, N\boldsymbol{\gamma} + \mathbf{F}] \quad (2)$$

$$\dot{\boldsymbol{\gamma}} + [\boldsymbol{\omega}, \boldsymbol{\gamma}] = 0 \quad (3)$$

$$(\mathbf{v} + [\boldsymbol{\omega}, \mathbf{r}], \boldsymbol{\gamma}) = 0 \quad (4)$$

where $\mathbf{J} = \text{diag}(A_1, A_2, A_3)$ is the central inertia tensor or the celt. Eq. ((1)) is the theorem of the change of the momentum of the celt, Eq. (2) is the theorem of the change of the angular momentum, Eq. (3) is the condition for the vector $\boldsymbol{\gamma}$ to be constant in an absolute coordinates, and Eq. (4) is the condition for the celt to be in contact with the supporting plane. The system (1)–(4) is closed with respect to the variables \mathbf{v} , $\boldsymbol{\omega}$, $\boldsymbol{\gamma}$ and N . From this system, the normal reaction of the supporting plane is determined

$$N = m(g + ([\mathbf{r}, \dot{\boldsymbol{\omega}}] + [\dot{\mathbf{r}}, \boldsymbol{\omega}], \boldsymbol{\gamma})) + ([\boldsymbol{\omega}, \mathbf{r}], [\boldsymbol{\omega}, \boldsymbol{\gamma}]) \quad (5)$$

then the system (1)–(3), taking into account Eq. (5) is considered

The resulting system of equations has solutions of the form

$$v_1 = v_2 = v_3 = 0, \quad \gamma_1 = \gamma_2 = 0, \quad \gamma_3 = 1, \quad \omega_1 = \omega_2 = 0, \quad \omega_3 = \omega \quad (\omega \in \mathbb{R}). \quad (6)$$

They correspond to uniform rotations of the elt around the principal axis of inertia which is normal to its surface and coincides with the vertical. The equation of the body surface at $\gamma_3 = 1$ can be represented in the form

$$f(\mathbf{r}) = x_3 + a_3 - \frac{(x_1 \cos \delta + x_2 \sin \delta)^2}{2a_1} - \frac{(x_1 \sin \delta - x_2 \cos \delta)^2}{2a_2} + O_3(x_1, x_2),$$

where a_1 , a_2 – are the main radii of curvature of the body surface at the point of contact, a_3 – is the height of the center of mass, δ — is the angle between the vectors of principal curvatures and principal axes (for celt the relations are satisfied $A_1 \neq A_2$, $a_1 \neq a_2$, $\delta \neq 0 \pmod{\pi/2}$).

3 STABILITY CONDITIONS

Linearized equations of perturbed motion of the system in the neighborhood of solutions Eq. (6) and the corresponding characteristic equation are in [1]. In the case of non-holonomic statement of the

Figure 2: $A_1 = 3 \text{ kg} \cdot \text{m}^2$, $A_2 = 4 \text{ kg} \cdot \text{m}^2$, $A_3 = 5 \text{ kg} \cdot \text{m}^2$, $a_1 = 5 \text{ m}$, $a_2 = 4 \text{ m}$, $a_3 = 2 \text{ m}$, $m = 1 \text{ kg}$, $\delta = 0.75$; $J = 3 \text{ kg} \cdot \text{m}^2$, $\omega_* = -3.13 \text{ s}^{-1}$

Figure 3: $A_1 = 3 \text{ kg} \cdot \text{m}^2$, $A_2 = 4 \text{ kg} \cdot \text{m}^2$, $A_3 = 5 \text{ kg} \cdot \text{m}^2$, $a_1 = 5 \text{ m}$, $a_2 = 4 \text{ m}$, $a_3 = 2 \text{ m}$, $m = 3 \text{ kg}$, $\delta = 0.75$, $J = -1 \text{ kg} \cdot \text{m}^2$

problem ($k \rightarrow +\infty$) the stability conditions have the form [1],[2]

$$A_1 < A_2 < A_3, \quad a_1 > a_2 > a_3, \quad 0 < \delta < \frac{\pi}{2} \quad (7)$$

$$J = (A_1 + A_2 - A_3) \left(\frac{a_1}{a_3} + \frac{a_2}{a_3} - 2 \right) - m a_3^2 \left(4 - 3 \left(\frac{a_1}{a_3} + \frac{a_2}{a_3} \right) + 2 \frac{a_1 a_2}{a_3^2} \right) > 0 \quad (8)$$

$$\omega < 0, \quad \omega^2 > \omega_*^2 = \frac{mg}{J a_3} (a_1 - a_3)(a_2 - a_3) \quad (9)$$

Eq. (7) means that the rotation occurs around the axis of the greatest moment of inertia, and the corresponding equilibrium ($\omega = 0$) is stable. Eq. (8) imposes constraints on geometric and dynamic parameters of the body. Eq. (9) means that only rotations in the negative direction and with a enough large angular velocity are stable.

In the case of an arbitrary coefficient of viscous friction, the linearized equations of the perturbed motion of the system in the neighborhood of the solutions Eq. (6) are rather cumbersome [1] and the analytical analysis of stability conditions is difficult. At Fig. 1, Fig. 2, Fig. 3 the stability regions for some parameters of the problem are given. In the case shown at Fig. 1, for sufficiently large friction

Figure 4:

coefficients, there are two regions of stability. One corresponds to a non-holonomic statement of the problem (below the dotted line), the second is located in a neighborhood of zero. As k decreases, these regions merge into one, containing almost all negative values of ω and a small range of positive values ω . At very small k the stability region has some symmetry with respect to the horizontal.

In the case shown at Fig. 2 (which differs from the previous only by the height of the center of mass), the stability region is divided into two parts: the region corresponding to the non-holonomic case and the region in the neighborhood of equilibrium. In the case shown at Fig. 3 (body mass increases) only the region of stability in the neighborhood of equilibrium remains.

4 NUMERICAL EXPERIMENTS

Numerical experiments were carried out for a celt with parameters

$$A_1 = 0.058 \cdot 10^{-3} \text{ kg} \cdot \text{m}^2, A_2 = 0.44 \cdot 10^{-3} \text{ kg} \cdot \text{m}^2, A_3 = 0.49 \cdot 10^{-3} \text{ kg} \cdot \text{m}^2 \\ a_1 = 0.661 \text{ m}, a_2 = 0.073 \text{ m}, a_3 = 0.0098 \text{ m}, m = 0.1 \text{ kg}, \delta = 0.1, J = -0.007 \text{ kg} \cdot \text{m}^2.$$

These parameters correspond to the model of a stone having the shape of an ellipsoid, and all obtained results of numerical experiments coincide with full-scale experiments.

The region of stability of permanent rotations for this model is presented at Fig. 4. Numerical experiments were carried out on a plane with a coefficient of friction $k = 50 \text{ s}^{-1}$. The initial conditions had the form

$$\gamma_2(0) = 0, \quad \omega_1(0) = \omega_2(0) = 0, \quad \mathbf{u}(0) = 0. \quad (10)$$

At Fig. 5 on the left are the results of experiments with different initial angular velocities of rotations with a very small initial deviation from the vertical ($\gamma_3(0) = 0.99999$), on the right for greater deviation ($\gamma_3(0) = 0.999$). The area of stability of rotations with a selected coefficient of viscous friction is highlighted in gray. As we see, stable rotations with a positive angular velocity of rotation have a very small region of attraction.

We note that in the non-holonomic statement of the problem for the chosen parameters there are no stable rotations ($J < 0$). In the case of the plane with friction and a small positive initial angular velocity of rotation, there is a change in the direction of rotation of the stone, with a subsequent exit to the stable uniform rotations.

The results of numerical experiments with sufficiently large initial angular velocities are presented at Fig. 6. Here such property of a stone, as the transition of rotational motions to vibrational motions

Figure 5: $\gamma_3(0) = 0.99999$ and $\gamma_3(0) = 0.999$

Figure 6:

and vice versa is observed. The final movement with a negative initial speed can be rotation in both the negative and positive directions.

5 TRANSIENT PROCESSES

For study the transient processes shown at Fig. 5 the equations (1)–(3) up to second-order terms in the variables $v_1, v_2, \omega_1, \omega_2, \gamma_1, \gamma_2$ are considered.

$$\dot{\mathbf{x}} = A(k, \delta, \omega_3)\mathbf{x} + \mathbf{b}(\mathbf{x}, k, \delta, \omega_3) + O_3(\tilde{\mathbf{x}}) \quad (11)$$

The changing of variables

$$v_1 = v \cos \psi, \quad v_2 = v \sin \psi, \quad \omega_1 = \rho_2 \cos \varphi_2, \quad \omega_2 = \rho_1 \sin \varphi_1, \quad \gamma_1 = \frac{\rho_1}{\xi_1} \cos \varphi_1, \quad \gamma_2 = \frac{\rho_2}{\xi_2} \sin \varphi_2$$

Figure 7: $\delta = 0$, $\gamma_3(0) = 0.999$

is performed, where $\xi_{1,2}^2 = mg(a_{1,2} - a_3)/A_{2,1}$. Averaging over variables ψ , φ_1 and φ_2 is carried out. Then the equations Eq. (11) have a view

$$\begin{aligned} \dot{v} &= -kv, \quad \dot{\rho}_1 = -k \frac{ma_3^2}{2A_2} \rho_1, \quad \dot{\rho}_2 = -k \frac{ma_3^2}{2A_1} \rho_2, \\ \dot{\omega}_3 &= -k \frac{m}{2A_3} \left(\frac{a_1^2 \cos^2 \delta - a_2^2 \sin^2 \delta}{\xi_1^2} \rho_1^2 + \frac{a_2^2 \cos^2 \delta - a_1^2 \sin^2 \delta}{\xi_2^2} \rho_2^2 \right) \omega_3 + \frac{mg}{2A_3} \sin 2\delta (a_1 - a_2) \left(\frac{\rho_1^2}{\xi_1^2} - \frac{\rho_2^2}{\xi_2^2} \right) \end{aligned} \quad (12)$$

For the case of the coincidence of the directions of the principal axes of the body with the directions of the principal curvatures ($\delta = 0$) the numerical solutions of the averaged system Eq. (12) (Fig. 7, dotted curves) and leanerized system (Fig. 7, solid curves) have a good coincidence. Solving the averaged system Eq. (12) for example, under the initial conditions Eq. (10), we have $v \equiv 0$, $\rho_1 = \rho_1(0) \exp(-mka_3^2 t / (2A_2))$, $\rho_2 \equiv 0$ and equality

$$\omega_3 = \omega_3(0) e^{\alpha_1(\rho_1^2 - \rho_1(0)^2)}, \quad \alpha_1 = \frac{a_1^2 A_2}{2a_3^2 A_3 \xi_1^2} \quad (13)$$

is fair. Under initial conditions differing only in the direction of rotation, the motions are completely analogous and differ only in sign ω_3 , and the corresponding curves $\omega_3(t)$ Fig. 7 are symmetrical with respect to the horizontal.

This property is not preserved for the Celt ($\delta \neq 0$), and the equality Eq. (13) takes the form

$$\omega_3 = \omega_3(0) e^{\alpha_1(\rho_1^2 - \rho_1(0)^2)} + \frac{g(a_1 - a_2) \sin 2\delta}{2k(a_1^2 \cos^2 \delta + a_2^2 \sin^2 \delta)} \left(1 - e^{\alpha_1(\rho_1^2 - \rho_1(0)^2)(a_1^2 \cos^2 \delta + a_2^2 \sin^2 \delta)/a_1^2} \right) \quad (14)$$

In this case, the solutions of the averaged system, differing only in the initial direction of rotation, are not symmetric with respect to the horizontal. However, the displacements arising in this case are sufficiently small, and, depending on the initial conditions, they can be directed both to the lower and upper half-planes. In this case, the solutions of the system Eq. (11) deviate significantly from the solutions of the averaged system (Fig. 8), but in reality the displacement is directed to the lower half-plane. The changing in the direction of rotation of the stone is explained by the deviations of the exact solution from the averaged solution, and the final value of the angular velocity of rotation is always in a small neighborhood of zero.

Key words: MR Damper, Magnetic Hysteresis, Magnetic Flux, Hysteretic Behaviour

Abstract. This study concerns modeling the magnetic hysteretic behaviour of magnetorheological (MR) dampers. Magnetic hysteresis is one of factors influencing the output of such actuators. The origin of magnetic hysteresis in the actuator's output is obvious - it is the inherent property of ferromagnetic materials which form the electromagnet's assembly of the actuator. Prior work on solenoid actuators indicates that hysteresis plays a major role in the flux generation mechanism, and it should be accounted for in the controls development process. So far less attention has been paid to studying the contribution of magnetic hysteresis on the output of MR dampers. Majority of studies on the hysteretic behaviour of MR dampers have virtually neglected that specific contributor. Instead, the hysteretic behaviour of MR actuators was studied by observing the relationships between the output (force/torque) and the inputs (current, velocity, position). Instead, in the present study we separate the magnetic hysteresis from the mechanical/hydraulic one by investigating the magnetic flux vs exciting current relationship of an exemplary MR damper subjected to sinusoidal current (voltage) loading. The resulting behaviour of the electromagnets is then examined using the nonlinear inductor approach with hysteresis. The performance of several hysteretic operators is then evaluated based on their ability to reproduce the magnetic flux output of the MR actuator.

1 INTRODUCTION

Magnetorheological (MR) fluids are well-known representatives of smart fluids. The material develops a yield stress when exposed to magnetic field [1]. The yield stress field-dependent change is of sufficient strength for the material to be used in commercial applications, namely, semi-active vehicle dampers or powertrain mounts [2].

It is well-known a typical MR flow-mode/shear-mode damper features an internal control valve in the form of an electromagnet with a fixed height flow channel. When supplied with an electric current in the coil it induces a magnetic field in the flow channel, thus activating the fluid. The result is a resistance-to-flow build-up manifested by changes in the output force or torque. The effect is reversible and fast. Various factors make the conversion process complicated [3, 4], namely, temperature, friction, material's liability to sedimentation, non-linear magnetisation characteristics of the materials forming the magnetic circuit of the damper, magnetic hysteresis, mechanical (hysteresis), driver dynamics, control coil dynamics, non-linear relationship between the magnetic flux and the field-dependent yield stress, etc. Generally, the contributors make the control algorithm development process a challenge.

In the present study we focus on the hysteretic behaviour of the MR damper's electromagnet. The hysteresis is present virtually in any ferromagnetic material although on a different scale. Although the electromagnetic circuit of MR valves are usually developed with soft magnetic alloys the flux's hysteresis should be accounted for in the damper design process or control algorithm development. In fact, the phenomenon has been subject to extensive research over the years [6]. In general, the existence of magnetic hysteresis in MR actuators is important for two reasons. First, it complicates the issue of controlling the output of such actuators. Second, it has an effect on the actuator's output force even at off-state conditions.

Briefly, magnetic hysteresis models can be classified into two groups [5]. The first one includes energy-based models of which the Stoner-Wohlfart (S-W) model or Jiles-Atherton (J-A) model are the most well-known representatives [7, 8]. The other category incorporates the so-called phenomenological models of Preisach [9], Duhem/ Hodgdon-Coleman [10] or Chua [11]. For this study we chose two representatives of the phenomenological group, namely, the Duhem model and the Bouc-Wen operator.

The significance of hysteresis on the force output of MR dampers has been recognized early on [14]. Since Spencer et al. numerous models have been developed and applied for the purpose of predicting the force/torque output of MR dampers [15]. However, few authors focused attempted to analyze the magnetic hysteresis independently of other hysteretic contributors [16, 17, 18, 19].

In general, the purpose of the research study is in examining the capabilities of two selected phenomenological models to copy the magnetic hysteretic behaviour of MR dampers. To accomplish the goal, we reconstruct the magnetic behaviour of a rotary MR brake (damper) from voltage and current measurements as in [3] to obtain the induced flux variation against the exciting current. Next, by employing the hysteretic non-linear inductor concept we examine the performance of each model. The sensorless flux estimation technique we use allows inspecting the damper behaviour without any knowledge of its internals.

Briefly, the paper is organized as follows. Section 2 contains the description of the lumped parameter model of the MR actuator's circuit. In Section 3 we explain the test setup and the hardware used. Next, Section 4 presents modeling results and a comparison of selected data against the hysteretic models. Finally, conclusion is presented in Section 5.

2 MODELING OF NONLINEAR INDUCTORS WITH HYSTERESIS

First, let us consider a nonlinear resistor-inductor model of the MR damper's circuit as in Figure 1. The model would include the input voltage source $u(t)$, the coil resistance R and the nonlinear inductance $L(i)$ in series with the resistor. The model equation is then as follows

Figure 1: Nonlinear inductor – proposed model

$$u(t) = iR + \frac{d\lambda}{dt} \quad (1)$$

where i denotes the coil current, and $\lambda = L(i)i$ refers to the structure's magnetic flux linkage. Equation 1 represents the dynamics of a simple nonlinear inductor. The relationship $\lambda(i)$ incorporates a hysteretic operator, and it may be further extended for use with eddy current models.

For reasons already explained above we proceed further with the Duhem model and the Bouc-Wen hysteretic operator, respectively. Briefly, in the following sections we highlight an MR damper experiment based on which we extract the $\lambda - i$ relationship. Then, we execute a model identification study using the above mentioned operators, and discuss the obtained results.

2.1 Duhem hysteresis model

Using the Duhem hysteresis model, the relationship between the flux linkage λ and the coil current i can be described as follows

$$\frac{d\lambda}{dt} = a \left| \frac{di}{dt} \right| [f(i) - \lambda] + g(i) \frac{di}{dt} \quad (2)$$

We define the shape functions $f(i)$ and $g(i)$ in Equation 2 as

$$\begin{cases} f(i) = b_1 \tanh(b_2 i) \\ g(i) = c \end{cases} \quad (3)$$

The model incorporates four parameters (a, b_1, b_2, c) which can be identified from experimental data, for instance. Furthermore, we assume the parameters depend on the exciting current. In the limiting case ($a = 0$) the hysteresis is effectively eliminated and the inductor model reduces to that of a nonlinear one without hysteresis. As a result, an initial estimate of the parameter c can be provided from coil inductance calculations, for example.

The model parameter set can be then used for varying the hysteresis width and shape. In Figure 2 the authors reveal the impact that each parameter of the model has on the $\lambda - i$ normalized loop shape; the arrow in each figure shows how each parameter was increased.

In the presented form, the Duhem model has the advantage over the generic Bouc-Wen model, for example, of being less complex as it requires half of the parameters (that the Bouc-Wen model needs) as shown below.

Figure 2: Duhem model: impact of the model parameters on the $\lambda - i$ loop

2.2 Bouc-Wen model

Considering the Bouc-Wen approach the relationship between the flux linkage and the circuit current can be implemented as follows

$$\begin{cases} \lambda = \alpha ki + (1 - \alpha)kDz \\ \frac{dz}{dt} = D^{-1} \left(A \frac{di}{dt} - \beta \frac{di}{dt} |z|^{n_1} - \gamma \left| \frac{di}{dt} \right| |z|^{n_2-1} \right) \end{cases} \quad (4)$$

where z - hysteretic operator, and A , α , β , γ , k , D , n_1 , n_2 control the hysteresis width and shape as illustrated in the normalized $\lambda - i$ plots in Figure 4. Here, the Bouc-Wen model is given in the form presented in [12, 13]. Again, it should be noted that in the limiting case ($\alpha = 1$) the model is effectively reduced to that of a nonlinear inductor without hysteresis. The parameter k is then equal to the circuit inductance $L(i)$. Also, if $\alpha < 1$, then the model's behaviour resembles that of elastic materials with hysteresis (see Figure 3), i.e. the $\lambda - i$ loop rotation is clockwise, otherwise it is counterclockwise for $\alpha > 1$. As in the Duhem model, the initial estimate of k can be obtained from coil inductance calculations or measurements.

3 TEST INPUTS, HARDWARE

In the research study we rely on the flux estimation technique illustrated in [3], and the reader should refer there for further details. In this specific case we carried out measurements of supply voltage and coil current using the test setup in Figure 5. Based on the data, the magnetic flux time histories were extracted through integration. In the study we examined the behaviour of one rotary (shear-mode) MR

Figure 3: Bouc-Wen model: impact of the parameter α on the model hysteresis

damper. The hardware of choice was a shear-mode rotary brake no. RD-2028 by Lord Corp. The rotary damper's coil resistance is appr. 8.9Ω , and the device can be operated up to 1 A. In order to examine the $\lambda - i$ behaviour of the damper we subjected it to sinusoidal input voltage waveforms at low frequency ($f = 1$ Hz) (to reduce the contribution of eddy currents). The input voltage was adjusted to result in the peak coil currents $I = \{0.2, 0.4, 0.6, 0.8, 1.0\}$ A. The sampling frequency was 1 kHz.

4 RESULTS

The experimental and modeling results are highlighted in the sections below. The material in the respective sections highlights the data obtained for each hysteretic model. The results are presented as time histories of the flux linkage λ and plots of $\lambda - i$. As highlighted in the above section, the magnetic flux linkage was extracted from the measured data through integration, and then used in the model identification stage with the `fmincon` solver of the MATLAB's Optimization Toolbox using the loss function V_λ of the following form

$$V_\lambda = \frac{1}{N} \sum_{i=1}^N (\lambda_i - \hat{\lambda}_i)^2 \quad (5)$$

where N – number of samples, λ_i – measured flux linkage sample, $\hat{\lambda}_i$ – hysteresis model prediction (Duhem - Equation 2, Bouc-Wen - Equation 4).

4.1 Duhem model

Here, we show the results involving the Duhem model. The obtained data are illustrated in Figure 6 and Table 1 for the current levels 0.2, 0.4, 0.6, 1.0 A, respectively. Based on the presented data, it seems the model well copies the $\lambda - i$ characteristics of the damper both in terms of hysteresis width, magnitude and shape.

Next, observations of the Table 1 contents imply variation of the model's specific parameters against the current which confirms our initial assumptions. In particular, the magnitude of the estimate of the parameter c nearly double during the transition from the highest current input to the lowest one. The estimates of the parameters b_1 and b_2 vary by appr. 10 percent, whereas the parameter a estimate remains fairly constant anywhere except for the smallest current level.

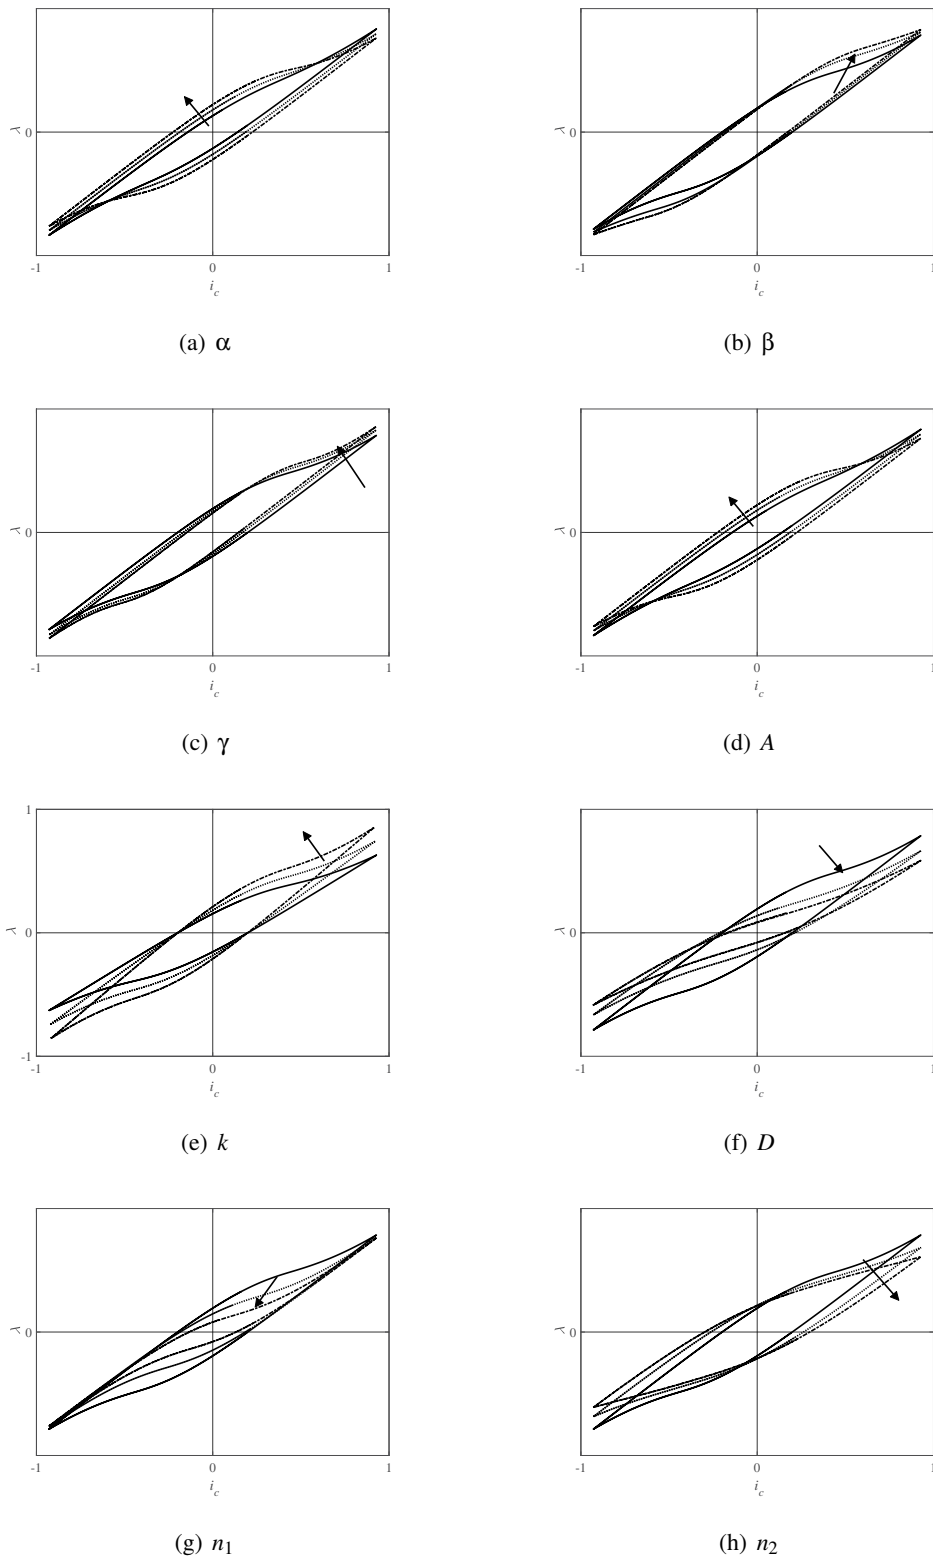

Figure 4: Bouc-Wen: impact of the model parameters on the $\lambda - i$ loop

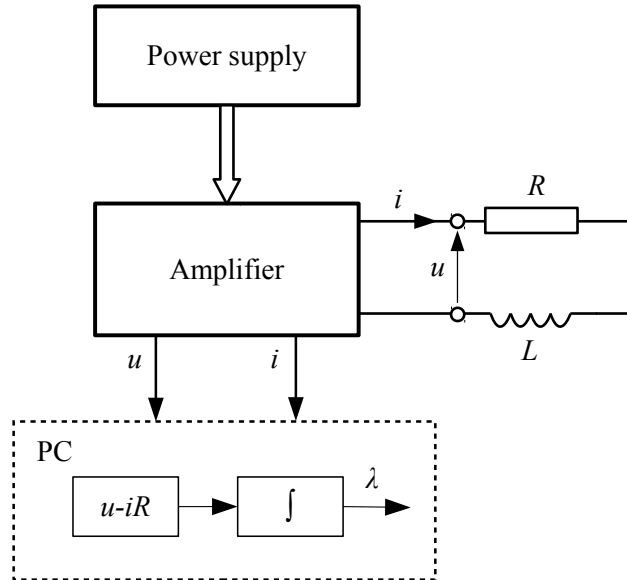

Figure 5: Test rig layout [3]

4.2 Bouc-Wen model

The results concerning the Bouc-Wen operator are presented in Figure 7 and Table 2 for the same current level range. Again, it seems the model well copies the $\lambda - i$ characteristics of the damper, however, inspecting the plots and the contents of the Table 2 shows that the Bouc-Wen model yields curve fits on the order of magnitude worse than the Duhem operator. Although the hysteresis width seems well predicted by the model the shape of the $\lambda - i$ loop predicted by the model is relatively poorly captured when compared against the Duhem based approach. That is most evident at the highest current levels – see Figures 7(g) and 7(h).

Similarly to the examined predecessor, the obtained estimates are current dependent and, except for the exponents n_1 and n_2 , they vary in a monotonous manner. This may explain the curve fitting problem at the highest current level as the exponents control the $\lambda - i$ shape. Note that the parameter k varies with the current similarly to the experimentally measured inductance of the rotary actuator in [3], although the identified variation range is different than that of the parameter c of the Duhem model.

5 SUMMARY

Magnetic hysteresis is one of the key factors affecting the output of MR dampers; it is an inherent property of the ferromagnetic material forming the damper electromagnetic circuit. As pointed out in previous study, it is of different nature than the mechanical (hydraulic) hysteresis of the devices as it does not vanish in the DC limit. It may present both control as well as engineering issues (off-state force increase due to the residual field).

As such, the present modeling study concerns the magnetic hysteresis only. It extends the concept of a

non-linear inductor with the magnetic hysteresis contribution. In the present form it captures the average flux variation in the structure, and it requires measurements of the damper's output. Therefore, it may be only used during a control algorithm development stage and is not suitable for, e.g. damper sizing studies. Of the two models which we examined the Duhem model's performance is clearly superior. The model captures all key features of the $\lambda - i$ loop. The Bouc-Wen operator is redundant in the analyzed form which may explain its poor performance at the highest current levels as the flux in the electromagnet approaches saturation. The authors intend to extend their use in transient studies by adopting a more complex and efficient inductor concept so that the effects of eddy currents and the hysteresis dependence on the excitation input frequency are well captured.

ACKNOWLEDGMENT

The authors wish to acknowledge the support of the grant no. PPI/APM/2018/1/00027/DEC/1 (NAWA – National Agency for Academic Exchange, Poland) and the statutory grant no. E3/611/2019/DS (Cracow University of Technology).

Key words: Structural dynamics, Vibration control, Tuned Mass Damper, Active Mass Damper

Abstract.

This paper presents a comparative study including the theoretical modelling and the practical implementation of two types of well-known devices for structural vibration control. Firstly, a lab scale model for a two-storey building is dynamically identified. Then, a tuned mass damper (TMD) and an active mass damper (AMD) are described, modelled and assembled in the upper floor, both of them with similar effective mass. After coupling the dynamic equations, the experimental results are compared with the numerical ones and their performance is discussed.

For modelling purposes, an experimental comparison and the corresponding computational simulation is carried out. Resulting assembled systems will undergo the same loading, consisting on an initial condition away from the equilibrium position and then released. The performance of each device is evaluated in terms of the time free oscillations take to return to rest (with accelerations within a 10% and a 5% band with regard to their maximum value). This is a relevant loading case from which interesting engineering conclusions can be drawn about not only the practical implementation of each proposed mitigation device but also about the computing and simulation capabilities.

1 INTRODUCTION

Several engineering structures can exhibit vibration problems that need to be mitigated. For vibrations under, let's say, 10 Hz (typical in slender buildings and civil structures) the problem can be addressed using passive or active approaches [1]. Assuming that the structure cannot be stiffened (nor additional supports neither bracings) the only solution is to inertially act on it. Among the possible inertial systems, TMDs (tuned mass dampers) or AMDs (active mass dampers) are standard mitigation devices. The TMDs are passive systems consisting of a moving mass linked to a mounting frame by guides, springs and dampers. The AMDs are actuators capable of accelerating a heavy block according to the corresponding signals from a microcontroller, which depend on some input records (usually via accelerometers).

Although it is much more common (and affordable) to equip large structures with TMDs, it is not uncommon to find AMD in high-rising buildings, communication towers or large-scale bridge towers for reducing wind-induced vibration or earthquake-induced vibration [1,2]. Usually AMD control exhibit superior performance but, depending on the type of loading and considering engineering issues such as manufacturing cost, power consumption, operating threshold or maintenance cost, passive systems [3,4,5] are often the chosen option.

2 MODEL DESCRIPTION

In order to illustrate and compare the effects of both mitigation devices, a specific benchmark structure (distributed by Quanser® [6] and presented in several papers [2, 7, 8, 9, 10]) is going to be studied. As it can be seen in Figure 1a, it is a building model consisting of two thick plates (or floors, letters A, B) and several slender plates joining them (or columns, C, D). The TMD and AMD mounting frames are attached on the top floor (E, F respectively). The AMD moving mass (G) is removed when the TMD device is under study and, complementary, the TMD moving mass (H) is removed when only the AMD effect is the one to be considered. The shaking table (I) is not used in this work.

Although more information will be presented later, it is convenient to anticipate some data: the first mode is at 1.57 Hz, having a modal mass of 3 kg and 0.5% of modal damping ratio. Both TMD and AMD devices will be installed on the upper floor with a moving mass of 22% of the modal mass. TMD will be tuned to mitigate this first mode of vibration. As it is known, the performance of both systems depends on the moving mass involved. Nevertheless, TMD and AMD also require some fixed mass (mounting frame, supports, etc.) affecting the modal parameters of the structure. To eliminate the influence of these fixed masses, some additional mass will be added to the model so the structure will have the same dynamic properties when the moving mass of the mitigation devices is removed. Also, friction on both devices can be neglected as mechanical parts (rotational bearings, linear ball guides, etc.) are high quality ones.

The physical model can be represented by the conceptual discrete model shown in Figure 1b, where all the building mass is concentrated on the first and second floors. Both floors are joint together and to the ground through two plates which restrain the movement to one vertical plane and provide stiffness and structural damping. The corresponding equations of motion,

considering the two degrees of freedom shown in Figure 1b, are shown in Eq. 1. There, m_1 and m_2 are the masses of each floor, k_1 and k_2 are the equivalent stiffness values of both plates and c_1 and c_2 their corresponding equivalent viscous damping coefficients. F_2 represents a force applied on the second floor. Forces applied on the first floor do not appear in this study.

$$\begin{aligned} m_1 \ddot{x}_1 + (c_1 + c_2) \dot{x}_1 - c_2 \dot{x}_2 + (k_1 + k_2) x_1 - k_2 x_2 &= 0 \\ m_2 \ddot{x}_2 - c_2 \dot{x}_1 + c_2 \dot{x}_2 - k_1 x_1 + k_2 x_2 &= F_2 \end{aligned} \quad (1)$$

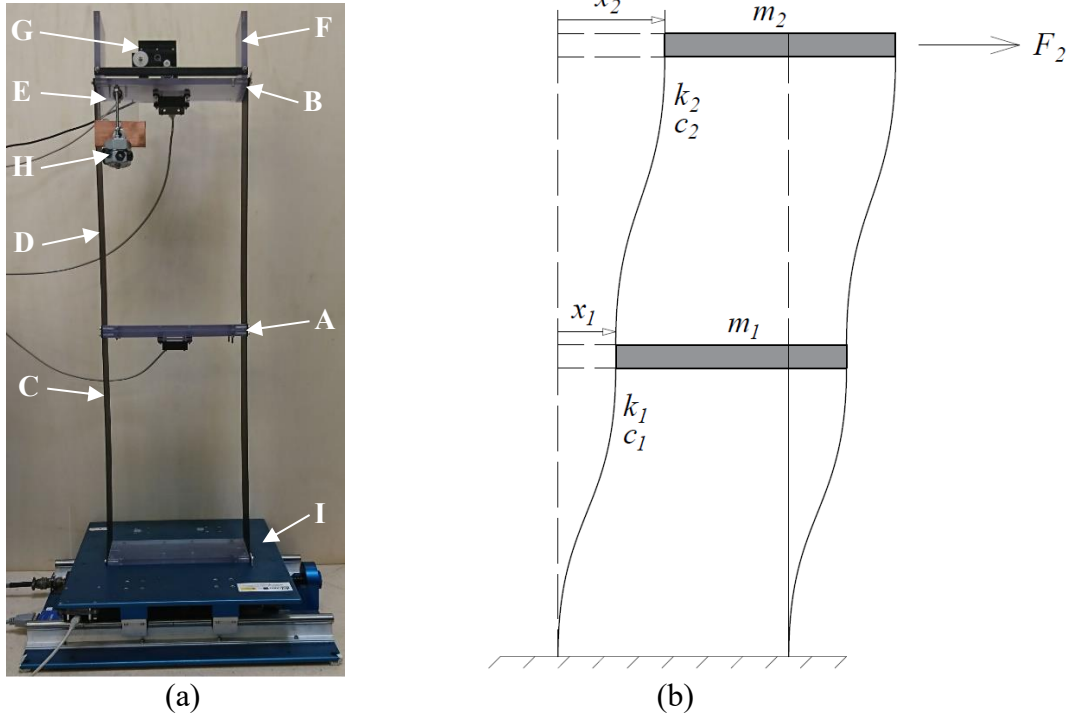

Figure 1: Real (a) and conceptual (b) building model

Bearing in mind control strategies, these equations are transformed into the equivalent state space model (Eq. 2). Considering as input $u = F_2$, the state vector containing both displacements and velocities ($x_0 = [x_1 \ x_2 \ \dot{x}_1 \ \dot{x}_2]^t$) and establishing as outputs the accelerations of both floors ($y_0 = [\ddot{x}_1 \ \ddot{x}_2]^t$), the state space matrices A_0 , B_0 , C_0 and D_0 in Eq. 3 are obtained.

$$\begin{cases} \dot{x}_0 = A_0 x_0 + B_0 u_0 \\ y_0 = C_0 x_0 + D_0 u_0 \end{cases} \quad (2)$$

A modal test has been performed in order to estimate the physical and modal properties of the model. Using an impact hammer, a measured force is applied on the second floor. The accelerations \ddot{x}_1 and \ddot{x}_2 are registered and correlated with the input force. In this way, two Frequency Response Functions (FRFs) are calculated using the H_v estimator and the two degree of freedom mathematical model is fit to them. For doing so, a routine has been scripted in

Matlab to minimize the squared error between both real and imaginary parts of the two FRFs. The built-in *fmincon()* function has been chosen as the solver. Results can be shown in Figure 2, comparing both the fitted FRFs and the time response of the building and the model subjected to the same initial conditions.

$$\begin{aligned} A_0 &= \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -\frac{k_1+k_2}{m_1} & \frac{k_2}{m_1} & -\frac{c_1+c_2}{m_1} & \frac{c_2}{m_1} \\ \frac{k_2}{m_2} & -\frac{k_2}{m_2} & \frac{c_2}{m_2} & -\frac{c_2}{m_2} \end{bmatrix} & B_0 &= \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1/m_2 \end{bmatrix} \\ C_0 &= \begin{bmatrix} -\frac{k_1+k_2}{m_1} & \frac{k_2}{m_1} & -\frac{c_1+c_2}{m_1} & \frac{c_2}{m_1} \\ \frac{k_2}{m_2} & -\frac{k_2}{m_2} & \frac{c_2}{m_2} & -\frac{c_2}{m_2} \end{bmatrix} & D_0 &= \begin{bmatrix} 0 \\ 1/m_2 \end{bmatrix} \end{aligned} \quad (3)$$

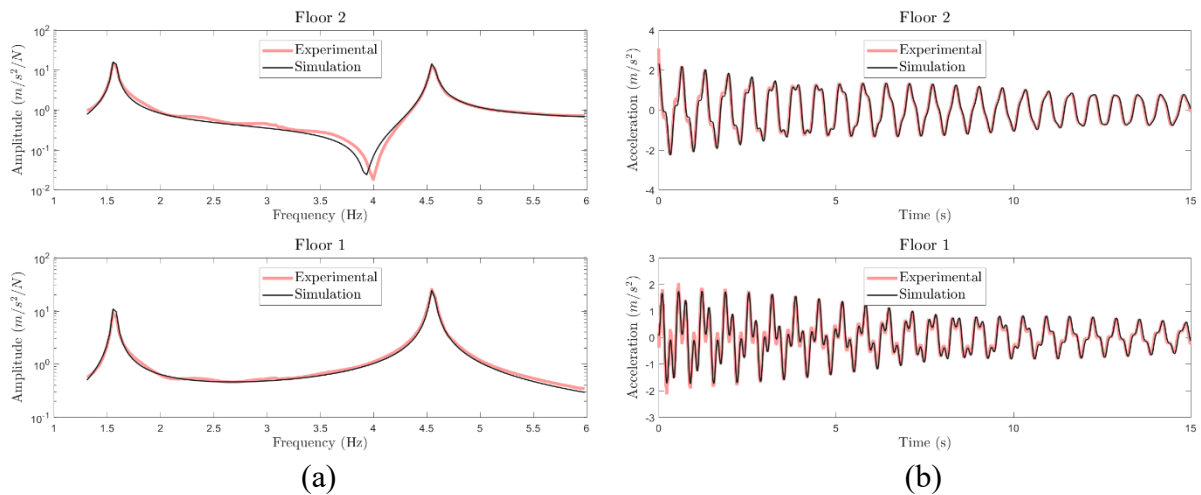

Figure 2: Frequency (a) and time (b) simulations of the bare building model

Table 1: Physical and modal properties of the model

		Floor 1 / Mode 1	Floor 2 / Mode 2
Physical properties	Mass (m_j)	1.89 kg	2.37 kg
	Stiffness (k_j)	491 N/m	662 N/m
	Damping (c_j)	0.651 Ns/m	≈ 0.00 Ns/m
Modal properties	Frequency (f_j)	1.57 Hz	4.56 Hz
	Damping ratio (ζ_j)	0.5 %	0.4 %
	Modal mass (\tilde{m}_j)	3.04 kg	2.67 kg

Finally, Table 1 summarizes the estimated physical and modal properties of the model. It must be noted that, with comparative aims, the mounting rigid frames of both mitigation devices and the different wires are considered as part of the structure and were present during all the tests carried out for this work.

3 VIBRATION MITIGATION DEVICES: TMD AND AMD

In this section both mitigation devices are described physically and mathematically. In both cases, the conceptual model, together with its mathematical model, is presented. Also, the FRFs and the response of the structure and the model subjected to the same initial conditions are depicted with and without the control device for comparison purposes.

3.1 TMD

The Tuned Mass Damper is composed by a moving mass joint to a point of the structure and contains an element sought to dissipate part of the energy the TMD receives. In this case, the device has been conceived as a pendulum (see Figure 1a, letter H), with no elastic members, so the restitution force is its own weight. For small amplitude displacements, the system can be linearized and an equivalent stiffness as well as a natural frequency and a modal damping ratio can be calculated. The damping is induced through a permanent magnet moving in front of a copper plate. The relative velocity between them induces magnetic forces and energy dissipation that oppose the movement, resulting in a simple system that can be modelled just like a viscous damping device [11]. The equation of motion of the resulting Single Degree of Freedom is shown in Eq. 4, where ω_t is the natural frequency of the pendulum (in rad/s) and ζ_t is its modal damping ratio. x_t represents its horizontal displacement (relative to the attachment point) and \ddot{x}_2 is the acceleration of the second floor, where it is installed.

$$\ddot{x}_t + 2\zeta_t\omega_t\dot{x}_t + \omega_t^2x_t = -\ddot{x}_2 \quad (4)$$

The linking force F_t between the TMD and the second floor can be calculated as stated in Eq. 5 (where m_t accounts for the device moving mass), and this, together with Eq. 4, can be combined in a state space model whose state vector is $\mathbf{x} = [x_t \ \dot{x}_t]^t$, the input is $u = \ddot{x}_2$ and the output is the force, $y = F_t$ resulting in the state space matrices shown in Eq. 6.

$$F_t = m_t(\ddot{x}_2 + \ddot{x}_t) = -m_t(2\zeta_t\omega_t\dot{x}_t + \omega_t^2x_t) \quad (5)$$

$$A_t = \begin{bmatrix} 0 & 1 \\ -\omega_t^2 & -2\zeta_t\omega_t \end{bmatrix} \quad B_t = \begin{bmatrix} 0 \\ 1 \end{bmatrix} \quad C_t = [-m_t\omega_t^2 \quad -2m_t\zeta_t\omega_t] \quad D_t = 0 \quad (6)$$

The properties of the TMD have been measured separately, resulting in a total moving mass of 0.66 kg with a natural frequency of 1.41 Hz and an equivalent modal damping ratio of 16%. Using these values and closing the loop as shown in Figure 3, a coupled model is built. This task is easily performed with Matlab thanks to its built-in *feedback()* function. In Figure 4a, the measured FRFs of the closed loop model are compared with the simulated ones and with the

original model (without any control device). This comparison is also done in the time domain (Figure 4b), comparing the responses of the three models subjected to the same initial conditions (0.011 m for the first floor and 0.019 m for the second one).

Figure 3: Feedback model of the structure with the TMD

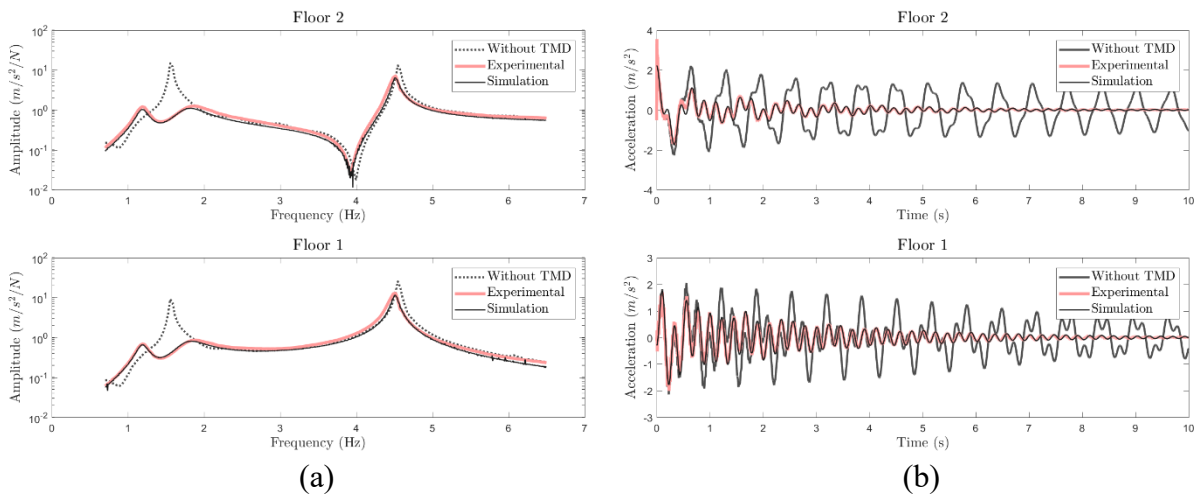

Figure 4: Frequency (a) and time (b) simulations of building model with the TMD

3.2 AMD

The Active Mass Damper system, from Quanser® [6], is composed by a linear actuator moving a 0.66 kg cart connected to a board which, in real-time conditions, measures two accelerometers, gives a voltage command to the actuator amplifier and measures its encoder to retrieve its relative position. The board is connected to a computer and the whole system is driven by Windows Real Time and a proprietary software named WinCon [6]. As the core of this technology, the selection of the best control algorithm is challenging. Although there are other alternatives [6] the traditional pole location control algorithm originally implemented by Quanser® is used.

The goal now is to command the linear actuator so the cart induces movements capable to mitigate the building vibrations. For this, the acceleration of both floors is measured in real-time and, by means of an observer, the state of the system is estimated. Finally, this state is fed back into the structure (which now contains the linear actuator) multiplied by a certain gain matrix. The closed loop system (Figure 5) should now have improved damping characteristics.

The actuator is composed by a guided moving mass, whose driving force is applied through

a DC motor, a planetary gearbox and a rack pinion mechanism to transform the rotary movement into linear displacement. The behavior of the whole system is expressed in terms of the properties of all these elements and the resulting driving force is shown in Eq. 7, where α and β are calculated from the electrical and mechanical parts of the cart, giving the values of 7.72 Ns/m and 1.72 N/V respectively. The driving force of the actuator has the same value than the force it produces on the second floor of the building, but in the opposite sense. In this way, the equation of motion associated to the second floor is modified as stated in Eq. 8 and a new equation of motion, Eq. 9, is added to the whole system to take into account the dynamics of the cart.

$$F_c = \beta V_m - \alpha (\dot{x}_c - \dot{x}_2) \quad (7)$$

$$m_2 \ddot{x}_2 + (c_2 + \alpha) \dot{x}_2 - c_2 \dot{x}_1 - \alpha \dot{x}_c + k_2 x_2 - k_2 x_1 = F_2 - \beta V_m \quad (8)$$

$$m_c \ddot{x}_c + (c_{eq} + \alpha)(\dot{x}_c - \dot{x}_2) = \beta V_m \quad (9)$$

To include the cart dynamics on the structure description, a new state space model must be built. The new inputs are the motor voltage and the external force applied to the second floor ($u = [V_m \ F_2]^t$). The state vector is $x = [x_c \ x_1 \ x_2 \ \dot{x}_c \ \dot{x}_1 \ \dot{x}_2]^t$ and the output signals are the three monitored magnitudes: $y = [x_c \ \ddot{x}_1 \ \ddot{x}_2]^t$, since the position of the cart can be registered thanks to its encoder. Such a model produces the state space matrices shown in Eq. 10.

$$\begin{aligned} A_c &= \begin{bmatrix} 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & -\frac{c_{eq} + \alpha}{m_c} & 0 & \frac{c_{eq} + \alpha}{m_c} \\ 0 & -\frac{k_1 + k_2}{m_1} & \frac{k_2}{m_1} & 0 & -\frac{c_1 + c_2}{m_1} & \frac{c_2}{m_1} \\ 0 & \frac{k_2}{m_2} & -\frac{k_2}{m_2} & \frac{\alpha}{m_2} & \frac{c_2}{m_2} & -\frac{c_2 + \alpha}{m_2} \end{bmatrix} & B_c &= \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ \frac{\beta}{m_c} & 0 \\ 0 & 0 \\ -\frac{\beta}{m_2} & \frac{1}{m_2} \end{bmatrix} \\ C_c &= \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & -\frac{k_1 + k_2}{m_1} & \frac{k_2}{m_1} & 0 & -\frac{c_1 + c_2}{m_1} & \frac{c_2}{m_1} \\ 0 & \frac{k_2}{m_2} & -\frac{k_2}{m_2} & \frac{\alpha}{m_2} & \frac{c_2}{m_2} & -\frac{c_2 + \alpha}{m_2} \end{bmatrix} & D_c &= \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ -\frac{\beta}{m_2} & \frac{1}{m_2} \end{bmatrix} \end{aligned} \quad (10)$$

Note that matrices B_c and D_c contain two columns, the first being associated with V_m and the second to F_2 . The next goal is to estimate a feedback gain matrix K so as the closed loop system satisfies some requirements. The input voltage is calculated just like $V_m = -Kx_c$, so the state equations are modified as shown in Eq. 11. The modal properties of the closed-loop system are the eigenvalues and eigenvectors of the state matrix $[A_c - B_{cV}K]$, where B_{cV} is the column from B_c associated to the input V_m .

$$\ddot{x}_c = A_c x_c + [B_{cV} \ B_{cF}]u = (A_c - B_{cV}K)x_c + B_{cF}F_2 \quad (11)$$

One way to calculate the matrix K is by placing the eigenvalues of the closed-loop state matrix $(A_c - B_{cV}K)$ in some appropriate values in order to satisfy the following conditions. In this case, the desired closed-loop eigenvalues are shown in Eq. 12. They limit the settling time of the free decay response to 1.5 s when initial conditions of 10 mm are applied to each floor [6]. In this sense, and using the *place()* function of Matlab, the matrix K is calculated and shown in Eq. 13.

$$CP = [-5.3 + 5.9j \quad -5.3 - 5.9j \quad -4.2 + 21.9j \quad -4.2 - 21.9j \quad -13.7 + 8.4j \quad -13.7 - 8.4j] \quad (12)$$

$$K = [51.74 \quad 159.3 \quad -500.1 \quad 4.930 \quad 30.60 \quad -25.42] \quad (13)$$

This closed loop system cannot be implemented yet, since the state of the system is not directly measurable. For overcoming this issue, an observer must be used. This observer will estimate the state of the system from the measurable magnitudes: V_m , x_c , \ddot{x}_1 and \ddot{x}_2 , which are one of the inputs and the output vector. The output of the observer is an estimation of the system state vector, x_o . The strategy followed in this work consists in using the same state space model that describe the dynamics of the structure but modified adding the measured output. According to Eq. 14, this output (y) and the observer output vector (y_o) form an error vector which is multiplied by a gain matrix G and modifies the dynamics of the observer.

$$\dot{x}_o = A_c x_o + B_{cV}V_m + G(y_o - y) \quad (14)$$

$$y_o = C_c x_o + D_{cV}V_m$$

$$y_{xo} = I_n x_o$$

$$\dot{x}_o = (A_c - GC_c)x_o + (B_{cV} - GD_{cV})V_m + Gy_o \quad (15)$$

$$y_{xo} = I_n x_o$$

After some manipulation, Eq. 15 is obtained, where it can be seen that the dynamics of the observer depend on the matrix $[A_c - GC_c]$. The matrix G should be designed in such a way that the resulting observer dynamics are fast and damped enough. The chosen eigenvalues for this work are shown in Eq. 16. Real eigenvalues in this case mean that the dynamics are critically damped ($\zeta_j = 100\%$ for all modes). Once again, using the *place()* function of Matlab the matrix G can be computed.

$$OP = [-40 \quad -45 \quad -50 \quad -55 \quad -60 \quad -65] \quad (16)$$

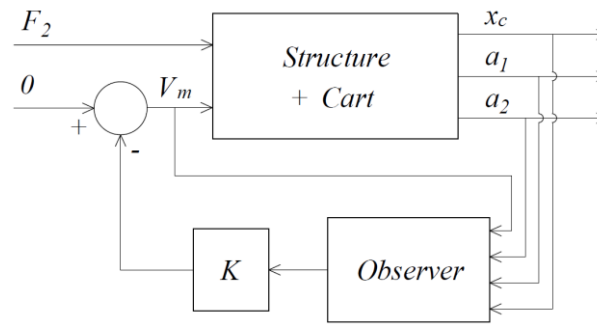

Figure 5: Feedback model of the structure with the AMD

After scripting the corresponding state space models, the loop can be easily closed as depicted in Figure 5 leaving one free input, F_2 , and three outputs (x_c , \ddot{x}_1 and \ddot{x}_2). Once again, FRFs have been experimentally estimated using the same procedure (impact hammer). A comparison between the experimental and simulated one is shown in Figure 6a. It is interesting to note a main difference between them around the first natural frequency. A peak at 1.37 Hz appears, which is probably due to the threshold value of the accelerometers used as input for control: for practical reasons, when accelerations are under 0.15 m/s^2 (estimated value) no output signal is generated. Due to this issue, the AMD does not interact for low accelerations so a residual movement, which is governed by the first mode of the structure, can only dissipate by the original structural damping, giving an appreciable peak around that frequency. The natural frequency (1.37 Hz) is lower than before (1.57 Hz, original model) because within the threshold the cart moves along with to the second floor of the structure, increasing its equivalent mass.

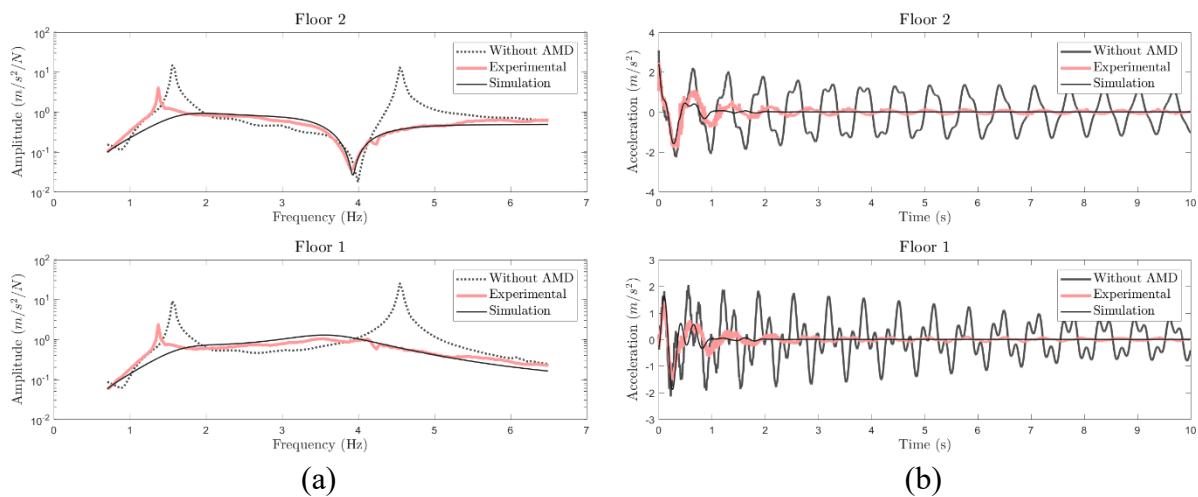

Figure 6: Frequency (a) and time (b) simulations of building model with the AMD

Also, a time comparison of the response of the system subjected to the same initial conditions is shown in Figure 6b. Here, more differences as before can be appreciated, mainly due to the aforementioned practical limitation together with the fact that an AMD system contains much more incertitude in its design and implementation.

4 DISCUSSION

To compare each system, two sets of results have been prepared. First, the plot in Figure 7 shows the poles and zeroes of the three treated models: the open loop uncontrolled system and the closed loop systems corresponding to the TMD and to the AMD. The horizontal axis represents the product $\omega_j \zeta_j$ of the corresponding eigenvalue whilst the vertical axis represents the product $\omega_j \sqrt{1 - \zeta_j^2}$.

As it can be easily seen, the uncontrolled structure (blue) has two natural modes (two pairs of poles) close to the vertical axis, which implies low damped modes (see Table 1). When adding the TMD (green), the first mode (the closest pair to the horizontal axis) is split into two new modes, one above and one below, which correspond to the two close peaks shown in Figure 4a. Both new pairs of poles are more damped than the original one, which translates into the damper effect of the device. When the AMD is considered, the original poles are notably moved to the left, which means an important increase of its modal damping. These results, theoretically, in an enormous increase of the damper effect and the efficiency of the system. However, as it has been mentioned and will be seen in Table 2, this is only true when the practical issues about the accelerometers measuring threshold are not considered.

Figure 7: Poles and zeroes of the structure without control, with TMD and with AMD

Finally, a chart summarizing the value of some indicators is presented in Table 2. The maximum of the FRFs of Figures 2a, 4a and 6a are shown in the first two rows. Note that only the greatest maximum values between the first and the second floors has been considered. Also, the settling time (S.T.) of the free decay response (Figures 2b, 4b and 6b) has been estimated, first assuming a band of $\pm 10\%$ of the first maximum of the response (third row) and then assuming a band of $\pm 5\%$ (last row). These values are taken, once again, from the floor which produces the worst values. Every indicator is expressed in terms of its absolute value and also in percentage improvement.

As it can be seen, both damping devices have great and similar performance, being the AMD better to reach the $\pm 10\%$ band, as expected. However, in a more demanding case, to get the $\pm 5\%$ band, the AMD takes a little longer than the TMD. This is due to the fact that the accelerometers belonging to the control loop output a null value when the structure

accelerations are below a certain threshold (around 0.15 m/s^2). This causes the AMD to stop working which forces the residual movement to dissipate by itself, taking at the end longer time than the TMD to get the $\pm 5\%$ band.

Table 2: Indicators summary

	Uncontrolled	With TMD		With AMD	
Max. FRF1 [m/s ² /N]	14.7	1.2	91.8%	4.0	72.8%
Max. FRF2 [m/s ² /N]	24.4	12.9	47.1%	1.0	95.9%
S.T. 10% [s]	37.9 (p2)	5.7 (p1)	85.0%	4.0 (p2)	89.4%
S.T. 5% [s]	52.3 (p2)	7.2 (p1)	86.2%	11.7 (p2)	77.6%

5 CONCLUSIONS

As it can be seen from the results presented in this work, when compared with the same amount of moving mass both mitigation devices have great performance in mitigating oscillations on slender structures. It is also notable that both systems can be numerically simulated accurately. For the demanding loading scenarios presented in sections 3.1 and 3.2, the correspondence between experiments and simulation is very good. Also, as it is known [5], for the impulsive load under consideration, both affect very little to the first peak of the response (Figures 4b and 7b). After that, they both decrease the response levels to acceptable ranges. However, they present some important differences:

- The TMD is intended to deal with the contribution of one single mode of the structure. If the structure has more than one mode contributing significantly to its response, then more than one TMD should be installed. In this sense, the AMD is able to deal with a wider frequency band, mitigating the contribution of more than one mode at the same time. This conclusion is also applicable to the case of evolutionary structures whose frequencies can significantly change due to the occupation, thermal changes, etc.
- The TMD is a purely mechanical system. Its dynamics are coupled to the structural ones and, once tuned, if the mechanical moving parts have a good enough quality (to avoid friction and wearing effects), its good performance is ensured. The AMD, however, is an electro-mechanical system whose efficiency, apart from the aforementioned mechanical issues, depends on the power supply, programming and electronic performance (quality of sensors, real-time processing, etc.)
- For practical reasons (power consumption, maintenance, stability, mechanical gaps, sensor issues, etc.) the AMD exhibit a dead zone for low response levels while the TMDs, assuming that friction is negligible, work throughout the whole range.
- For the particular scenarios presented in sections 3.1 and 3.2, the settling time for a band of $\pm 10\%$ is 1.7 s shorter with the AMD but when a more demanding band ($\pm 5\%$)

is required, the TMD is 4.5 s quicker. Although these differences may not seem relevant, for loading cases (as vortex shedding, for example) where comfortability or serviceability conditions are compromised, it may be a factor to bear in mind.

Although other loading scenarios have to be considered, the results of this study show that the selection of the proper vibration control device is a hard task that depends on multiple factors. Being the performance a vital engineering factor, the durability, reliability and cost (including initial budget and operation and maintenance expenses) are also relevant issues.

Key words: Isolated R.C. Framed Building; Fixed-Base Steel Framed Elevator Shaft; Internal Pounding, Eddy Current Dampers, Nonlinear Seismic Analysis.

Abstract. Internal pounding effects between closely spaced structural parts (e.g. in the case of an insufficient gap between elevator and surrounding building) may be found in seismically isolated structures, due to notable displacement at the level of the isolation system under severe earthquakes. To study this poorly investigated question, a reinforced concrete (r.c.) building, with a hybrid isolation system including elastomeric and sliding bearings, is considered. The building, which is located in the Sicilian town of Augusta, is comprised of a basement and three storeys above the ground level, and is seismically isolated at the top of rigid columns in the basement, while a steel framed elevator shaft crosses the isolation level. A very common structural configuration is presented here, with a gap between the fixed-base elevator shaft and the building. Despite the gap, internal pounding may occur at all levels of the superstructure when the elevator with maximum load stops at the upper floors. To reduce pounding effects, a smart eddy current damped interconnection (ECDI) between adjacent corners of the elevator and the surrounding building at the floor level is proposed. This occupies less space than traditional passive dampers and transmits considerably less forces compared to a rigid link configuration. Specifically, an eddy current damper (ECD) consists of an outer cylindrical tube, as conductor, and an inner tube, equipped with an array of axially magnetized and ring-shaped permanent magnets separated by iron pole pieces, as mover. The relative motion between conductor and magnets, during seismic loading, induces an eddy current producing electromagnetic damping. Given that viscoelastic linear behaviour can be hypothesized for the ECDs, a simplified iterative design procedure of the ECDI is proposed. Finally, to evaluate the effectiveness of the ECDI, nonlinear seismic analysis is carried out with regard to five structural models: i.e. no connection (i), flexible links (ii), rigid links (iii), viscous damped links (iv), eddy current damped links (v).

1 INTRODUCTION

Internal pounding between a fixed-base elevator shaft and/or stairs crossing the isolation level and structural parts of the surrounding building may occur in seismically isolated buildings, due to the fact that the difference in the dynamic properties of independent units may lead to out-of-phase movements inducing structural interaction during an earthquake [1]. Previous studies showed that seismic pounding may lead to significant damage of the lighter structure (e.g. the elevator shaft), whereas the behaviour of the heavier structure (i.e. the main building) is only slightly influenced by collisions [2]. Moreover, the high deformability of an isolated structure may lead to amplification in the pounding under anomalous ground motions like those recorded near-faults [3, 4], where considerable displacement is expected under long-duration and high-amplitude velocity pulses [5]. Seismic codes provide the minimum design gap between independent units of the same building, depending on maximum horizontal displacement of the two units at the corresponding level under the design basis [6] and/or maximum considered [7] earthquakes. The simplest way to avoid or reduce internal pounding is to design a separation joint between the potentially colliding systems, but a wide gap may well conflict with practical considerations that may make the creation of a sufficiently wide internal gap problematic. One alternative is to minimize the effect of pounding through decreasing lateral motion at the level of the isolation system with a self-stopping mechanism [8] or a passive gap damper [9], but a substantial increase of the shear and drift demands of the superstructure represents the counterpart [10]. In-phase motion of adjacent structures is expected with rigid links placed at critical locations (e.g. floor levels), but an increase of base shear on the stiffer structure [11] and notably higher forces are reciprocally transmitted in comparison to damped links also increasing damping capacity [12].

With the aim of studying the effects of damped links to reduce internal pounding effects, a recent commercial building in the Sicilian town of Augusta (Italy) is considered as test structure. Specifically, an r.c. framed structure with rectangular plan, composed of a basement and three storeys above ground level, is seismically isolated with a hybrid system including sixteen elastomeric (i.e. High-Damping-Rubber Bearings, HDRBs) and sixteen sliding (i.e. Low-Friction-Sliding Bearings, LFSBs) bearings. An internal elevator shaft with a fixed-base steel framed structure crosses the isolation plane and emerges in the basement. In order to prevent mutual pounding under severe earthquakes, the idea of connecting two structures with different dynamic properties by using traditional passive devices was explored in early 70's. This paper proposes a major innovation in the form of a smart eddy current damped interconnection (ECDI) at the floor levels, between adjacent corners of the elevator and surrounding building, because it takes up less space than traditional damped links while allowing a damping of the same order as viscous dampers. An eddy current damper (ECD) produces an electromagnetic damping force by using an array of axially magnetized ring-shaped permanent magnets separated by iron pole pieces [13]. Stiffness and damping properties of the smart coupling and alternative traditional links are first designed through an iterative procedure where minima floor displacements of the elevator are selected as performance targets. A seismic gap is also designed to verify the possibility of displacement of the steel structure and deformation of the isolation system of the unconnected r.c. superstructure. The effectiveness of coupling with links placed only at top level and at all levels is checked by means of nonlinear dynamic analysis of the said building subjected to strong near-fault earthquakes.

2 SEISMICALLY ISOLATED BENCHMARK BUILDING

An r.c. framed commercial building located in the Sicilian town of Augusta (Italy), composed of a basement and three storeys above ground level (Figure 1a), is considered as test structure. It is seismically isolated with a hybrid system including sixteen HDRBs and sixteen LFSBs inserted at the top of rigid columns in the basement (Figure 1b). The building plan is symmetrical with respect to the transversal (Y direction), but not with respect to the longitudinal (X direction) due to the presence of a steel framed elevator structure crossing the isolation level (Figures 1c,d).

The design of the isolation system is carried out on the basis of the following assumptions for the horizontal seismic loads at the collapse prevention (CP) limit state: equivalent viscous damping of the isolation system $\xi_H=15\%$; high-risk seismic zone (peak ground acceleration on rock, $a_g=0.406g$); stiff subsoil (class B, with subsoil parameter $S_S=1.018$); topographic class T1 (stratigraphic parameter $S_T=1$); displacement demand $d_{dc}=270$ mm. The fundamental vibration period of the seismically-isolated structure is equal to $T_{1H}=2.38s$ [14], corresponding to a mass of the superstructure equal to 2400 tons and a horizontal stiffness of the isolation system of 16.45 kN/mm. The latter is divided between the sixteen HDRBs on the assumption that the stiffness contribution of the sixteen LFSBs is negligible. Type SI-N500/150 is selected for the HDRBs produced by FIP Industriale [15], corresponding to normal rubber compound with a shear modulus $G=0.8MPa$, assuming the geometrical and mechanical properties shown in Table 1: i.e. external diameter of the isolator (D); total thickness of the rubber (t_r); primary (S_1) and secondary (S_2) shape factors; equivalent horizontal (ξ_{eH}) and vertical (ξ_{eV}) viscous damping ratios; horizontal (K_{H0}) and vertical (K_{V0}) stiffnesses at the shear deformation $\gamma=1$; maximum vertical load (P_c) and displacement capacity (d_c) at the collapse prevention (CP) limit state.

(b) Plan of the isolation level

(c) Transversal section A-A

(d) Plan of the first level

Figure 1: The Augusta building, Italy (units in cm)

Two types of LFSBs produced by the same company are placed in the building plan

depending on the maximum loading capacity (Figure 1b): i.e. type 1, VM 200/600/600, and type 2, VM 150/600/600, where the first number represents the vertical load capacity in tons (P_c) and the other two the permitted longitudinal and transversal movements in mm ($\pm d_c$). Moreover, a dynamic-fast friction coefficient $\mu_{fast}=1.7\%$ is the outcome of a calibration process.

Table 1: Geometrical and mechanical properties of the HDRBs (units in kN, mm and s)

D_b	t_r	S_1	S_2	ξ_{eH}	ξ_{eV}	K_{H0}	K_{V0}	P_c	d_c
500	150	20	3.2	15%	5%	1.05	1016	1200	300

The design of the superstructure is carried out at the ultimate life-safety (LS) limit state, under the corresponding horizontal seismic loads (i.e. $a_g=0.285g$ and $S_S=1.136$), assuming nearly elastic response (behaviour factor, $q=1.5$). The gravity loads used in the design are represented by dead- and live loads, equal to: 6.47 kN/m^2 and 4 kN/m^2 , for the first three levels; 5.27 kN/m^2 and 2 kN/m^2 , for the roof level. Perimeter masonry infills without openings are placed along the short side of the building, at the second storey, and in the central bay of the long side of the building, at the first and second storey, while additional masonry infills are placed around the staircase. A cylindrical compressive strength of 30 N/mm^2 for the concrete and a yield strength of 450 N/mm^2 for the steel are assumed as characteristic values for the r.c. cross sections. The length of the frame members is shown in Figure 1, where cross-sections of columns (Figure 1c) and beams (Figure 1d) are also reported.

The steel frame elevator shaft crosses the isolation plane and emerges in the basement where it is fixed-base and separated from the surrounding building by a gap (Figure 2a). The elevator shaft is classified as non-dissipative (i.e. behaviour factor $q=1$) and designed at the LS limit state. A dead load of 10 kN plus a live load of 10 kN , depending on the maximum number of persons allowed, are considered for the elevator. Moreover, a lightweight infill panel of the elevator shaft equal to 0.43 kN/m^2 is applied on three sides of its perimeter.

Figure 2: View of stairs and elevator shaft (units in cm)

For the elevator eight design scenarios are considered, assuming maximum ($W_{\text{elev.}}=20$ kN) and minimum (i.e. empty, $W_{\text{elev.}}=10$ kN) loads combined with four different vertical positions, corresponding to the basement (level -1) and three floors above (levels 0, 1 and 2 shown in Figures 2b-2e). The elevator shaft is designed to fulfil the full operational ($\Delta/h=0.33\%$, defined as interstorey drift (Δ) normalized by the storey height (h)) and operational ($\Delta/h=0.5\%$) deformability limit states, under the corresponding horizontal seismic loads (FO: $a_g=0.056g$ and $S_S=1.20$; OP: $a_g=0.076g$ and $S_S=1.20$), and ultimate LS limit states for strength and buckling. Cross-sections of steel frame members are assumed constant along the height and ductile, in line with class 1 (i.e. double-T steel sections type HEA 120 for beams) and 2 (i.e. double-T steel sections type HEA 160 for columns, with principal axis oriented as shown in Figure 2a) provided by the Italian seismic code [6]. Yield and ultimate strengths of 355 N/mm² and 510 N/mm² are assumed for the steel, respectively. Finally, the dynamic properties of the elevator shaft for different vertical positions of the elevator at maximum load are presented in Table 2: i.e. fundamental vibration periods ($T_{1,X}$ and $T_{1,Y}$) and effective masses ($m_{e1,X}$ and $m_{e1,Y}$) along the principal in-plan directions.

Table 2: Dynamic properties of the elevator shaft

Elevator at maximum load ($m_{\text{tot}}=8.16$ ton)				
Position of the elevator	$T_{1,X}$ (s)	$m_{e,X}$ (% m_{tot})	$T_{1,Y}$ (s)	$m_{e,Y}$ (% m_{tot})
-1	0.914	70.04	0.715	75.37
0	0.923	61.09	0.721	65.04
1	1.049	78.65	0.817	82.06
2	1.147	78.81	0.909	81.54

A three-spring-three-dashpot viscoelastic model can be adopted for an HDRB, consisting of an axial spring acting in parallel with a viscous dashpot both in the horizontal and vertical directions. Specifically, coupled nonlinear elastic springs in the horizontal ($F_{K,x}$, $F_{K,y}$) and vertical (P_K) directions proportional to horizontal and vertical displacement ($u_{H,x}$, $u_{H,y}$ and u_V), with a vertical displacement (u_V^*) taking into account the axial shortening or lengthening due to second order geometric effects, are assumed [4]

$$\begin{Bmatrix} F_{K,x} \\ F_{K,y} \end{Bmatrix} = \bar{K}_{H0} \cdot \left(I - \left(\frac{P}{P'_{cr}} \right)^2 \right) \cdot \begin{Bmatrix} u_{H,x} \\ u_{H,y} \end{Bmatrix} = K_{H0} \cdot [0.337 + 0.663 \cdot e^{-4.64 \cdot \gamma}] \cdot \left(I - \left(\frac{P}{P'_{cr}} \right)^2 \right) \cdot \begin{Bmatrix} u_{H,x} \\ u_{H,y} \end{Bmatrix} \quad (1a,b)$$

$$P_K = \bar{K}_{V0} \cdot u_V^* \cong \frac{K_{V0} \cdot \text{sgn}(u_V)}{1 + 48 \cdot \left(\frac{u_H}{\pi \cdot D_b} \right)^2} \cdot \left(|u_V| - \frac{16 \cdot \alpha_b}{\pi^2 \cdot D_b \cdot S_2 \cdot \alpha_{K0}} \cdot u_H^2 \right) \quad (1c)$$

where $\alpha_{K0}(=K_{V0}/K_{H0})$ is the nominal stiffness ratio, P'_{cr} is the reduced critical buckling load and $\alpha_b=h_b/t_r$, h_b being the total height of the bearing. It is worth noting that the horizontal stiffness is characterized by significant variation when shear deformation (γ) is lower than 1 and is practically constant for γ values greater than 1. On the other hand, taking into consideration that the equivalent viscous damping in the horizontal direction depends on the amplitude of displacement, the bearing is subjected to and, ultimately, on the amplitude of the shear strain [15], the following uncoupled damping axial forces ($F_{C,x}$, $F_{C,y}$ and P_C), proportional to the horizontal and vertical velocity ($\dot{u}_{H,x}$, $\dot{u}_{H,y}$ and \dot{u}_V), are assumed

$$\begin{Bmatrix} F_{C,x} \\ F_{C,y} \end{Bmatrix} = \bar{C}_{H0} \cdot \begin{Bmatrix} \dot{u}_{H,x} \\ \dot{u}_{H,y} \end{Bmatrix} = C_{H0} \cdot [0.543 + 0.457 \cdot e^{-2.843 \cdot \gamma}] \cdot \begin{Bmatrix} \dot{u}_{H,x} \\ \dot{u}_{H,y} \end{Bmatrix} \quad (2a,b)$$

$$P_C = C_{V0} \cdot \dot{u}_V \cong \frac{\xi_V \cdot K_{VI} \cdot T_{IV}}{\pi} \cdot \dot{u}_V \quad (2c)$$

with significant differences for low horizontal displacements and almost the same values when $\gamma > 1$ are obtained (see Equations 2a,b).

For sliding bearings with low values of the friction coefficient (i.e. steel-PTFE low friction flat sliding bearings, LFSBs), the force-displacement behaviour in the horizontal directions can be idealized as bilinear (rigid-plastic). In particular, variable axial load (i.e. $N = W \pm \Delta N$, W being the weight of the superstructure and ΔN the additional axial load, positive when compressive, due to the overturning moment produced by the horizontal ground acceleration) and constant value of the friction coefficient (i.e. μ equal to the dynamic fast value μ_{max}) can be represented by hysteretic model with biaxial interaction

$$\begin{Bmatrix} F_x \\ F_y \end{Bmatrix} = \mu \cdot N \cdot \begin{Bmatrix} Z_x \\ Z_y \end{Bmatrix} = \mu_{max} \cdot N \cdot \begin{Bmatrix} Z_x \\ Z_y \end{Bmatrix} = \mu_{max} \cdot N \cdot \begin{Bmatrix} \cos\theta \\ \sin\theta \end{Bmatrix}, \quad \theta = \arctan\left(\frac{\dot{u}_{H,y}}{\dot{u}_{H,x}}\right) \quad (3a,b)$$

where the dimensionless quantities Z_x and Z_y are governed by two coupled differential equations which account for the interaction between the x and y directions [4]. Furthermore, a gap element with infinitely rigid behaviour in compression is assumed in the vertical direction to account for the fact that a sliding bearing does not resist tensile axial loads and is thus free to uplift at any given moment during an earthquake

$$P = N \quad \text{for } u_V \geq 0 \quad \text{and} \quad P = 0 \quad \text{for } u_V < 0 \quad (3c)$$

neglecting the equivalent viscous damping in the vertical direction.

3 CONNECTION FOR MITIGATING OF INTERNAL POUNDING

A seismic gap (g_d) between the fixed-base elevator shaft (Es) and base-isolated surrounding building (Sb) (Figure 3a) is first designed on the basis of current Italian [6] and European [7] seismic codes. Specifically, three different thresholds are evaluated as function of the lateral load resisting system (i.e. base-isolated or fixed-base structure), the LS (i.e. $PGA_{LS} = 0.324$ g) and CP (i.e. $PGA_{CP} = 0.413$ g) limit states and the elevator height (i.e. $H = 14.06$ m): i.e. sum of the horizontal top displacements of both systems at the LS limit state (i.e. $g_{d,NTC18} = 33$ cm), no less than $2 \cdot H / 100 \cdot a_g \cdot S/g$; square root of the sum of the squares of the maximum top horizontal displacements of both systems, at the LS (i.e. $g_{d,EC8.1} = 24$ cm) and CP (i.e. $g_{d,EC8.2} = 35$ cm) limit states. To ensure that the seismic gap is large enough to cope with sizeable horizontal displacements induced by strong earthquakes, the Es-Sb relative displacements are evaluated along the in-plan X (i.e. $u_{Es,i}$ and $u_{Sb,i}$) and Y (i.e. $v_{Es,i}$ and $v_{Sb,i}$) directions

$$g_{X,i}(t) = u_{Es,i}(t) - u_{Sb,i}(t), \quad g_{Y,i}(t) = v_{Es,i}(t) - v_{Sb,i}(t), \quad i = 1-4 \quad (4a,b)$$

on the assumption that a positive value corresponds to a coordinate of the Es corner greater than that of the corresponding Sb corner (Figure 3b).

Then, the problem of connecting two different subsystems of the same structure is examined for four types of connection between the four couples of corner joints at each floor level (Figure

3c): i.e. flexible links (FLs); rigid links (RLs); viscous damped links (VDLs); eddy current damped links (ECDLs).

Figure 3: Internal pounding between the fixed-base elevator shaft and base-isolated surrounding building

Once selected the type of connection, the model of coupling between the base-isolated Sb and fixed-base Es is made under the following assumptions along both the principal in-plan directions (X and Y): i) mass, stiffness and damping of the Sb ($m_{Sb,j}$, $k_{Sb,j}$ and $c_{Sb,j}$) and Es ($m_{Es,j}$, $k_{Es,j}$ and $c_{Es,j}$) and stiffness and damping of the connective links ($k_{L,j}$ and $c_{L,j}$) can be varied along the height ($j=0-3$); ii) viscous damping of the Sb is considered only at the isolation level ($c_{Sb,0}$), while the contribution of the superstructure is not considered; iii) assuming an equivalent viscous damping ratio $\xi_{Es,H}=2\%$, the Rayleigh approach is used to evaluate the viscous damping of the Es; iv) the Sb and Es are modelled as shear- (r.c.) and flexible-type (steel) plane frames, respectively; v) classical damping simplification is assumed, given that the fundamental frequencies of Sb and Es are well separated; vi) floor elevations are the same for Sb and Es, without taking into account the extra head at top of the elevator shaft; vii) the Sb and Es are connected only at the top floor (case A, Figure 4a) or at all floors (case B, Figure 4b).

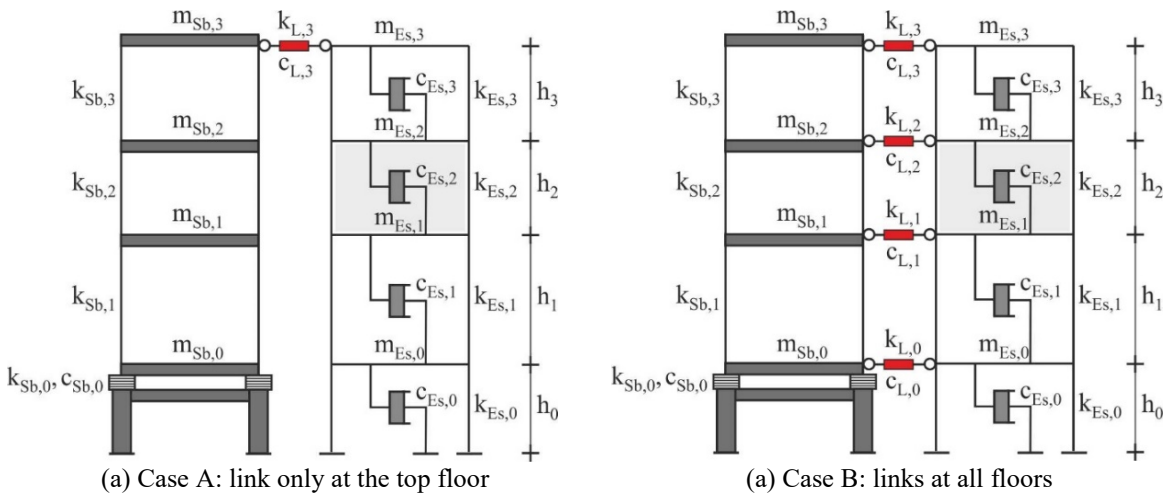

Figure 4: Model of coupling between surrounding building (Sb) and elevator shaft (Es)

The main properties of the surrounding building (Sb) and elevator shaft (Es) are reported in Table 3. It should be noted that Sb stiffness is the same for the principal X and Y directions, since all columns have a square section, while stiffness and damping of Es are not reported because a static condensation of the number of degrees of freedom reduces the number of free displacement to eight (i.e. four horizontal displacements for Sb and Es, respectively).

A design procedure of the links ($k_{L,j}$) is first developed to evaluate the distribution of vertical stiffness, with the aim of minimizing horizontal displacement of the elevator at all levels (u_j , $j=0-3$). In detail, a four-sweep-four-step iterative approach is adopted, in which the k -th sweep consists of four steps each with the aim of evaluating stiffness by reducing the horizontal displacement at one level at a time, for fixed values of stiffness at the other levels. Then, damping force of the dissipative links is evaluated based on a stiffness-proportional criterion, with equivalent viscous damping ratio $\xi_{DL,H}=25\%$. Results of the iterative procedure, in terms of the horizontal displacement ratio ($u_j/u_{j,max}$), are shown in Figure 5, with reference to both principal in-plan directions assuming that the most critical internal pounding condition occurs when the elevator with maximum load stops at the first level (Figure 4).

Table 3: Main properties of the model of coupling between Sb and Es

Floor level	h_i [m]	m_{Sb} [ton]	k_{Sb} [kN/m]	c_{Sb} [kNs/m]	m_{Es} [ton]
0	2.85	722	16450	1798	1.847
1	4.25	776	563670	-	1.660
2	3.12	631	1260500	-	3.939
3	3.12	271	212830	-	0.714

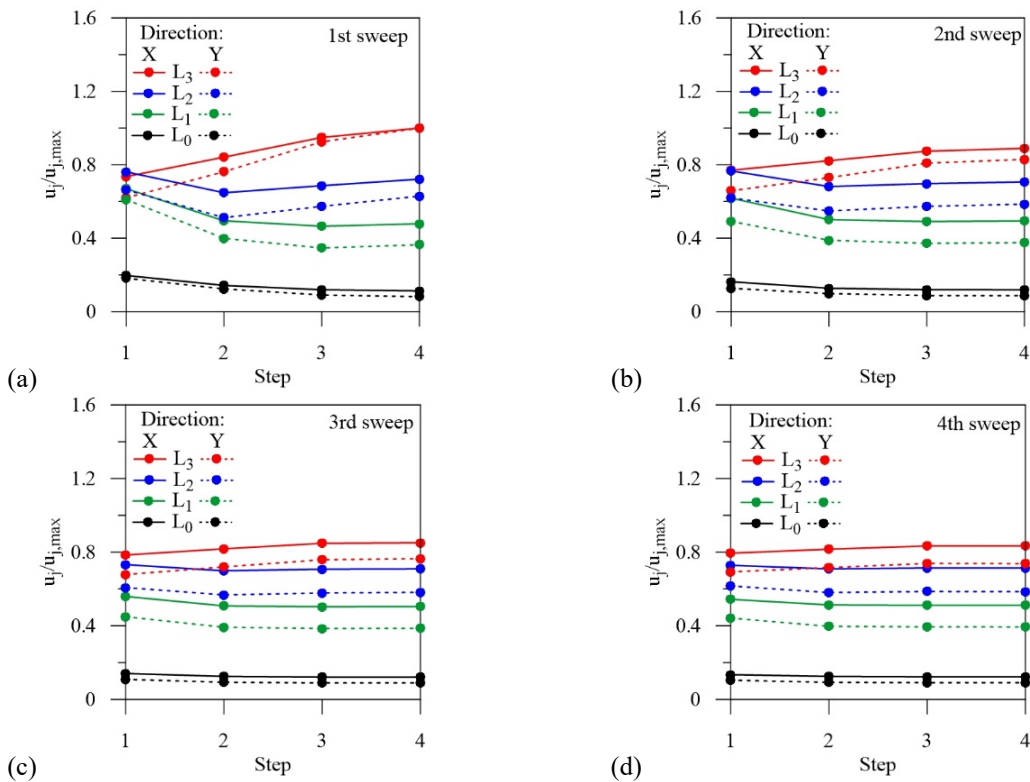

Figure 5: Results of the four-sweep-four step iterative design procedure of links

Note that maximum displacement (i.e. $u_j/u_{j,max}=1.0$) is obtained to step four of the first sweep along both the principal in-plan directions (Figure 5a). Moreover, gradual reduction of the ratio $u_j/u_{j,max}$ occurs at all four levels proving the effectiveness of the iterative procedure (Figure 5d). Finally, stiffness and damping properties of the links are summarized in Table 4 for cases A and B and both principal directions.

Table 4: Main properties of links (units in kN, m and s)

	Case A: X direction		Case A: Y direction		Case B: X direction		Case B: Y direction

A sketch of an Eddy Current Damped Link (ECDL) is shown in Figure 6, consisting of an outer cylindrical tube, as conductor, and an array of axially magnetized ring-shaped permanent magnets, separated by iron pole pieces, as a mover [13]. In detail, eddy currents are generated in the copper conductor following the relative motion from the magnets, where the direction of magnetization for each permanent magnet is indicated by bold arrows. It should be noted that these eddy currents produce an electromagnetic damping force proportional to the velocity of the conductor so that the ECDL acts as a viscous damper but with a significant improvement because it takes up less space. For the sake of brevity, only the main parameters of the ECDL are reported in Table 5, with reference to maximum values of stiffness and damping shown in Table 4 in the Y direction: i.e. t_c , conductor thickness; t_m , magnet thickness; t_p , pole thickness; r_m , annular magnet radius; r_r , cylindrical rod radius; air gap, a_g ; number of magnets (n_m) and poles (n_p); conductivity of copper, σ_c ; residual magnetic flux density, B_r .

4 NUMERICAL RESULTS

To investigate the effectiveness of different types of connection between Sb and Es of the Augusta building for mitigating internal pounding, nonlinear dynamic analyses are carried out

considering the horizontal components of seven spectrum-compatible near-fault earthquakes characterized by forward directivity [4]. R.c. frame members of the superstructure are described by a lumped plasticity model, while an elastic-linear response consistent with the design hypotheses is adopted for the steel framed structure of the elevator shaft. On the other hand, the three-degrees-of-freedom model of the HDRBs and the simplified model of the LFSBs, previously described, are adopted for the hybrid isolation system. Preliminary analysis is carried out with a view to identifying the critical incidence angle of the selected bi-directional earthquakes (i.e. $\alpha=150^\circ$), then results are obtained as the mean of those for each pair of records.

Firstly, plots of the maximum internal pounding parameter (i.e. the relative displacements g_x and g_y between Sb and Es) along the building height are reported in Figure 7, for the adjacent corner joints n.1 (Figures 7a,b) and n.3 (Figures 7c,d) and both directions. Flexible (FL) and rigid (RL) links without dissipation are compared with viscous damped (VDL) and eddy current damped (ECDL) links, assuming connection only at the top floor (case A) or at all floors (case B). As shown, internal pounding is confirmed for the unlinked configuration, exceeding in some cases the EC8 upper and lower bound values (Figure 7b) and in others the NTC18 threshold (Figure 7c). In terms of mitigation of internal pounding, the best performance is attained when more than one connection is considered (case B). Moreover, coupling of stiffness and damping (i.e. ECDLs) is more effective than a viscous connection on its own (i.e. VDLs) or a flexible spring (i.e. FLs). With reference to rigid links, the observed performance highlights remarkable reduction of internal pounding.

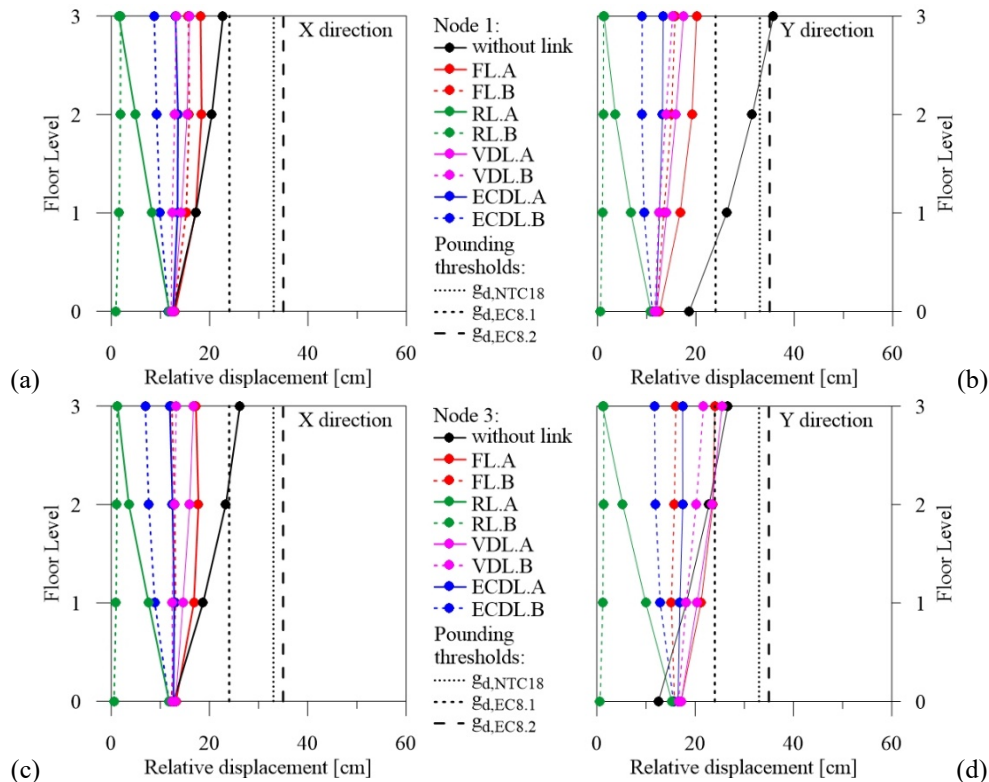

Figure 7: Internal pounding of Sb and ES along the building height

Graphs similar to the previous ones are shown in Figure 8, where maximum values of floor acceleration (Figures 8a,b) and storey drift (Figures 8c,d) of the elevator shaft at corner joint n. 2 are plotted, with a view to serviceability and damage conditions, respectively. It is interesting to note that ECDLs continue to prove the best coupling solution. On the contrary, FLs and RL.A correspond to accelerations comparable with those of the solution without link, while RL.B is ineffective at reducing storey drift, producing too high values at level 0 where the elevator shaft is forced to undergo the same displacement as the isolation system when connection at all levels is assumed.

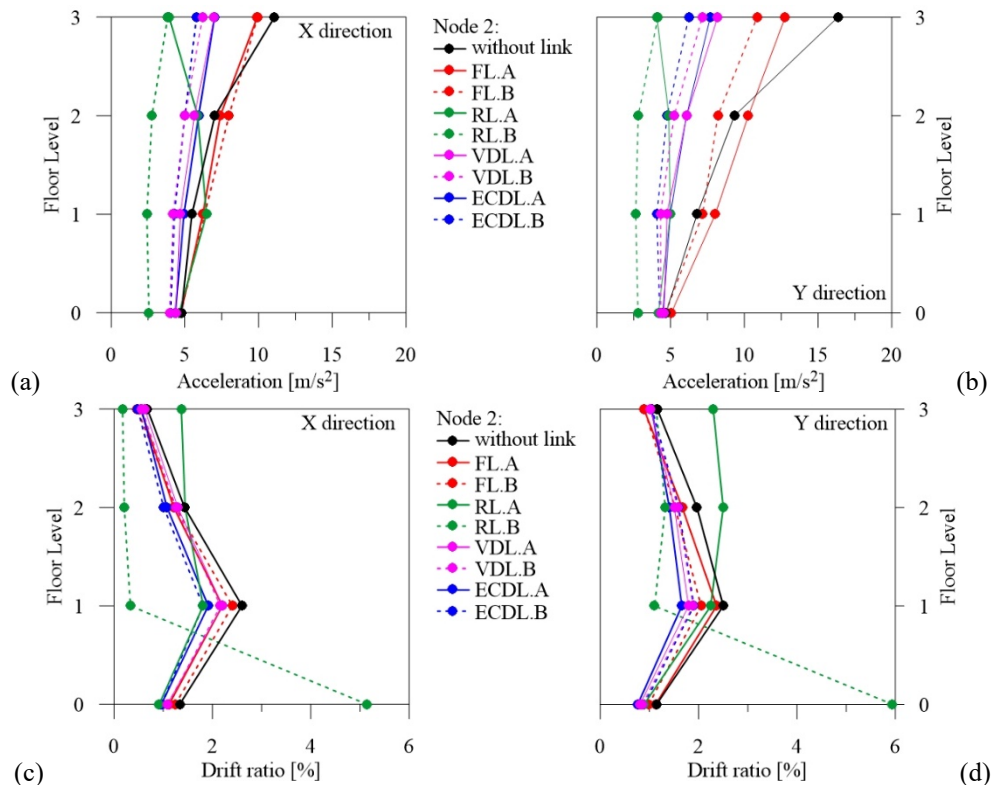

Figure 8: Floor acceleration (a, b) and storey drift (c, d) of the ES along the building height

5 CONCLUSIONS

The effectiveness of coupling between independent units of seismically isolated buildings located near an active fault for mitigating internal pounding is investigated here, through a case study of a four-storey r.c. framed structure in the Italian town of Augusta (Sicily). An elastomeric-friction hybrid isolation system at ground level, crossed by the steel framed structure of a fixed-base elevator shaft, is considered. First, a four-sweep-four-step iterative design procedure is proposed, to evaluate stiffness and/or damping properties of four types of connections between the four couples of corner joints, only at the top floor or at all floors: flexible links (FLs); rigid links (RLs); viscous damped links (VDLs); eddy current damped links (ECDLs). Then, nonlinear dynamic analysis is carried out to test their performance during spectrum-compatible near-fault earthquakes. The results show that the coupling of stiffness and damping (ECDLs) is always more effective than a viscous connection (VDLs) on its own, while

FLs and RL.A are ineffective because of accelerations comparable with those of the solution without link, and RL.B produces excessive storey drift, especially at isolation level.

Key words: Hg(II)-imprinted polymer gels, Smart materials, Solid phase extraction, Mercury speciation, Cold vapor atomic absorption spectrometry.

Abstract. In this study, Hg(II) imprinted copolymer gels (Hg(II)-IIPs) are prepared and used as smart sorbents for selective solid phase extraction of mercury ions from surface water samples. Hg(II)-IIPs are synthesized by dispersion copolymerization of 1-vinylimidazole, methacrylic acid or 2-hydroxyethyl methacrylate as functional monomer, trimethylolpropane trimethacrylate as cross-linking agent and 2,2'-azoisobutyronitrile as initiator in the presence of a Hg(II)–1-(2-thiazolylazo)-2-naphthol (Hg(II)-TAN) complex. The structure and morphology of the prepared Hg(II)-IIPs are defined using scanning electron microscopy, and nitrogen adsorption–desorption measurements. The extraction efficiency (degree of sorption/desorption, selectivity, capacity) of the Hg(II)-IIPs toward inorganic mercury ion (Hg(II)) are studied using batch procedure. The optimal pH value for the quantitative sorption is 7, and full desorption is achieved by 0.1 mol/L thiourea in 0.1 mol/L HCl. The Hg(II)-IIPs exhibit excellent selectivity towards Hg(II) over methylmercury, Cd(II), Ni(II) and Pb(II), due to the introduced memory effect. The prepared copolymer gel with 1-vinylimidazole as a functional monomer has higher capacity and selectivity towards Hg(II). Adsorption process is characterized by Langmuir isotherm model. Analytical scheme for Hg speciation and enrichment in surface waters is developed based on the high selectivity of Hg(II)-IIPs toward Hg(II).

1 INTRODUCTION

Mercury and its compounds are considered extremely harmful and toxic environmental pollutants and according to the European legislation are identified as priority hazardous substances [1]. Although all mercury species have detrimental impact on the human and ecosystems health, their toxicity, mobility and bioavailability strongly depend on the particular chemical form. In general, organic Hg species, especially methylmercury (MeHg) are known to be much more toxic than inorganic (e.g. Hg(II) and Hg(I)) because of their lipid solubility which facilitates relatively easy passing through biomembranes and subsequent accumulation in living cells. Due to the significant differences between toxicity of Hg(II) and MeHg as well as their extremely low concentrations in the environment, a reliable procedure for enrichment and further speciation analysis is often required. Widely used approach in analytical practice is based on preliminary separation and preconcentration of the mercury species by solid-phase extraction (SPE) with ion imprinted polymers.

Ion imprinted polymers (IIPs) are a new generation synthetic “smart” materials combining the selective recognition properties for a template ionic species with the ability to respond to specific external stimuli (such as the presence of another ions, pH, magnetic field etc.) with consequent changes in their properties including the affinity of the polymeric matrix toward the template [2, 3]. Based on ion imprinting technology “smart materials” are created by integrating a template ion into the polymer network during the preparation of these polymeric materials. [4, 5]. In brief, the most commonly used synthetic scheme for the preparation of IIPs involves several stages: (i) complexation of a template species (metal ions or their complexes with specific ligands) with functional monomers, (ii) copolymerization of these monomers around the template ion with the help of a cross-linking agent in the presence of an initiator, and (iii) removal of the imprinted ion by extraction which leaves cavities with a size, shape, charge and chemical functionality complementary to those of the template ion species. Thus, ion level information is transferred from the template ion species to the polymers in the form of a three-dimensional “memory” of the template’s characteristics. IIPs have the advantage that they not only can respond to external stimuli, but they also have ion recognition ability for template ion species [5, 6]. Choosing the right functional monomer and chelating ligand is very important because this will determine, on one hand, the stability of the complex formed before and during the polymerization process and, on the other hand, the subsequent ability of the IIP to interact selectively with the target ion. Numerous studies on IIPs and their application for selective preconcentration and separation of Hg species have been reported [7-15]. Recently, our group reported an easy synthetic procedure for synthesis of Hg(II)-IIPs via dispersion copolymerization using methacrylic acid (MAA) as a monomer, trimethylolpropane trimethacrylate as a cross-linking agent and 1-(2-thiazolylazo)-2-naphthol (TAN) [8] or pyrrolidine dithiocarbamate [9] as specific Hg(II) ligands. According to authors’ knowledge, the effect of the type of functional monomer (basic, acidic or neutral) on the adsorption properties and selectivity of Hg(II)-IIPs has not been investigated yet.

In the present study, Hg(II)-IIPs were synthesized via dispersion copolymerization using three different functional monomers – MAA, 1-vinylimidazole (VIA) or 2-hydroxyethyl methacrylate (HEMA), trimethylolpropane trimethacrylate (TMPTMA) as a cross-linking agent, and TAN as a non-polymerizable chelating agent and Hg(II) as a template ion. Critical comparison between extraction efficiencies, adsorption capacities, and selectivities of Hg(II)-imprinted copolymer gels prepared on the basis of MAA, VIA or HEMA was presented. Finally, SPE procedure using Hg(II)-IIPs as sorbent and next subsequent cold vapor atomic absorption spectrometric (CV AAS) measurements were developed and applied for Hg speciation in water samples. The analytical scheme proposed consists of two steps: (1) selective determination of Hg(II) and (2) determination of total Hg as Hg(II) after water sample digestion. The content of methylmercury is defined as the difference between these two measurement results.

2 EXPERIMENTAL

2.1 Materials

1-Vinylimidazole (VIA), methacrylic acid (MAA), 2-hydroxyethyl methacrylate (HEMA), trimethylolpropane trimethacrylate (TMPTMA), 2,2'-azobisisobutyronitrile (AIBN), thiourea (TU) (Merck), 1-(2-thiazolylazo)-2-naphthol (TAN, Fluka)) and acetonitrile (ACN, Labscan)

were used to prepare the Hg(II) ion-imprinted and non-imprinted polymer sorbents. Stock standard solutions for Hg were: inorganic Hg(II), stock standard solution for AAS, Trace CEPT™, 998 µg/mL in 2 mol/L HNO₃, (Sigma-Aldrich). Methylmercury stock solutions (100 mg/L) were prepared by dissolving the appropriate amount of methylmercury(I) chloride (highly toxic, handle with care), PESTANAL®, analytical standard, Fluka (33368) in 5 mL of methanol and diluting to 100 mL with water. The exact concentration of this solution was defined against standards prepared from inorganic Hg(II). All stock solutions were stored in dark glass bottles at 4 °C. Working standard solutions for calibration were freshly (daily) prepared by successive dilution and contained reagents used for sample preparation or elution; e.g. 0.1 mol/L thiourea in 0.1 mol/L HCl. Reductant solutions of sodium tetrahydroborate(III) NaBH₄ (Merck) 0.04 % (m/V) and 0.4% (m/V) in 0.1 % (m/V) NaOH were prepared fresh daily and was used without filtration. The stock standard solutions for Cd(II), Ni(II) and Pb(II) (1000 µg/mL) were Titrisol (Merck), in 2 % HNO₃ (V/V).

All reagents were of analytical-reagent grade and all aqueous solutions were prepared in deionized water (DW).

2.2 Apparatus

CV AAS measurements were carried out with a Perkin Elmer AAnalyst 400 atomic absorption spectrometer (Perkin Elmer, USA) equipped with a MHS 15 Mercury Hydride System and externally heated quartz tube atomizer at room temperature for inorganic Hg(II) and in air/acetylene flame for MeHg. The optimal instrumental parameters for Hg species determination include: pre-reaction purge time 7 s, post reaction purge time 60 s. Solutions of NaBH₄ 0.04 % (m/V) and 0.4 % (m/V) were used as reductants for inorganic Hg(II) and MeHg respectively.

A scanning electron microscope (SEM, JEOL JSM-5500) was used for the determination of the microbead shape and morphology. Specific surface area and pore size distribution were measured through nitrogen adsorption–desorption isotherms at 77 K using a Brunauer–Emmett–Teller (BET) analyzer (Quantachrome NOVA 1200, Quantachrome). A microprocessor pH meter (Hanna Instruments) was used for pH measurements. A centrifuge EBA 20 (DJB Labcare) was used to separate micro particles and extracted metal ion solution in batch experiments.

2.3 Synthesis of the Hg(II) ion-imprinted and non-imprinted copolymer gels

The imprinted and non-imprinted copolymer gels were synthesized as described earlier with minor modification [16]. Reaction scheme for Hg(II)-IIPs preparation is shown in Fig. 1. As template the complex (0.046 mmol) of the imprinted ion Hg(II) with TAN was used. The Hg(II)-IIPs were prepared via a cross-linking dispersion copolymerization using three various functional monomer – VIA, MAA or HEMA (0.862 mmol), TMPTMA (0.373 mmol) as a cross-linking agent, AIBN (32 mg) as an initiator, and acetonitrile (10 mL) as a porogen solvent at temperature 60 °C for 24 h. The following types copolymer gels were prepared: (i) with VIA as a functional monomer (named Hg(II)-VIA-IIP); (ii) with MAA as a functional monomer (named Hg(II)-MAA-IIP); (iii) with HEMA as a functional monomer (named Hg(II)-HEMA-IIP); and (vi) non-imprinted polymers (named VIA-NIP, MAA-NIP and HEMA-NIP) synthesized in the same way as described above, in the absence of template. They were

recovered by centrifugation, washed with ACN to remove unreacted monomers and other ingredients.

Mercury was removed from the produced polymer networks by several, sequential elution steps using 4 mol/L HNO₃ and 0.5 mol/L TU in 0.5 mol/L HCl as eluents. This procedure was repeated until the Hg concentration (template ions) in the eluate solution is below the LOD as measured by CV AAS. Then IIPs were dried in a vacuum oven at 60 °C. The non-imprinted polymer gels were treated in the same way.

2.4 Solid-phase extraction of Hg(II)

A portion of the solution containing 0.1 µg Hg(II) was diluted to a 10 mL total volume and pH was adjusted with buffer solution to the desired value. Polymer microbeads of ca. 50 mg were added to this solution and stirred for 20 min. The sample was centrifuged (5000 rpm), the supernatant was removed and the polymer gel was washed twice with DW. In order to investigate the degree of Hg(II) sorption the supernatant was collected and analyzed by CV AAS as an effluat. The Hg(II) was eluted from the copolymer gels with 2 mL of various reagents for 30 min. The degree of Hg elution was determined in the eluate solutions by CV AAS.

The degree of sorption (D_S %) of Hg(II) ions is defined as:

$$D_S \% = [(A_i - A_{eff}) / A_i] \cdot 100, \quad (1)$$

The degree of elution (D_E %) of sorbed Hg(II) ions from loaded sorbent is defined as:

$$D_E \% = (A_{el} / (A_i - A_{eff})) \cdot 100, \quad (2)$$

where A_{el} [µg] is the amount of metal cations in solution after elution process.

2.5 Capacity and adsorption isotherms

The adsorption capacity (Q) was defined following the procedure: 50 mg of copolymer gels (imprinted or non-imprinted) were added to 10 mL solution with various concentrations of mercury ions (from 100 to 600 µmol/L) at pH 7. The mixtures were shaken for 20 min at temperature 25 °C. The total mercury ions sorbed was quantified by CV AAS after elution with mixture of 0.1 mol/L TU in 0.1 mol/L HCl. The adsorption capacity ($Q_{max,exp}$), the amount of Hg(II) adsorbed by 1 g of copolymer gel at equilibrium, was calculated according to the equation:

$$Q_{max,exp} = (C_0 - C_e) \cdot V / m, \quad (3)$$

where: $Q_{max,exp}$ is the mass of Hg(II) ions adsorbed per unit mass of the copolymer gel, µmol/g; V is volume of the solution; m is the mass of the sorbent, g; C_0 is concentration of Hg(II) ions in the initial solution, µmol/L; C_e is equilibrium concentration of Hg(II) in solution after adsorption, µmol/L.

2.6 Selectivity experiments

A 10 mL solutions containing model, metals mixture solution containing 5 ng Hg(II), 5 ng MeHg and 10 µg Pb(II) and Ni(II), Cd(II) were treated with the Hg(II)-IIPs or non-imprinted sorbents (50 mg) at pH 7 and shaken for 20 min with an electric shaker. The solutions were

centrifuged, sorbent particles were washed twice with deionized water and elution was performed with 10 mL 0.1 mol/L TU in 0.1 mol/L HCl for 30 min. The concentrations of Hg(II) and MeHg were measured by CV AAS and Cd(II), Ni(II), Pb(II) in the supernatant and eluate solutions were determined by flame AAS.

The distribution ratio (D) is defined as

$$D = (A_i - A_{eff}) / A_{eff} \quad (4)$$

The selectivity coefficient ($S_{Hg/Me}$) is

$$S_{Hg/Me} = D_{Hg} / D_{Me} \quad (5)$$

where D_{Hg} and D_{Me} are the distribution ratios for Hg(II) and Cd(II), Ni(II), Pb(II), and MeHg, respectively.

2.7 Analytical procedure for Hg(II) and MeHg determination in surface waters

Water sample 100 mL was shaken with 50 mg Hg(II)-VIA-IIP for 20 min. After centrifugation (5000 rpm) the supernatant was removed and polymer was washed twice with DW, finally Hg(II) was eluted with 2 mL 0.1 mol/L TU in 0.1 mol/L HCl. The eluate was transferred in 10 mL volumetric flask and diluted up to the mark with DW. Hg(II) was measured by CV AAS under optimal instrumental parameters. In a parallel procedure, 100 mL water sample was MW digested with concentrated nitric acid (in order to transform MeHg into Hg(II)) and then passed through the same already described analytical protocol. In this case the sum Hg(II) + MeHg was determined by CV AAS. Finally, MeHg content in the analyzed water sample was defined as a difference between two measured values.

3 RESULTS AND DISCUSSION

3.1 Synthesis of Hg(II)-IIPs and characterization studies

The functional monomer plays an important role in the adsorption performance of IIPs because from one side it has to interact with the template molecule and give a good polymerization performance with the crosslinking agent and from the other side do not influence the sorption activity of the sorbent. In this work, in order to get Hg(II)-IIPs with high adsorption capacity, selectivity and fast sorption/desorption rate, three different monomers, including VIA (basic), MAA (acidic) and HEMA (neutral) were synthesized and studied.

Hg(II)-IIPs were synthesized by “trapping” technique, i.e. complexes between target metal ion and non-vinylated chelating agent were trapped inside the polymer matrix during the polymer formation. Preparation of Hg(II)-IIPs included several steps (Fig. 1). The first one was formation of the prepolymerization complexes between template species (complex of Hg(II) ion with TAN) and the functional monomers (VIA, MAA or HEMA) in ACN. The second step was, the dispersion cross-linking copolymerization of these complexes with the TMPTMA as cross-linking agent producing copolymer network. Finally, Hg(II) ions were removed from copolymer gels prepared leaving behind some specific binding sites with functional groups in a predetermined orientation and cavities with special size of templates.

Scanning electron micrographs of the obtained Hg(II)-VIA-IIP and VIA-NIP copolymer particles are shown in Fig. 2. Analogous micrographs are obtained for Hg(II)-MAA-IIP, Hg(II)-HEMA-IIP, MAA-NIP and HEMA-NIP. As can be seen from Fig. 2, the shape of particles

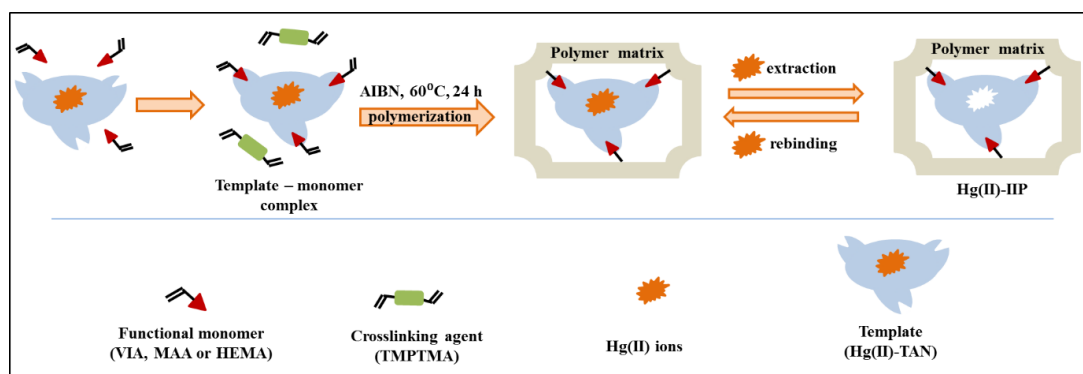

Figure 1: Scheme of the Hg(II)-IIPs preparation.

Figure 2: Scanning electron micrographs of Hg(II)-VIA-IIP and VIA-NIP at a 10 000× magnification.

of the non-imprinted copolymer gel is close to spherical. The surface structure and morphology of the particles of Hg(II)-imprinted sorbent is different – Hg(II)-VIA-IIP is in the form of bigger aggregates with irregular shape. Rough surface of ion imprinted polymers as compared to the non-imprinted polymer suggests that cavities were formed on the sorbent surface after template removal [17].

The specific surface area, total pore volume and average pore diameter, for the Hg(II)-IIPs and non-imprinted copolymer gels were determined from nitrogen adsorption–desorption isotherms. The three Hg(II)-imprinted copolymer gels have similar surface areas (Hg(II)-VIA-IIP: 4 m²/g; Hg(II)-MAA-IIP: 5 m²/g; and Hg(II)-HEMA-IIP: 3 m²/g) and average pore diameters (9 nm, 15 nm and 12 nm, respectively), while non-imprinted copolymer gels have higher surface area (VIA-NIP: 55 m²/g; MAA-NIP: 28 m²/g; and HEMA-NIP: 9 m²/g) and average pore diameters (15 nm, 28 nm and 18 nm, respectively). As it is evident, all the polymer gels studied could be described as a mesoporous structures. These typical results after imprinting are explained with the incorporation of Hg(II)-TAN complex in polymer network which causes a certain filling of the pores and reduced adsorption of N₂ [18].

3.2 Optimization of chemical parameters for quantitative sorption and desorption of Hg(II) with Hg(II)-imprinted and non-imprinted copolymer gels

The sorption of metal ions on the IIPs resulted from the combined effect of the chemistry of metal ions in aqueous solutions and their interactions with the chelating agent and the functional

groups present in the polymeric network. The extraction efficiency of three synthesized copolymer gels toward Hg(II) was studied at pH values in the range 3–8 (Section 2.4). The results obtained for the influence of pH on Hg(II) selective sorption are presented in Fig. 3. As can be seen the degrees of sorption for Hg(II)-MAA-IIP and Hg(II)-VIA-IIP were significantly higher than those of other studied sorbents. The quantitative sorption of Hg(II) ions on the Hg(II)-MAA-IIP and Hg(II)-VIA-IIP was achieved at pH 7, while for the sorbent imprinted with HEMA as a functional monomer the maximal degree of sorption was around 85%. Probably the neutral functional monomer HEMA could not form a stable prepolymerization complex with template molecule (Hg(II)-TAN complex) and the prepared copolymer gel had less amount of specific Hg(II) binding cavities [19]. In the same time, for the weak basic and acidic functional monomers VIA and MAA, the prepolymerization complex formed more stable structures, and the specific binding cavities could remain in the prepared IIPs, which provides quantitative sorption of the analyte and high adsorption capacity (see Section 3.3). The adsorption pattern for non-imprinted copolymer gels was found similar to Hg(II)-IIPs, but as might be expected in all cases lower degrees of sorption were observed (Fig. 3). This can be attributed to the non-specific interaction of Hg(II) with the functional groups in the polymer matrix and the lack of specific binding sites. Moreover, monomers aggregation leading to a suppressed number of binding sites in the NIPs additionally affected the adsorption efficiency [20].

The choice of the suitable eluent is important for the next application of sorbent in analytical procedure for solid phase extraction. In order to elute mercury adsorbed on the copolymer gels, different eluents were tested (HNO_3 , HCl , $\text{HCl} + \text{TU}$). Among the acids employed as eluents, HCl has been reported to have an enhanced performance due to its complexing abilities toward mercury. However in the present study the quantitative elution of Hg(II) could not be achieved even with 4 mol/L HCl . Quantitative elution of adsorbed Hg(II) was achieved using a combination of 0.1 mol/L thiourea in 0.1 mol/L HCl with minimum volume of 2 mL. The kinetics of both processes of sorption and desorption of Hg(II) were investigated by batch procedure with 50 mg of imprinted nanoparticles for 5–60 min. Quantitative sorption was reached for 20 min while for quantitative desorption 30 min has to be used.

Figure 3: pH-dependence of the degree of sorption of Hg(II) ions onto Hg(II)-imprinted and non-imprinted copolymer gels (50 mg polymer gel, $T = 25\text{ }^{\circ}\text{C}$).

3.3 Capacity and adsorption isotherms

The maximum experimental sorption capacity ($Q_{max,exp}$) of the Hg(II)-MAA-IIP, Hg(II)-VIA-IIP, MAA-NIP and VIA-NIP was determined after saturation of the sorbents with mercury ions under optimum conditions at temperature 25 °C (Fig. 4a). For this purpose, increasing amounts of Hg(II) (100–600 $\mu\text{mol/L}$) were added to 50 mg copolymer gel and the equilibrium Hg(II) concentration after adsorption was measured by CV AAS. As can be seen in Fig. 4a, the amount of Hg(II) adsorbed per unit mass of sorbent increased with the initial concentration of Hg(II) and reach the plateau values, determining the adsorption capacity values. The determined $Q_{max,exp}$ of Hg(II)-MAA-IIP, Hg(II)-VIA-IIP, MAA-NIP and VIA-NIP are given in Table 1. As expected the adsorption capacity of Hg(II)-IIPs are higher versus non-imprinted polymer gels, indicating that the cavities created after removal of the template in Hg(II)-imprinted polymer gels are more complementary to the imprinted ion in size, shape, and chemical functionality. The results presented in Table 1 also show that the polymer gel containing the basic functional monomer VIA (78.0 $\mu\text{mol/g}$) has higher adsorption capacity than the polymer synthesized using acidic MAA (73.7 $\mu\text{mol/g}$).

τ **Table 1:** Adsorption parameters of the Langmuir isotherm model for the adsorption of Hg(II) ions onto the imprinted and non-imprinted polymer gels-at temperature 25°C

Copolymer gel	$Q_{max, exp}$ ($\mu\text{mol/g}$)	Adsorption parameters		
		Q_{max} ($\mu\text{mol/g}$)	b (L/ μmol)	R^2
Hg(II)-VIA-IIP	78.0	78.1	0.033	0.996
VIA-NIP	44.4	44.8	0.117	0.998
Hg(II)-MAA-IIP	73.7	73.5	0.145	0.994
MAA-NIP	38.4	38.1	0.308	0.997

Langmuir isotherm model was used for curve fitting in order to derive data describing adsorption process. According to the Langmuir isotherm theory [21] the sorption process occurs in a surface monolayer of homogenous sites which number is fixed. The expression of the linearized Langmuir isotherm (Eq. (6)) is

$$C_e/Q_e = C_e/Q_{max} + 1/(b \cdot Q_{max}) \quad (6)$$

where: C_e ($\mu\text{mol/L}$) is the equilibrium concentration of Hg(II) in the solution, Q_e ($\mu\text{mol/g}$) is the adsorption capacity of the adsorbed mercury ions onto the copolymer gel at equilibrium, Q_{max} ($\mu\text{mol/g}$) is the theoretical maximum adsorption capacity, b (L/ μmol) is the Langmuir constant that relates to the affinity of binding sites. The linearized Langmuir isotherm (Fig. 4b) and the isotherm parameters calculated from their analysis are presented in Table 2. The high R^2 value achieved for the adsorption of Hg(II) ions onto all copolymer gels show that the Langmuir equation gives very good mathematical fit to the adsorption isotherm. The slope of the curves (Fig. 4b) was used for the calculation of theoretical (monolayer) capacities (Q_{max}) of the Hg(II) on the Hg(II)-IIPs and non-IIPs. The experimental values of sorption capacity, determined according to the procedure described in paragraph 2.5 are very close to the calculated values by Langmuir model (Table 2). The sorption capacities of non-imprinted copolymer gels were lower than these obtained for imprinted particles.

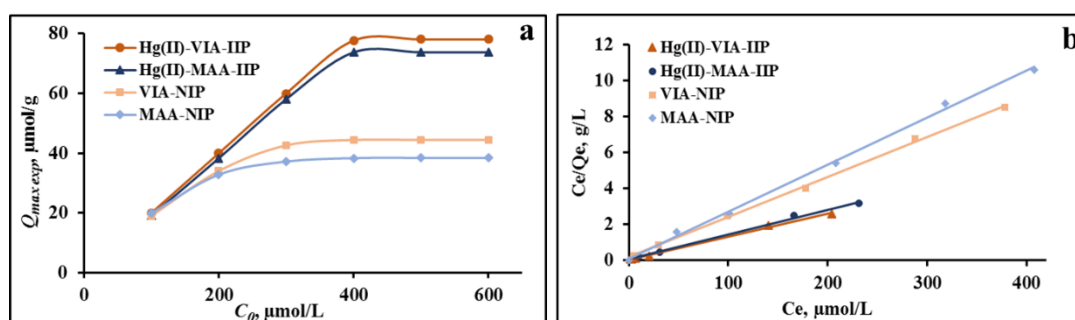

Figure 3: Experimental adsorption isotherms (a) and linearized form of Langmuir isotherm (b) of Hg(II) onto Hg(II)-MAA-IIP, Hg(II)-VIA-IIP, MAA-NIP and VIA-NIP (50 mg copolymer gel, pH 7, $T = 25^\circ\text{C}$).

3.4 Selectivity experiments

The high selectivity toward templated ion is an important characteristic of the imprinted polymers due to specific recognition sites created in the obtained three-dimensional polymer network. In order to confirm the selectivity of Hg(II)-IIPs, a competitive adsorption of Cd(II), Cu(II), Ni(II), Pb(II) and MeHg from their model mixture was studied as well. The experiments were carried out with Hg(II)-MAA-IIP, Hg(II)-VIA-IIP, MAA-NIP and VIA-NIP in batch mode at pH 7. The degrees of sorption (D_S) of cations, achieved by using copolymer gels are given in Fig. 5. The D_S values of Hg(II)-IIPs sorbent toward Hg(II) were highest and decreased in order $\text{Pb(II)} > \text{Cd(II)} \approx \text{Ni(II)} \gg \text{MeHg}$ most probably due to the selective coordination-geometry of the sorbent toward Hg(II) providing the ligand groups arranged in a suitable way required for best coordination of Hg(II) [22]. The greatest difference is established between degrees of sorption of Hg(II) and MeHg. The large size of MeHg probably hinders the ion diffusion and further interaction with functional groups resulting in a very low extraction efficiency of Hg(II)-IIPs toward MeHg and highest values for selectivity coefficients $S_{\text{Hg/Me}} = 4851$ for Hg(II)-VIA-IIP and 4625 for Hg(II)-MAA-IIP (Table 2). These results unambiguously confirm the very good selectivity of Hg(II)-MAA-IIP, Hg(II)-VIA-IIP toward the target (imprinted Hg(II)) ions and its applicability for Hg speciation.

Figure 5: Degree of sorption of template and competitive ions upon SPE with Hg(II)-MAA-IIP, Hg(II)-VIA-IIP, MAA-NIP and VIA-NIP (50 mg copolymer gel, pH 7, $T = 25^\circ\text{C}$).

Table 2: Selectivity coefficients ($S_{Hg/Me}$) of Hg(II)-IIPs and non-IIP for Hg(II)

Copolymer gel	$S_{Hg/Me}$			
	MeHg	Cd(II)	Ni(II)	Pb(II)
Hg(II)-VIA-IIP	4851	254.6	282	210
VIA-NIP	9	8	9	6
Hg(II)-MAA-IIP	4625	136.7	131	131
MAA-NIP	4	5	5	4

3.5 Analytical application

Selective and quantitative sorption of Hg(II) on Hg(II)-VIA-IIP was used for the development of non-chromatographic solid phase extraction procedure for Hg speciation in surface waters. As a first step recovery studies were performed for the influence of water matrix on the selectivity and degree of sorption of Hg(II). Results obtained showed that recoveries in the range between 93-97% were obtained for Hg(II) in the presence of mineral, sea or river water. As a second step the selectivity of Hg(II)-VIA-IIP toward Hg(II) was studied in the presence of increased concentrations of MeHg in matrices like sea water and highly mineralized underground water. The results obtained show that independently of the matrix the selectivity of Hg(II)-VIA-IIP toward Hg(II) is very high. Even at 1:10 ratio between Hg(II) and MeHg the recoveries for MeHg are negligible while for Hg(II) they are close to 95-96%. Additional experiments for the sample volume breakthrough showed that volumes of about 100 mL might be used still ensuring quantitative sorption of Hg(II). As a final step analytical procedure was developed for Hg speciation in surface waters. Two parallel; water samples were prepared with pH adjusted to 7. One of the samples was mineralized and 50 mg of Hg(II)-VIA-IIP sorbent were added to both samples. After sorption the sorbents were recovered by centrifugation, the sorbents were washed with doubly distilled water and elute in a defined eluent mixture followed by Hg measurements by CV-AAS. Total Hg content is determined in mineralized sample and Hg(II) in a parallel nonmineralized one. The content of MeHg is obtained as a difference between these measurements. The analytical figures of merit were defined based on 10 parallel measurements of model solutions containing 5 µg/L of both Hg(II) and MeHg. The detection limits achieved based on 3σ criteria are 0.005 µg/L for Hg(II) and 0.006 µg/L for MeHg. Relative standard deviation varied for both Hg species between 4-9% for concentration range 1-10 µg/L content of Hg. The validity of developed procedure was confirmed by parallel analysis of certified reference material. Additionally, total Hg content determined by developed solid phase extraction procedure agreed very well with content measured by ICP-MS. In addition the sorbent is characterized with good mechanical stability and reusability (almost 50 sorption/desorption cycles with equal extraction efficiency).

4 CONCLUSIONS

In the present paper new Hg(II) imprinted copolymer gels microbeads were successfully synthesized by a dispersion crosslinking copolymerization with VIA, MAA or HEMA as functional monomers in the presence of Hg-TAN complexes as template species. All prepared Hg(II) imprinted copolymer gels are characterized with fast sorption/desorption kinetics and good chemical and mechanical stability. Better binding properties and highest selectivity toward Hg(II) was observed for imprinted copolymer gel based on VIA as monomer. The

application of Hg(II)-VIA-IIP for the determination of inorganic and methylmercury in surface waters samples was demonstrated.

Key words: fiber-optic strain sensors, Bragg grating, process-induced strains, concrete.

Abstract. Strain evaluation in various objects is crucial for preventing accidents. Information about the mechanical state is usually collected by various sensors or using visual inspection methods, according to special maintenance schedule. Fiber-optic strain sensor (FOSS) discover new possibilities for measuring strain in materials. The greatest interest is connected with FOSS applications for materials, in particular concretes, in the volume of which the sensors can be embedded at the technological stage of manufacturing. The information obtained in real time from fiber-optic strain sensor (FOSS) can provide an early warning about the violation of the structure integrity and, thus, help to avoid serious losses. Such information is also useful for adapting and updating new and existing structures. The purpose of this study is to obtain experimental results that demonstrate the possibility of the application of FOSS based on Bragg gratings embedded in concrete to measure strains, including process-induced strains.

1 INTRODUCTION

Concrete structures are a significant part of all engineering structures. However, in many objects made of concrete, one can see serious wear after active use for several years. It is necessary to monitor the mechanical state over time to ensure the safety of such structures. Non-destructive methods are commonly used for structural health monitoring of concrete structures. These methods use a various electrical sensors, as well as sensing elements for displacements, rotations measurements at various points along the structure [1].

Cheaper production and consequently the wide distribution of fiber optics and fiber-optic sensors led to an increased interest in the use of this type of sensors. The first works on the use of fiber-optic strain sensors (FOSS) for assessing the mechanical state in concrete structures began to appear about twenty years ago. The authors of the study [2] showed that FOSS have several advantages compared with standard sensing elements. Various schemes have been developed for the application of FOSS based on fiber Bragg gratings (FBGs) for surface mounting and for embedding in concrete structures. Thus, the authors of [3] carried out a finite-element modeling and proposed a protection scheme for fiber-optic sensors mounted on the surface of the concrete structure. Also, experiments were carried out to confirm the operability

of FOSS to assess the condition of concrete cylinders. In a review paper [4], the main works on the use of FOSS based on Bragg gratings for various engineering structures were gathered. It should be noted that in most of the studies, where the FOSS is embedded inside the concrete, it is encapsulated by a steel tube. Since “pure” FBGs are very fragile in nature this additional steel shell of the FOSS is required to preserve the integrity of the sensor during structural monitoring, as well as to protect the sensor itself from the strong external alkaline environment of the cement. In the review authors also note that in most cases the sensitivity to strain of encapsulated FBG is significantly different from “pure” one. Therefore, calibration of the encapsulated FBG is necessary. This must be done before the sensor is used in the actual structure. In [5], protective coatings of embedded FBGs are considered in detail to determine the deformation of concrete structures. For one particular coating, optimal curing conditions were found that showed good repeatability. The response of the sensor under static load was compared with a surface-mounted electrical resistance strain gauge (ERSG) and an embedded fiber-optic EFPI sensor. Similar work was done by researchers in [6]. The study describes preliminary work of creating an economical and easy-to-use technology of protecting fiber optic sensors by resin using 3D printing methods to create a reliable, inexpensive sensor system usable with concrete structures for surface mounting and for embedding inside. In [7] a method of detection of corrosion cracking of reinforced concrete by FBG is presented. The effectiveness of the proposed method was confirmed experimentally. It is shown, that the crack detection technology using FBG is capable of tracking corrosion cracking in real time. The study [8] compares the readings obtained using FBG with the data obtained by the method of digital image analysis. The test results show that the digital image analysis method gives more accurate cracks development data on the surface area of the structure when compared with FBG. However, the authors showed that the high sensitivity of FBG sensors can be used at low levels of deformation to study very small strain changes that cannot be reliably detected by the digital image analysis method.

It can be noted from the review, that the embedded FOSS based on Bragg gratings in most cases are encapsulated by a metal tube, and, therefore, at least calibration is necessary to obtain reliable values. In addition, there is the danger of inaccurate strain transfer from material to FBG.

The authors have already tested a method for measuring process-induced strains in polymer composite materials using FOSS based on Bragg gratings [9]. This method allows to track the evolution of strain during the entire technological process of product manufacturing from a polymer composite material. In this paper, the authors propose to apply this technique for detection of the process-induced strains in the manufacturing of objects from granular composites, i.e. concrete products, using the embedded fiber-optic strain sensors based on Bragg gratings.

2 THE PRINCIPLE OF FBG OPERATION

A fiber Bragg grating is a section of a single-mode fiber optic core with a periodically varying refractive index. Figure 1 shows the principle of FBG operation: when an optical signal is transmitted through a fiber optic core in a given broadband wavelength range, a part of this signal is reflected on the Bragg grating.

Figure 1: FBG principle [7].

The reflected optical signal has a central wavelength λ , the magnitude of which is directly proportional to the effective refractive index of the core n and the geometric length of the Bragg grating period L . This dependence can be described by the relation:

$$\lambda = 2nL \quad (1)$$

When FOSS interacts with a deformable material, a change in the Bragg grating length occurs, leading to a change in the wavelength of the reflected spectrum $\Delta\lambda$, which is recorded by the interrogator. Under the uniaxial stress state of the optical fiber, the change in the wavelength of the reflected spectrum is related with the strain of the fiber in the Bragg grating zone by the equation [10]:

$$\frac{\Delta\lambda}{\lambda^*} = \left(1 - \frac{n_1^2}{2} (p_{12} - \nu(p_{11} + p_{12})) \right) \varepsilon_3 \quad (2)$$

$$\text{or} \quad \varepsilon_3 = \frac{1}{k} \cdot \frac{\Delta\lambda}{\lambda^*} \quad (3)$$

where ε_3 – axial strain along the optical fiber, p_{11}, p_{12} – Pockels coefficients, ν – Poisson's ratio of the optical fiber.

In [11] it was found that for a silica glass optical fiber that does not interact at the location of the Bragg grating with other solids, the strain coefficient has the value $k \sim 0.78$. It should be noted that in the FOSS embedded in the material there will be a complex stressed state, and using the relation (3) will require additional conditions, for example, the use of calibration coefficients.

3 EXPERIMENT DESCRIPTION

To obtain experimental data and to achieve the objective of the study, an experimental stand was designed and created. An experimental stand is shown in figure 2. The studied problem involves monitoring of the shrinkage process of a test specimen made of concrete B15 for a long period of time. The duration of the experiment is determined by the stages of hardening and drying of the specimen. The duration of the experiment was defined as the time required for the test specimen under the current conditions of temperature and humidity until the shrinkage completely stops.

Figure 2: Experimental stand

The experimental stand is designed in such a way that the shrinkage of the test specimen placed on it passes under the control of all the necessary parameters, the analysis of which can give the information about the completion of the shrinkage process. The elements of the experimental stand include:

- Steel frame (1) with planar dimensions of 300x300 mm and height of 1000 mm, made of metal equal angle 35x35x3 mm. On the frame two movable brackets (2) are placed for laser position sensors at the top and bottom level of the sample. Also on the frame the mounting beam for fiber optic strain sensors line (3) is placed.
- Laser position sensor (4) with built-in microprocessor control system LS (manufactured by PRIZMA, Russia). The range of displacement measurement for the sensor is 10 mm with a resolution of 0.01%.
- Weight platform (5), equipped with two strain gauge strain sensors to control the sample weight. The strain gauges are assembled according to the “Wheatstone Full Bridge” scheme with thermal compensation on a separate part (strain gages produced by UK Sibtenzopribor, Russia).
- Sensor (6) for monitoring the sample temperature (immersion type) - DTS3105PT1000 (manufactured by OWEN, Russia).
- Sensor (7) for monitoring temperature and humidity of the environment - PVT10 (manufactured by OWEN, Russia).
- Sensor interrogation modules and interface converter for communication with a PC - MW110-224.4TD (8), MW110-224.8A (9), AC4 (10) (manufactured by OWEN, Russia).

The sample is a concrete cylinder with a diameter of 150 mm and a height of 400 mm, the formation and curing of which is carried out in a polypropylene tank of cylindrical shape with a bottom and a free top surface of the corresponding dimensions. At the beginning of the experiment, the tank not filled with concrete is placed inside the steel frame of the experimental stand (1) on the weighing platform (5). Inside the tank (through the bottom) on the beam of the stand (3) a fiber-optic strain sensors line is placed on the suspension in the center of the tank. After placing a line of fiber-optic strain sensors, layered (with compaction and vibration) filling of the tank with concrete mix to the level of the free surface is performed. A line of FOSS remains immersed in a concrete sample by means of a plumb with a predetermined pre-tension. Next, laser position sensors LS5 (4) are applied to the bottom of the tank and the upper free surface of the concrete mix to monitor the shrinkage of the sample. A temperature sensor DTS3105Pt1000 (6) is immersed in the sample to monitor its change at all stages of hardening and shrinkage. The change of temperature and humidity of the surrounding space is measured by means of a PVT10 sensor (7) located in the vicinity of the sample on the free surface level of the top of the tank. The weight of the sample is controlled by the weighing platform on which it is placed (5). The weighing platform is equipped with two strain gauge strain sensors assembled according to the “Wheatstone Full Bridge” scheme with thermal compensation on a separate element. All measuring equipment is commuted by means of the MV110-224.4TD (8), MB110-224.8A (9) interrogation modules and the AC4 interface converter (10). After filling the tank with a concrete mixture and setting up all measuring equipment, the stand with the sample is closed with a thermo-insulating casing made of extruded polystyrene foam.

The measurements of the sensors in the 24/7 mode with a frequency of 1 time per second are recorded in the database on a separate personal computer. In the same place, the process of sample hardening is periodically monitored via a graphical interface on the SCADA system. During the manufacture of the sample and throughout the entire technological mode, the data was recorded using the FOSS line with five FBG sensors and the FS 2100 interrogator. The readings from the FBG sensors were recorded 1 time per second for a week into the database on a separate personal computer. Figure 3a shows a scheme of the specimen with embedded FOSS. A fiber line with 5 FBGs spaced 10 mm apart was placed in the center of the sample. Figure 3b shows a photograph of an experimental sample with embedded FOSS based on Bragg gratings.

4 EXPERIMENTAL RESULTS ANALYSIS

Shrinkage of the sample of concrete mix occurs in three stages. The first stage is plastic or capillary shrinkage, which occurs as a result of the water evaporation from the concrete mixture prior to hardening. The second stage is autogenous shrinkage of concrete, associated with direct curing of the mixture and further “drying” as a result of cement hydration and water evaporation during cement exotherm. The third stage - shrinkage during the drying of the sample, associated with the removal of all remaining water, which did not enter into a hydration reaction and was not evaporated at the stage of autogenous shrinkage. Shrinkage during drying depends on the humidity and temperature of the ambient air, being reversible, unlike capillary and autogenous. The control of shrinkage processes, shown in figure 4, allows to determine the time interval after which the shrinkage processes do not lead to a change in the sample geometry. This interval is ~ 13 hours.

Figure 4: Registration of the shrinkage process in the sample

Figure 5 shows the change in process-induced strains recorded for 194 hours by FOSS, placed in the sample according to the scheme shown in figure 3. These results lead to the following conclusions. Process-induced strains in concrete begin to appear after the completion of shrinkage processes, which were controlled by changing the sample geometry. The level of process-induced strains increases with distance from its surface. The results of the change in process-induced strains over time give a qualitative and quantitative picture of relaxation processes in concrete and can serve as the basis for building models, which can quantitatively describe the concrete creep.

Figure 5: Registration of process-induced strains in the sample

5 CONCLUSIONS

- The paper describes the technological process of creating a concrete sample with embedded fiber-optic strain sensors based on Bragg gratings. An experimental stand was designed and built, equipped with the necessary sensors to monitor sample shrinkage.
- With the help of five fiber Bragg gratings, the entire history of process-induced strains arising during the sample fabrication process is recorded in real time and saved.
- A brief description of the principle of the FOSS operation is given, as well as relations for obtaining the strain values with the help of FBG.
- The information on process-induced strains in concrete is received, which allows to give a quantitative idea of their level, assess the non-uniform strain distribution in the volume and the information about the rheological behavior of concrete.

Abstract. This newly developed modelling framework for the simulation of electric current flow in ZnO varistors is based on an equivalent circuit representation of the varistor microstructure, where the grain boundaries are represented by nonlinear resistors in the circuit. The present approach extends similar models introduced earlier by including the effect of mechanical stress on the grain boundary conductivity. This effect is based on the coupling between the semiconducting and the piezoelectric properties of ZnO. The model used for the calculation of single grain boundary conductivities is based on the theories of Blatter et al. and Verghese et al.. It includes a self-consistent solution for the interface charge and for the potential barrier of the boundary, taking into account the local stress in the grain. 2D varistor models are constructed using appropriate Voronoi tessellations. The stress distribution within the material is calculated by FEM, and the electric current flow patterns within the microstructure are obtained by solving the nonlinear circuit equations for each applied voltage and stress condition of the sample. The simulated current-voltage characteristics reveal a significant sensitivity of the bulk electrical conductivity to stress. Furthermore, the simulations demonstrate the current concentration effect in the voltage breakdown region.

1 INTRODUCTION

Zinc oxide (ZnO) was one of the earliest functional materials to see extensive use in many engineering fields, and still plays an important role to this day. In single-crystal form, ZnO is utilised in UV and blue light emitting diodes [1], solar-blind photodetectors [2], transparent thin film transistors [3] and many other applications. Bulk ceramic ZnO is commonly employed as a varistor for voltage surge protection in power transmission lines [4] as well as in low voltage electronic circuits [5]. The capability of ZnO varistors to almost instantly absorb large amounts of electric energy is due to the diode-like current-voltage characteristic of the material. This characteristic is attributed to the double Schottky barriers that form at the boundaries between the individual ZnO grains with an effective electrical response corresponding roughly to that of a back-to-back pair of Zener diodes [6].

Recently, ZnO has attracted great interest as a tunable electromechanical material. The modulation of the electric conductivity of ZnO under applied mechanical stress is due to the piezotronic effect [7]. This effect has been recently studied for tunable ZnO nanowires [8], strain gated transistors [9] and photonic-strain mapping [10]. Specifically, the stress sensitivity of the electrical conductivity for ZnO

varistor ceramics was studied in [11, 12]. The authors observed huge gauge factors of up to 800 for conventionally manufactured ZnO varistor samples of several millimeters in size under applied uniaxial compressive stress of the order of 100 MPa. This clearly qualifies the material for macroscopic scale sensing applications.

The piezotronic effect occurs here due to the coupling between the semiconducting and piezoelectric properties of ZnO. The strain-induced piezoelectric polarization modifies the trapped interface charge distribution at the grain boundaries, thus changing the effective grain boundary potential barriers. This leads to a modification of the current-voltage switching characteristics of the material. Such a mechanism was originally proposed by Verghese et al. [13], where the effect of internal stress on the electrical conductivity of ZnO varistors was studied. However, it was not until very recently that the piezoelectric contribution to the grain boundary conductivity was experimentally verified. Raidl et al. [7] showed that the electrical conductivity for ZnO bicrystals depends on the reciprocal grain polarity as expected by Verghese's theory.

While the basic piezotronic effect at the grain boundaries is well understood, the electromechanical characterization of bulk materials remains a challenge. Macroscopic size varistor samples consist of a large number of grains of different sizes, shapes and crystallographic orientations. Due to these purely geometric factors, each grain boundary experiences a different mechanical stress. Thus, depending on the distribution of crystallographic orientations and the mechanical stress field within the material, the conductivity of some grain boundaries will increase, while that of others decreases. Furthermore, even if all grain boundaries were electrically identical, they operate at different working points along the current voltage characteristic and thus feature different conductivities. This causes the electric current to concentrate along a few conductive paths within the material [14]. The resulting current flow pattern in the material, and therefore its effective electrical conductivity, depend not only on the current voltage characteristics of any single grain boundary, but also on the details of the varistor microstructure.

In this paper, we introduce a modeling approach for the electro-mechanical characterization of ZnO varistors. The model extends on the equivalent circuit analysis for varistor ceramics originally proposed in [15]. In this approach, the grain boundaries are modeled as the current branches of a large nonlinear network representing the varistor microstructure. This enables the computation of the current flow patterns in the material by solving a global set of circuit equations. In addition to this, we compute the mechanical stress field in the material for different applied stresses using FEM, in order to take into account the piezotronic effect. The local stress at each grain boundary is then introduced into a self-consistent grain boundary model, describing the mechanical modulation of potential barriers due to piezoelectric polarization. Several simulations using 2D varistor models under different mechanical stress conditions are performed and the corresponding gauge factors of the material characteristics are computed.

2 THEORY

2.1 Grain Boundary Theory

A detailed description of the charge carrier transport through grain boundaries in polycrystalline semiconductors has been presented by Blatter et al. [16, 17]. The band bending at the grain boundary induced by an applied potential is calculated in the Schottky approximation by imposing consistency conditions with the deep trap states and the bulk Fermi level relative to the conduction band of the material. The solution for the electrostatic potential across the boundary resembles that of a potential barrier with height

$$\phi_B(V) = \frac{1}{4}V_c \left(1 - \frac{V}{V_c}\right)^2 + \frac{1}{q\gamma} \sum_{v=1}^n \gamma_v (\varepsilon_v - \varepsilon_\xi), \quad (1)$$

where q is the positive unit charge, V is the applied voltage, V_c is the switching voltage and ε_v and ε_ξ are, respectively, the deep trap positions and the bulk Fermi level relative to the conduction band. γ is the total charge in the deep traps defined as $\gamma = \sum_{v=1}^n qN_v/\varepsilon\varepsilon_0$ where N_v is the density of deep trap states and ε is the relative permittivity of the material.

Furthermore, the switching voltage V_c is related to the interface charge Q_i at the grain boundary by

$$V_c = \frac{1}{2\gamma} \left(\frac{Q_i}{\varepsilon\varepsilon_0} \right)^2. \quad (2)$$

where the interface charge is determined by the interface density of states, $N_i(E)$, assuming that the electron traps are filled up to the Fermi level ξ_i^n of the neutral interface:

$$Q_i = q \int_{\xi_i^n}^{\infty} N_i(E) f_i(E) dE, \quad (3)$$

with $f_i(E) = \frac{1}{1+e^{(E-\xi_i)/k_B T}}$, ξ_i the quasi Fermi level of the interface, k_B the Boltzmann constant and T the temperature.

In order to determine the interface charge in (3), however, the modification of the interface density of states, $N_i(E)$, due to the grain boundary potential must be taken into account. In other words, according to Blatter's theory [16], Q_i and ϕ_B are mutually dependent. When a bias V is applied to the junction, the interface states are shifted according to $N_i(E) = N_{i0}(E - \phi_B(V))$. Thus, given an assumption for the distribution of interface states $N_{i0}(E)$ in absence of a boundary potential, a self-consistent solution of (1)-(3) is required. Such a solution can only be obtained numerically as described in Section 3.1.

Finally, the electron current density emitted across the grain boundary is [16]

$$J = A^* T^2 \exp\left(\frac{-q\phi_B + \varepsilon_\xi}{k_B T}\right) \left[1 - \exp\left(\frac{-qV}{k_B T}\right)\right], \quad (4)$$

where A^* is the Richardson constant. In the following, the above relation is applied to determine a lumped nonlinear electrical resistance for each of the grain boundaries in the equivalent circuit model.

2.2 Piezoelectric Coupling

The coupling mechanism suggested in [13] is based on the piezoelectrically induced polarisation charges that emerge at the grain boundary when a mechanical stress is applied. These charges add to (or subtract from) the interface charge Q_i , resulting in an increase (or a decrease) of the barrier height. This effect can be expressed by a modification of the switching voltage as

$$V_c = \frac{1}{2\gamma} \left(\frac{Q_i + \mathbf{n} \cdot (\mathbf{P}_l - \mathbf{P}_r)}{\varepsilon\varepsilon_0} \right)^2, \quad (5)$$

where \mathbf{n} is the grain boundary normal and \mathbf{P}_l and \mathbf{P}_r are polarization vectors defined in the two grains on the left and on the right hand side of the boundary, respectively. The polarization vectors are obtained from the stress tensor field, $\boldsymbol{\sigma}$, and the piezoelectric tensor \mathbf{d} in the respective grain as $\mathbf{P} = \boldsymbol{\sigma} \cdot \mathbf{d}$. Thus, the effect depends on the reciprocal crystallographic orientations of the two grains sharing the boundary, as well as on the strength and orientation of the applied stress. Furthermore, it should be noted that the

Figure 1: Schematic representation of head-to-head (a), tail-to-tail (b) and head-to-tail (c) reciprocal grain orientations.

barrier height, as well as the unbounded interface charge Q_i will depend on the mechanical stress seen by the grain boundary. This is a result of the complicated relationship between the two, that requires now the simultaneous solution of (1), (3) and (5).

An important special case, is that of a uniform uniaxial stress applied to two grains with aligned crystallographic orientations. This occurs in three main forms with head-to-head, tail-to-tail, or head-to-tail crystallographic orientations (see Fig. 1). Note, that in the head-to-tail case the piezoelectric charges induced at the boundary cancel and thus no piezoelectric coupling can occur. For a ZnO-bicrystal with such a grain alignment, Raidl et al. [7] observed that, indeed, in this case the grain boundary conductivity depends only very weakly on the applied mechanical stress.

3 THE BICRYSTAL

3.1 Grain Boundary Model

In the present model, a grain boundary is represented by the sub-circuit shown in Fig. 2. This approach is similar to the one used by Votja et al. [18]. It incorporates the nonlinear grain boundary resistance defined by (4), R_{gb} , a large Ohmic resistance, R_s , accounting for leakage currents across the boundary, as well as the contribution of the grain bulk resistivity to the total current denoted by R_g . Each grain center is associated with a voltage node, whereas the grain boundary is represented by a current branch of the circuit. Furthermore, we assume that the mechanical stress is uniformly distributed within the grains. For ZnO, this assumption is justified by the comparatively high stiffness of the crystal [19]. Thus, the mechanical condition of a grain boundary is uniquely defined by the two pairs (σ_1, d_1) and (σ_2, d_2) of the stress and piezoelectric tensors characterizing the two grains sharing the boundary, respectively.

In order to determine the grain boundary barrier, the coupled equations (1), (3) and (5) are solved using a symbolic computation package [20]. Typical parameters used in the calculation are displayed in Table 1. Here, we assume a single dominant bulk state energy, ϵ_v . Otherwise, the grain boundary parameters are similar to the ones given in [16, 15]. All energies are given relative to the valence band edge energy.

The obtained solutions for the grain boundary potential and interface charge are depicted in Fig. 3. The calculations are performed exemplarily for the case when the crystallographic orientations of the two neighboring grains are normal to the grain boundary and pointing in opposite directions in a head-to-head configuration (cf. Fig. 1). A uniaxial compressive as well as tensile mechanical stress field is assumed in the direction normal to the boundary. The results are similar to those reported previously in [16], with the only difference being that here the effect of mechanical stress is included. These results reveal the strong

Figure 2: Lumped conductivity model using an equivalent electrical circuit for current flow at a grain boundary.

$\varepsilon_v(\text{eV})$	$A_b(\text{m}^2)$	ε	$R_l(\Omega)$	$R_g(\Omega)$	
3.18	100	8.81	2×10^9	5×10^6	

Figure 3: Potential barrier (b and d) and interface charge (a and c) solutions for a single grain boundary. This is shown first for compressive stress (a and b), and also for tensile stress (c and d).

impact of piezoelectric charges on the barrier height. As expected, in the compressive case, the barrier height is lowered with increasing stress whereas in the tensile case the barrier is increased. Nevertheless, this effect is strongly nonlinear as it depends on the electric voltage applied to the boundary.

In order to be able to consider general polycrystalline configurations and arbitrary mechanical stresses, the potential barrier solutions obtained by this procedure are tabulated with respect to voltage, V , and piezoelectric charge, Q_p . In the following simulations, these tables are incorporated into larger equivalent circuit models for more complicated varistor structures.

3.2 Mechanical Model

In the general case, with ZnO grains of arbitrary orientations, the mechanical stress is calculated by the Finite Element Method (FEM) using the software package Elmer [21]. We solve for the mechanical equilibrium condition in the crystal:

$$-\text{div} \cdot \boldsymbol{\sigma} = \mathbf{f}, \quad (6a)$$

$$\sigma_{ij} = \mathbf{C}^{ijkl} \epsilon_{kl} - \beta^{ij} (T - T_0). \quad (6b)$$

where \mathbf{f} is the applied force density, \mathbf{C} is the stiffness tensor, $\boldsymbol{\epsilon}$ the strain, $\boldsymbol{\beta}$ the thermal expansion tensor and T the temperature. Throughout the paper the stiffness tensor for a hexagonal type ZnO crystal in the Voigt two-index notation is assumed as [19],

$$\mathbf{C} = \begin{bmatrix} 210 & 120 & 105 & 0 & 0 & 0 \\ 120 & 210 & 105 & 0 & 0 & 0 \\ 105 & 105 & 211 & 0 & 0 & 0 \\ 0 & 0 & 0 & 43 & 0 & 0 \\ 0 & 0 & 0 & 0 & 43 & 0 \\ 0 & 0 & 0 & 0 & 0 & 44 \end{bmatrix} / \text{GPa}. \quad (7)$$

and the thermal expansion tensor for a ZnO crystal with principal axis pointing in the z -direction is

$$\boldsymbol{\beta} = \begin{bmatrix} 4.31 & 0 & 0 \\ 0 & 4.31 & 0 \\ 0 & 0 & 2.49 \end{bmatrix} / \mu\text{K}^{-1}. \quad (8)$$

3.2.1 Effect of Thermal Stress

To illustrate the coupled model, we consider the effect of internal thermal stress due to cooling in the simple bicrystalline structure shown in Fig. 4. The thermal stress is computed for cooling from a stress-free state at 1500 K to 300 K, given the known matrix of thermal expansion coefficients. The grains shrink upon cooling, which produces a mechanical stress at the interface. The mechanical stress and the piezoelectric vector in each grain is computed according to (6), using (7) and (8). The simulated thermal stress distribution in the bicrystal is shown in Fig. 4 (left). The resulting current-voltage characteristic and the non-linearity coefficient of the thermalised bicrystal and at room temperature after thermal treatment are shown in Fig. 4 (right). Obviously, the main effect of thermal stress, in this case, consists in shifting the switching voltage of the bicrystal to higher values by approximately 1V.

Figure 4: Distribution of residual thermal stress in the z -direction remaining in a $10 \mu\text{m} \times 10 \mu\text{m} \times 20 \mu\text{m}$ bicrystal after cooling from 1500 K (left) and the resulting current-voltage characteristic (right).

3.2.2 Applied Stress

In the following, we consider the effect of applied, compressive uniaxial stress on the bicrystal system. Three different bicrystal configurations are considered. In the first configuration, the grain's c -axis are oriented head-to-head as in Fig. 1(a). In the second configuration, the c -axis of one of the grains is rotated by 90 degrees with respect to the other grain. Finally, in the third configuration, the grains are oriented head-to-tail as in Fig. 1(c). As expected, in the latter case, no piezoelectric coupling occurs (see Fig. 5(c)). In the other two cases, a strong effect of the applied stress on the resulting current-voltage characteristics is observed. Hereby, it is important to note that piezoelectric coupling becomes important even when the grain orientations are not co-linear as is the case in the rotated grain configuration shown in Fig. 5(b). The effect of this coupling is two fold. First, the switching voltage of the barrier is shifted to lower values. Second, the nonlinearity degree of the characteristic curve is decreased. As seen in Fig. 5(a), for high applied stresses the electrical response becomes linear and the varistor property of the material is completely lost.

Figure 5: Current-voltage plots showing the stress sensitivity of a single grain boundary in a head-to-head orientation (a), grain orientations forming a 90° angle (b) and a head-to-tail orientation (c).

4 POLYCRYSTALLINE MODEL

For 2D polycrystalline structures, an equivalent electrical network is constructed, consisting of a large number of grain boundary sub-circuits (see Fig. 2) of different current-voltage characteristics depending on the local mechanical stress distribution. The polycrystalline microstructure is modeled using a Voronoi tessellation of the varistor sample as suggested in [14]. This is realised by means of the software package Neper [22]. The package provides, furthermore, a set of grain orientations randomly distributed within the sample volume.

Using such a description for the microstructure, an FEM mesh is generated with the open source program Gmsh [23] and the strain-stress equations (6) are solved numerically with Elmer [21]. Fig. 6 shows, exemplarily, the resulting Voronoi structure for a varistor sample of dimensions $200 \times 300 \mu\text{m}$ and an average grain size of $10 \mu\text{m}$. The computed stress distribution in the material for an applied uniaxial stress of 200 MPa in the vertical direction is depicted in Fig. 6(a). Furthermore, the current flow pattern within the sample resulting from the numerical solution of the circuit equations for an applied external voltage of 5 V is shown in Fig. 6(b). The well known current concentration effect for polycrystalline varistors [14] is hereby clearly observed.

Figure 6: Mechanical stress distribution and current flow map for the non-linear region of a 2D polycrystal of size $200 \times 300 \mu\text{m}$ and average grain size of $10 \mu\text{m}$ when a uniaxial compressive stress of 200 MPa is applied (left). Electrical current pattern in the sample for an applied voltage of 5 V. The current in each grain is given relative to the total current flowing through the sample.

Current-voltage plots for network simulations based on Voronoi structures are shown in Fig. 7. Note that, as in the head-to-head bicrystalline case, a compressive stress results in a reduction in the switching voltage exhibited by the polycrystal, as shown by the progressive shift of the curves to the left along the voltage-axis. This is because, although grain boundaries with configurations close to tail-to-tail will exist, these are ignored by the current in favor of more conductive grain boundaries. Thus, the overall effect, is comparable to that of a single head-to-head grain boundary. Nevertheless, since the effect is the

result of current flow through many grain boundaries in series, few of which are likely to be of a perfect head-to-head orientation, this shift is less pronounced than for a bicrystal.

Also in Fig. 7, the gauge factor of the sample is shown. This is defined as the relative change of sample's resistivity with applied stress, $GF = \frac{\delta R/R}{\epsilon}$, where ϵ is the mechanical strain in the material and R is the effective resistance of the sample. In this case, gauge factors of more than 1800 are observed. The peak gauge values for a given mechanical stress are always retained in the corresponding switching voltage region of the varistor. Furthermore, the simulation reveals that the highest gauge sensitivity is obtained for lower applied stresses and at the corresponding moderate switching voltage values.

Figure 7: Electrical characteristics (left) and gauge factor (right) for the 2D polycrystal show in Fig. 6.

One important consideration is the effect of sample size on the effective current voltage characteristic of the material. In Fig. 8 simulations are performed for varistor samples of different sizes while keeping the average grain size constant. It can be seen that, for a varistor sample with 600 grains, a saturation occurs, after which edge effects from the sample no longer have an influence on the effective characteristics. This sample size is thus sufficient for the characterization of the bulk varistor material.

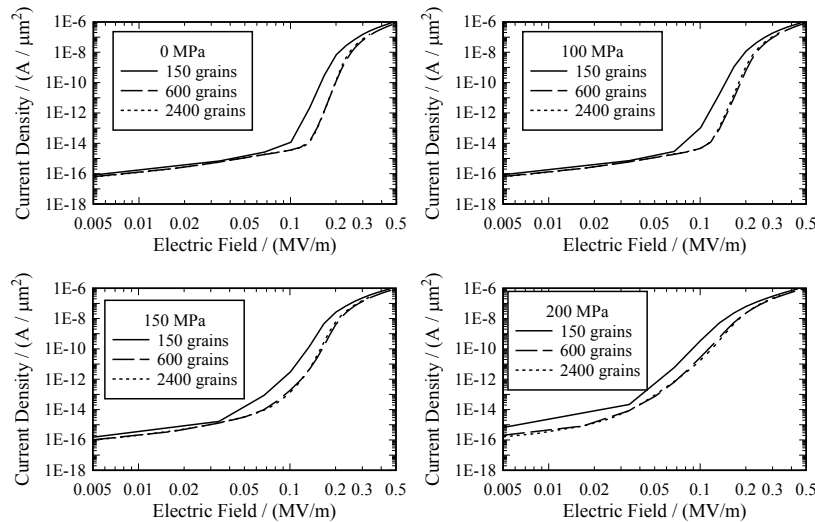

Figure 8: Stress dependent current-voltage characteristics for different sizes of the varistor sample. In all cases, the average grain size is $10\mu m$.

In Fig. 9, current flow maps, similar to the one presented in Fig. 6(b), are shown to illustrate the effect of applied stress on the current path pattern within the microstructure. The varistor sample considered is the same as the one examined in Fig. 6. It can be seen from the left-most column that, even when no external stress is applied, the varistor current flows through a single dominant path of high conductivity, emerging at a switching voltage of about 60 V. The topology of this path is determined essentially by the geometry of the microstructure (cf. [11]). When a compressive stress is applied to the material, three main effects are observed. First, the current concentration effect occurs already at lower (switching) voltages, corresponding to the lowering of the potential barriers for the conducting grain boundaries. Second, the location of the current paths is modified. The topology of current conducting paths depends now, in addition, on the mechanical stress distribution and the crystallographic orientations of the individual grains. Finally, the current concentration effect at higher applied stresses is less pronounced and the current distribution is more homogeneous. Two or more conductive paths within the sample can be observed. This corresponds to the overall lowering of the nonlinearity coefficient of the single grain boundary characteristics induced by the applied stress, as described in Section 3.2.2.

Figure 9: Current concentration for varying applied voltages and uniaxial compressive stresses in a 2D polycrystal of size $200 \times 300 \mu\text{m}$ and average grain size of $10 \mu\text{m}$. The current in each grain is given relative to the total current flowing through the sample.

5 CONCLUSIONS

A self-consistent coupled model for calculating the stress dependent grain boundary potential barriers, and thus the current-voltage characteristics of polycrystalline ZnO microstructures, has been developed. This model holds in both the context of externally applied stresses and those remaining within microstructures as a result of the thermal expansion anisotropy occurring in ZnO polycrystals. This method can be used for any given varistor sample described by its granular microstructure and the distribution of crystallographic grain orientations. The method provides, furthermore, insight into the current flow patterns within the material under the influence of mechanical stress. Based on these calculations, a stress induced reduction in the switching voltage of the polycrystal, as well as the decrease in the nonlinearity degree of the effective electrical characteristics under applied stress can be observed. This stress sensitivity can be quantified by use of the gauge factor, and doing so shows comparable values for ZnO polycrystals to those measured experimentally. Furthermore, the impact of system size on the model's output was investigated and assessed.

Key words: Model Predictive Control (MPC), Physical Constraints, Semi- Active Suspension, Magneto-Rheological (MR) Damper

Abstract. This study presents vibration control performance of model predictive control (MPC) for a quarter car suspension system equipped with a MR damper suffering from the saturation on damping force of MR damper. The MPC controller is designed and then applied to the suspension system to take into account the constraints associated with MR damper. The performance of MPC controller is compared to a conventional control method where the constraint of control input is handled by using a saturation function. The effectiveness of the MPC controller is evaluated by using bump excitation in time domain.

1 INTRODUCTION

Suspension system plays an important role in vehicle vertical dynamics by enhancing the performances of the vehicle system in term of ride comfort and road handling . Among different types of suspension, the semi-active suspension system has received much attention because it provides the best compromise between control performance and energy consumptions compared to others including passive and active suspension system [1]. However, the main challenge faced by semi-active suspension control problems is how to deal with the dissipativity constraints of semi-active dampers which usually works as an actuator of the semi-active suspension system [2]. In practice, the most common semi-active damper used for the vehicle suspension system is magneto-rheological (MR) damper which uses MR fluids to provide controllablle damping force [3]. To date, a couple of control strategies have been developed for the semi-active suspension with semi-active damper [4]. Although lots of advanced control algorithms exist, only little can handle the dissipativity constraints of semi-active dampers in efficient way [5]. Model predictive control (MPC) is one of the promising control schemes which can meet the physical constraints on both control inputs and outputs while guarantee the control performance of the control system as semi-active suspension system [6]. It is obvious that the semi-active dampers as MR damper which has the dissipativity constraints can be handled elegantly within the MPC framework. However, since MPC has to solve an online constrained optimization problem at every sampling time, it usually requires high computational time for real time implementation.

In fact, several studies have employed the MPC control for the vehicle suspension system in

the literature. Many research has investigated the feasibility and performance of MPC controller for quarter car semi-active suspension system [7]. Some of works also proposed a methodology for optimal semi-active suspension system based on a fast MPC scheme for a quarter car model while a road profile preview is used by using expensive and not standard sensors [8]. In addition, MPC controller is also extendedly adapted to a half car [9] and full car [10] suspension model.

In this study, a practically implementable semi-active suspension MPC controller is developed for a quarter car system equipped with MR damper. The MPC controller is proposed for the semi-active suspension system which has physical constraint of 800 N on damping force of MR damper. As a first of step, the equations of motion of a quarter car suspension with MR damper are derived. The MPC controller is designed to satisfy the constraints on both control input and outputs and then applied to the suspension system. The performance of the proposed controller is also compared to the conventional optimal controller where the constraint of damping force is handled by using a standard saturation function which is not strong enough to deal with the physical constraint of control input. The effectiveness of the MPC controller is evaluated by using a bump excitation. As a result, MPC controller shows a much better vibration control performance compared with the other conventional controllers while meet the constraint on damping force of MR damper.

2 MODELING OF THE QUARTER CAR SUSPENSION SYSTEM

In this study, a two degree of freedom (2-DOF) quarter car suspension with a MR damper is considered for designing MPC controller as illustrated in Figure 1. It is assumed that the spring coefficient of the suspension and tire are linear, then the equation of motion (EOM) of the suspension system can be formulated as follows

$$\begin{aligned} m_s \ddot{z}_s &= -c_s (\dot{z}_s - \dot{z}_u) - k_s (z_s - z_u) - F_{MR} \\ m_u \ddot{z}_u &= c_s (\dot{z}_s - \dot{z}_u) + k_s (z_s - z_u) - k_t (z_u - z_r) + F_{MR} \end{aligned} \quad (1)$$

where m_s is the sprung mass, c_s denotes damping coefficient of the suspension, k_s is the stiffness of the suspension which includes the effective stiffness of the MR damper induced by air chamber, k_t indicates the stiffness of tire. Moreover, z_s , z_u , and z_r are the vertical displacements of sprung mass, unsprung mass and road disturbance, respectively. From Eq. (1), the state space equation of the quarter car suspension system with MR damper can be represented by

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t) + Ew(t) \\ y(t) &= Cx(t) \end{aligned} \quad (2)$$

where

$$x(t) = [z_s \quad \dot{z}_s \quad z_u \quad \dot{z}_u]^T, u(t) = F_{MR}, w(t) = z_r \quad (3)$$

are state variables, control input and road disturbance, respectively.

$$\begin{aligned}
 A &= \begin{bmatrix} 0 & 1 & 0 & 0 \\ -k_s/m_s & -c_s/m_s & k_s/m_s & c_s/m_s \\ 0 & 0 & 0 & 1 \\ k_s/m_u & c_s/m_u & -(k_t+k_s)/m_u & -c_s/m_u \end{bmatrix} \\
 B &= \begin{bmatrix} 0 & -1/m_s & 0 & 1/m_u \end{bmatrix}^T, \quad E = \begin{bmatrix} 0 & 0 & 0 & k_t/m_u \end{bmatrix}^T \\
 C &= \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}
 \end{aligned} \tag{4}$$

Table 1: Parameters of the quarter car suspension control system

Parameters	Value	Unit
Sprung mass (m_s)	315	kg
Unsprung mass (m_u)	41.5	kg
Stiffness coefficient (k_s)	21,000	N/m
Tire stiffness (k_t)	210,000	N/m
Damping coefficient (c_s)	1,400	Ns/m

Figure 1: A quarter car suspension control system with MR damper

3 DESIGN AND CHARACTERISTIC OF MR DAMPER

3.1 Design of MR damper

In this study, a flow type MR damper is designed for the proposed quarter car suspension system. The schematic diagram of prototype MR damper is illustrated in Figure 2. The damping force of the MR damper consists of three components: viscous damping force, controllable

force, air force induced by the air chamber. It is assumed that the MR fluid is incompressible and that the pressure in one chamber is uniformly distributed. Then, the flow type Bingham damping force of an MR damper can be represented as follows

$$F_{MR} = F_{vis} + F_a + F_{air} \quad (5)$$

where F_{vis} denotes the viscous damping force of MR fluid, F_{MR} is the field-dependent damping force controlled by current applied to the coil, F_{air} indicates the air force induced by the air chamber when the piston is moved. According to the reference [11], the damping force induced by the MR damper can be derived as follows

$$F_{MR} = k_e x_p + \frac{6\mu L}{\pi d^3 R_d} (A_p - A_r)^2 \dot{x}_p + 2c \frac{L_p}{d} \tau_y (A_p - A_r) \text{sgn}(\dot{x}_p) \quad (6)$$

where

$$c = 2.07 + \frac{12Q_l \mu}{12Q_l \mu + 0.8\pi R_d d^2 \tau_y(B)} \quad (7)$$

$$Q_l = (A_p - A_r) \dot{x}_p$$

where x_p and \dot{x}_p are the displacement and velocity of piston, Q_l is the flow rate of the MR fluid; $\text{sgn}(\cdot)$ is the signum function, k_e is the stiffness coefficient related to gas pressure inside gas chamber; A_p and A_r are the area of the piston and piston rod; μ is its post-yield viscosity; L and L_p are the piston length and magnetic pole length; R_d and d are the average radius, and gap of MR fluid path; τ_y is the yield stress produced by applied magnetic field, B is the magnetic flux density dependent on the magnetic field, c is a coefficient that depends on the piston velocity.

Figure 2: Configuration design of MR damper

3.2 Characteristics of MR damper

The characteristics of MR damper is estimated through simulation where MR fluid is modeled based on Bingham model. Figure 3 presents the measured field-dependent damping force of the MR damper. The maximum damping force is approximately 2300 N at input current of 1.5 A. It is obvious that the damping force is constrained at the maximum allowable input current. Even though the maximum of damping force reaches 2300 N at 1.5A through simulation but in practice we may be cannot use this maximum value of damping force because a maximum allowable power consumption should be required or the experimental results is not the same as the simulation results sometimes. In this study, the maximum allowable damping force is set as 800 N to validate the effectiveness of MPC controller with better output responses under constraint of actuator while reduce energy consumption of MR damper. Table 2 indicates design parameters of MR damper.

Table 2: Design parameters of the MR damper

Parameters	Value	Unit
Acceptable current (I)	1.5	A
Piston area (A_p)	0.0008668	m ²
Piston rod area (A_r)	0.00007854	m ²
Length of the piston (L)	0.031	m
Length of magnetic pole (L_p)	0.012	m
Circumference of inner core (b)	0.1078	m
Gap of MR fluid path (d)	0.0007	m

Figure 3: Characteristics of the prototype MR damper

4 MPC CONTROLLER DESIGN

To design MPC controller for the quarter car suspension, the continuous state equation of the semi-active suspension system should be formulated in discrete time domain with sampling time T_s (10 ms) as follows

$$\begin{aligned} x(k+1) &= (I + T_s A)x(k) + T_s B u(k) + T_s E w(k) \\ y(k) &= C x(k) \end{aligned} \quad (8)$$

where $A_d = I + T_s A$, $B_d = T_s B$, $E_d = T_s E$, $C_d = C$

The discrete time state equation can be rewritten as

$$\begin{aligned} x(k+1) &= A_d x(k) + B_d u(k) + E_d w(k) \\ y(k) &= C_d x(k) \end{aligned} \quad (9)$$

To establish an optimization problem, a cost function is defined as follows,

$$\begin{aligned} \min_{u_0, u_1, \dots, u_{N-1}} \quad & J = x_N^T P x_N + \sum_{k=0}^{N_p-1} x(k)^T \bar{Q} x(k) + \sum_{k=0}^{N_c-1} u(k)^T \bar{R} u(k) \\ \text{s.t.} \quad & x(k+1) = A_d x(k) + B_d u(k) \\ & y_{\min} \leq C_d x(k) \leq y_{\max} \\ & u_{\min} \leq u(k) \leq u_{\max} \end{aligned} \quad (7)$$

where x_N is the terminal states of each state variable which are determined as zeros for the suspension system. N_p and N_c are the length of prediction horizon and control horizon ($N_c \leq N_p$); $P > 0$ is defined to ensure the stability of the MPC control problem which is a solution to the Riccati equation

$$P = A_d^T P A_d + Q - A_d^T P B_d (R + B_d^T P B_d)^{-1} B_d^T P A_d \quad (8)$$

\bar{Q} and \bar{R} are symmetric and positive definite weighting matrices which is represented as

$$\bar{Q} = \begin{bmatrix} Q & 0 & \dots & 0 \\ 0 & Q & \dots & \vdots \\ \vdots & \vdots & \ddots & 0 \\ 0 & \dots & 0 & P \end{bmatrix}, \quad \bar{R} = \begin{bmatrix} R & 0 & \dots & 0 \\ 0 & R & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \dots & 0 & R \end{bmatrix} \quad (9)$$

The positive definite matrix Q and R should be selected appropriately to minimize the performance index [1]. In this study, the weighting matrix Q and R are set as follows

$$Q = \text{diag}([6e9 \ 100 \ 100 \ 100]), \quad R = 0.12 \quad (10)$$

Performance index in Eq. (10) is a combination of sprung mass and unsprung mass displacements and velocities, respectively with the main object is to improve the ride comfort of the suspension system. The simulation parameters are represented in Table 3

Table 3: Simulation parameters for MPC controller

Parameters	Value	Unit
Prediction horizon (N_p)	10	--
Control horizon (N_c)	5	--
Sampling time (T_s)	10	ms
Constraint of damping force (F_{MR})	$-800 \leq F_{MR} \leq 800$	N

4 SIMULATION RESULTS

The performance of the MPC controller is evaluated by using a bump road profile as shown in Figure 4. In fact, the bump excitation is usually used to evaluate the transient characteristic in time domain. Figure 4 shows the output responses of the bump excitation to evaluate two controllers including the controller using saturation function and MPC controller. The sprung mass acceleration, suspension travel, damping force and unsprung mass acceleration are shown in Figures 4 (a), (b), (c), (d), respectively. It is obvious that two controllers show good performance, and the unwanted vibration induced from the bump excitation are remarkably attenuated. The output responses of the MPC controller are always less than the controller with saturation function.

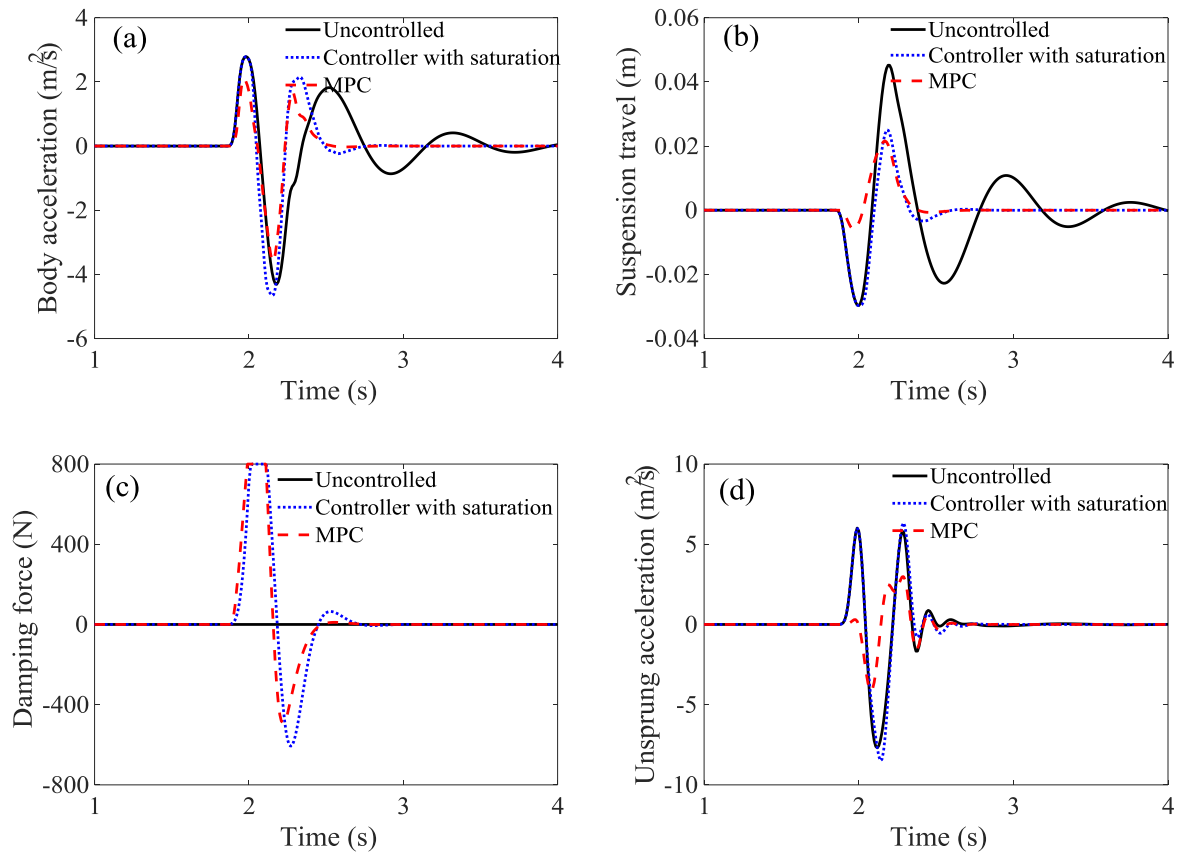

Figure 4: Output responses to bump excitation (a) sprung mass acceleration (b) suspension deflection (c) damping force (d) unsprung mass acceleration.

6 CONCLUSION

The MPC controller is applied for vibration control of a quarter car suspension with MR damper. An MR damper was designed based on the Bingham characteristics of the MR fluid, and its characteristics were experimentally evaluated to reveal the constraints of the controllable damping force. The vibration control performance of the MPC controller was investigated

under bump excitation in time domain. It is shown that the vibration of the suspension system is significantly reduced by applying the MPC controller compared to the controller which using a conventional saturation function. Especially, even though the damping force of MR damper is constrained, the ride comfort of the suspension system is remarkably improved.

Key words: grandstand structure, modal analysis.

Abstract. The article presents the results of measuring the natural vibration frequencies, mode shapes for the sports complex stands. Operational modal analysis based on the results of measurements was performed by ARTEMIS Extractor Pro. In work the equipment of firm Reftek was used. The results of identification of EFDD and SSI CVA with indication of confidence intervals (with a given confidence level of 95%) and corresponding coefficients of variation are presented. The measured frequency of the first form of natural oscillations is in the range of 3.61 ± 0.46 Hz (EFDD). Based on the analysis of the shape of the oscillations (all points of the structure synchronously to each other make vertical oscillations), this form of oscillations refers to the vibrations of construction-foundation system. As a result of measurements of the response of the tribune structure from the ambient vibrations, it was revealed that the first natural frequency of vertical oscillations of the investigated structures is higher than 6 Hz, which does not limit the operation of these structures for various measures according to the frequency criterion.

1 OBJECT DESCRIPTION

Ice arena “Arena-Omsk” has the following dimensions in plan 148.2 x 88.2 meters. Cross-section is shown on figure 1. Top of cover girders have level 19.35 meters. Building’s frame consists of reinforced concrete columns, hinged seated on them metal girders with span from 31 meters to 78 meters. Also frame contains reinforces concrete beams of grandstand structure implemented in monolith and precast variants. Spatial stiffness provided by vertical ties held on columns, stiffness diaphragms, vertical and horizontal ties on cover girders, and by spacers. Grandstand structure represents by slab-bar system consisted by prefabricated reinforced concrete columns, beams, tribune elements (shells) and slabs. Beams of grandstand has span from 5.5 meters to 12 meters. Tribune elements have span from 1 meter to 12 meters.

Figure 1: Cross-section of ice arena

2 SETTING GOAL

In life cycle of ice arena occurred requirement in provision not only sport events but also mass culture events. These events characterized by different activity of spectators, which seated or stayed on grandstand structure. Elements of grandstand structure must have required load bearing capacity for all variant of activity from spectators.

In this work authors of paper were followed by interim guidance on assessment and design for permanent grandstands [2]. Accordantly to this document significant dynamic load can be applied on tribune within process of music concerts by crowd that stomps to the beat of music. Moreover crowd can acts rhythmically within sports events, when people jumping on grandstand, and also swaying or applauding. When crowd suddenly jump up and then return, it also can apply significant dynamic loading. It should be noted that crowd can generate vertical and horizontal loadings.

Vertical dynamic loading can be applied due to crowd action with follow characteristics:

1. In frequency range 1.5-3.5 Hz from small group of people;
2. In frequency range 1.5-2.8 Hz for greater group of people (this frequency range is smaller due to synchronization problem).

Horizontal dynamic loading can be applied due to crowd action in frequency range 0.7-0.9 Hz.

Grandstand structure satisfied to requirements of dynamic comfort and strength when minimum natural frequency of vertical oscillations greater than 3.5 Hz for sports events and greater than 6 Hz for all events. Minimum natural frequency of horizontal oscillations is limited by 3 Hz.

The goal of current work was measurement of natural frequencies of grandstand fragments. In terms of advisory note [3] the goal we pursued was “type 1 tests” with natural frequencies measurement by AVS (ambient vibration survey). Bellow represented measurements results of grandstand structure free oscillations due to ambient vibration of sport arena “Arena-Omsk”.

3 WORK IMPLEMENTATION TECHNIQUE

3.1 Common information

All works divided on two series stages – field investigation and analytical works. All

stages were done in 2013 year.

Analytical works can split into follow parts:

1. Choosing adequate methods with following data processing.
2. Results assessment, making conclusions and recommendations.

Operational modal analysis was performed by ARTeMIS Extractor Pro [1] software.

Shown below figures with mode shapes were made by GNU Octave [5] software. Statistical calculations also were performed in GNU Octave.

Follow seismic measurement equipment made by RefTek are used [6]:

1. Two 1-axis accelerometers RefTek 131B-01/1 with sensitivity 1.6 V/g, measurement range $\pm 4g$, self noise $2 \mu g^2/Hz$, dynamic range 112 dB.
2. One 3-axis accelerometers RefTek 131B-01/3 with semi characteristics to RefTek 131B-01/1.
3. One seismic recorder RefTek 130-01 with 24-bit ADC, dynamic range 138 dB.

Current work is continuation of work [4]. Unlike previous work, the results of measurements on several grandstand elements are obtained here. Observed fragments as rule have the largest span. As a typical result of measurements outcomes for fragment in axes 11-11.1_G-H are shown bellow.

3.2 Statistical evaluation of data

For each measurement result of natural frequency follow calculations were done:

- mean values \bar{x} ;
- bounds of confidence intervals $\bar{x} - \delta$ and $\bar{x} + \delta$ for specified confidence level 95%;
- variation coefficients V , expressed as a percentage.

Bounds of confidence intervals were determined accordantly to ГOCT P 54859—2011 [7] with follow formulas:

$$(\bar{x} - \delta; \bar{x} + \delta), \delta = \mu\sigma \quad (1)$$

where \bar{x} - is a sample mean; σ - a standard deviations; μ - a parameter obtained by tables in applications in [7] for specified probability (it is a function of count of measurements and confidence level).

Variation coefficient is shown for relative assessments of natural frequencies obtained with different methods. Formula for variation coefficient calculation:

$$V = \frac{\sigma}{\bar{x}} 100 \% \quad (2)$$

4 NATURAL FREQUENCIES AND MODE SHAPES OF FRAGMENT 11-11.1_G-H

Accelerometers disposition scheme for measurements of natural frequencies and mode shapes for fragment 11-11.1_G-H is shown on figure 2 (a). Location of this grandstand fragment on plan is shown on figure 2 (b). In measurement experiments accelerometers were fixed to embedded plates – seating deck anchor bolts. One accelerometer RefTek 131B-01/1 was used as reference sensor and other accelerometers were rearranging in different points accordantly to shown on figure 2 (a) scheme.

Figure 2: Accelerometers disposition scheme for fragment of grandstand structure in axes 11-11.1_G-H (a) and location of this fragment on plan (b)

Identification results by methods EFDD (enhanced frequency domain decomposition) and SSI CVA (stochastic subspace identification – canonical variate analysis) are shown on figure 3 and 4 respectively.

Figure 3: Average of the normalized singular values of spectral density matrices for fragment 11-11.1_G-H

Figure 4: Poles SSI CVA for fragment 11-11.1_G-H

Natural frequencies obtained by EFDD and SSI CVA methods with confidence intervals (with specified confidence level 95%) and variations coefficients are shown in table 1. As shown in advisory note [3] for tests performed by AVS only natural frequencies and mode shapes can be measured. Damping coefficients determination for this type tests in this work was unreliable. Obtained variation coefficients for damping coefficients were significantly greater then variation coefficients for natural frequencies.

Table 1: Natural frequencies from EFDD and SSI CVA methods for fragment 11-11.1_G-H

EFDD				SSI CVA			
Frequency				Frequency			
$\bar{x} - \delta$, [Hz]	\bar{x} , [Hz]	$\bar{x} + \delta$, [Hz]	V , [%]	$\bar{x} - \delta$, [Hz]	\bar{x} , [Hz]	$\bar{x} + \delta$, [Hz]	V , [%]
2.63	3.53	4.44	10.83	3.15	3.61	4.07	5.35
8.86	9.75	10.65	3.89	9.49	9.64	9.78	0.63
12.69	14.10	15.51	4.23	13.21	13.98	14.75	2.34
17.37	17.78	18.19	0.97	16.95	17.90	18.85	2.25

MAC (modal assurance criterion) coefficients for mode shapes obtained by EFDD and SSI CVA methods are shown in table 2. Mode shapes are shown on figure 5.

Table 2: MAC coefficients

		SSI CVA			
		3.61 [Hz]	9.64 [Hz]	13.98 [Hz]	17.90 [Hz]
EFDD	3.53 [Hz]	0.593	0.667	0.021	0.140
	9.75 [Hz]	0.390	0.877	0.038	0.064
	14.10 [Hz]	0.019	0.067	0.290	0.101
	17.78 [Hz]	0.032	0.007	0.062	0.711

Natural frequencies for fragment 11-11.1_G-H with confidence intervals graphically are shown on figure 6.

Figure 5: Confidence intervals for natural frequencies for fragment 11-11.1_G-H

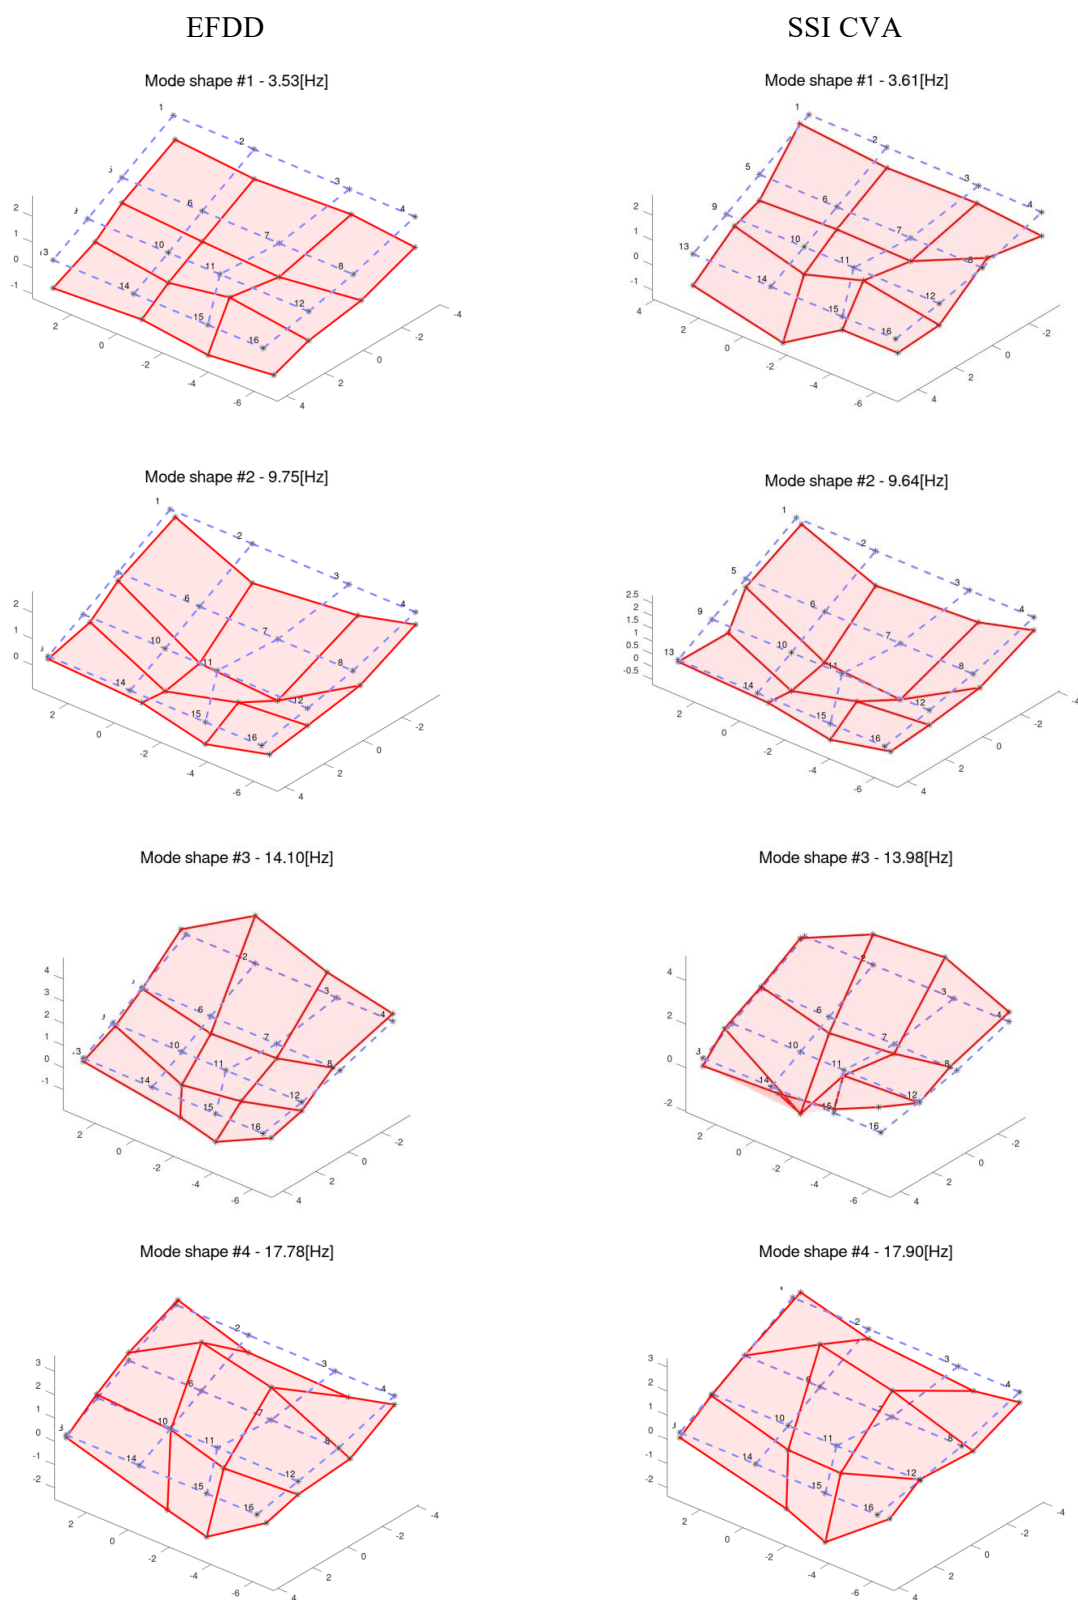

Figure 6: Mode shapes for fragment 11-11.1_G-H

5 CONCLUSION

1-st natural frequency for fragment 11-11.1_G-H was in interval 3.61 ± 0.46 Hz (EFDD). Corresponded mode shape is characterized by synchronous vertical deflections of all observed point – on tribune elements and on supports (columns). 1-st natural frequencies of other investigated grandstand fragments had similar values. It says that this mode shape refers to construction-foundation system.

2-nd mode shape was in interval 9.75 ± 0.9 Hz (EFDD). This mode shape refers to grandstand construction.

For all investigated grandstand fragments lowest natural frequency was greater than 6 Hz. Therefore there are not limitations for providing all sports and mass culture events according to frequency criterion [2].

Abstract. The EHD(Electro-hydro-dynamics) fluid is one of the smart fluid. The devices such as pumps using EHD fluid are developed and the researches especially about EHD ion-drag micro-pump have been performed to obtain the high performance. The circular pipe EHD pump with circular pipe electrodes unlike a pump shape developed in the past is proposed for the applications such as in small scale liquid cooling systems. The pumps are structurally simple, easy to fabricate, and the flow direction can be reversed by simply swapping the positive and negative electrodes. In the present study, the induced two-dimensional flow between electrodes is explained under application of the electric fields by the experimental flow visualization and CFD (Computational Fluid Dynamics) methods. The distributions of the velocity, the electric force and the charge density, which are obtained by the CFD method near the electrodes are shown and the numerical results are confirmed by the experimental flow visualization. In the next, the small pump based on cylindrical electrodes developed to utilize the flow analysis results and to induce one directional flow is explained. Furthermore we produced the pumps in which the electrode contains multiple holes to increase one-directional flow velocity and the load pressure. We measured the pressure-flow rate characteristics of the cylindrical electrode pump and the multi-holes electrode pair pumps, and compared their performances. As a result, the mechanism to induce one directional EHD flow near the electrodes under application of the voltage is understood clearly and the pressure-flow rate characteristics of the present pump based on cylindrical electrodes and the multi-holes electrodes are shown.

1 INTRODUCTION

The EHD fluid is one of the smart fluid. The flow of the EHD fluid is induced under the application of the electric field and the flow properties of the EHD flow such as pressure, flow velocity and flow rate can be controlled by the electric fields.

The development of the EHD pumps is conducted eagerly because those have no moving part and quite. In recent years, a review on EHD pumps is introduced and three different methods of EHD pumping such as ion-drag, induction and conduction are briefly outlined in the review paper [1]. It is pointed out that the ion-drag pumps show the higher flow rates compared with other two types of pumping in the paper. From the merit of the ion-drag pump

the researches about EHD ion-drag micro-pump have been performed [2-5]. However, it seems not to be led to practical use yet.

In the present study the EHD pump with circular pipe electrodes unlike a pump shape developed in the past is proposed for the applications such as in small scale liquid cooling systems. This small scale technology can be thought to be applied for microscale system. In the chapter 2 of the present paper, the induced flow between electrodes is explained under application of the electric fields using the experimental and the numerical flow visualizations. The velocity distributions obtained by the numerical method between electrodes are shown and the numerical results are confirmed by the experimental flow visualization. From the results, it is found that the one directional flow can be generated in some range of the electrode configuration. In the chapter 3, the small pump based on cylindrical electrodes developed to utilize previous research using liquid crystal [6] and to induce one directional flow is explained. Finally, we produced the pumps in which the electrode contains multiple holes to increase one-directional flow velocity and the load pressure [7]. In the present experiment the influence of the asymmetries of the electrode width on the relation between the flow rate and the pressure is examined. We measured the pressure-flow rate characteristics of multi-holes electrode pair pumps and compared their performances. Our pumps are structurally simple, easy to fabricate, and the flow direction can be reversed by simply swapping the positive and negative electrodes.

2 FLOW ANALYSIS OF EHD FLUID

The two-dimensional numerical simulation of EHD fluid flow in the simple flow channel is conducted when steady electric fields are generated through a direct current by two plate electrodes at the bottom of the flow channel.

2.1 Governing equations

The governing equations used in the present calculation are (1) Continuous equation, (2) Navier-Stokes equation, (3) Gauss' law and (4) Charge conservation law. The velocity vector, pressure, charge density and electric potential are unknown variables to solve the equations. The influence of the electric field on the flow is considered by the body force term in Navier-Stokes equation. We regard the coulomb force as the principal body force that generates the flow in the electric fields. HSMAC (Highly Simplified Marker and Cell method) is used to derive the velocity and Poisson equation is used to derive the pressure in the present calculation.

2.2 Flow field

In order to understand the EHD-induced flow velocity, the flow visualization was carried out. The flow channel and a plate electrode pair used in these measurements are illustrated in Fig.1(a). Each electrode plate EF, GH had a width of 1 mm and the gap between the two plates was 0.2 mm. The width of the channel perpendicular to the paper surface is 5mm. An electric field was generated at the bottom of the flow channel by applying a voltage to the plate electrode pair. Specifically, the cathode and anode of a DC power supply were connected to electrodes EF and GH, respectively. To enable visualization, the EHD fluid was first mixed with green fluorescent polymer microspheres (Duke Scientific Corporation Co., Ltd, particle diameter 8 μm), after which the mixture was introduced into the flow channel. The channel was placed on

a hot plate and the temperature of the mixture was maintained at 30 ± 1 °C. A voltage was then applied to the electrode pair to generate an electric field, thus initiating the fluid flow. A laser sheet was used to illuminate the center of the flow channel, and the flow behavior was observed from the front of the flow channel using a video camera. The flow was observed both above the electrode pair and in the entire channel during experiments, which were conducted at 1.5 kV. The experimental observed region ABCD is shown in Fig.1 (a). The calculated region A'B'C'D' is shown in Fig.1(b). The calculated region is reduced to save the computational time and the free boundary condition is applied at the boundaries B'C'D'A'.

Figure 1: Flow field

2.3 Calculated results

The distributions of the electric potential and the electric field are shown in Figs.2(a) and (b) in the case of 1.5kV at $t=5.23 \times 10^{-5}$ s. The voltage is added at $t=0$ to the electrode GB' (GH) and the electrode A'F is ground. The distribution of the electric potential is symmetric for the axis of $x=0$. The large value of the electric field is concentrated near the points F and G of the electrodes. The direction of the electric field vectors is from the electrode GB' to the electrode A'F.

The distributions of the charge density and the electric force which is the coulomb force are shown in Figs.3 (a) and (b). The coulomb force is derived from the charge density times the electric field. The distribution of the charge density is shown in Fig.3(a). The positive charge density is generated and is diffused from the high electric potential electrode. The negative charge density is also generated from the ground electrode, however the generated region is small compared to the positive charge density region. The positive charge density region outside the negative region near the ground electrode can be seen. The positive region seems to be transported by the advection from the positive region and the all distribution of the charge density is asymmetric.

2.4 Comparison with experimental results

The visualization result is shown in Fig.4(a). The fluid called HFE-7100 (methoxy-

nonafluorobutane) is used as one of the EHD fluid. The sketched lines to indicate the flow direction clearly are shown. The vortex flow is indicated by white line and one directional flow from the boundary B'C' to the boundary A'D' is indicated by red line. It is recognized that the one directional flow is generated probably due to the asymmetric distribution of the charge density shown in Fig.3(a). The velocity distribution is shown in Fig.4(b). The magnitude of the velocity near the points F, G is large. The flow configuration such as the vortex upper the electrodes and the one-way streamline is very similar between the experimental observation and the simulated results.

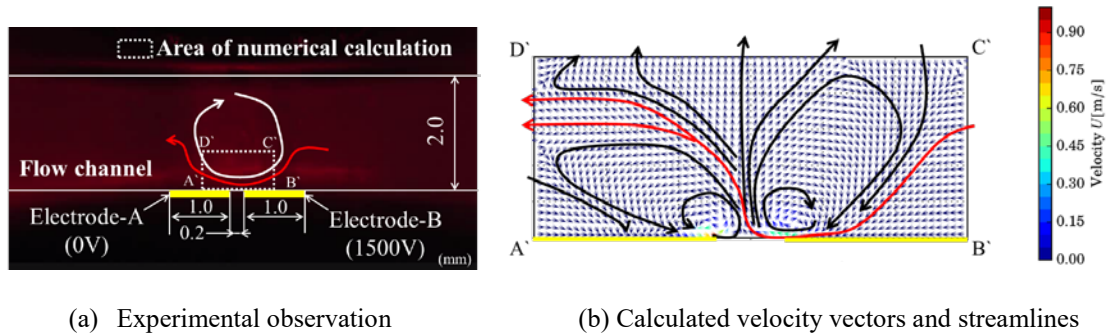

Figure 4: Flow visualization results

3 CIRCULAR PIPE PUMP

3.1 Pump based on cylindrical electrodes

The concept of the pump based on the cylindrical electrode pairs is shown in Fig. 5. The electrode material was copper plated with tin. An electric field was generated at the channel inside the cylindrical electrode pair by applying voltage. The one-directional flow generated by this electric field is caused by rotational flows, as shown in Fig. 4. The pump has a very simple structure and hence can be made easily. The cylindrical electrode pair is symmetric about a section perpendicular to its central axis, so the direction of the one-directional flow can be reversed by switching the anode and cathode.

The one of the pumps based on the cylindrical electrode pairs is shown in Fig.6(a). The pressure-flow rate characteristics plot in Fig.6(b) is approximately linear. Furthermore, the approximate line of the graph translates in the direction of decreasing pressure or flow rate when the applied voltage is decreased. Therefore, we concluded that the pressure and flow rate of the pump increase with the applied voltage. We also found that the pressure doubles when two pumps are connected in series.

Figure 5: Pump based on cylindrical electrodes

(a) Pump based on the cylindrical electrode pairs

(b) Flow rate and pressure

Figure 6: Characteristics between flow rate and pressure

3.2 Pumps based on the electrode with the multiple holes

Four types of multi-holes electrode pumps, termed Types I ~IV which are illustrated in Fig. 7 respectively. The disk electrodes used in the Type I~IV pump contain nine holes (1 mm diameter). The distance between the electrodes is 1mm. The width of one electrode of the pump is changed from 0.25 to 1mm. The electrode material was copper and the flow channel between the electrodes was produced from transparent acrylic resin. An electric field was generated in the flow channel of the multi-hole electrode pair by connecting the cathode and anode of a DC power supply, respectively.

The flow rates are measured by measuring the flow velocity inside the pump after the pressure is given by setting up the difference of the high between inlet and outlet of the pump. One of the typical characteristics between the flow rate and the pressure is shown in Fig.8. The pumps are connected series and the voltage is 5.0kV. The results are almost linear as same as the pumps based on the cylindrical electrode pairs. The flow rate and the pressure of the type II whose electrode widths are 1 and 0.5mm are large compared to other pump.

Figure 7: Pumps based on the electrode with the multiple holes

Figure 8: Relation between flow rate and pressure

4 CONCLUSIONS

The induced flow between electrodes was explained under application of the electric fields using CFD method and the flow observation technique. Especially it is found that the distributions of the charge density and the electric field are important because the coulomb force to induce the flow is affected by the charge density and the electric field. In addition it is found that the one directional flow can be generated by the asymmetry of the charge density distribution. For the characteristics of the pressure-flow rate of the EHD pump, the influence of the asymmetries of the electrode width on the relation between the flow rate and the pressure was examined and we found that both the pump pressure and flow rate can be increased by changing the widths of the electrode asymmetrically for the multi-holes electrode pair pumps.

5 ACKNOWLEDGEMENT

The author thanks Mr. Takahiro Shimizu, Taisei Tajima and Rei Suzuki for their generous support.

Key words: Tower Cranes, *In-situ* Measurements, Modal Analysis, Linear Dynamic Analysis, Seismic Vulnerability.

Abstract. Low to moderate size tower cranes used essentially in construction sites are very slender steel structures designed to carry high loads (1 to 3 tons) to distances up to 50 m around a central tower standing alone. They are required in many sites where working place is exiguous and easy to handle construction materials. Essentially they are composed by a tower with height varying according to the height of the construction and by an horizontal jib and counter-jib spanning a few tens of meters. We will analyse a particular tower crane with 33 m height and a jib with 35 m. These structures are very light, slender and flexible. Additionally they can be subjected to winds and earthquakes. Even though there are thousands of these structures all over the world specially in developing areas, there is very few published work for these type of structures. However, many disasters have occurred causing damage to people or urban equipment in the vicinity due to total or partial collapse of the structure. Wind has been in the past probably the most frequent cause of collapse, even though the jib is loose and can rotate freely around the tower axis. For earthquakes the main problem is the existence of large mass (a few tons) placed at a high position at an eccentric position. We developed a 3-D mathematical linear model of the structure with a finite element program SAP2000 and compared analytical frequencies with *in-situ* measurements. The maximum error for the 2 translation identified modes in X and Y direction was respectively 2.1%. Frequencies corresponding to the first modal shapes of this type of structure are very low (well below 0.5 Hz, depending on height of tower and counterweight). It has been found that the dynamic behaviour of the crane is largely dependent on the way its foundation is designed, which in this case is made of bogies supported on rails with concrete ballasts providing stability to the structure. Consequently the higher percentages of excited mass of the structure are associated with the more rigid vibration modes. We applied ground motion at the base to understand the dynamic 3-D behaviour of the whole system. The results indicate that a moderate ground motion ($PGA=1.5m/s^2$) shaking does not pose safety problems for this type of structure. However, caution should be exercised in order to maintain the concrete ballasts located at the foundation in place, to any type of seismic action.

1 FRAMEWORK AND DESCRIPTION OF THE STRUCTURE

This study focuses on the analysis of the dynamic behaviour of a tower crane and its vulnerability to a seismic action.

The subject in question is of great importance given the shortage of studies concerning the behaviour of this type of structures in the face of a moderate to intense seismic action and given the serious consequences inherent to their collapse [1].

During the research for this study it was found one of the few studies concerning this subject by Li-Jeng, et al [2] and also a regulatory document named as ISO 11031 [1].

Additionally, together with a growth of the construction in certain cities, there is a natural increase to use this type of structures.

The case study (Alto do Olival Crane) is located in Lisbon, Portugal.

The tower cranes are considered lightweight structures, essentially due to their geometry and the material used, steel, which although is not light (high volume weight), allows the application of slender profiles with adequate resistance.

In addition to this structural material, concrete ballasts are also used only as weight.

On the one hand, steel is used in the cross sections, the connections between profiles by means of bolts and welds and in the jib and counter-jib suspension cables.

On the other hand, concrete ballasts provide weight to the structure, ensuring its balance. In the present crane concrete ballasts serving as counterweight of about 3.9 tons are located at the end of the counter-jib and another group at the foundation for stabilization with 2x16 tons (see figure 1b)).

In the course of this chapter the crane is characterized sequentially from the ground to the top, starting from the foundation, the tower, and, finally, the jibs. This distinction is made on the basis of differences in terms of geometry, function, installation and functionality.

Firstly, the foundation is made of steel beams and is laid on rails, i.e. there is a possibility of changing the position crane if necessary. However, when it is in operation, four welded steel restrainers are placed on the rails to prevent the translation of this one. In addition, there are ballasts made of concrete with high mass, which accumulate on each side of the base a mass of 16 tons, providing stability to the tower crane.

Figure 1: Bottom view (a) and side view (b) of the tower crane base

As far as the tower is concerned, it has a spiral arrangement, consisting of modules that are repeated in height with different dimensions and profiles. The steel profiles applied along the tower are characterized by L and U sections and are gradually smaller along the height (figure 2). The tower reaches a height till the jib of 33 m.

Figure 2: Tower crane modules

Finally, the jibs are divided into two types, the jib, a longer one with a length of about 35 m, which aims to lift and transport the loads in the perimeter of influence, and the counter-jib, a smaller one with a length of 13 m, which has the counterweight at its end, in order to provide a balancing force to the load on the jib. While the jib is attached to the tower by a steel suspension cable with a diameter of $\phi=5$ cm, the counter-jib is connected by two suspension cables with $\phi=2.5$ cm each (figure 3).

Figure 3: Zone of connection between the tower and jibs

Again, the jibs also contain modules that are repeated throughout their development. In these zones tubular profiles are used essentially with square or sometimes circular sections (RHS and CHS sections).

2 STRUCTURE MODELING

The structure under study was modeled using the finite-element analysis program SAP2000 [3].

The following table presents the constituent elements of the structure and the way in which they were modeled.

Table 1: Elements forming the structure

Elements	Model
Steel profiles	Frame
Steel suspension cables	Cable
Concrete slabs	Area with distributed load

As can be seen to ensure the correct behaviour of the various constituent parts of the structure, three types of elements were used.

In figure 4 we can see the wide application of the frame in the model.

Figure 4: Application of the frame element in the model: a) base; b) tower-jibs connection and c) jib

Then, the effect of the concrete ballasts in the structure was counted through loads distributed in areas (shells) equivalent to the occupied size by these weights (Figure 6).

Figure 5: Application of the area element in the model: a) counter-weight e b) weights located in the base of the structure

Finally, in order to guarantee the correct behaviour of the suspension steel cables, which work only at tension, they were modeled as element “cable”.

Figure 6: Application of the cable element in the model: a) photography of the real structure and b) model

After completing the modeling phase of the structure in geometric terms, the following numerical model was obtained (figure 7).

Figure 7: Numerical model of the case study with identification of steel elements under safety check

4 MODAL CHARACTERIZATION

4.1 *In situ* dynamic characterization

Not only to ensure a closer proximity between the numerical model and the actual structure, as well as to provide a greater credibility of the results exposed in this work, a dynamic identification test based on ambient vibrations was performed in the structure under analysis (figure 8).

Figure 8: Frequencies according to the direction X (longitudinal) obtained through the dynamic identification test

From the analysis of this graphic it can be concluded that this type of structure is able to offer a wide range of results with great clarity and quality, thus facilitating the identification of the natural frequencies of the structure and, consequently, the calibration of the model.

Table 2: Frequencies obtained in the experimental test in the Y and X direction

f_y (Hz)	f_x (Hz)
0.32	0.29
-	0.78
0.83	0.82
1.90	1.90
2.35	-
2.80	2.80
3.10	-
3.51	-

It should be noted that in this test only the frequencies corresponding to the translation of the structure in the x and y direction, and not to torsional movements around were obtained. This is due to the location at which the accelerometer was placed (platform on the tower shaft of the structure), obtaining frequencies associated with torsional movements would require placing the apparatus at the tip of one of the jibs.

4.2 Modes of vibration

In this phase the vibration modes and respective dynamic characteristics of the structure under analysis are described.

It should be noted that the following table is composed of already adjusted and calibrated values, based on the results obtained in the dynamic identification test performed.

Table 3: Vibration modes and mass participation factors of the numerical model (orange color - most influential vibration modes, green color - cumulative mass participation factor of 90%)

91	0.018	55.804	0.04	0.94	0.00	0.99	0.00	0.99	0.00	0.99

As it is generally known, the overall response of the structure must be composed of all modes of vibration that contribute significantly. As such, in order for the sum of the mass participation factors of the structure to reach a minimum value of 90% of the total mass of the structure, a total of 91 vibration modes were recorded.

From the analysis of the vibration modes and its respective factors of mass participation, it highlights an interesting fact that must be evidenced.

As can be seen, the first twelve vibration modes of the structure do not generate high

percentages of excited mass ($\approx 33\%$), thus, the number of vibration modes under analysis has been widened in order to reach the minimum condition of 90% of excited mass of the structure. Consequently, it has been noted that the higher percentages of excited mass are associated with the translation of the base of the structure in each direction, x and y, which in turn concerns the more rigid modes of vibration.

The following table compares the results of the numerical model and the experimental test.

Table 4: Comparison of the model and *in situ* frequencies and error calculation

Direction	f (Hz)		Error (%)
	Model	<i>In situ</i> test	
x1	0.299	0.293	2.1
y1	0.311	0.317	-1.9
x2	0.663	0.770	-13.9
y2	0.871	0.830	4.9

From the analysis of the results it is concluded that the values obtained from the *in situ* test reveal a great quality, being close to three modes of vibration of the structure, thus proving a good approximation between the numerical model and the real structure.

From this comparison the lowest error obtained is around 1.9% and the maximum 13.9%, it should be noted that this maximum error is associated with a second mode of vibration in the y direction, and as such may possibly correspond to a less clear mode compared to the first two modes of translation vibration.

The following is a brief description of the most influential vibration modes in the behaviour of the structure.

4.2.1 1° Vibration mode

The first mode of vibration (figure 9) corresponds to a torsional mode with a period of 6.86 s and a mass participation factor of 97%.

As can be seen in the following figure, the movement of the structure occurs around the axis of the tower, guaranteeing a high percentage of excited mass.

Figure 9: 1st Vibration mode - Torsion around the axis of the tower

4.2.2 2° Vibration mode

The second mode of vibration (figure 10) represents the vibration of the structure in the x

direction, that is, in the direction of the jibs, with a period of 3.34 s and a mass participation factor of 12%.

Unlike the first mode of vibration, this mode has a reduced percentage of excited mass.

Figure 10: 2nd Vibration mode - Translation in the x direction

4.2.3 3^o Vibration mode

The third mode of vibration (figure 11) is characterized by a translation in the y direction, direction transverse to the length of the jibs, with a period of 3.22 s and a mass participation factor of 23%.

Once again, the percentage of excited mass is reduced.

Figure 11: 3^o Vibration mode – Translation in the y direction

The following modes of vibration represent the modes with the greatest influence on the dynamic behaviour of the tower crane, since they concentrate mainly on the mass excitation located at the base of the structure. Of note, the high discrepancy between the mass of the base of the structure and the rest of it.

Thus, the dynamic behaviour of a crane is largely dependent on the way its base is designed.

4.2.4 4^o Vibration mode

This mode of vibration (figure 12) represents a translation of the base of the structure in the y direction with a period of 0.042 s and a mass participation factor of 39%.

As can be seen this is a rather rigid mode and with a considerable excited mass percentage.

Figure 12: 42° Vibration mode - Translation of the base in the y direction

4.2.5 89° Vibration mode

This mode of vibration (figure 13) is characterized by a translation of the base of the structure in the x direction with a period of 0.018 s and a mass participation factor of 45%.

Once again a greater percentage of excited mass associated with a more rigid vibration mode is found.

Figure 13: 89° Vibration mode - Translation of the base in the x direction

In this way, it is fundamental not to neglect the influence of these last rigid modes of vibration on the dynamic behaviour of the structure.

5 SAFETY CHECK

In the context of a security analysis and verification, it was decided to subject the structure not only to a seismic record characteristic of the earthquake that occurred in Portugal in the past (1969), which is considered a small earthquake, but with very low frequency content, but also to the seismic action by means of a response spectrum (CEN, 2013) [4]. In this analysis the structure was considered without any loading along the jib.

Figure 14: Seismic action applied to the structure

The structure is located in Lisbon and implanted on a soil type B. According to the National Annex [4] (portuguese version) for a type I and type II seismic action corresponds respectively a maximum reference acceleration of 1.5 m/s^2 and 1.7 m/s^2 (RP = 475 years).

Thus, based on each type of seismic action, it was intended to evaluate the tensions acting on the various elements, the reactions in the base and the resistance of the restrains that prevent the movement of the crane base. As previously mentioned the crane is supported on rails and, in order to prevent the translation of this was welded some profiles to the rails.

5.1 Stress analysis

In terms of tensions, it is observed that the axial stresses predominate in the various profiles that make up the structure and that the transverse stress and bending moment are practically negligible (figure 15)

Figure 15: Axial stress in different zones of the structure (red and green – tension and blue – compression)

Therefore, we identified the most conditioning zones and compared the design loads with the design strength. In the case of a steel structure, the influence of the bending lengths and the reduction coefficients according to the possible directions must be taken into account. Fortunately, a tower crane consists of modules contemplating small lengths between profiles.

Table 5: Security check for certain profiles

Identification (from figure 8)	Designation	Seismic action	Ned (kN)	Nb,Rd (kN)	Check?
1	Base knee brace	Sismo 1 (X+0,3Y)	177,9	614,4	Yes
		S69-EW-UX	132,6		
2	Module 2 - L15	Sismo 1 (X+0,3Y)	222,1	1308,4	Yes
		S69-EW-UX	149,8		
3	Module 8 - L12	Sismo 1 (X+0,3Y)	166,3	847,0	Yes
		S69-NS-UX	116,7		
4	Jib – Suspension cable	Sismo 1 (X+0,3Y)	145,4	697,0	Yes
		S69-EW-UX	123,4		
5	Counter-jib – Suspension cable	Sismo 1 (X+0,3Y)	105,3	174,3	Yes
		S69-EW-UX	102,5		

It is concluded that the structure does not present problems due to the effects from both seismic actions.

5.2 Reactions on base and resistance of restraints

Then, the reactions in the base are quantified as a result of the seismic action applied in the structure, which makes it possible to analyze the resistance of the restraints and the capacity of the crane to maintain equilibrium.

Table 6: Base reactions due to the seismic record (Earthquake of 1969) and to the seismic action based on a response spectrum

Seismic action	Base reactions	
	R _x (kN)	R _y (kN)
S69 - EW-UX	12,5	19,0
Sismo II (0,3X+Y)	25,7	36,9
Sismo I (X+0,3Y)	28,8	27,1

From the analysis of this table it is verified that the application of the seismic record associated to the earthquake of 1969 brings results smaller than those obtained according to the seismic action regulating through a spectrum of response.

Thus, the values of the reactions in the base are compared with the resistance of the restraints provided by the welds. Safety was checked in the longitudinal direction of the welded section.

Table 7: Safety check of welded steel profiles on rails (restraints)

R _y (kN)	F _{w,rd} (kN)	Check?	Ratio (%)
36,9	1910	Yes	1,9

6 CONCLUSIONS AND FURTHER STUDIES

Thus, the most relevant issues are pointed out in the course of this study:

- In the first place, a collection of information was indispensable for the modeling of the structure in question. However, there was a lack of detailed information regarding the dimensions of the steel profiles and their connections, as such, field visits and photographic collections were carried out, which allowed to some extent reduce the uncertainties related to the characteristics of the structure.

- Next, it is with the realization of a dynamic identification test based on environmental vibrations that one has had the opportunity to calibrate the numerical model, thus approaching it of the real structure. Not only was a set of results obtained with great clarity through the test, but they also came close to a large part of the vibration periods characteristic of the model. A maximum error of 2.1% was thus obtained for the first two modes of translation vibration in the X and Y direction.

- In the next phase, the most relevant vibration modes of the structure and their dynamic characteristics were described. The most flexible vibration mode of the structure corresponds to a torsion mode around the tower axis with a period of 6.85 s.

- In general, the structure can be considered as flexible, taking into account the first modes of vibration with high vibration periods, however it was only in the higher frequency modes that there were higher percentages of excited mass. This is due to the concentration of most of the mass at the base of the structure. As such, the design of the base of a crane can greatly influence its dynamic behaviour.

- In order to verify the minimum condition of 90% of the excited mass of the structure, 91 modes of vibration were considered in the analysis of the results;

- In the analysis and safety check, the structure was requested to two types of seismic action, seismic action equivalent to the earthquake that occurred in Lisbon in 1969 through seismic records and a regulatory seismic action through a response spectrum. On the one hand, it was

verified that the earthquake of 1969 is less conditioning than the seismic action regulating and, on the other hand, the structure presents a good resistance to these actions both in terms of tensions and in terms of reactions in the base.

- As a recommendation, it is pointed out qualitatively that concrete ballasts located at the base of the structure are not properly confined, which may lead to the sliding of these during the seismic action.

- Consequently, this sliding would cause the collapse of the structure. To avoid this problem it is suggested to confine these concrete ballasts through a set of vertical and horizontal steel profiles, thus creating a containment box for these concrete ballasts.

Further studies include: (i) the study of performance of the crane for areas with higher seismic action and (ii) the analysis of other cranes of similar morphology but with other dimensions, to check if the present conclusions can be extended to other cranes. In Table 8 we present the main characteristics of a few cranes under study, for which *in-situ* measurements were already obtained, and in Figure 17 we show the correlation of the first longitudinal frequency with the total length of the crane (tower+jib).

Table 8: Main characteristics of several cranes already subjected to *in-situ* testing

Cranes	Supplier	Tower	Jib	Load (kg)	Tower	flong1 (Hz)	flong2 (Hz)	ftrans (Hz)
Location		Height (m)	Length (m)		Width (m)

Key words: Ice Gouging, Mohr-Coulomb, Dense Sand, Coupled Eulerian-Lagrangian.

Abstract. The integrity of subsea pipelines in the Arctic regions is threatened by ice-related subsea geohazard. A common practice for physical protection of the pipelines against the ice loads is to bury them inside the subsea trenches. However, determining the minimum burial depth of the pipeline to minimize the construction cost is a challenging design aspect of Arctic offshore pipelines. This requires an in-depth understanding of the ice-soil-pipe interaction, which in turn is significantly affected by ice-soil interaction. Mohr-Coulomb soil model is conventionally used for continuum modeling of dense sand by adopting the constant friction and dilation angles. However, this approach neglects the pre-peak hardening and the post-peak softening behavior of dense sand. In this study, a smart self-correcting soil model was incorporated into an advanced Coupled Eulerian-Lagrangian (CEL) analysis to automatically update the shear strength parameters by the magnitude of plastic strains. The analysis was conducted using ABAQUS/ Explicit scheme incorporating the soil model that was coded into a user-defined subroutine. The soil strength parameters are self-corrected to model the nonlinear hardening, softening and pressure dependency behavior of dense sand by considering the ice keel bearing pressure and octahedral shear strain. The pre-peak hardening and post-peak softening behavior of dense sand were captured through a series of free-field ice gouging analysis. The sub gouge soil deformation and ice-soil contact pressure were extracted and compared with the results of the original Mohr-Coulomb model, the existing analytical solutions, and the published test data. The study showed the significance of incorporating the strain rate dependency of dense sand on seabed response to ice gouging. The methodology was found to be a strong but simple framework that can be used in daily engineering analyses. It was observed that the magnitude of the subgouge soil deformation is overestimated by the

conventional decoupled methods. Also, the required burial depth was found to be smaller than those recommended by conventional methods, which in turn can significantly reduce the construction effort.

1 INTRODUCTION

Ice scouring is one of the most hazardous challenges that the subsea pipeline has faced in the Arctic region. The most common way to protect the pipeline is to bury them under the seabed. Obtaining the minimum burial depth is a significant design aspect due to the dependency of the project cost and the uncertainties with the ice gouging features. A deep understanding of ice gouge process is needed to find the best burial depth, and it can be gained through proper modeling of this event. During the last two decades, many studies have been conducted on both cohesive and cohesionless soils to improve the offshore industries' prospects on ice gouging characteristics [1,2].

Figure 1: Ice gouging process and subgouge deformation

The conventional Mohr-Coulomb (MC) soil model considers the constant friction and dilation angles for the numerical modeling of the ice gouging in the sandy region; however, it does not consider the non-linear stress-strain characteristics of dense sand such as non-linear pre-peak hardening, post-peak softening, effects of density and confining pressure [3], and the type of shearing (triaxial or plane-strain condition) [4]. These simplifications cause inaccuracy in the predicting of the soil behavior within the gouging area.

In this study, a set of key aspects from some developed non-linear models were employed by a simplified approach to studying all the non-linear behavior associated with dense sand in an ice gouging event [e.g., 4,5]. A Coupled Eulerian-Lagrangian (CEL) model was developed in ABAQUS/Explicit to simulate the ice gouging process, and the soil model was tailored in a user-defined subroutine (VUSDFLD). In each time increment, the ABAQUS called the subroutine to update the shear strength parameters of the seabed through using accumulated plastic shear strain, loading condition, density and confining pressure.

The results of MC and Modified Mohr-Coulomb (MMC) models were conducted and also by published experimental investigations [6]. The outputs show that the MC model is not able to capture the results accurately and overestimated the sub gouge deformation, frontal mound, and the keel reaction forces. The MMC model fully captured the soil response and solved the problem of overestimation of the MC model, and its results were also well close to the test. The cyclic response of the keel was also captured which has been stated in the experimental results

and was not reported in any other previous numerical simulations in the past.

2 NUMERICAL MODELING

In this study, the free field ice gouging analysis was conducted using finite continuum element (FE) analysis. These type of research has been proven to be valuable in order to understand the soil behavior under the ice gouging load and then applying this behavior to the pipeline by using simple beam spring method to investigate the critical aspects of design [7-13]. Although this model is computationally effective, it suffers from the superposition errors and directional load decoupling influences during the discretized soil media [14].

ABAQUS/EXPLICIT has proven to be a powerful tool in capturing large deformation behavior of soil under the ice gouging load [15]. In this study, a half-space ice/soil model was simulated. The dimension of the soil media is $76 \times 22 \times 40$ m which are respectfully length, width and height. The seabed was implemented in Eulerian domain, and the boundaries of this domain were considered large enough to prevent any boundary effect and also allowed the material to flow freely inside the Eulerian body. The 8-noded linear reduced integration hexahedral elements were used for meshing the Eulerian part.

Figure 2: The constructed FE model configuration

The ice keel was modeled as a rigid body [16]. The void part in Figure 2 was considered to allow the material to move within the Eulerian mesh. Unlike the Lagrangian mesh, the nodes are not attached to the Eulerian mesh and material is able to move inside the mesh without distorting the mesh. The ABAQUS built-in “general contact” was used to simulate the ice/soil interaction. This feature of ABAQUS captures any contact between the Lagrangian body (ice) and Eulerian domain (soil) in a CEL model which enhance the accuracy of the model. The frictional behavior was defined as a penalty based contact with a friction coefficient of (μ) of 0.7 (i.e., $\tan(\varphi_\mu)$). The parameter φ_μ is the ice/soil friction angle and varies between $\varphi'_p/2$ and φ'_p of sand [17]. The “hard” pressure overclosure was used for normal surface contact. This feature controls the penetration of the slave body into the master body. Once the two surfaces become into contact, these relationships stop the tensile transfer at the interface of the contact surfaces [15].

For using the CEL method, the velocity or displacement boundary conditions of the Eulerian

body should be restricted to prevent the mesh from moving. The ice was free just to move forward and the vertical displacement and rotation boundaries were secured. To consider the soil column pressure, the geostatic stress was employed to the model [18]. An initial geostatic condition was defined while the gravity load was applied to the whole model in the first step. This step is crucial to mitigate the instabilities that applying the gravity load may cause. In the second step, the ice moved horizontally forward. To avoid causing any dynamic effects for the model, the velocity of ice was increasing gradually in a small part of the time from zero to the velocity of the test and then advanced with the same velocity. A finer mesh was used in gouging affected area, and a coarse mesh was applied for another area to minimize the computational cost of the simulation. Different tracer sets were defined to record the soil displacement and subgouge deformation. Moreover, both 2D and 3D tracer particles were planted in the model to visualize the subgouge mechanism.

3 SOIL MODEL

One of the most important factors in ice gouging modeling is the soil model which is employed in the model [e.g., 19]. Regards to the cohesionless material, Mohr-Coulomb soil model was proved to be approximately accurate and able to capture the desired behavior; however, the ABAQUS built-in Mohr-Coulomb model utilizes constant friction (φ') and dilation angle (ψ) which result in unrealistic results and dilation. This excessive dilation can affect an ice gouging model significantly. The subgouge deformation, reaction forces and frontal mound which are the most important results of an ice gouging simulation are dependent on the friction and dilation angles. Therefore, in this study, a modified Mohr Coulomb model was adopted after Roy et. al, (2015) to overcome these problems. In this soil model, the pre peak, post peak softening behavior of sand was applied by increasing the friction angle from and initial value (φ'_{in}) to a peak value (φ'_P) and then decrease it to a critical value (φ'_C). The same thing also happens for dilation angle (ψ) [5].

Bolton (1986) has come up with an equation for peak friction angle after investigating 17 sands sample [4].

$$\varphi'_P - \varphi'_C = A_\psi I_R \quad (1)$$

where φ'_P indicates the friction angle in the peak point and φ'_C is the critical friction angle. A_ψ is 3 for the triaxial condition and 5 for plain strain condition. $I_R = I_D(Q - \ln p') - R$ in which I_D is the relative density ($I_D = Dr(\%)/100$) and in $0 < I_R < 4$, $Q = 10$ and $R = 1$ are the best match to show the sand behavior [4].

As Bolton (1986) discussed, the peak dilation angle (ψ_P) is related to the φ'_C and φ'_P :

$$\varphi'_P - \varphi'_C = k_\psi \psi_P \quad (2)$$

k_ψ is equal to 0.5 for the triaxial and 0.8 for plain strain conditions [4].

$$\gamma_P^P = \gamma_C^P \left(\frac{p'}{p'_a} \right)^m \quad (3)$$

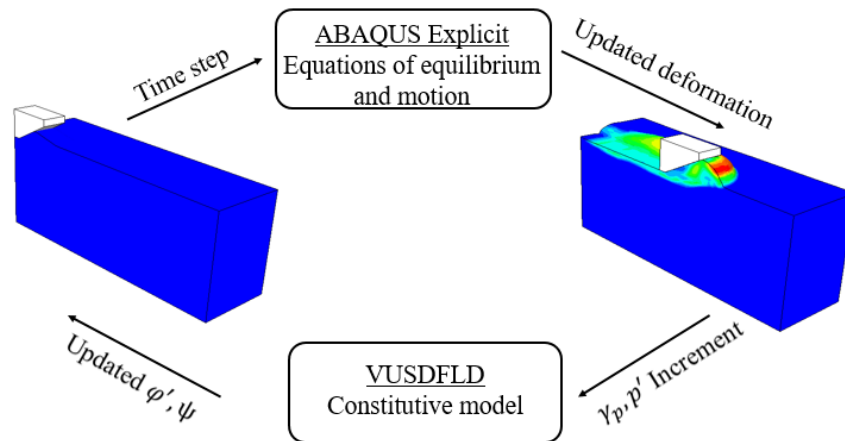

$$\gamma_C^P = C_1 - C_2 I_D \quad (4)$$

where γ_C^P is the softening parameter and p'_a is the atmospheric pressure. m , C_1 and C_2 are the

Table 1: Soil parameters for Mohr-Coulomb and developed model

Parameters		Values	
		Mohr-Coulomb	Modified Mohr-Coulomb
$\varphi'(^{\circ})$		$\varphi'_c = 35$	Eqs. 1-7
$\psi(^{\circ})$		6	Eqs. 1-7
Cohesion (kPa)		2	
Parameters of variation of φ' and ψ	A_{ψ}	3 [5]	
	k_{ψ}	0.5 [5]	
	φ_{in}	29 [5]	
	C_1	0.22 [5]	
	C_2	0.11 [5]	
	m	0.25 [5]	

The soil model was coded in VUSDFLD user subroutine to apply the nonlinear variation of the φ' and ψ with the plastic shear strain, mean effective stress, density. The stress components were called into the subroutine in each time increment using VGETVRM utility in the subroutine. Using the stress components, p' was calculated and stored as the first field variable FV1. VGETVRM is not able to call the principal plastic strains; therefore, the VSPRINC utility was used to call the principal plastic strains and the maximum principal plastic strain was deposited as major principal plastic strain component (ε_1^p) and the minimum one was deposited as minor principal plastic strain component (ε_3^p). The plastic shear strain (γ^p) was calculated as $\gamma^p = \varepsilon_1^p - \varepsilon_3^p$ and stored as the second field variable FV2. The γ^p was calculated during the time of analysis and accumulated. In the input file, the mobilized φ' and ψ were defined in a tabular table using the equation discussed before. During the analysis, this process happened in each time increment and the software updated the values of the φ' and ψ [5]. Figure 4 shows the VUSDFLD process in ABAQUS/EXPLICIT.

**Figure 2:** VUSDFLD in ABAQUS/EXPLICIT

4 FINITE ELEMENT MODEL VALIDATION

The last step in a finite element modeling is to validate the simulation with experimental results or other published numerical models. To be able to compare the numerical model with the physical tests, the developed model must match the test in regards to the dimension, soil material, and ice condition. Therefore, the model described before was similar to the centrifuge tests conducted by Yang (2009) as part of the Pipeline Ice Risk Assessment (PIRAM) project that was used for validation [6]. The test parameters have been shown in Table 2.

Table 2: The centrifuge tests parameters

Parameters		Values	
		PIRAM P06	PIRAM P07
Gouge Depth (m)		2.3	2.4
Ice Velocity		0.11 m/s	0.55 m/s
D_r		% 50.8	%39
Ice Keel	Speed (m/s)	0.11	0.55
	Attack Angle	30°	
Young Modulus (MPa)		26	
Poisson's Ratio		0.32	
Density (Kg/m ³)		1455	1421

The ice was planted in the centrifuge tests, and an initial mound was created by hand in front of it. In the numerical model, the exact thing happened which caused reaching to steady state sooner than penetrating to the ice down. Further, putting the ice in the gouge depth and applying an initial mound is also preventing the dynamic effects of pushing the ice down.

5 RESULTS AND DISCUSSION

Two comparisons between the conventional Mohr-Coulomb model and modified Mohr-Coulomb model are shown in the following. The reaction forces and subgouge deformation were obtained as the most important output results commonly study in ice gouging process. The test results are also provided to show the consistency of the proposed model with the physical test results.

Figure 3: The comparison of the subgouge deformation, a., test P06, b., test P07

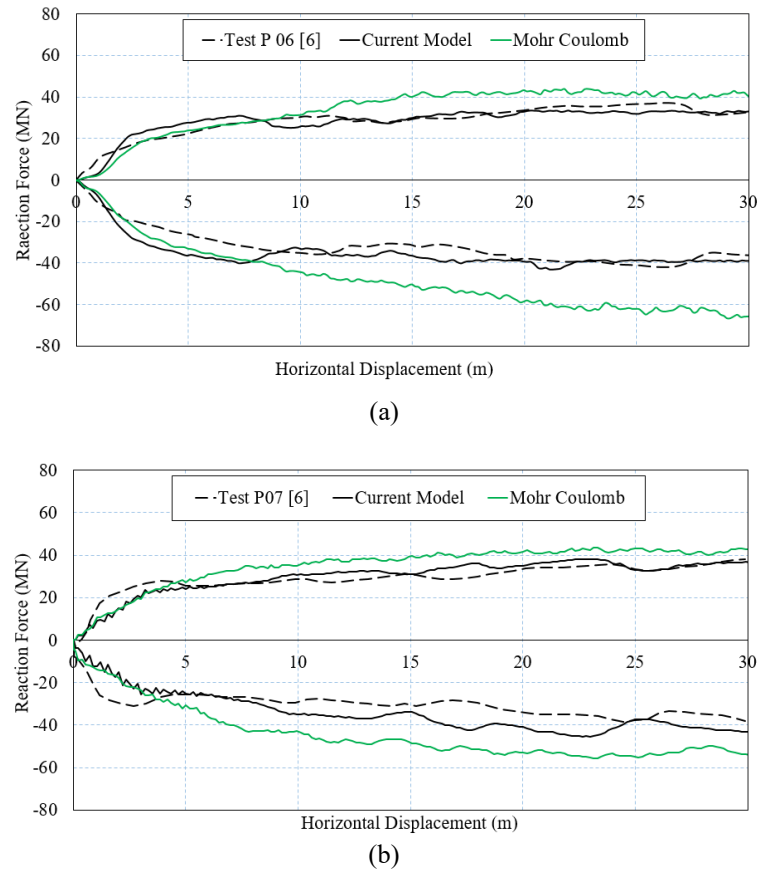

Figure 4: The comparison of reaction forces, a., test P06, b., test P07

Less subgouge deformation was observed in denser sand, and more subgouge deformation was seen in looser sand in MMC models which in all cases were in more consistency with the tests. Also, the reaction forces were smaller in both simulations and closer to the test. It can be concluded that the MC model overestimates the sand response to the ice gouging load (See Figures 5 and 6). The cyclic steady state is also seen in both tests and MMC models [6].

There are other soil models that can solve the excessive dilation problem of Mohr-Coulomb model such as Norsand model. However, this soil model associated with many parameters and difficulties in technical methodology for applying these parameters. The MMC model proved to be time efficient, simple to use and accurate for large models like ice gouging.

Figure 7 shows the excessive dilation caused by MC model in comparison to the MMC soil model. In addition, the current model predicts and visualizes the basal shear bands where the plastic shear strain is largely developed. This visualization cannot be conducted in a simple Mohr-Coulomb model in ABAQUS.

Figure 5: Comparison of the dilation of Mohr-Coulomb and Modified Mohr-Coulomb in test P06, a., Modified Mohr-Coulomb model, b., Mohr-Coulomb model

Figure 6: Tracer particles inside the developed model of the current model

The tracer particles were planted in the model as shown in Figure 8. These particles will show the trajectory of soil deformation from different views in the last stage of ice gouging in the current model.

6 CONCLUSION

Finite element analysis of the free field ice gouging in the sand was created. Coupled Eulerian-Lagrangian method was utilized for large deformation analysis. A modified Mohr-Coulomb was adopted and tailored in a user-defined subroutine to update the friction and dilation angles with maximum plastic shear strain and effective stress. The model simulated the pre-peak hardening and post-peak softening behavior of sand within the basal and other shear bands. The cyclic steady-state response of the keel was captured. It was concluded that the modified Mohr-Coulomb resulted in more accurate simulation and closer subgouge deformation and reaction forces to the physical experiments. This can lead to the less excavation and trenching depth requirement and therefore a more economical design. Further investigation is still conducting to study the performance of the model in coupled ice-soil-pipe interaction and the resultant stresses and strain in the buried subsea pipelines.

Abstract. In this study, raffinose-coated silver nanoparticles (Ag@Raff NPs) with narrow size distribution were synthesized by green ultrasound-assisted reduction method employing raffinose as both reducing and protecting reagent in alkaline reaction medium. UV-visible absorption spectrum of the light yellow aqueous nanoparticle dispersion showed surface plasmon resonance band at λ_{\max} of 411 nm. The electrostatic surface potential of Ag@Raff NPs was -47.2 ± 1.1 mV at pH 6.8. The polycrystalline solid product mainly consisted of quasi-spherical silver nanoparticles of mean diameter 27.2 ± 6.7 nm. Some polyhedral nanoparticles were also observed in the TEM micrographs. XRD analysis showed broad diffraction peaks with 2θ of 38.2° , 44.4° , 64.6° and 77.4° corresponding to the (111), (200), (220) and (311) planes, respectively, of the face-centered cubic (fcc) silver.

The analytical method developed for Cr(III) and Cr(VI) determination consists of two steps: (i) Addition of Ag@Raff NPs dispersion to water sample, containing Cr(III) and Cr(VI). Cr(III) is selectively sorbed on the nanoparticle surface under optimized chemical conditions and determined by using ETAAS; (ii) Addition of Ag@Raff NPs dispersion to parallel water sample, containing Cr(III) and Cr(VI); Cr(VI) was in-situ reduced by ascorbic acid to Cr(III) and determined through the sensitive and selective optical response of Ag@Raff NPs at optimized ratios between the components and optimal contact time. The proposed method was successfully applied for chromium speciation in surface water samples.

1 INTRODUCTION

Chromium is an element found in rocks, animals, plants, water and soil [1]. Chromium and its compounds are used in variety industries – chemical, medical/health care industry, leather tanning, textile dyes, and metallurgical technologies [2]. The most common forms of chromium in the environment are the trivalent form Cr(III) (chromium oxide and chromium

sulphate) and hexavalent form Cr(VI) (chromium trioxide, chromic acid and dichromate) [3]. The trivalent chromium is nontoxic and it is involved in several biochemical processes: glucose metabolism, enzymes reactions, body fat decrease [2]. The hexavalent chromium is toxic to the most living organisms and could be the cause of lung-cancer, dermatitis, allergies, kidney-damage [2, 4]. For these reasons, the quantification of chromium is really important in the control of environmental pollution.

Different methods have been developed for chromium detection: flame atomic absorption spectroscopy [5], graphite furnace atomic absorption spectroscopy [6], x-ray fluorescence spectrometry [7], chromatography [8], inductively coupled plasma, atomic emission spectrometry and inductively coupled plasma-mass spectroscopy [9]. Although these methods show high sensitivity and accuracy in the determination of total chromium, they are costly and time-consuming.

Nanoparticles and nanomaterials have attracted great attention from scientists in recent years due to their unique physical and chemical properties. Aragay et al. has been presented a comprehensive review about macro-, micro-, and nanomaterial-based tools and strategies for detection of heavy metal in the environment [10]. The application of noble metal nanoparticle for drinking water purification from different types of contaminants (halogenated organics including pesticides, heavy metals and microorganisms) has been presented [11]. Zhang and Fang presented the recent progress of detection and treatment of persistent organic pollutants and heavy metal by using nanomaterials and analytical nanotechnology [12]. El-Ansary and Faddah elucidated the possibility of using nanoparticles functionalized with antibodies as markers for proteins in their review [16]. Starch-stabilized silver nanoparticles were synthesized and used for optical sensor of hydrogen peroxide [13]. Colorimetric methods based on metal nanoparticles are extremely attractive, because they are rapidly, low-cost and can be easily read out with the naked eye. Many examples for using of noble nanoparticles (gold and silver) for colorimetric detection of heavy metal ions (e.g., Hg(II), Pb(II), Cu(II)) have been reported [14]. Ravindran et al. has been presented excellent results for selective colorimetric sensing of cysteine in aqueous solutions using silver nanoparticles and a presence of Cr³⁺ [15]. Lai and Tseng used 5-thio-(2-nitrobenzoic acid) modified gold nanoparticles for sensing of Cr(VI) [3].

The aims of this study were: (i) synthesis and characterization of raffinose-coated silver nanoparticles and (ii) investigations on the possibility of their application as both effective sorbent for solid phase microextraction of Cr(III) from aqueous solutions and optical probe in LSPR based sensing system for quantitative, selective and sensitive determination of Cr(VI). Silver nanoparticles have been already explored as sorbents/colorimetric probes for metal ions determination, but their capabilities for chromium speciation are still not reported.

2 MATERIAL AND METHODS

2.1 Apparatus

UV-Vis absorption spectra were recorded on an Evolution 300 spectrometer (Thermo Scientific, USA) within the 200–800 nm range using quartz cuvettes with 1 cm optical path length. High-purity water was used as a reference sample for background absorption. The formation of Ag@Raff NPs was further confirmed by X-ray diffraction (XRD). Briefly, 2 mL of Ag@Raff NPs dispersion (on portions of 100 µL) were placed on microscope glass and air-

dried. The XRD patterns of the dried samples were determined using X-ray powder diffractometer (Siemens D500) equipped with $\text{CuK}\alpha$ radiation ($\lambda = 1.54\text{\AA}$) in 2θ ranging from 15° to 80° . The morphology and particle sizes were examined using a high resolution transmission electron microscope (TEM, JEOL JEM-2100 operating at an accelerating voltage of 200 kV). Volume of 5 μl Ag@Raff NPs suspension was placed on a carbon-covered copper grid for TEM and air-dried. The histogram of Ag@Raff NPs size distribution and mean diameter of nanoparticles were determined by counting at least 200 nanoparticles from the different TEM images using Image J software. Some structural details of the nanoparticles were analysed using the high-resolution TEM image and SAED pattern. The zeta potential of nanoparticles was measured with a Zetasizer Nano ZS (Malvern) instrument.

ETAAS measurements were carried out on AAnalyst 400 spectrometer (Perkin Elmer) under optimal instrumental parameters. A microprocessor pH-meter (Hanna Instruments, Portugal) was used for pH measurements. Shaver, model "BOECO OS-20", Germany and centrifuge model "K-1000" KUBOTA Corporation, Japan were used sorption experiments.

2.2 Chemicals

All chemicals used were of analytical-reagent grade and all aqueous solutions were prepared in high-purity water (18 M Ω , Millipore Corp., Milford, MA, USA). Silver nitrate (AgNO_3 , 99.8 %), sodium hydroxide (NaOH , 99 %), nitric acid (HNO_3 , 65 %), salts of the different cations studied (NaCl , KCl , MgCl_2 , CaCl_2 , $\text{Pb}(\text{NO}_3)_2$, ZnCl_2 , CuCl_2 , NiCl_2 , CdCl_2 , CoCl_2 , FeCl_3) from Merck, Germany, pharmaceutical grade D-(+) raffinose from Alfa Aesar, Germany were used. The stock standard solutions for Cr were: Cr(III), Spex Certiprep 1000 mg/L in 2% HNO_3 and Cr(VI) Spex Certiprep 1000 mg/L in H_2O . Working standard solutions were prepared daily by appropriate dilution.

2.3 Synthesis and characterization of raffinose-coated silver nanoparticles

Raffinose-coated silver nanoparticles were prepared by one-step, one-phase "green" synthesis following the synthetic procedure described in our previous study [17]. Silver nanoparticles were obtained through a reduction reaction of silver nitrate with trisaccharide raffinose as both reducing and stabilizing agent in the presence of suitable sodium hydroxide amount as a reaction catalyst. Figure 1 shows the reaction scheme of preparation and coating of silver nanoparticles with raffinose.

Figure 1. Reaction scheme for obtaining raffinose-coated silver nanoparticles

Briefly, 0.75 mL stock solution of AgNO_3 (0.1 mol/L) were diluted with 60.75 mL high-purity water and homogenised for 5 min in an ultrasonic bath (power 100 W, frequency 38 MHz). After that, 7.5 mL raffinose aqueous solution (0.1 mol/L) were added and left for at least 15 min to form a complex under ultrasonic treatment. The reaction was started by addition of 6 mL NaOH aqueous solution (0.1 mol/L) and continued for 1 h at constant temperature (30 ± 2 °C) in an ultrasonic bath to assure the homogeneous formation of the silver nanoparticles. A change of the solution color from colorless to pale brown and subsequently to yellow orange was observed, indicating nanoparticle formation.

The as-prepared Ag@Raff NPs dispersion with Ag concentration 1×10^{-3} mol/L (110 mg/L) was kept in a dark glass flask at room temperature and was used in the following experiments without any purification. Prior to each experiment, Ag@Raff NPs dispersion was homogenized by an ultrasonic bath for 30 min.

2.4 Evaluation of Ag@Raff NPs as a nanosorbent for the selective separation of Cr(III) and Cr(VI) species in aqueous solution

Volumes of 0.25 mL Ag@Raff NPs dispersion and 1.25 mL solution, containing both chromium chemical species (100 µg/L Cr(III) and 100 µg/L Cr(VI)), were mixed in 2 mL centrifuge tube. pH value of the resulting solution was adjusted with 10 mol/L NH_3 solution in the range 7-9. The analyte sorption was carried out under continuous stirring for contact time 0-30 min. The sample was centrifuged in ultra-centrifuge at 14 000 rpm. The effluent was decanted. The analyte, adsorbed on Ag@Raff NPs surface, was eluted/dissolved with 0.050 mL c. HNO_3 and diluted with 1 mL high-purity water. The Cr concentrations in the eluate (c_{el}) and the effluent ($c_{\text{supernatant}}$) were determined by ETAAS. The degree of analyte sorption was presented as $D, \% = [1 - (c_{\text{supernatant}}/c_{\text{ini}})] \cdot 100$, where c_{ini} is the initial concentration of the metal ion in the sorption solution.

2.5 Assessing the Ag@Raff NPs dispersion as an optical probe in LSPR based sensing system for Cr(VI)

An aliquot of 200 µL Ag@Raff NPs dispersion and 1400 µL high purity water were consecutively added into a small quartz cuvette, followed by addition of 150 µL of 5×10^{-3} mol/L solution of ascorbic acid. 500 µL The solution was vortexed for 30 s, and then 250 µL Cr(VI) solution with varying concentration were added and homogenized for 30 s. The concentration of Cr(VI) solution ranged from 1×10^{-6} mol/L to 1×10^{-4} mol/L. The pH of the solution was maintained in the range 3.5-4 with hydrochloric acid solution. After contact time in the range of 0-30 min, UV-Vis absorption spectrum was taken in the wavelength range 300-800 nm. In order to investigate the sensitivity of colorimetric assay towards other ions, raffinose-coated Ag NPs were allowed to interact separately under the same conditions with 50 µmol/L solutions of alkali, alkaline earth, and transition-metal ions (separately for each ion). Resulting solutions were monitored by UV-Vis absorption spectroscopy.

3 RESULTS AND DISCUSSION

3.1 Characterization of raffinose-coated silver nanoparticles

The optical properties of as synthesized raffinose-coated silver nanoparticles and after their

storage were examined by UV-Vis spectroscopy and shown in Figure 2.

Figure 2. UV-Vis absorption spectra and photograph of raffinose-coated silver nanoparticles taken after nine-fold dilution of the aqueous dispersion immediately after synthesis, after one week, and after 2 months of storage

UV-Vis absorption spectrum of fresh synthesized aqueous dispersion shows the presence of single, narrow and high-intensive localized surface plasmon resonance (LSPR) band with λ_{max} of 411 nm, which indicates the formation of mainly spherical nanosized silver particles with a narrow size distribution [18]. The yellow color of silver nanoparticle aqueous dispersion (left in Figure 2) obtained by the synthesis procedure described is consistent with spectroscopic observation. Registered reproduction of the optical characteristics (wavelength of the surface-plasmon resonance peak and half-width of the band) after prolonged storage of aqueous nanoparticle dispersion indicates a high stability of raffinose-coated silver nanoparticles. The electrokinetic measurement of surface electrostatic potential (ξ) of silver nanoparticles shows a value of -47.2 ± 1.1 mV at pH 6.8, which is indicative of high electrostatic stabilization in addition to the steric nanoparticle stabilization due to the surface layer of raffinose. The negative value of ξ -potential is most likely due to the sorption of negatively charged oxidized forms of raffinose fragments (resulting from the alkaline raffinose degradation in the course of nanoparticle synthesis) onto nanoparticle surface [19].

The conclusion concerning the formation of silver nanoparticles with narrow size distribution and approximately spherical morphology (based on the shape and location of LSPR absorption band in the UV-vis spectrum of synthesized nanoparticle dispersion) is further confirmed by TEM/HRTEM observations (Figure 3a,b,c). TEM micrographs illustrate that quasi-spherical Ag@Raff NPs with narrow size distribution and average size of 27.2 ± 6.7 nm are obtained by the synthesis method developed. In addition to the nanospheres, some typical polyhedral nanoparticles (multiple twined nanocrystals) are also observed in the HRTEM images (Figure 3c). The diffused rings in SAED pattern of Ag@Raff NPs confirmed the polycrystalline nature of the synthesized nanoparticles (inset in Figure 3b).

The crystallinity of raffinose-coated silver nanoparticles was confirmed by XRD analysis. The XRD pattern of Ag@Raff NPs (Figure 3d) showed four relatively broad diffraction peaks with 2θ of 38.2° , 44.4° , 64.6° , and 77.4° corresponding to the (111), (200), (220) and (311)

planes respectively, of the face-centered cubic (fcc) silver (PDF 04-0783). The relatively broad diffraction peaks indicated either imperfect or fine nanocrystallite nature of the polycrystalline Ag@Raff NPs [20]. The results from XRD analysis are consistent with the SAED pattern obtained in TEM observations. Furthermore, the characteristic diffraction reflections of raffinose were not observed in the diffractogram of Ag@Raff NPs. This could be due to the formation of non-crystalline complexes of raffinose with silver nanoparticles [13]. The halo at reflection angles in the range 20–30° is due to the glass support, which used in the sample preparation. No impurity peaks were observed in the X-ray diffraction pattern of silver nanoparticles synthesized.

3.2 Optimization of extraction parameters of Ag@Raff NPs toward Cr(III)

Effect of pH and sorbent amount

The extraction efficiency of Ag@Raff NPs toward Cr(III) was examined at pH values in the range 6–9, achieved with 10 mol/L NH_3 solution, applying the sorption procedure described in Section 2.4. The results presented in Figure 4a show that quantitative sorption of Cr(III) is achieved at pH 8–9, whereas the sorption degree of Cr(VI) is 2%. Most probably, the

retention of Cr(III) is a combination of electrostatic attraction between the positively charged ammonium complexes of Cr(III) (formed in the presence of ammonia solution) and the negatively charged raffinose-coated silver nanoparticles, with further complexation between the analyte and the deprotonated functional groups of raffinose, while the negatively charged Cr(VI) species remain in the solution. This assumption is confirmed by the negative values of ξ -potential of silver nanoparticles at pH 7–9: -48.8 ± 1.5 mV (pH 6.9); -47.2 ± 1.1 mV (pH 7.8); -47.0 ± 1.9 mV (pH 8.8).

In a neutral, pH 7, or slightly acidic environment, pH 6, the resulting sorption degree is lower - about 70% or 10%, respectively. Probable reason for this drastic reduction in Cr(III) sorption degree below pH 7 is the electrostatic repulsion between the complexes $\text{Cr}(\text{H}_2\text{O})_5(\text{OH})^{2+}$ or $\text{Cr}(\text{H}_2\text{O})_4(\text{OH})_2^+$ (which are the predominant chemical forms of Cr(III) under these conditions [21]), and the partially protonated, positively charged functional groups of raffinose [22], in combination with a limited complexation potential of chromium, due to the inertness of its complexes ($\text{Cr}(\text{H}_2\text{O})_5(\text{OH})^{2+}$ and $\text{Cr}(\text{H}_2\text{O})_4(\text{OH})_2^+$). The insignificant Cr(VI) sorption, registered at the optimal pH 8.5 for Cr(III) sorption (achieved with ammonia solution), demonstrates the potential of Ag@Raff NPs to be used as an effective nanosorbent for chromium speciation analysis of water samples.

The experiments, performed with different amounts of Ag@Raff NPs (between 10 and 45 μg Ag as nanoparticle aqueous dispersion), showed that 22 μg Ag, contained in 0.2 mL Ag@Raff NPs dispersion, is the optimal silver amount for quantitative Cr sorption. The Cr(III) sorption with lower or higher volume of Ag@Raff NPs was below 80%, in the first case due to the lower density of negative charges, and in the second case most probably due to the blocking of raffinose functional groups.

Sorption kinetics

The sorption kinetics of both Cr(III) and Cr(VI) on the raffinose-coated silver nanoparticles was studied for time period of 2–40 min at pH 8.5 (procedure in Section 2.4). The samples were shaken on a shaking machine. As can be seen from the results presented on Figure 4b, at least 0.5 h is necessary for selective and quantitative sorption (> 99 %) of Cr(III) on the surface of Ag@Raff NPs, while Cr(VI) remains quantitatively in the solution. Relatively rapid sorption is most likely associated with the high nanoparticle contact surface in the aqueous dispersion.

Experiments for the influence of sample volume on the sorption degree of Cr(III) and Cr(VI) were performed with sample volume ranged between 10 and 50 mL using 0.2 mL Ag@Raff NPs dispersion. The experimental results defined 20 mL as an optimal sample volume ensuring a selective separation of both Cr species for 0.5 h sorption time. The adsorption capacity, achieved under these chemical conditions, is 10 mmol Cr(III)/mg sorbent. This capacity is completely sufficient for retention and separation of Cr(III) even in relatively polluted surface and ground waters.

Elution study

The effect of eluent concentration (HNO_3) on the Cr(III) desorption and regeneration of sorbent particles was studied at relatively soft conditions from 2 mol/L HNO_3 to 4 mol/L HNO_3 , taking into account chemical instability of Ag@Raff NPs in acidic solutions. The results obtained showed that HNO_3 with concentration 2 mol/L does not ensure a quantitative

elution of Cr(III), which does not allow complete nanoparticle regeneration for the next sorption cycle. More concentrated HNO₃ ensures complete Cr(III) desorption (Table 1), however the nanoparticles partially dissolve and again are not suitable for next sorption cycle. Consequently, the synthesized Ag@Raff NPs are not recyclable and new sorbent amount has to be used for each sorption cycle of Cr(III). Taking into account the simple synthesis procedure, this fact just ensures application of fresh sorbent for each sorption cycle and thus reproducible degree of sorption on the fresh nanoparticle surface.

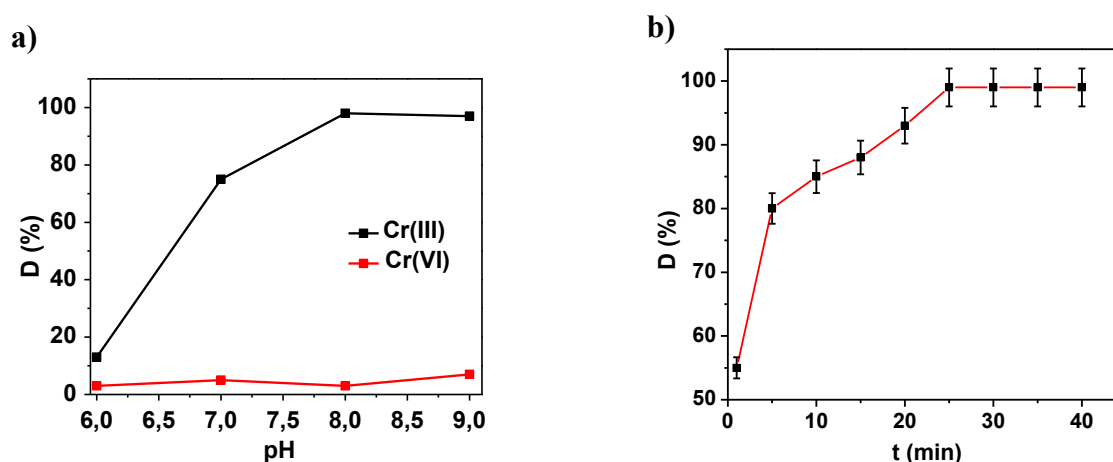

Figure 4. (a) Effect of pH on the degree of sorption of Cr(III) and Cr(VI) on Ag@Raff NPs (sample volume - 20 mL; contact time - 60 min); (b) Kinetics of Cr(III) sorption on Ag@Raff NPs (sample volume - 20 mL; volume of Ag@Raff NPs dispersion - 0.2 mL)

3.3 Optimization of chemical parameters for colorimetric detection of Cr(VI) using Ag@Raff NPs dispersion as optical probe

Several parameters were investigated systematically in order to establish optimal conditions for the colorimetric detection of Cr(VI), *in-situ* reduced to Cr(III) by ascorbic ratio (AA), in the presence of Ag@Raff NPs. As a first step, the pH value was adjusted taking into account the analysis of real samples and their preservation. The experiments performed showed that pH about 4, achieved by hydrochloric acid, ensured the highest sensitivity and could be accepted as an optimal sample medium. This acidity is obtained as a result of the following optimal volume ratios:

$$V(\text{Ag@Raff NPs dispersion, mL}):V(\text{Cr(VI) standart solution, mL}):V(\text{AA solution, mL}) = 0.20:0.25:0.15$$

In order to evaluate the optimal contact time, the kinetic of interaction between Ag@Raff NPs and *in situ* obtained Cr(III) by chemical reduction of Cr(VI) with ascorbic acid in a hydrochloric acid aqueous solution (pH 4), was followed within half hour by measurements of UV-Vis absorbance. Typical evolution of UV-Vis absorbance spectrum with time, due to the interaction of Ag@Raff with 5×10^{-5} mol/L Cr(VI), *in situ* reduced to Cr(III), is shown in

Figure 5a. For comparison, the kinetics of interaction between Ag@Raff NPs and Cr(III) was also studied at the same conditions and presented in Figure 5b.

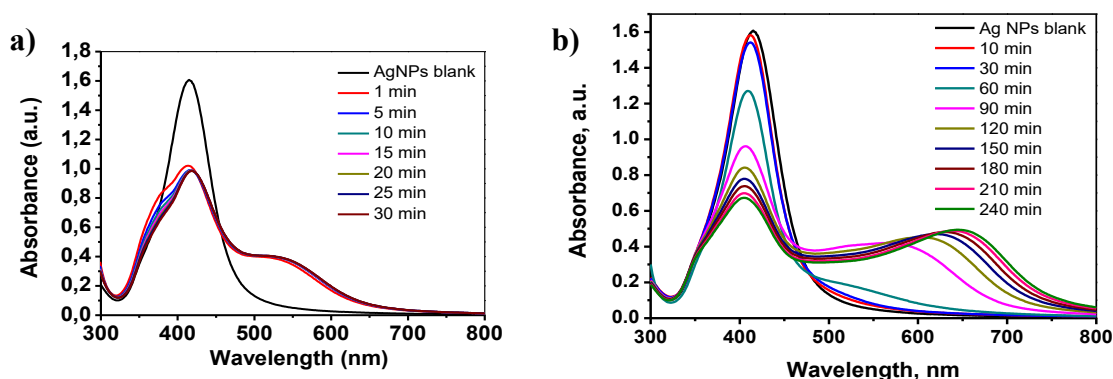

Figure 5. (a) Evolution of UV-Vis absorbance spectrum of Ag@Raff NPs upon the addition of 5×10^{-5} mol/L Cr(VI) reduced to Cr(III) by ascorbic acid at pH 4, and (b) upon the addition of 5×10^{-5} mol/L Cr(III)

It is seen that the sensor's response toward Cr(VI) is significant during the first five minutes of the contact time and a negligible change in the absorption intensity of Ag@Raff NPs at λ_{\max} is observed over this time in the presence of Cr(III). This fact allows selective analytical detection of Cr(VI) species within only five minutes. This difference in the response kinetics of developed optical probe to a standard aqueous solution of Cr(III) on the one hand and to Cr(III) obtained *in situ* by reduction of Cr(VI) with ascorbic acid could be explained by the extremely high inertness of complex $\text{Cr}(\text{H}_2\text{O})_6^{3+}$ in the standard solution.

As a next step, the sensitivity and applicability of Ag@Raff NPs for quantitative determination of Cr(VI) were studied under the defined optimal conditions. The colorimetric response and LSPR band behavior were monitored as a function of Cr(VI) concentrations in the range of 1.0–11.5 $\mu\text{mol/L}$ Cr(VI) (Figure 6a). As seen from the UV-Vis absorbance spectra (5-min contact time), a gradual decrease of the intensity of the characteristic plasmon band of the AgNPs at 411 nm is observed with increase of Cr(VI) concentration. In addition, a shoulder band appears at the wavelength range of 550–650 nm, which intensity increases accompanied by a slight blue shift along with decreasing intensity of the main plasmon absorbance band as a result of partial nanoparticle aggregation in the presence of freshly produced Cr(III) ions, which reaches varying degrees depending on the analyte concentration. This phenomenon is already reported and described as a change of the refractive index of the particles as a result of sorption of the positive Cr(III) produced by Cr(VI) reduction onto the negatively charged nanoparticle surface [23].

For quantitative determination of Cr(VI), the change of the intensity of LSPR band at 411 nm upon the addition of analyte with various concentrations was estimated as a ratio A_t/A_0 , where A_0 corresponds to the intensity of absorbance maximum of blank Ag@Raff NPs dispersion (without Cr(VI)) and A_t corresponds to the intensity of absorbance maximum of Ag@Raff NPs 5 min after the addition of Cr(VI) standard solutions at optimized conditions (Figure 6b). A linear correlation exists between the relative values of absorbance maximum intensity and the concentration of Cr(VI) over the concentration range 2.5–7.5 $\mu\text{mol/L}$:

$$A_r = 0.1019 \times c(\text{Cr(VI)}) - 0.1287 \quad R^2 = 0.9798$$

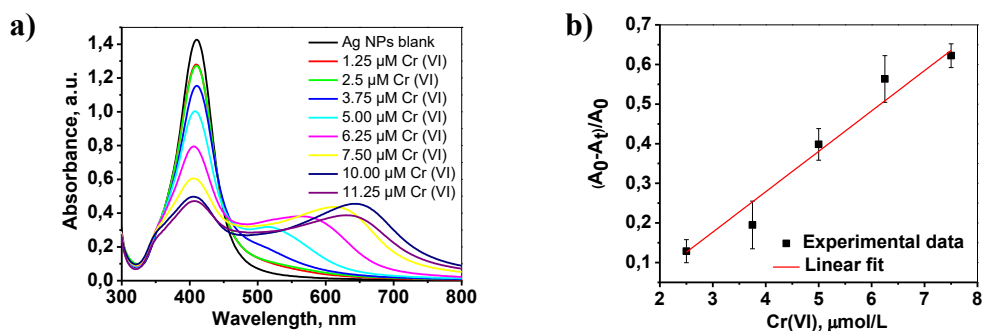

Figure 6. a) UV-Vis absorption responses of Ag@Raff NPs recorded 5 min after the addition of various concentrations of *in-citu* reduced Cr(VI) with ascorbic acid at pH 4; (b) Calibration curve

3.4 Analytical application

Analytical procedures for Cr speciation in surface waters was developed based on fast screening for Cr(VI) content using Ag@Raff NPs as efficient optical sensor or determination of both Cr(III) and Cr(VI) using selective sorption of Cr(III) on the sorbent Ag@Raff NPs and ETAAS measurement. Model experiments performed with various types of surface waters (river, lake and mineral) spiked with Cr(III) and Cr(VI) showed insignificant influence of water matrix on both optical sensor response or the degree of sorption of Cr(III) on Ag@Raff NPs (recoveries achieved varied between 94-97%) as well as on the selectivity in the presence of Cr(VI). Detection of Cr(VI) by optical sensing is an efficient way for fast and simple on site evaluation of the content of Cr(VI) in surface waters (see Figure 7a). Limit of quantification achieved 1.9 $\mu\text{mol/L}$ and relative standard deviation 3-5% fulfil the requirements for field studies for Cr(VI) content in surface waters.

Figure 7. Schemes of analytical procedures for Cr speciation in surface waters: a) Ag@Raff NPs as selective sorbent for Cr(III) and b) Ag@Raff NPs as efficient optical sensor for Cr(VI)

Reliable quantitative determination of both Cr(III) and Cr(VI) is possible using ETAAS measurements: Sorbent, 200 μL Ag@Raff NPs dispersion, was added to 10 mL water sample

and shaken for 30 min. Sample solution is centrifuged and Cr(VI) was measured in the effluate, sorbent is washed with distilled water and dissolved in 2 mL c. HNO₃ (see Figure 7b), where Cr(III) is measured by ETAAS. Analytical figures of merit as well as validity studies of developed method were shown in Table 2. As can be seen, very good agreement was achieved for the sum of Cr species determined by proposed SPE procedure with total Cr content measured by direct ICP-MS. The values of detection limit were 0.01 µg/L and 0.05 µg/L for Cr(III) and Cr(VI), respectively; the relative standard deviation varied between 4-6 % for both Cr species in the range 0.1-50 µg/L.

Table 2. Analytical figures of merit and validity studies of developed method

Parameter	Cr(III), µg/L	Cr(VI), µg/L	Total Cr (by ICP-MS)

4 CONCLUSIONS

- Raffinose-coated silver nanoparticles were successfully synthesized and their physicochemical characteristics were analyzed.
- Promising applications of Ag@Raff NPs were demonstrated as both effective sorbent for solid phase microextraction of Cr(III) from aqueous solutions and as optical probe in smart LSPR based sensing system for quantitative, selective and sensitive determination of Cr(VI).

Key words: Structural Health Monitoring, Bayesian Inference, Dynamic Identification, Damage Detection, Masonry structures

Abstract. The paper focuses on the development of an elementary Bayesian framework for the assessment of damage occurrence from subspace-based indicators. The proposed method is tested on real data, acquired by a complex monitoring system installed in a masonry monumental structure, the basilica of Santa Maria di Collemaggio in L'Aquila, Italy. The procedure is calibrated on two sets of data, measured from the façade accelerometers, before and after the CLT (Cross-Lam Timber) roof connection, interpreted as damage and reference states respectively. The application of Bayesian inference, based on two different damage indicators, for the assessment of the façade's structural modification, is presented and compared with the results of the χ^2 -tests by Dohler et al. The issue of the choice of the reference data set is further considered, providing a computation procedures for the built of a reference statistical model.

1 INTRODUCTION

The problem of detecting faults, interpreted as changes in the eigenstructure of a linear dynamical system, has been investigated following various approaches [1, 2, 3, 4, 5, 6, 7, 8]. During the last two decades there has been a growing interest in subspace-based linear system identification methods [9, 10]. Many have attempted to design fault detection algorithms based on subspace identification [11, 12, 6]. In particular several damage detection tests, which do not require the computation of modal parameters, so-called non-parametric damage tests, have been proposed [13, 14]. They compare output data measured during the structure's reference state to those coming from the possibly damaged state using a subspace-based residual function [15].

Following Rytter [16], the ultimate goal of SHM is to determine the four levels of damage identification at the earliest possible stage: (i) existence, (ii) location, (iii) severity of damage and (iv) remaining useful life. According to [6], the vibration-based structural health monitoring (SHM) problem could be considered as a double task problem; (i) detecting damages modelled as changes in the eigenstructure of a linear dynamic system, (ii) and localizing the detected damages within a finite element model (FEM) of

the monitored structure [6]. Besides, the assessment of the damage occurrence (1st task of both [16] and [6]), by means of subspace-based damage detection tests, shows to be quite complex, if proper criteria for the choice of the reference data are not adopted. Most vibration-based damage detection methods can in fact acquire satisfactory verification on analytical or numerical structures, but they may encounter problems when applied to real-world structures under varying environments [17, 18, 19].

In this paper, the performance of three damage indicators have been investigated against a masonry structure, the Santa Maria di Collemaggio basilica in L'Aquila, Italy.

So far, the basilica has represented an important case of study [20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35].

It is a Romanesque masterpiece characterized by a dense, fascinating history and construction phases, which began in 1270, with many stratified interventions occurred across the centuries. The church, seriously damaged by the 2009 earthquake¹, was subjected to an extensive rehabilitation, ended in 2017. The observed seismic behaviour was characterized by the presence of specific damage patterns as well as collapse mechanisms in well-defined parts of the structure [36, 37]: the damage was in fact mainly related with the collapse of structural portions (macro-blocks), principally due to the lack of stiff floors able to provide diaphragmatic action, the so-called “box behaviour” [38].

The use of dynamic-based methods to detect the damage on this type of structures is an attractive, but complex tool [39]. Many methods and applications have been presented in the literature for damage identification based on vibration data, see e.g. [40, 41, 42, 43, 44, 45, 46, 47], but there are only a few papers related to masonry-like structures [39, 48]. Damage indicators reliability is highly affected by the lack of a thorough mechanical interpretation as well as by the sensitivity to damage severity, localization and variations in the excitation conditions: in fact, in a no-damage situation, which acquisition should be the most qualified candidate to represent the reference condition, under varying operational environments? It has been attempted to overcome the problem of the reference choice, by means of a general statistical model, detailed in the following sections.

The paper is organized as follows: in the first section an overview about subspace-based damage detection tests, implemented in the paper, is presented; in the second section an elementary Bayesian framework is outlined; In the third section the monitoring system in the Santa Maria di Collemaggio basilica is briefly described; In the last sections the application of Bayesian inference, based on two different damage indicators, for the assessment of the façade's structural modification is presented and commented.

2 DAMAGE DETECTION TESTS

Subspace-based damage detection tests, implemented in the current paper, are briefly reviewed.

2.1 State space representation

State-space representation for output-only vibration-based structural monitoring corresponds to the following discrete time model

$$\begin{aligned}x_{k+1} &= Ax_k + v_k \\ y_k &= Cx_k + w_k\end{aligned}\tag{1}$$

¹On April 6th, 2009, at 3:32 a.m. an earthquake (Richter Magnitude 5.9) struck L'Aquila (Central Italy): 309 victims, 65,000 displaced people. More than 10 billion Euro of estimated damage, about 100 churches uninhabitable for the major collapses, along with thousands of historic buildings in the old town centres.

with the states $x_k \in \mathbb{R}^n$, the outputs $y_k \in \mathbb{R}^r$, the state transition matrix $A \in \mathbb{R}^{n \times n}$ and the observation matrix $C \in \mathbb{R}^{r \times n}$, where r is the number of sensors and n is the system order. The excitation v_k is an unmeasured Gaussian white noise sequence with zero mean and constant covariance matrix $Q = E(v_k v_k^T) = Q\delta(k - k')$, where $E(\cdot)$ denotes the expectation operator and w_k is the measurement noise.

2.2 Residual matrices

In [5, 49] a residual function was proposed to detect changes in the system's eigenstructure from measurements y_k , without actually identifying the eigenstructure in the possibly damaged state. The considered residual is associated with a covariance-driven output-only subspace identification algorithm. Let $G = E(x_{k+1} y_k^T)$ be the cross-covariance between the states and the outputs, let $R_i = E(y_k y_{k-i}^T) = CA^{i-1}G$ be the theoretic output covariances and

$$H_{p+1,q} = \begin{bmatrix} R_1 & R_2 & \dots & R_q \\ R_2 & R_3 & \dots & R_{q+1} \\ \vdots & \vdots & \ddots & \vdots \\ R_{p+1} & R_{p+2} & \dots & R_{p+q} \end{bmatrix} = \text{Hank}(R_i) \quad (2)$$

be the theoretic block Hankel matrix. Using measured data $(y_k)_{k=1,\dots,N}$, a consistent estimate $\hat{H}_{p+1,q}$ is obtained from the empirical output covariances:

$$R_i = \frac{1}{N} \sum_{k=1}^n y_k y_{k-i}^T \quad (3)$$

$$H_{p+1,q} = \text{Hank}(R_i) \quad (4)$$

The residual function, originally proposed by [5, 49], compares the system's undamaged or reference state with the damaged or current one. The considered residual matrix writes

$$R_c = \hat{S}^T H_{p+1,q} \quad (5)$$

where \hat{S}^T is the left null space of the block Hankel matrix $H_{p+1,q}$ in the reference state and $H_{p+1,q}$ is the covariance block Hankel matrix in the current one.

In practice, the excitation covariance Q may change between different measurement sessions of the system due to different environmental factors, while the excitation is still assumed to be stationary during one measurement. A change in the excitation covariance Q leads to a change in the cross-covariance between states and outputs G and thus in the Hankel matrix. Dohler et al. [14, 15] proposed a new residual, which is robust to changing excitation. Let U_1 be the matrix of the left singular vectors obtained from an SVD of $H_{p+1,q}$. As U_1 is a matrix with orthonormal columns, it can be regarded as independent of the excitation Q , which qualifies its use for a residual function, that is robust to changes in the excitation covariance. Then, the residual matrix writes

$$R_r = \hat{S}^T U_1 \quad (6)$$

²The system parameters in terms of eigenvalues and eigenvectors in the reference and current states are respectively θ_0 and θ . [13] proposed a non-parametric version of the damage detection test, adopted in the current paper, where the system parameters θ_0 do not need to be known explicitly in the reference state. Instead of using the null space $S(\theta_0^T)$ on the parameterized observability matrix [5, 49], an empirical (non-parametric) null space \hat{S} is computed on an estimated block Hankel matrix from data in the reference state using e.g. an SVD.

As stated by [15], other residual matrices (see (5)) are not ideal candidates for structural damage detection, since the amplitude of the residues, resulting from erroneous definition of the system order or the amplitude's excitation, may mask the residues variation due to small structural damages.

2.2.1 Dohler et al. non parametric damage detection tests

Following a procedure used by Basseville et al. [5] and Fritzen et al. [50], the residual matrix (5), is rearranged in a vectorial form. The formulation adopted by [13] is followed³:

$$\xi_N^Q = \sqrt{N} \text{vec}(\hat{S}^T U_1) \quad (7)$$

The index Q of the residual vector ξ_N^Q indicates the excitation covariance of the system, corresponding to the measured data $(y_k)_{k=1,\dots,N}$ used for the computation. It is tested if this residual function is significantly different from zero. A non-parametric test to decide if ξ_N^Q is significantly different from zero or not, following the one reported by [13], is adopted by [14] for the new robust residual matrix. The mentioned non-parametric test boils to the following χ^2 -test:

$$\hat{\gamma}_N^2 = (\hat{\xi}_N^Q)^T \hat{\Sigma}_\xi^{-1} (\hat{\xi}_N^Q) \quad (8)$$

which should be compared to a threshold and where $\hat{\Sigma}_\xi$ is a consistent estimate of the asymptotic covariance of ξ_N^Q . The computation of the $\hat{\Sigma}_\xi^{-1}$ matrix is a numerically critical issue, as it involves the inversion of big low-rank matrices.

2.2.2 Yan et al. damage detection tests

Yan [15], clinging to the geometric interpretation of the residual matrix, as expression of a loss of orthonormality, proposed a damage indicator given by the maximal singular value of the matrix R_r

$$\bar{\sigma}_N^2 = \text{norm}(R_r) \quad (9)$$

where $\text{norm}(\cdot)$ is an operator giving the maximal singular value of a matrix.

3 BAYESIAN UPDATING

An elementary Bayesian framework is outlined in order to interpret results from damage detection tests.

Generally, the lack of a structural model does not allow an *a priori* definition of damage indicators thresholds, however, even without any information about the structure, the occurrence of damage or more properly of a structural modification could be assessed anyway. The deviation between the statistical model, representative of the indicators reference population, and that of the current population is in fact a sort of marker of the occurrence of a structural modification. In order to assess such deviation between the current statistical model and the reference one, over time, using incoming measurements, continuous Bayesian updating may be implemented.

Theoretically, for an overall appreciation of the modification of the statistical reference model over time, a number of thresholds I_T ⁴ could be defined with respect to certain probabilities of exceeding

³*vec* denotes the vectorization operator.

⁴The indicators thresholds I_T do not correspond to Damage Limit States or Damage thresholds.

(p_E) the probability distribution of the indicators reference population. p_E may change over time as the number of measurements increases: the (p_E -incoming measurements) curve will provide information about the effectiveness of the reference statistical model in predicting the current indicators statistics. Rates of change and the slope of such curve could be interpreted as markers of the deviations from the reference model, which may converge towards other statistical representations.

3.1 Multiparameter Bayesian updating

The issue of Bayesian updating damage detection tests may fall into the problem of updating normal distributions with unknown mean and variance, assuming the variance as a *nuisance parameter*. Let I_d be a certain damage indicator, the *a priori* or reference probability distribution writes

$$p(I_d) = N(\mu_0, \sigma_0^2) \quad (10)$$

Suppose a sample of independent and identically distributed damage indicators in both the reference and damaged state is measured, $y_i = (y_{i,1}, \dots, y_{i,n_0})$ $\dim(y_i) = n_0 \times 1$ and $y_d = (y_{d,1}, \dots, y_{d,n})$ $\dim(y_d) = n \times 1$ respectively, where the first represents initial information, I , and the latter actual data, D . Let σ^2 be the unknown damage indicator variance. The joint posterior density of I_d and σ^2 , given initial information I and actual data D , may be factored in [51]

$$p(I_d, \sigma^2 | D, I) \propto p(I_d, \sigma^2 | I) p(D | I_d, \sigma^2) \quad (11)$$

where $p(I_d, \sigma^2 | I)$ is the joint prior density and $p(D | I_d, \sigma^2)$ the likelihood function. The population mean, I_d , could be assumed as the estimand of interest, and so the objective of Bayesian analysis is the marginal posterior distribution of I_d , which can be obtained by integrating the joint posterior density over σ^2 .

$$p(I_d | D, I) \propto \int_0^\infty p(I_d, \sigma^2 | I) p(D | I_d, \sigma^2) d\sigma^2 \quad (12)$$

The cumulative probability associated to the occurrence a certain damage indicator threshold, given initial information and actual data, writes

$$p(I_d > I_{DLS} | D, I) \propto 1 - \int_{-\infty}^{I_{DLS}} \int_0^\infty p(I_d, \sigma^2 | I) p(D | I_d, \sigma^2) d\sigma^2 dI_d \quad (13)$$

As reported in Appendix A, the joint prior density could be factored in the marginal distribution of σ^2 , which is scaled inverse- χ^2 , and the conditional distribution of I_d given σ^2 , which is normal. Given the normal likelihood, the marginal posterior density is a t -distribution with the following parametrization [51]

$$\begin{aligned} p(I_d > I_{DLS} | D, I) &\propto \int_{-\infty}^{I_{DLS}} p(I_d | D, I) dI_d \\ &= \left(1 + \frac{k_n (I_d - \mu_n)^2}{v_n \sigma_n^2} \right)^{(v_n+1)/2} \\ &= \int_{-\infty}^{I_{DLS}} t_{v_n}(I_d | \mu_n, \sigma_n^2 / k_n) dI_d \end{aligned} \quad (14)$$

where $\mu_n = \frac{k_0}{k_0+n}\mu_0 + \frac{n}{k_0+n}\bar{y}_d$; $v_n\sigma_n^2 = v_0\sigma_0^2 + (n-1)s^2 + \frac{k_0n}{k_0+n}(\hat{y}_d - \mu_0)^2$; $k_n = k_0 + n$; $k_0 = n_0$; $\mu_0 = \frac{1}{n_0}\sum_{i=1}^{n_0}y_{i,i}$; $\sigma_0^2 = \frac{1}{n_0-1}\sum_{i=1}^{n_0}(y_{i,i} - \mu_0)^2$; $v_0 = n_0 - 1$; $\hat{y}_d = \frac{1}{n}\sum_{i=1}^n y_{d,i}$; $s = \frac{1}{n-1}\sum_{i=1}^n (y_{d,i} - \hat{y}_d)^2$;

The issue of Bayesian updating the damage indicators PDF in the reference state, given the actual possibly damaged state, represents the well-known problem of updating normal data with a conjugate prior distribution. By means of Bayesian inference, the prior state of knowledge about the presence of structural damage is updated and quantified in the light of actual data (14).

As new damage indicators are computed from incoming measurements, the sole likelihood function is affected. It follows that the sole mean, \hat{y}_d , and variance, s , are continuously updated. Continuous Bayesian estimation is the extension of (14) using incoming measurements. Let D_{k+1} be the set of actual data up to the $(k+1)$ -th measurement.

$$\begin{aligned} p(I_d, \sigma | D_{k+1}, I) &\propto p(I_d, \sigma | I) p(D_{k+1} | I_d, \sigma) \\ &= p(I_d, \sigma | I) p(D_k | I_d, \sigma) p(y_{d,k+1} | I_d, \sigma) \end{aligned} \quad (15)$$

As the likelihood function does not change except for its parameters, the continuous update of the marginal posterior distribution is obtained by updating the t-distribution parameters. The probability of exceeding a certain threshold writes

$$\begin{aligned} p(I_{d,k} > I_{DLS} | D_k, I) &\propto 1 - \int_{-\infty}^{I_{DLS}} p(I_{d,k} | D_k, I) dI_{d,k} \\ &= \int_{-\infty}^{I_{DLS}} t_{v_n}(I_{d,k} | \mu_k, \sigma_k^2/k_k) dI_{d,k} \end{aligned} \quad (16)$$

where $\mu_k = \frac{k_0}{k_0+k}\mu_0 + \frac{k}{k_0+k}\bar{y}_{d,k}$; $v_k\sigma_k^2 = v_0\sigma_0^2 + (k-1)s_k^2 + \frac{k_0k}{k_0+k}(\hat{y}_{d,k} - \mu_0)^2$; $k_k = k_0 + k$; $k_0 = n_0$; $\mu_0 = \frac{1}{n_0}\sum_{i=1}^{n_0}y_{i,i}$; $\sigma_0^2 = \frac{1}{n_0-1}\sum_{i=1}^{n_0}(y_{i,i} - \mu_0)^2$; $v_0 = n_0 - 1$; $\hat{y}_{d,k} = \frac{1}{k}\sum_{i=1}^k y_{d,i}$; $s = \frac{1}{k-1}\sum_{i=1}^k (y_{d,i} - \hat{y}_{d,k})^2$;

4 MONITORING SYSTEM

A permanent monitoring system was installed in the Santa Maria di Collemaggio basilica. The system consists of a network of sensors, supported by a service platform, which synchronizes, interrogates, transmits and manages the alarms from the different sensors.

The monitoring system acquires data from the sensors, according to two possible recording patterns: (i) following a time schedule or (ii) when a certain acceleration threshold is exceeded. The installed sensors are of two types, the ones for the measurement of dynamic quantities, the others for the measurement of static quantities⁵, Fig.1.

Both low-intensity tremors and strong-motion earthquakes can be effectively recorded.

5 APPLICATION OF DAMAGE DETECTION TESTS

A set of damage indicators is tested: accelerometric data from the façade macroelement, corresponding to two different structural conditions, have been compared: a first data set, recorded before the CLT-roof was connected to the façade, is assumed as the *actual or damaged state*; A second data set, recorded

⁵9 potentiometers crack measurement devices, 78 FBA accelerometers (2 triaxial 12 biaxial and 48 monoaxial), 14 inclinometers and 5 temperature/humidity sensors have been installed

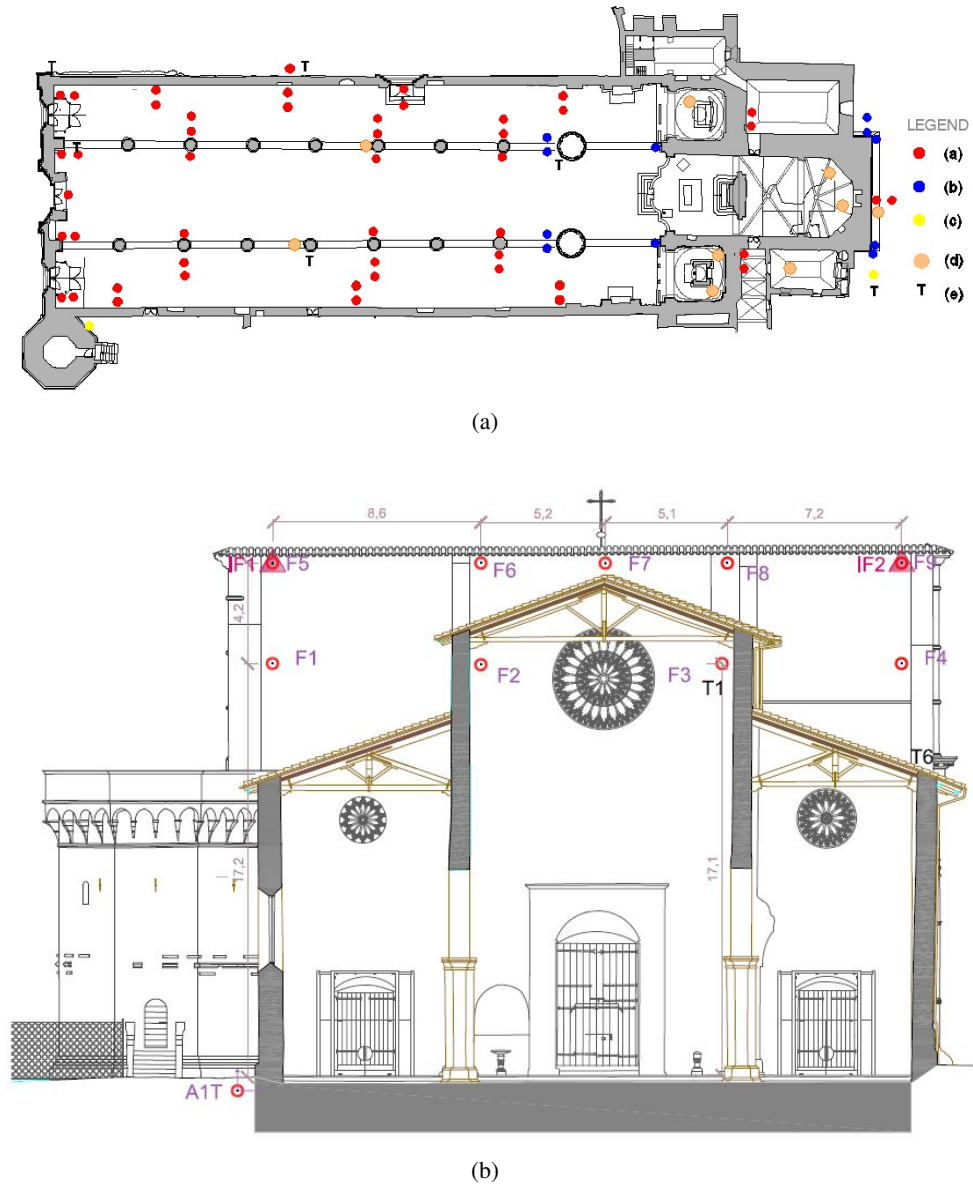

Figure 1: (a) Monitoring system layout, (a) monoaxial FBA (Force Balance Accelerometer), (b) biaxial FBA, (c) triaxial FBA, (d) inclinometers, (e) crack monitoring device, (f) temperature and humidity sensor; (b) Layout of the façade FBA;

after the CLT-roof was connected to the façade (Fig.2), is assumed as the *reference or un-damaged state*. 21 and 162 acquisitions, recorded from the façade FBA accelerometers, have been used as a first and

Figure 2: Detail of the connection between the facade and the CLT roof; Sketch of the roof-facade interaction before and after the connection, (a) and (b) respectively; Picture of the connection (c).

second data set. Three damage detection tests are implemented, the first (17) is from Yan et al. [15], the second (18) is the square of the Euclidean norm of the residual vector, the third (19) is the χ^2 -test itself [14].

$$I_{d,Y} = \hat{\sigma}_N^2 = \text{norm}(R_r) \quad (17)$$

$$I_{d,D} = (\hat{\xi}_N^Q)^T (\hat{\xi}_N^Q) \quad (18)$$

$$\chi^2\text{-test} = \hat{\gamma}_N^2 = (\hat{\xi}_N^Q)^T \hat{\Sigma}_\xi^{-1} (\hat{\xi}_N^Q) \quad (19)$$

5.1 Damage Indicators computation

Two different methods are followed for the computation of the reference and damage population of the three damage indicators. Let n_0 be the number of recordings during the un-damaged state and n the number of recordings during the damaged state.

- The first criterion assumes as reference population the indicators from all possible cross-comparison between data acquired during the reference condition, excluding self comparisons. The size of the reference population will be $n_0(n_0 - 1) = 26082$, while that of the damaged one will be $nn_0 = 3402$; It means that, following such criterion, every actual or damaged recording should be compared with all reference acquisitions.
- A sole recording is assumed as reference data set. The size of the reference population will be $n_0 - 1 = 161$, while that of the damaged one will be $n = 21$;

The first computation method comes from the assumption that the choice of a reference data set is extremely difficult and critical. It is often complex to discriminate changes in structural systems response, caused by damage, from those caused by environmental factors, whose effects might cover the actual presence of damage. Therefore, an effective damage detection procedure is required to be not only sensitive to damage but also insensitive to varying operational environments [17]. Acquisitions, recorded under different environmental conditions, will produce in fact a varied reference population. A way to include the environmental effects and to monitor the actual presence of damage in dynamic systems could be achieved by means of the proposed first criterion, since the variability of the indicator is embraced by the reference statistical model.

The second criterion may be considered more standard, since all data are compared with a single reference, accurately chosen according to disparate criteria [17, 41]. The results of the two computation methods are reported and compared in the following subsections.

5.2 First method

Following the first computation method two sets of damage indicators are evaluated, Fig.3. The vertical line, in Fig.5(a), 5(b) and 5(c), divides the reference population from the actual or damaged one. The $I_{d,Y}$ (17), $I_{d,D}$ (18) and χ^2 -test (8) visually belong to two different statistical models. The $I_{d,Y}$ (Fig.5(d)) population almost resembles a normal distribution, while that of $I_{d,D}$ (Fig.5(e)) is likely to gather around two different values, as if two statistical models were behind the system's dynamics. The χ^2 -test results seems to fit a chi-squared distribution Fig.5(f). In Fig.4 the PDF and CDF from the two data sets are

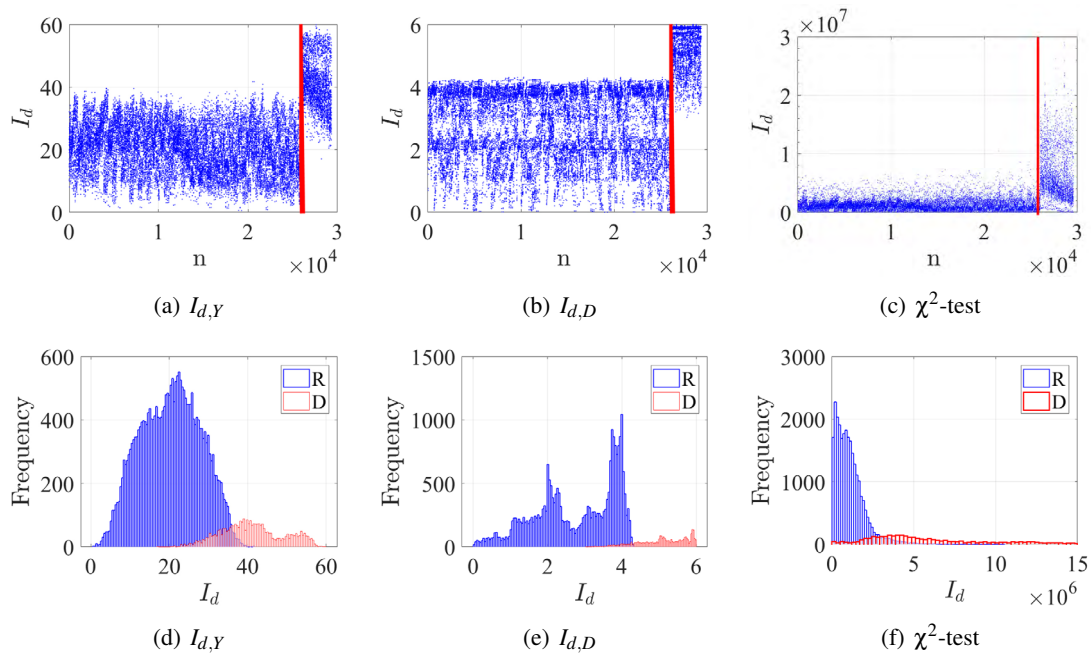

Figure 3: (a)-(c) General trend of the results of damage detection tests; The vertical line separates the reference population from the actual or damaged one; (d)-(f) Frequency histogram of the results of damage detection tests; "R" stands for Reference population, "D" for Damaged or Actual population.

reported: the curve (R) corresponds to the normal distribution associated with the reference population $p(I_{d,reference}) = N(\mu_0, \sigma_0^2)$ (10), the curve (D) indicates the normal distribution associated with the actual or damaged population $p(I_{d,damage}) = N(\hat{y}_d, s)$, the curve (B) indicates the marginal posterior density t-distribution (14) given actual data (actual population) and initial information (reference population). The t-distribution obtained from the Bayesian updating of the conjugate prior distribution, representative of the reference population, shows a negligible deviation from the R curve. While the χ^2 -test results seem to be very sensitive to the effects of the specific structural modification (Fig.3), the Bayesian treatment of data is not very effective, given the position of the D curve, representative of the actual population: the t-distribution seems to be reluctant to change. The causes are due to the different sizes of the reference and actual populations, 26082 vs 3402 respectively. The larger the size of the reference population, the larger the size of the damage population must be in order to significantly update the prior distribution.

Figure 4: Results from the Bayesian updating of the reference population given the actual or damaged population in terms of PDF (a)-(b) and CDF (c)-(d). The curve (R) corresponds to the normal distribution associated with the reference population $p(I_{d,reference}) = N(\mu_0, \sigma_0^2)$ (10), the red (D) indicates the normal distribution associated with the actual or damaged population $p(I_{d,damage}) = N(\bar{y}_d, s)$, the curve (B) indicates the marginal posterior density t-distribution (14) given actual data (actual population) and initial information (reference population).

A size reduction of the reference population will increase the "reactivity" of the prior distribution to the effects of a structural change. For these purposes a proper truncation of the reference population could be adopted. Fig.5 shows the evolution of mean μ_0 and variance σ_0 of the reference population as the number of samples increases: they converge towards a certain value; Thus the size of the reference pop-

Figure 5: Evolution of mean μ_0 and variance σ_0 of the reference population as the number of samples increases.

ulation may be truncated as soon as the oscillation is contained within a certain threshold. The dotted line represents the truncation threshold adopted in the current application. Fig.6 reports the results of

Figure 6: Results from the Bayesian updating of the reduced reference population given the actual or damaged population in terms of PDF (a)-(c) and CDF (d)-(f). The blue curve (R) corresponds to the normal distribution associated with the reference population $p(I_{d,reference}) = N(\mu_0, \sigma_0^2)$ (10), the red curve (D) indicates the normal distribution associated with the actual or damaged population $p(I_{d,damage}) = N(\bar{y}_d, s)$, the pink curve (B) indicates the marginal posterior density t-distribution (14) given actual data (actual population) and initial information (reference population).

the Bayesian updating from the reduced reference data set: the t-distribution markedly differs from the statistical model of the reference population, approaching the red curve. Four dashed lines are drawn over the probability distributions in Fig.6, corresponding to four thresholds arbitrarily chosen from the reference distribution, μ_0 , $\mu_0 + \sigma_0$, $\mu_0 + 2\sigma_0$, $\mu_0 + 3\sigma_0$ respectively. As new damage detection tests are performed, the t-distribution (16) is updated, so that the probability of exceeding p_E the indicator thresholds, I_T , changes with respect to the original p_E corresponding to the reference population, Fig.7. The

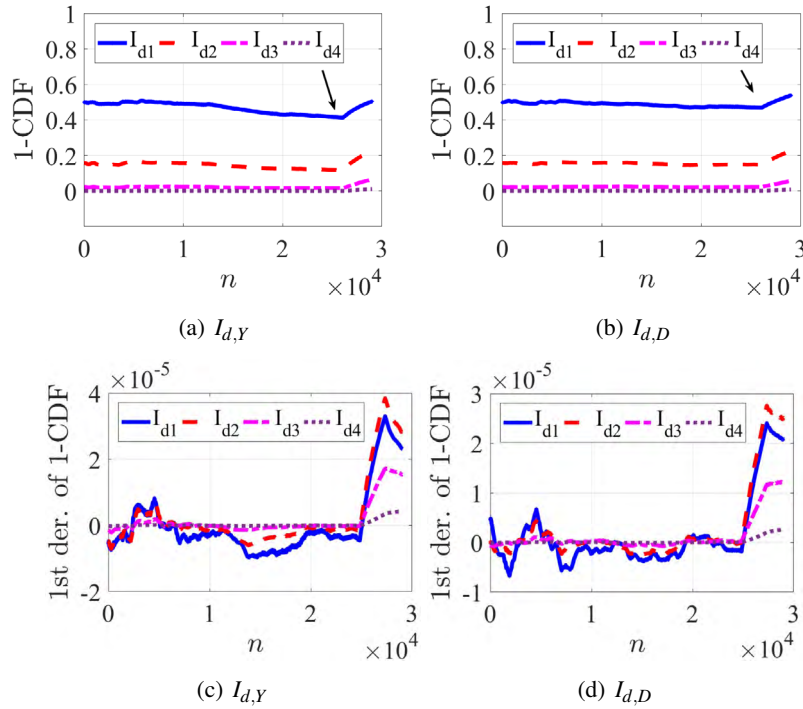

Figure 7: General trend of the probability of exceeding p_E four indicators' thresholds, reported in the legend, using incoming damage tests results ($I_{d1} = \mu_0$, $I_{d1} = \mu_0 + \sigma_0$, $I_{d1} = \mu_0 + 2\sigma_0$, $I_{d1} = \mu_0 + 3\sigma_0$). In (a)-(b) all damage indicators are representative of both the reference and actual condition, sequentially concatenated, in order to simulated a chronological evolution, while in (c)-(d) damage indicators are representative of the sole actual condition.

occurrence of a structural modification is significantly manifested by the $I_{d,Y}$ and $I_{d,D}$ indicators, Fig.7: a sudden change in the curve's slope testifies the occurrence of a modification of the statistical model representative of the actual condition under test. In order to amplify the effects of a structural modification, an approximation of the first derivative of (16) is estimated, Fig.9(c)-(d): the peaks manifest the occurrence of the structural modification.

5.3 Second method

Following the second computation method two sets of damage indicators are evaluated. Between the 162, the results from the tests referred to the 53rd reference acquisition, which best manifests the occurrence of damage, are reported in Fig.8: the results are shown in terms of the general trend of the indicators values, sequentially concatenated, in addition with the curves, which track the statistical model evolution from incoming measurements (16). The $I_{d,Y}$ and $I_{d,D}$ indicators seem to be less sensitive to the specific damage, Fig.10(d)-(e). There is not a marked variation in the curve's slope, as in Fig.9(a)-(b). A

satisfactory performance emerges from the χ^2 -test results, although the population's size in the damage state is too small to obtain a significant plot of the frequency distribution, Fig.10(f).

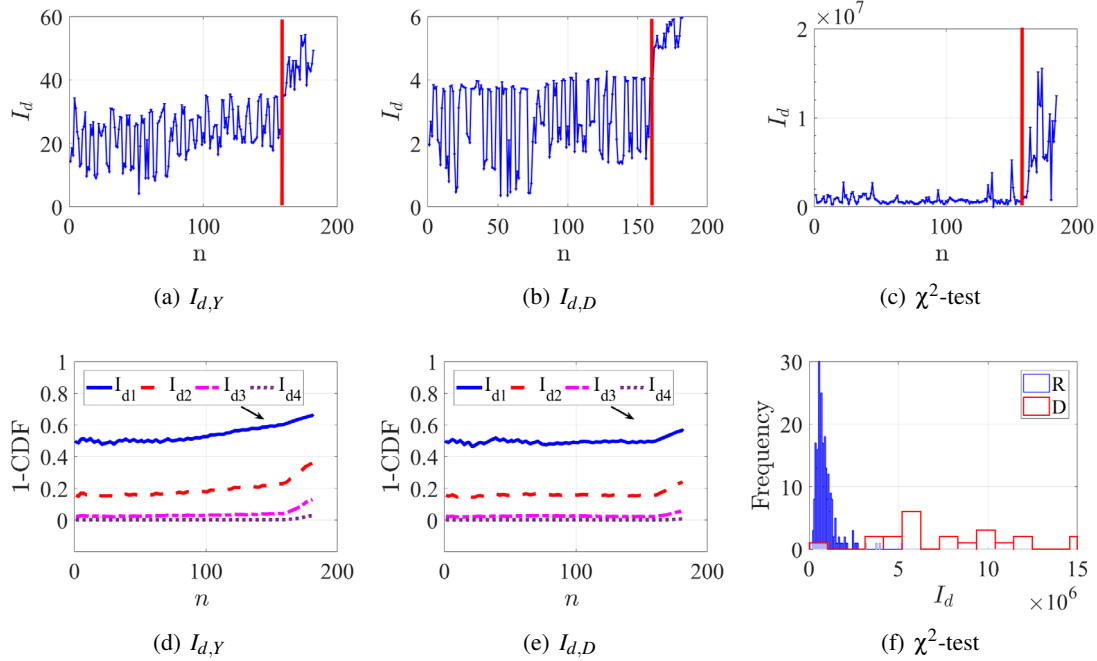

Figure 8: General trend of the results from damage detection tests, assuming the 53rd acquisition as reference data set (a)-(c); The vertical line separates the reference population from the actual or damaged one; In (d)-(e) the evolution of the probability of exceeding p_E four indicator thresholds, described in the legend ($I_{d1} = \mu_0$, $I_{d1} = \mu_0 + \sigma_0$, $I_{d1} = \mu_0 + 2\sigma_0$, $I_{d1} = \mu_0 + 3\sigma_0$), from incoming measurements (reported on the horizontal axis), starting from the p_E in the normal distribution representative of the reference population; In (f) the frequency histogram of the results of the χ^2 -test; "R" stands for Reference population, "D" for Damaged or Actual population.

5.4 COMMENTS

- In real case applications, the use of the robust residual (6) may not provide independence from ambient factors; The variability in the excitation conditions, between different measurement sessions, may not be modelled as a change in the covariance of a random Gaussian process. If the independence from operational environments is not obtained from the robust residual, it should be statistically achieved. The first method proposed for the building of the reference population attempts to capture all the variability of damage detection tests, induced by operational conditions, alternatively assuming each recording as a possible reference state. The so-built reference population will be represented by a statistical model, which may be more stable, since all the results variability may have been experienced in a first step. Hence any discrepancy from the reference statistical model could be more likely attributed to structural modifications, in successive analysis. For these reasons, the first method, proposed for the choice of the reference population, could to be more effective in detecting structural modifications, Fig.8 and Fig.9. Besides the $I_{d,D}$ indicator, Fig.8(b), in the reference state, seems to be more stable than the $I_{d,Y}$, Fig.8(a).
- The χ^2 -test, which was validated by Dohler et al. [14], seems to be effective in detecting the specific structural modification in a masonry structure despite the varying environmental factors.

Theoretically, the second computation method, for the estimate of the reference population, may be considered more rigorous, since each recording is compared with a single acquisition, assumed as reference state; However the χ^2 -test may benefit from the first computation method: the cross comparison between all data in the reference state explores all possible variability of the test results, thus accounting for varying environments in the built of an empirical chi-squared distribution.

- In the presented statistical framework, reference data, represented by the conjugate prior distribution, are not updated from incoming measurements. They express in fact a certain structural condition, estimated during a specific reference time interval. Actual data are instead continuously updated from incoming measurements: the sole likelihood function is affected by the continuous model updating.
- Other damage detection tests could be alternatively derived from the residual matrix and effectively implemented in the proposed Bayesian framework. The statistical treatment of data is not embedded in the damage test itself, as in the χ^2 -test, but it is achieved *a posteriori*, by manipulating data coming from an arbitrary indicator built on the residual (6). Non intrinsically robust indicators may acquire insensitivity to environmental factors by means of the proposed method.
- As only 21 acquisitions were recorded, before the CLT roof connection, the convergence of the test results towards the statistical model, representative of the damage state, cannot be fully appreciated.
- The proposed elementary Bayesian framework could represent an effective tool in tracking the evolution of a statistical reference model, for the purposes of SHM.

6 ACKNOWLEDGEMENTS

The authors thank *ENI* for having financed the structural rehabilitation and the monitoring system, giving back to the city of L'Aquila one of the most identifying monument.

7 CONCLUSIONS

An elementary Bayesian framework based on subspace-based damage detection tests is applied to a masonry structure, the Santa Maria di Collemaggio basilica, severely injured by the 2009 earthquake of L'Aquila, where a monitoring system is installed. So far, few damage detection methods have been proved to be effective for real-life structures owing to the fact that most of the existing damage features or indices are not immune to the field environmental effects that are more complicated than those appearing in analytical or well-controlled laboratory studies. An application of three damage detection tests is shown. Two computation methods, for the choice of the reference population of damage indicators, support an elementary Bayesian framework, which drives the comparison between two different data sets, representative of two structural conditions. The first method (i) assumes as reference population the indicators from all possible cross-comparisons between data, acquired during the reference condition, excluding self comparisons. In the second method (ii) a sole recording is assumed as reference data set. The first method seems to be more effective in assessing the occurrence of a specific structural modification (lack of the CLT roof connection to the basilica's facade). It is likely that the cross comparison (i) between all reference data could account for the variability of environmental factors, making the damage detection test more robust to varying operational environments. The occurrence of a structural modification is detected from the curve, which shows the probability of exceeding certain numerical values of the indicators, as new damage detection tests are performed from incoming measurements.

The change in the curve's slope marks the occurrence of a modification in the statistical model representative of the current state. The implementation of the proposed method could be effectively used for tracking the structural behaviour over time from incoming measurements. The correlation between the expected value of the indicator, the particular structural modification and the associated probability of failure could represent the ultimate goal of a monitoring system which aims to a general procedure for the structural reliability assessment, continuously performed over time; However relevant research and field application verification are, at present, lacking.

Abstract. Transparent fiber-reinforced polymer composites are designed for high mechanical and sensory performance. In this study, it was aimed to elaborate optically transparent glass fiber-reinforced polymer composites as building components in futuristic architecture. E-glass fabric was used as fiber reinforcement. The polymeric matrix, which was designed to have the same refractive index value with glass fibers, was synthesized from a calculated ratio of styrene and methyl methacrylate comonomers and was used as the polymeric matrix of optically transparent fiber-reinforced composites with strain sensing capabilities. The synthesized polymer was first melt-pressed into a film structure; then two sheets of these films and glass fabric were melt-pressed together in a sandwich manner. Poly(ethylenedioxythiophene-poly(styrenesulfonic acid) (PEDOT:PSS) was used as conductive material. It was printed onto the finished composite, i.e. onto the surface of the polymer matrix. By matching the refractive index values of the thermoplastic matrix with those of the glass fabric and by using PEDOT:PSS, optically transparent polymer-based fiber-reinforced composite for sensory application were produced.

1 INTRODUCTION

A transparent composite with fiber reinforcement is a long-term studied topic. Firstly, one needs to understand how optical transparency can be obtained. The matrix material of the composite has to be either non-crystalline or the largest crystal of that material must be smaller than the wavelength of visible light. The reinforcement material of the composite (particles and fibers) should have exactly the same refractive index value than the matrix component. This way, the light will not be further refracted when passing through the reinforcement material. Another way to have fully transparent fiber-reinforced polymeric

composites is to have fiber diameter smaller than the wavelength of the visible light.[1] When the nano-additive is smaller than one-tenth of the wavelength of light, it cannot scatter the light and will be optically transparent though the additive is semi-crystalline.[2]

Transparent fiber-reinforced polymer composites are designed for high mechanical and thermal performance while having the optical transparency required for various applications. Generally, polymer composites are supposed to have a strength/weight ratio advantage compared to silica glass. Application candidates for transparent composites: high-impact resistance windshields [3], lightweight armor[3], opto-electronics[4-6], antibacterial[7], UV-protection[8], fire retardancy[9]

Fiber-reinforcement does not only give mechanical strength or toughness but also allows for an adjustment of the direction of the enforcement taking advantage of the anisotropy of the fibers. Anisotropy is the most important difference between fiber reinforcement compared to small particle improvements. Thus, self-reinforced poly(ethylene terephthalate) (PET) composites have a translucent structure with an elevated impact toughness due to anisotropy coming from the PET fibers.[10]

Decreasing the coefficient of thermal expansion is a major issue for polymer composites. Compared to inorganic materials like glass, polymeric materials have larger coefficients which make them thermally unstable for critical applications. Thus, glass fiber-reinforced composites need to be tested in terms of CTE performance as well. By using the difference in CTE, it is possible to design adaptive engineering materials, which are transparent in a temperature interval and opaque or translucent beyond that adjusted interval.

So far, major approaches to achieve this aim entailed, e.g., either the blending of a polymer matrix with small molecules or particles, which can tune the overall refractive index of the polymer matrix, the grafting of small molecules onto a polymer chain.[11] Krug et al. produced S-glass mat-reinforced epoxy composites. In order to match the refractive indices of the components, epoxy resin was mixed with epoxy-functionalized polyhedral oligomeric silsesquioxanes (POSS) molecules. [12] POSS molecules with a wide variety of functional groups can be tuned to match the targeted RI values. [13]

Velez et al. matched epoxy resin's refractive index with soda-lime glass ribbon and tested these composites with impact tests simulating bird crushes at the aircraft industry.[3, 14] Kagawa et al. blended a commercial epoxy resin with glass particles in order to adjust/decrease the coefficient of thermal expansion (CTE) while maintaining the transparency of the resin.[15]

As mentioned, when nanoparticles or nanofibers are used, they cannot scatter the light and will be inert in terms of refractive index matching. The critical issue is the possible agglomeration issues of these particles/fibers so they might start scattering the light. For such kind of nanocomposites, bacterial cellulose (BC) nanofibers based composites are important examples: They can have optical transparency due to nanometer size diameters of the fibers.[2, 16] Though the fibers are semi-crystalline and though they have distinctly different refractive index values[2] compared to the polymer matrix of the composite, fibers cannot reflect the light since they are smaller than the wavelength of the visible light.[2, 16-18] Also BC nanocomposites reduced the temperature-based refractive index change with the different polymer matrix.[18] Besides the mechanical and optical advantages, BC nanocomposites have low CTE.[2, 16] Nogi et al. acetylated BC nanofibers in order to reduce their hygroscopicity for optoelectronics applications, and showed that the high transparency, low CTE, but also

reduced hygroscopicity can be managed in a BC composite.[16] The same group tried various degree of substitution (DS) in terms of acetylation of BC and found the optimum level for high transparency, low CTE, low hygroscopicity, and lower refractive index.[19] Optimum wt. % of the BC nanofibers was decided in terms of their reduction in light transmittance and performance to decrease CTE.[20] By using 7.4 wt. % of BC nanofibers, composites lost only 2.4% in light transmittance, while CTE was successfully reduced for 56%.[20] Like bacterial cellulose attempts, nanofibers were produced by grinding wood pulp fibers, and their nanocomposites can be optically transparent even with 70 wt. % fiber content.[17, 21] Nanofibers made out of wood pulp fibers were effective to decrease the composites' coefficient of thermal expansion as well.[17, 21] As an alternative production way, transparent acrylic resins were deposited on to cellulose nanofiber sheet and independent from the difference in refractive indices transparency of the composites were achieved.[22]

For PMMA, at room temperature, relative humidity is in correlation with the refractive index.[23] Generally, an increase in temperature decreases the refractive index value of the polymers drastically.[23, 24] PMMA was reinforced with borosilicate glass fiber as they are matching in refractive index.[25-27] Besides mechanical evaluations[25], a strong dependence of refractive index on temperature changes[26, 27] was shown. Recently, Keaney et al. showed the optimum amount of fillers in a PMMA composite in order to have a high level of transparency.[28]

Optically transparent fiber-reinforced composites were made not only by using polymeric material. Iba et al. produced oxynitride glass fiber composites by hot-pressing different types of glass powders as matrix material.[29] Nanofibers made out of chrysolite, a natural mineral, had also 85% transparency when the refractive index of the resin is matched.[30, 31] Like other nanofibers or nanostructures [17, 32, 33], carbon nanotube-based composites showed also a high level of transparency.[34] Aloui et al. defined how the refractive index of the matrix polymer changes during photopolymerization.[35] As the conversion of monomers goes on, the material transforms from liquid to sol-gel, and eventually to solid state (glassy). Until it gets solidified refractive index increase, and thermo-optic coefficient decrease so its refractive index value gets more stable upon changes in temperature.[35]

In this study, it was aimed to elaborate optically transparent glass fiber-reinforced polymer composites as a building component of a futuristic architecture project. Also, an optically transparent fiber-reinforced material with sensory properties was to be realized.

2 MATERIALS AND METHODS

Styrene and methyl methacrylate monomers were purchased from Merck Millipore, Germany in order to synthesize the polymer matrix of the composites. Glass fabric (HexForce – 02116) was purchased from Hexcel Corporation, France. Its weight was 106 g/m² and plain-woven.

2.1. Polymer Synthesis

The polymer matrix of this study was synthesized by free radical copolymerization of styrene (100-42-5) and methyl methacrylate (80-62-6) and used after distillation to remove stabilizers. Azobisisobutyronitrile (AIBN) (Sigma Aldrich, 78-67-1) was used after recrystallization in methanol. The styrene/methyl methacrylate ratio was 51.15 – 48.85 wt.% and the AIBN amount was 0.1 mol% with respect to all monomers. Polymerization was accomplished in an ultrasonic bath at 80°C within 24 h.

2.2. Foil Production via Melt pressing

Polymer synthesis was done in reaction tubes. Due to the N₂ formation, a lot of bubbles were trapped in the polymer bars. After removing the reaction tubes, those bars were melt-pressed by using a Meyer press (Herbert Meyer GmbH, Germany) operated at 200°C and 6 bar for 20 minutes. As a result of this process, flat polymer foils without bubbles were produced. After individual polymer bars were transformed into the films, glass fabric was placed between two layers of those films and pressed together again at 200°C and 6 bars for 20 minutes. Just before this process, glass fabric was immersed into the styrene monomer to increase the affinity between the fabric surface and the copolymer. Since the surface morphology is critical to adjust the highest level of transparency, we decided to use polyimide (PI) foil purchased from Haufler GmbH, Germany. Generally, the surface that touches to the composite surface must be absolutely flat, have low thermal expansion constant, high thermal stability, and low affinity to the composite material. With high surface roughness, we can lose the light transmittance of a %100 non-crystalline material due to the light scattering of those surface features.

2.3. Screen Printing of PEDOT: PSS

In order to gain sensory properties, PEDOT:PSS (Clevios SV3; Heraeus Epurio, Germany) was applied to the composite surface via screen printing tools (Johannes Zimmer GmbH, Austria). For both pure polymer film, and to the final composite with fabric support 1 and 20 layers of printing was applied to observe the possible change in the electrical conductivity and also light transmittance.

2.4. Electrical Resistance Measurement

Four-point surface resistivity tests were accomplished using Fluke 8846A Multimeter (Fluke Corporation, USA)

2.5. Mechanical Tests

The tensile properties of the polymer film, glass fabric, and the fiber-reinforced composites were evaluated using a Zwick/Roell (Zwick Universal Typ 144503). The grip-to-grip distance was 5 cm. The width of all specimens was 3 cm and test speed was set as 5 mm/min. Each material was tested at least five times.

2.6. Refractive Index Measurement

The refractive index of the polymer film was measured with the aid of an Abbe Mark III refractometer (Reichert Analytical Instruments, USA). The refractive index of the glass fabric was evaluated using the standard refractive index liquids (Cargille Laboratories, USA) and Becke Line test was done under the optical microscope (Zeiss AG, Germany).

2.7. Transmission Intensity Measurement

The transparency level of the composites was evaluated by RC2 Ellipsometer (J.A. Woollam Co., Inc., USA) between the wavelengths of 210 – 1690 nm at normal incidence in a transmission configuration. In addition, Mueller matrix measurements were performed, in order to check the isotropy of the samples. The Mueller matrices showed no amplitude in the off-diagonal elements, which justifies the isotropy of the samples.

3 RESULTS AND DISCUSSION

Synthesized copolymer bars were successfully melt-pressed and films with smooth surface were produced (see Figure 1-a). Their average refractive index was 1.55, which perfectly matched the refractive index of the E-glass. The refractive index of the glass fabric was found to be ≈ 1.552 . Besides matching the refractive indices of two materials accurately, surface adhesion of the polymer to the glass is critical as well. If there is no good level of adhesion then air gaps might form at the interface of those materials and optical transparency will be impossible as the refractive index of the air is 1.0003. In fact, we observed this phenomenon, too. In order to overcome that, glass fabric was immersed into styrene monomer (refractive index 1.5471) just before the final melt-pressing it between two sheets of the polymer film. This step enhanced the adhesion, so overall the optical transparency of the composite (see Figure 1-b).

Figure 1: Materials of this study in front of the logo: (a) Pure poly(styrene)-*co*-poly(methyl methacrylate)-based polymer film, (b) polymer matrix with glass fabric, (c) only glass fabric, (d) polymer printed with single layer PEDOT:PSS, (e) polymer overprinted with 20 layers of PEDOT:PSS.

Tensile test results (see Figure 2 and Table 1) showed that the glass fabric almost doubled the tensile strain and significantly reduced the modulus of the polymer film. Both aspects are positive for the final application as a sensory material. In the final composites, the average glass fabric ratio to the polymer matrix was ≈ 29 wt.%.

Figure 2: Comparison of the tensile tests, representative strain-stress diagrams of the composite and its components

Table 1: Summary of tensile test results.

	Composite	Copolymer Film	Glass Fabric
E_{mod} (GPa)	0.202 ± 0.08	1.847 ± 0.289	0.455 ± 0.015
Strain% at largest Stress	2.7±0.3	1.8±0.3	3.33±0.3
Maximum Stress (MPa)	44.2±6.2	27.1±3.7	124.1±4.9

Figure 3 displays the transmitted light intensity percentage through the materials. This is the ratio of the directly transmitted light, which was neither absorbed, reflected or refracted by the material components. It is obvious that glass fabric in the composite causes an important level of refraction. Screen printing of PEDOT:PSS causes less loss in transmission of light than the glass fabric, however, it is worth mentioning that PEDOT:PSS layers do allow infrared (IR) light to pass through the material when it is overprinted twenty times. In Figure 4, we compare the overprinting effect of PEDOT:PSS. It is clear that a single-layer of printing does not cause a big loss in transparency. Also, the response to infrared cannot be seen anymore. The maximum number of overprinted layers of PEDOT:PSS to fully block IR transmission are currently under investigation.

Figure 3: Comparison of the percentage of transmitted light intensity illustrating the effect of PEDOT:PSS printing and fabric composites.

It is important to discuss the electrical resistance values of the samples with PEDOT:PSS. Samples with single-layer printing have an average surface resistance of $\approx 240\text{k}\Omega/\text{sq}$, while it reduces to $\approx 150\text{k}\Omega/\text{sq}$ when PEDOT:PSS was overprinted 20 times. Considering the big loss in transmitted light intensity (See Figure 4), single layer printing is a better option since overprinting PEDOT:PSS does not provide a big advantage in the electrical conductivity but a relatively big loss in the transmitted light intensity.

Figure 4: Comparison of transmitted light intensity (%) values between different times overprinted composites of PEDOT:PSS

4 CONCLUSIONS

In this study, optically transparent glass fiber-reinforced polymer composites as a building component of a futuristic architecture project were produced. The glass fabric ratio to the polymer matrix was ≈ 29 wt.%. Optimized products might be developed in terms of transmitted light intensity in case the refractive indices match perfectly to the fourth digit after the decimal point. Another alternative might be changing the surface chemistry of the glass fabric to increase the adhesion of the polymer matrix to the fiber. The performance of PEDOT:PSS, both in terms of changing the surface resistance and to light-transmittance was evaluated. It is concluded that single layer printing of PEDOT:PSS is good enough to test it in the final sensory applications. As the final step, these materials will be tested for the optimum sensory applications.

Key words: Discontinuous Shear Thickening, Variable Stiffness, Non-linear damping, Force response system.

Abstract. The unique rheological properties of discontinuous shear thickening fluids (STF) have been employed in various engineering applications in recent years. In a commercial aspect, this has most notably been body armor and protective equipment, but also specialized smart structures in damping and force-coupling applications. The topic of this work is the application of STF in a translational element for an articulating prosthetic foot. Connected in series and parallel to a spring system, the element can be used to affect the force transfer within the system and thereby influence the stiffness of the prosthetic foot dynamically over the gait cycle. The device described in this work is a STF filled piston/cylinder design. The objective is a velocity dependent force response over the translational motion. Ranging from dampened, compliant deflection at low velocity, to efficient force transfer (coupling) for energy storage and return in the spring system at higher speed. The rapid viscosity increase in the STF at a critical shear rate is used to produce a stepwise force response, thereby enabling adaptive response of the foot for different walking speeds and other various tasks, such as standing up from a seated position. The adaptive response results in a greater range of motion with easier rollover through stance phase for slow movement without sacrificing the energy return needed in faster walking.

1 INTRODUCTION

Modern passive prosthetic feet can be described mechanically as efficient and designated spring systems. The force reaction to deflection, follows a fixed curve that is aimed at imitating as closely as possible the reaction of the biological foot through the gait cycle [1]. Passive or controlled damping is also added in some models [2] and most standard prosthetic feet are used with a visco-elastic cover, that provides additional damping. It has been demonstrated that different tasks and conditions in ambulation would benefit from varying stiffness of the foot [3–5]. The aim of this research is to design a device that will provide variable stiffness to the spring system as a function of speed. Previous work has indicated that the stiffness of a certain model of a prosthetic foot can be changed dynamically with a non-linear, speed-dependent damping element [6]. The purpose of the element described in this work, is to provide a compliant, dampened force reaction at slow speeds. Then, at a certain speed of translational displacement of the element, the damping should increase rapidly, approaching force coupling function. The element is to be connected in parallel and series to the springs in the system so that, as the function changes from damping to coupling, the stiffness of the overall system changes. It is hypothesized here that the unique properties of shear thickening fluids (STFs) can be utilized to realize this element. Concentrated suspensions of solid particles are known to show a non-Newtonian change in viscosity with changing shear rate. The sharp increase in viscosity of several orders of magnitude, or discontinuous shear thickening (DST), observed in a jamming effect in certain colloidal suspensions [7] is of particular interest. The aim is to employ this property for the change of function from damping to coupling. The challenge is to design the device so that the speed at which the function changes can be adapted. Analysis of the application has revealed specific speeds at which the reaction forces are required to increase. The required force value requirements of the element have also been mapped.

STFs have been commercially utilized in a number of applications and are actively being researched [8,9]. One commercialized field of use is impact protection for various applications, e.g. personal protective equipment and protectors for sensitive devices [10,11]. Of similar category is the embedment of STF in textile, e.g. for puncture resistance of body-armor [12,13]. The use of STFs for damping in structures has also been a research topic. Guo et al. [14] used STF to dampen flange connections on pipe assemblies and Yeh et al. [15] proposed a STF filled piston damper designed for earthquake protection of buildings. Furthermore, Zhang et al. [16] and Zhou et al. [17] designed and built STF filled piston dampers. Devices working on the principles of STF properties have also been proposed in torque brakes [18].

The design proposed here is a linear piston damper, comparable to the ones referenced above but with the objective being, transition from damping to force coupling and control of the speed at which the transition occurs. The gap, between piston and cylinder in the damper, serves as the orifice. The dimension of the gap is varied to affect the reacting force as a function of velocity. Our results show that the forces realized in the prototype damper fulfill the requirements. The DST effect is apparent in the tests, but further modifications are required to the damper to obtain control of the transition speed. Testing of varying STF properties shows that reaction forces drop with reducing DST effect and that critical shear rate has little effect on transition speed of the damper.

2 METHODS

2.1 System characterization

The prosthetic foot model studied is a system of serial and parallel connected leaf springs, articulating around a pivot point. The design change involves replacing a rigid mechanical link with the adaptive STF damper and a serial connected spring. The effect is a more compliant pivoting movement, as a new translational joint is introduced in the system. Figure 1 shows schematically the functions as intended for speed dependent stiffness. At low velocity movement over the element, a dampened deflection will render a more compliant force reaction of the whole system. As the velocity of movement over the element reaches a critical value that translates to the DST of the STF, and particle jamming occurs, the piston will couple the force over the element. The intention is that this coupling will make the whole system response approach the effect of the original rigid link. The force in the element is compressive at heel strike and rolls over to extension as the weight is moved over the foot in roll over in the step.

Figure 1: Schematic of a speed dependent stiffness system, connected in prosthetic foot model, replacing a rigid mechanical link.

The parameters of the design goals of the STF damper are determined by the results from simulation of the prosthetic foot system [6]. The compliant dampening forces prior to DST should be minimized while the coupling force after DST should exceed 2 kN. The critical shear rate of the fluid should translate to a speed of 5-8 mm/s linear movement of the piston. This critical speed should be adjustable to adapt the device to different users. This initial study aims at characterizing the piston design to approach these values.

2.2 Fluid properties

The STF material used is a commercially available suspension of silica particles in polyethylene glycol (STF Technologies, Delaware) [19]. The nominal particle size was determined ~200 nm with a scanning electron microscope. The silica content is not disclosed but stated in data sheet as 50-70 wt.% [20]. The shear thickening properties of the STF can be adjusted by diluting the suspension with carrier fluid. Viscosity of the STF, as stated by the supplier, is shown in figure 2. The dilution of the STF will result in a higher critical shear rate and a lower viscosity. Although it is not indicated in the chart, the viscosity is expected to drop quite rapidly after the maximum value is reached in the DST, as indicated in literature [21]. Measurements of varying gap dimensions are done on undiluted STF. To investigate the effect

of fluid properties, three mixtures are made for testing of diluted STF; 2.5 and 7.5 wt.% diluted.

Figure 2: Viscosity of the STF [19].

2.3 Piston damper design

The STF damper design is a symmetric piston damper with an axial piston-rod, eliminating the need for a compensator; see Figure 3. The cylinder and endcaps are made of aluminum alloy but the piston/rod and seal/bearing insert are from stainless steel. Low friction seals and bearings are selected to minimize forces at low velocities. The cylinder inner diameter is 20 mm and the rod diameter is 12 mm. Four piston diameters were prepared; 19.50, 19.36, 19.16 and 18.56 mm. The piston length is $l = 16$ mm. These result in dimensions of the annular gap (orifice) between piston and cylinder, h ; 250, 320, 420 and 720 μm , respectively. The available piston stroke is 13 mm.

Figure 3: STF damper, section view.

2.4 Orifice flow case

As the piston is displaced forward at a velocity U_p , the piston pushes the STF back through the annular gap orifice. For an analytical model of the flow in the orifice, we consider the combined Couette-Poiseuille (pressurized Couette) flow between moving and fixed, parallel

plates. The velocity profile of the developed flow is a superposition of the linear profile due to the moving plate and the parabolic profile due to the pressure gradient. For all test setups of the piston damper; dimensions, velocity and fluid properties, the Reynold's-number for the orifice flow fulfills, $Re < 1$. Hence, laminar flow through the gap is assumed. Furthermore, it is assumed that for shear rates below the critical shear rate of DST, the flow is fully developed of homogenous properties and that entrance/exit effects can be neglected. Figure 4 shows a schematic representation of the two-dimensional, axis symmetric flow between the piston and cylinder wall.

Figure 4: Schematic illustration of the Couette-Poiseuille flow case assumptions for the orifice gap.

The velocity profile $u_x(y)$, derived from the momentum equation and the no-slip boundary conditions, is well known and adapted here from [22]. The first term is due to the flow being driven by the pressure gradient in the x direction, P , and the second due to the wall driven flow,

$$u_x(y) = \frac{P}{2\mu}y(h-y) + U_p \frac{y}{h} \quad \text{where} \quad P = -\frac{dp}{dx} \quad (1)$$

where, μ is fluid viscosity.

The flow through the gap is the integral of the velocity profile over the full gap width. Assuming that the flow is incompressible and continuous, the flow equals the product of pushed area of the piston, D_p , and the piston speed.

$$Q = \int_0^h u_x(y) dy = \frac{Ph^3}{12\mu} + \frac{U_p h}{2} = D_p U_p \quad (2)$$

Solving for P and get,

$$P = \frac{12U_p\mu}{h^3} \left(D_p - \frac{h}{2} \right) \quad (3)$$

The force acting on the piston is a linear function of the pressure gradient, piston length and viscosity, so we can assume the force is dependent of the piston diameter and gap height in the form $F(D_p^2, h^{-3})$.

Of particular interest is the shear rate of the flow and relations to onset of DST.

$$\dot{\gamma}(y) = \frac{du_x}{dy} = \frac{P}{2\mu}(h-2y) + \frac{U_p}{h} \quad (4)$$

It is furthermore assumed that the DST phenomena initiates at the boundaries, ($y = 0$ and y

= h). Evaluating the shear rate for these, yields;

$$\dot{\gamma}(y) \Big|_{y=0}^{y=h} = \pm \frac{6U_p}{h^2} \left(D_p - \frac{h}{2} \right) + \frac{U_p}{h} \quad (5)$$

The onset of shear thickening at the critical shear rate is thus assumed to depend on the pushed area and gap thickness as $\dot{\gamma}(D_p, h^{-2})$. Attention is drawn to the dependency of force and shear rate on the thickness, h . The above indicates that decreasing gap dimension will affect the resulting damper-force more than the shear rate and therefore the velocity at which the DST will occur.

2.5 Force-displacement measurements

The force-displacement of the damper is measured with an electric dynamic testing machine, Instron ElectroPuls E3000 (Instron, Norwood). The control settings are displacement at constant speed. For each test, the piston is displaced for 17 runs at incrementing speeds. For each run the piston is pulled a displacement of 5 mm and then pushed back to the original position. After each displacement and between runs, the instrument is stopped for 1 s to allow the fluid to recover from thickened state. The speed is increased in 1 mm/s increments up to 14 mm/s, and thereafter; 16, 18, 20 mm/s. The displacement is done over the mid-range of the piston stroke length, to avoid end effects.

Figure 5: Test setup of the STF damper in an electro pulse dynamic test instrument.

The highly non-linear characteristics of the damper result in an increasing deviation from set velocity value, as the reaction forces increase, as shown in figures 6-8. The data is filtered in steps to clarify the plots. Data for negative direction (push) is filtered out as it is symmetric to the positive direction. Data for the initiation of each run is filtered out in terms of position, so the first 0.4 mm of each stroke are dismissed. Similarly, the last 0.2 mm of each stroke are

discarded. Runs for each set velocity are shown up to where the resulting force starts to increase due to DST. For higher forces, cycles for even number velocities are plotted. For the smaller gap dimensions, the force reaction of runs at higher speed, exceed the load capacity of the test machine, ~ 4 kN, so these are omitted.

3 RESULTS

3.1 Varying gap dimension

Results for different gap dimension of the piston damper are shown in figure 6. An increase in damping force and decrease in critical velocity is seen with decreasing gap dimension. The consecutive curves for runs of each test are plotted in same color (dots). Polynomial regression lines are plotted through the maximum force for each run after DST to capture the general trend.

Figure 6: Damping force vs. piston velocity for different gap dimensions. Measured for each run (dots) and regression lines through maximum force for each test.

For the application studied, the 250 and 320 μm gap arrangements generate damping forces that meet the criteria of $F > 2$ kN in the velocity range stated. As detailed further in table 1. The transition for these occur at a piston velocity that is below required values (Section 2.1). Although the control parameters are fixed speed, the step-wise increase in viscosity at the DST results variation from set value and severe overshooting (100%), especially for the 420 and 720 μm gaps. Rapidly decreasing viscosity for shear rate, higher than critical shear rate, could also induce this overshooting. The force for each run, as the piston is accelerated, is lower than the force during deceleration, for same measured velocity. Therefore, each run shows hysteresis curve, indicating a time dependency of the force. Anti-thixotrophy in concentrated suspensions has been described by Mewis et al. [23] as time dependent increase in viscosity under steady shear. Whether this phenomenon is apparent in the above measurements or if this is due to a time effect in the development of the flow through the length of the orifice, is outside the scope of this study. However, this effect is beneficial for the intended application as it generates a more efficient force transfer.

For a closer look at the onset of DST, the data in figure 6 is plotted again as force vs. average fluid velocity in the orifice, calculated from $\bar{u}_x = Q/h$; see figure 7. The data is further filtered out of runs exceeding maximum forces above 600 N. Regression lines are plotted for the data set after DST. The evaluated critical velocities at DST of the measured piston velocity, U_p , and calculated fluid velocity, \bar{u}_x , are further presented in table 1.

Figure 7: Damping force vs. average fluid velocity in orifice, for different gap dimensions. Regression lines for data sets above DST

A close look at the results of 720 μm gap at velocities below DST reveals a slight decrease of force with increasing fluid velocity. This is consistent with the shear thinning properties of the STF for shear below critical shear rate; see figure 2. The results in figure 7 indicate an independency of the DST to the average fluid velocity, as sudden rise in force gathers around a fixed fluid velocity value of ~ 20 mm/s. Further evaluation of the values in table 1, indicate that the critical U_p at transition is a linear function of h . This is in contrast with equations 4 and 5, where the shear rate is a function of gap height, $\dot{\gamma}(h^{-2})$. This indicates that the onset of DST is not only due to the shear stresses described by the Couette-Poiseuille model. Other effects in the actual flow case, like entrance/exit effects, could influence the propagation of DST.

Table 1: Critical velocities for different gap dimensions and ratio between them.

Gap dim. h [μm]	Piston velocity U_p [mm/s]	Piston area / gap area D_p/h [-]	Calc. fluid velocity \bar{u}_x [mm/s]
250	1,4	12,0	16,4
320	2,2	9,2	19,9
420	3,3	6,8	22,5
720	5,7	3,6	20,7

3.2 Fluid properties

To quantify the effect of shift in critical shear rate of DST in the fluid, the damper was further tested with varying dilutions of the STF. The force vs. piston velocity results for undiluted STF are compared to those from tests of fluid diluted 2.5 and 7.5 wt.%.. The tests were made with a piston of 19.16 mm diameter, or a gap of 420 μm . The results are shown in figure 8. The onset of DST occurs at a similar piston velocity for the three fluid mixtures, $U_p \sim 4 \text{ mm/s}$, and appears to be unaffected by dilution of the fluid. These results further imply that the onset of DST in the piston damper is initiated by other dynamics than the shear rate, derived from the Couette-Poiseuille flow equations.

Figure 8: Damping force vs. fluid velocity for different STF dilutions

4 CONCLUSIONS

In this paper we described the design objectives and requirements for a bi-functional STF piston damper. The damper is intended as an active element in a variable stiffness system. The damper shows velocity dependent behavior that shifts from compliant damping to force transfer at critical value of speed, dependent on gap dimension. Testing of the prototype showed that reaction forces above 2 kN, for $h < 320 \mu\text{m}$, meeting the requirements. The transition from damping to coupling, for these gap dimensions, occurred at a piston velocity below the required range (5 – 8 mm/s).

The results indicate time dependency in the fluid flow, where forces for deceleration are higher than during acceleration of the linear displacement of the piston. Whether this time dependency originates from time dependent increase of viscosity or transition in the flow regime is inconclusive. It is noted that the effect will increase the force reaction for deceleration and therefore be beneficial to the force coupling intended for the application. It was demonstrated that the analytical model does not capture the full complexity of the onset of DST. Furthermore, it was shown that the onset of DST was unaffected by change in critical shear rate of the STF, further demonstrating the deviance to the simplified Couette-Poiseuille flow.

It is the result of this initial study that there is potential in use of STFs for velocity dependent

force transfer, as defined here. Future work will focus on the transition at critical shear rates and how it can be translated to the linear displacement. This will include further development of the piston geometry for both shift in the transition velocity as well as adaptability.
