PREFACE

This e-book is the edited proceedings of SMART2019, the 9th ECCOMAS *Thematic Conference on Smart Structures and Materials* that held from 8 to 11 July at Paris (France). This biennial (odd years) series, has started in 2003 and progressed successfully over the years. Its earlier editions were located in Poland (2003, 2007), Portugal (2005, 2009, 2015), Germany (2011), Italy (2013) and Spain (2017).

The present edition aimed to: i) increase participants number, ii) raise contributions quality, iii) increase international (non-European) participants, iv) bring industrials, v) involve effectively the scientific committee (SC) in the organization, and vi) provide a good social program. To reach these goals, the SC has been revised according to the earlier edition active members and successful mini-symposia (MS) organizers' responses to a priori 'intended active participation' questionnaire. The general topics, meant for later general sessions (GS), were focused on seven only and hot ones, in the form of MS and Special Sessions (SS), have been introduced with the help of active members of the SC and experts in the suggested up-to-date topics. The technical program resulted in 5 GS, 13 MS and 2 Poster session (PS). In details, 195 contributions were presented in 37 sessions of which are 7 plenary lectures (PL), 28 oral sessions and 2 PS. From these, 176 full papers were submitted in order to be included in the present e-proceedings. Out of the PLs, for which full papers were not expected, this represents ~94% of the 188 talks (170) and Posters (18). Some of the missing 12 papers, related to talks (9) or Posters (3), were expected as they concern industrial (1), Keynote (1) or very late (3) submissions.

SMART2019 was supported by the 3 chairmen's affiliations (Ensam, Le Cnam and Supméca) and by 3 prestigious journals: *Smart Materials and Structures* (SMS), *Journal of Intelligent Material Systems and Structures* (JIMSS) and *Journal of Vibration and Control* (JVC). Presenting authors of a selection of papers from the present e-proceedings will be invited to revise and extend their contributions in order to be potentially published, after the journals regular review processes, in SMART2019 devoted special (JIMSS, JVC) or regular (SMS) issues. The organizers are then very thankful to their affiliations and to the editor-in-chiefs (Daniel J. Inman for JIMSS, Mehdi Ahmadian for JVC and Christopher S. Lynch for SMS) and JIMSS special issues' editor (Norman M. Wereley) for their valuable supports. The present proceedings editors are also very thankful to the authors for their contributions, to the SC active members for their effective involvement, to the MS organizers, chairwomen and chairmen for their help, to Mr. Alessio Bazzanella (CIMNE) for the present proceedings administrative edition, and to the local organization help from Mr. Christophe Canu, our colleagues, Post-Docs and PhDs.

As a closure, the editors wish sincerely that these proceedings will be very useful to academic and industrial researchers, and to engineers in this highly active topic of smart structures and materials.

Ayech BENJEDDOU, Nazih MECHBAL and Jean-François DEÛ (Editors)

ACKNOWLEDGEMENTS

The conference organizers acknowledge the support of the following organizations:

Arts et Métiers – Ensam (Paris Campus)

Conservatoire national des arts et métiers

Supméca

PLENARY SPEAKERS AND MS ORGANIZERS

We would like to thank the Plenary Speakers and the MS Organizers for their help in setting a high level Scientific Programme.

Plenary Speakers: Daniel J. Inman, Christopher S. Lynch, Mehdi Ahmadian, Michael Kyriakopoulos, Farhan Gandhi, Rainer Schweppe and Johannes Riemenschneider.

Minsymposia Organizers: Aurelio Araujo, Olivier Bareille, Tarak Ben Zineb, Andrea Bergamini, Christian Bolzmacher, Álvaro Cunha, Sergio de Rosa, Elke Deckers, Wim Desmet, Christophe Droz, Peter Eberhard, Farhan Gandhi, Jan Holnicki-Szulc, Alexander Humer, Lukasz Jankowski, Michael Krommer, Pawel Kudela, Boris Lossouarn, Theodoros Loutas, Pawel Malinowski, Nazih Mechbal, Filipa Moleiro, Carlos Moutinho, Euripedes Nóbrega, Wieslaw Ostachowicz, Przemyslaw Perlikowski, Marc Rebillat, Oliver Sawodny, Werner Sobek, Malte von Scheven, Norman Wereley, Wael Zaki and Dimitrios Zarouchas.

SUMMARY

MINISYMPOSIA

MS01: Smart & Adaptive Engineering Structures	31
<i>Organized by Malte von Scheven, Werner Sobek, Oliver Sawodny and Peter Eberhard</i>	
MS02: Identification, Control & Structural Health Monitoring of Civil Structures	146
<i>Organized by Carlos Moutinho and Álvaro Cunha</i>	
MS03: Adaptive Mitigation of Dynamically Induced Structural Response	323
<i>Organized by Lukasz Jankowski, Przemyslaw Perlikowski and Jan Holnicki-Szulc</i>	
MS04: Health Monitoring of Advanced Composite Structures	381
<i>Organized by Wiesław Ostachowicz, Paweł Malinowski and Paweł Kudela</i>	
MS05: Morphing Aircraft and Rotorcraft Systems	433
<i>Organized by Farhan Gandhi</i>	
MS06 : Spatial Control of Sound and Vibration	485
<i>Organized by Nazih Mechbal, Marc Rebillat, Euripedes Nobrega and Christian Bolzmacher</i>	
MS07: Modelling and Design of Smart Composite Structures	543
<i>Organized by Aurelio Araujo and Filipa Moleiro</i>	
MS08: Advances in Non-linear Modeling of Smart Materials and Structures	650
<i>Organized by Alexander Humer and Michael Krommer</i>	
MS09: Functional Materials with Multiphysics Coupling and their Applications	787
<i>Organized by Tarak Ben Zineb and Wael Zaki</i>	
MS10: Vibration Mitigation through Electromechanical Couplings	884
<i>Organized by Boris Lossouarn and Andrea Bergamini</i>	
MS11: Smart Design of Periodic Structures	1058
<i>Organized by Christophe Droz, Olivier Bareille, Wim Desmet and Elke Deckers</i>	
MS12: Integrated Prognostic and Health Monitoring of Complex Aeronautical Structures	1189
<i>Organized by Nazih Mechbal, Marc Rebillat, Theodoros Loutas and Dimitrios Zarouchas</i>	
MS14: Magnetorheological Fluids, Devices, and Integrated Adaptive Systems	1270
<i>Organized by Norman Wereley</i>	

GENERAL SESSIONS

GS1: Smart structures	1319
GS2: Smart materials	1377
GS3: Smart systems	1435
GS5: Health monitoring	1501
GS7: Engineering Applications	1622

POSTER SESSIONS

Poster	1671
---------------------	-------------

CONTENTS

MINISYMPOSIA

MS01: Smart & Adaptive Engineering Structures

Organized by Malte von Scheven, Werner Sobek, Oliver Sawodny and Peter Eberhard

An adaptive structure with a metamorphic robotic system	31
<i>M. Pieber and J. Gerstmayr</i>	
Combining Optimal Control and Shape Optimization for an Adaptive Engineering Structure with Parameterized Reduced Order Finite Element Models	43
<i>B. Fröhlich, J.L. Wagner, M. Böhm, O. Sawodny and P. Eberhard</i>	
Condition health monitoring of a suspension strut cap/ upper strut mount using piezoelectric sensor for electro-mechanical impedance technique....	55
<i>S. Moharana and V. S. A</i>	
Dynamic Optimal Control of Building Energy Adapting to External Factors Predictions	65
<i>S. Ben Ayed, D. Kim, J. Borggaard and E. Cliff</i>	
Experimental testing of a small-scale simply supported truss beam that adapts to loads through large shape changes	72
<i>A.P. Reksowardojo, G. Senatore and I. F. C. Smith</i>	
Nonlinear Bending of Functionally Graded Dielectric Composite Plate Reinforced by Graphene Platelets	81
<i>Y. Wang, C. Feng, Z. Zhao and J. Yang</i>	
Nonlinear Modeling and Control of Tension-only Elements in Adaptive Structures	90
<i>J. L. Wagner, M. Boehm and O. Sawodny</i>	
Selected Results on the Development and Testing of Smart Blades Technologies for Wind Turbines.....	102
<i>Z. Montano, S. Opitz, J. Riemenschneider, V. Petrovic, R. Unguran, L. Neuhaus, P. Singh, E. Werthen, C. Balzani and M. Bätge</i>	
Sensor and Actuator Placement in Tensegrity Structures through Cellular Morphogenesis	118
<i>O. Aloui and L. Rhode-Barbarigos</i>	
Simulative Study and Potential Analysis of Inflatable Facade Elements to Balance Environmental Disturbances	125
<i>J. Guenther, M. Oei, N. Harder and O. Sawodny</i>	

Topology optimization of piezoelectric smart structures under active control	137
<i>Z. Jia and X. Zhang</i>	

MS02: Identification, Control & Structural Health Monitoring of Civil Structures

Organized by Carlos Moutinho and Álvaro Cunha

A New Neutral Equilibrium Mechanism Applied to Force Control and its Application	146
<i>M. H. Shih and W. P. Sung</i>	

Active warping control for damping of torsional beam vibrations	158
<i>D. Hoffmeyer and J. Høgsberg</i>	

Assessment of Mode Shapes Based Damage Detection Methods for Building Structures	169
<i>C. M. Chang, H. F. Chiang and J. Y. Chou</i>	

Changes in modal frequencies of a steel plate girder caused by local damage and thermal expansion.....	177
<i>C. W. Kim, T. Hirooka, T. Mimasu, G. Hayashi and Y. Goi</i>	

Contribution to new solutions of instrumentation of Civil Structures for continuous dynamic monitoring	189
<i>C. Moutinho and A. Cunha</i>	

Electromechanical Impedance Method applied to Debonding Identification of NSM FRP Strips in Concrete	200
<i>R. Perera, L. Torres, M. Baena and C. Barris</i>	

Least-squares reverse time migration for flaw characterisation using ultrasonic bulk waves.....	207
<i>J. Rao and Z. Fan</i>	

Multiobjective optimization for identification of a moving load path	215
<i>M. Gawlicki and Ł. Jankowski</i>	

New application of piezoelectric sensors in health monitoring of rocks.....	223
<i>P. Negi, T. Chakraborty and S. Bhalla</i>	

Novel Technique of On-Demand Monitoring of Slider Displacement in Seismic Isolator.....	233
<i>S. Takhirov</i>	

Smart bridge developing based on micro-truss optimization method.....	243
<i>Y. Yokotani, I. Ario, Y. Chikahiro and M. Nakazawa</i>	

Statistical analysis of damage indicators based on ultrasonic testing with embedded piezoelectric transducers	251
<i>A. Deraemaeker, C. Dumoulin, N. Dervilis, E. Cross and K. Worden</i>	
Supervised classification with SCADA data for condition monitoring of wind turbines	263
<i>E. Hoxha, Y. Vidal and F. Pozo</i>	
The use of different modal quantities for identification of damage.....	275
<i>F. Vestroni, J. Ciambella and A. Pau</i>	
Topology optimization approach for dense sensor network distribution over large bridge structures	284
<i>B. Blachowski, P. Tazowski, A. Swiercz and Ł. Jankowski</i>	
Vibration monitoring on a PC girder bridge during a bridge collapse test	291
<i>Y. Kondo, Y. Oshima and C. W. Kim</i>	
Vibration suppression and energy harvesting potential in wind excited buildings equipped with ground floor tuned inerter damper	301
<i>Z. Wang and A. Giaralis</i>	
Vibration-based long-term scour monitoring for an in-service railway bridge	313
<i>K. Yoshitome, C. W. Kim, Y. Goi, S. Kitagawa, M. Shinoda, H. Yao and Y. Hamada</i>	
 MS03: Adaptive Mitigation of Dynamically Induced Structural Response 	
<i>Organized by Lukasz Jankowski, Przemyslaw Perlikowski and Jan Holnicki-Szulc</i>	
An experimental investigation of the Prestress Accumulation Release strategy for local mitigation of structural vibrations.....	323
<i>G. Mikulowski, B. Poplawski and Ł. Jankowski</i>	
Continuously Variable Transmission for Application in Tuned Mass Damper ..	333
<i>M. Lazarek, P. Brzeski and P. Perlikowski</i>	
Inverse Lyapunov based method for semi-active control of energy transfer between vibration modes	345
<i>M. Ostrowski, B. Blachowski, Ł. Jankowski and D. Pisarski</i>	
Semi-active decentralized mitigation of randomly excited vibrations in 2D frame structures.....	357
<i>B. Poplawski, G. Mikulowski and Ł. Jankowski</i>	
SMA-based multi-modal adaptive TMDs: model and tests	364
<i>M. Berardengo, G. Della Porta, S. Manzoni and M. Vanali</i>	

Tuned mass damper with inerter and non-linear damper	373
<i>M. Lazarek, B. Polniak, P. Brzeski and P. Perlikowski</i>	

MS04: Health Monitoring of Advanced Composite Structures

Organized by Wiesław Ostachowicz, Paweł Malinowski and Paweł Kudela

Approaches for localization of damage in composites using propagation of lamb waves	381
<i>K. Balasubramaniam, T. Wandowski and P. Malinowski</i>	

Damage assessment in composite powerboat using electromechanical impedance method	390
<i>W. Ostachowicz, T. Wandowski, P. Malinowski and B. Puchowski</i>	

Damage detection based on multivariate approach: application to aerospace composite structures	402
<i>R. Hadjria and O. D'Almeida</i>	

Effects on bond strength and quality of embedding optical glass fibre sensors in adhesively bonded joints formed by structural film adhesives	409
<i>N. Grundmann, H. Brüning, K. Brune and M. Mayer</i>	

Experimental investigations on the mechanical damage behavior of multifunctional composites with printed electronics	421
<i>M. Linke, T. Genco and R. Lammering</i>	

MS05: Morphing Aircraft and Rotorcraft Systems

Organized by Farhan Gandhi

A novel concept of a modular shape-adaptable sandwich panel able to achieve multiple shapes	433
<i>O. Testoni, A. Bergamini, S. Bodkhe and P. Ermanni</i>	

Analysis of Multifunctional SMA/Piezoelectric/Composite Beam Structure for Morphing and Energy Harvesting	443
<i>N. Mallik</i>	

Integration of the Spiral Pulley Negative Stiffness Mechanism into the FishBAC Morphing Wing	452
<i>C. Wang, J. Zhang, A. Shaw, M. Amoozgar, M. Friswell and B. Woods</i>	

Shape Memory Alloy Actuation Technology for Adaptive Low Boom Supersonic Transports	462
<i>J. Mabe, D. Lagoudas and D. Hartl</i>	

Tailored Nonlinear Negative Stiffness Mechanisms for Linear Motion.....	473
<i>J. Zhang, A. Shaw, C. Wang, M. Amoozgar and M. Friswell</i>	

MS06 : Spatial Control of Sound and Vibration

Organized by Nazih Mechbal, Marc Rebillat, Euripedes Nobrega and Christian Bolzmacher

Adaptable ball-screw inerter for optimal impact absorption	485
<i>R. Faraj, C. Graczykowski, Ł. Jankowski and J. Holnicki-Szulc</i>	

Analysis and Control of Damped Flexible Structures	492
<i>Y. Halevi</i>	

Bending waves focusing in arbitrary shaped plate-like structures: application to spatial audio.....	503
<i>N. Benbara, M. Rébillat and N. Mechbal</i>	

Open-loop transient control of modes for the generation of localized tactile tunable patterns on haptic devices.....	515
<i>C. Giraud-Audine, E. Enferad, F. Giraud, M. Amberg and B. Lemaire-Semail</i>	

Piezoelectric transducer for low frequency sound generation on surface loudspeakers.....	527
<i>C. Bolzmacher, N. Benbara, M. Rebillat and N. Mechbal</i>	

Ultra-Light, Deployable Space-Truss Structures with Dynamic Response Mitigation	537
<i>A. Swiercz and J. Holnicki-Szulc</i>	

MS07: Modelling and Design of Smart Composite Structures

Organized by Aurelio Araujo and Filipa Moleiro

Accurate Characterization of Fluidic Artificial Muscle Force Response for Improved Model Fidelity	543
<i>J. M. Chambers and N. M. Wereley</i>	

ACELAN-COMPOS Package for Finite Element Simulation of Active Composite Materials	551
<i>A. V. Nasedkin</i>	

Application of a Dual PZT Sparse Array with Lamb Wave Mode Decomposition for Damage Localization in an Aluminum Aircraft Wing.....	562
<i>J. R. McCullum, B. Yoo, D. J. Pines and N. M. Wereley</i>	

Bending shape memory process of a fabric-reinforced shape memory polymer composite plate: experimental investigation and numerical simulation	571
<i>P. Fan, W. Chen, J. Gao, G. Fang, F. Peng and Z. Cao</i>	

Design of Electro-Viscoelastic Sandwich Panels for Noise Reduction	580
<i>F. Vieira and A.L. Araujo</i>	
Environmentally-friendly Auxetic Piezoelectric Composites for Additive Manufacturing: Nonlocal and Nonlinear Effects.....	592
<i>A. K. Jagdish, F. C. Buroni, F. Garcia-Sanchez, R. Melnik, L. Rodriguez-Tembleque and A. Saez</i>	
Exact Vibration Analysis of Laminated Piezoelectric Plates through Strong SaS Formulation	599
<i>G. M. Kulikov, N. P. Merkusheva and S. V. Plotnikova</i>	
Multi-dimensional models for the global-local analysis of smart layered structures	610
<i>E. Zappino and E. Carrera</i>	
Optimization of piezoelectric patches with passive shunted damping for noise reduction in sandwich panels	618
<i>A.L. Araujo and J. F. A. Madeira</i>	
Process and Structural Health Monitoring of a "smart" Polymer-Matrix Composite using an in-situ piezoelectric sensor.	628
<i>C. Tuloup, W. Harizi, Z. Aboura, Y. Meyer and K. Khellil</i>	
The development of the prototype of the system for monitoring a stress-strain state of a outlet guide vane with the help of a fiber optical sensors	640
<i>A. Anoshkin, G. Shipunov, A. Voronkov, K. Pelenev, E. Shustova and A. Tikhonova</i>	

MS08: Advances in Non-linear Modeling of Smart Materials and Structures

Organized by Alexander Humer and Michael Krommer

A complete direct approach to electrostrictive polymer plates and shells	650
<i>M. Krommer, E. Hansy-Staudigl and A. Humer</i>	
A scale-adaptive indicator for the simulation of thermomechanically loaded SMA matrix composites	662
<i>M. Praster and S. Klinkel</i>	
Analysis of an energy-based model of the polarization process in ferroelectric materials	674
<i>A.S. Pechstein, M. Meindlhumer and A. Humer</i>	
Application of a microstructural model to simulation of a TiNi beam bending performance and calculation of thickness stress distributions.....	686
<i>A.E. Volkov, M. E. Evard, F. S. Beliaev, N. A. Volkova and P. S. Liulchak</i>	

Assessment of Second Piola-Kirchhoff Stress Tensor in Laminated Piezoelectric Structures through SaS Shell Formulation.....	696
<i>M. G. Kulikov, S. V. Plotnikova, S. A. Mamontov and G. M. Kulikov</i>	
Finite element reduced-order models to predict the geometrically nonlinear dynamics of piezoelectric laminated structures.....	709
<i>A. Givois, O. Thomas and J. F. Deü</i>	
Non-linear Electromechanical Coupling: Large Deformation and Hysteresis	721
<i>A. Humer, A.S. Pechstein, M. Meindlhumer and M. Krommer</i>	
Nonlinear Electromechanical Conversion and Sensory Response of Multi-Stable Piezoelectric Shallow Shells with Piezoelectric Films	730
<i>D. Varelis and D. Saravanos</i>	
Parameter-free optimization of material orientation for high performance composite shell structures	742
<i>M. Shimoda and Y. Muramatsu</i>	
Rate-dependent thermomechanical modelling of entropy changes in superelastic SMA	754
<i>A. Kaup, O. Altay and S. Klinkel</i>	
Shear behaviour of magnetorheological elastomers: viscoelastic and magnetorheological properties	764
<i>A. Bellelli and A. Spaggiari</i>	
Variational inequalities for ferroelectric constitutive modeling	775
<i>M. Meindlhumer, A.S. Pechstein and A. Humer</i>	

MS09: Functional Materials with Multiphysics Coupling and their Applications

Organized by Tarak Ben Zineb and Wael Zaki

A thermomechanically coupled finite-strain constitutive model for Iron-based Shape Memory Alloys accounting for coupling between phase transformation and plastic sliding	787
<i>A. Sallami, W. Khalil, T. Bouraoui and T. Ben Zineb</i>	
Ambient heat-transfer effects on magnetic shape memory alloy actuators	797
<i>S. Zhang, G. Qin and Y. He</i>	
Bending model for laminated composite cantilever beams with multiple embedded shape memory alloy layers	805
<i>W. Zaki and V. Nguyen</i>	

Effect of Cobalt Particle Morphology on Properties of Magnetorheological Elastomers	816
<i>X. Dong, Y. Tong, M. Qi and N. Ma</i>	
Fatigue Analysis of Nitinol Stent Used in Endovascular Aneurysm Repair (EVAR) Considering Anisotropic Aortic Walls	825
<i>R. Jayendiran, B. Nour and A. Ruimi</i>	
Modeling of Fatigue Crack Growth in Shape Memory Materials - Keynote Lecture	837
<i>J. Yaacoub and H. Sehitoglu</i>	
Phenomenological Modeling of Porous Shape Memory Alloys.....	844
<i>G. Ozerim, Z. Moumni and G. Anlas</i>	
Self-heating and fatigue of superelastic shape memory alloy structures.....	855
<i>L. Saint-Sulpice, S. Arbab Chirani, S. Calloch, C. Doudard and V. Legrand</i>	
Sensors integrated inside metal castings verified to respond to force.....	866
<i>R. Carlsson, C. Johansson, L. Elmquist, A. Thore, F. Ahrentorp, M. Törnvall, B. Israelsson, V. Schaller and P. Johannisson</i>	
Study of the pseudoelastic damping behaviour of the Fe-30Mn-6Si-5Cr shape memory alloy	877
<i>M. Megdiche, A. Sallami, F. Thiebaud, T. Bouraoui, T. Ben Zineb and S. A. Chirani</i>	
 MS10: Vibration Mitigation through Electromechanical Couplings	
<i>Organized by Boris Lossouarn and Andrea Bergamini</i>	
A robust calibration procedure for multiple electromechanical shunt absorbers on a flexible structure	884
<i>J. Høgsberg</i>	
Broadband vibration damping of a non-periodic plate by piezoelectric coupling to its electrical analogue	896
<i>R. Darleux, B. Lossouarn and J. F. Deü</i>	
Enhancement of a Dynamic Vibration Absorber by means of an Electromagnetic Shunt Damper.	908
<i>M. Auleley, O. Thomas, C. Giraud-Audine and H. Mahé</i>	
High voltage synthetic inductor in piezoelectric shunt to damp flexible vibrating structures	922
<i>K. Dekemele, P. Van Torre and M. Loccufer</i>	
Hybridization of active control and passive resonant shunt	930
<i>A. Paknejad, G. Raze, G. Zhao, M. Osée, A. Deraemaeker, F. Robert, G. Kerschen and C. Collette</i>	

Integration of piezostacks as frequency dependent stiffness elements in load bearing structures.....	942
<i>J. Schmied and A. Bergamini</i>	
Passive Vibration Damping of Hydrofoils using Resonant Piezoelectric Shunt.....	952
<i>L. Pernod, B. Lossouarn, J. A. Astolfi and J. F. Deü</i>	
Resonant piezoelectric shunt tuning based on the electric current and voltage response to pseudo-random vibration excitation	961
<i>J. F. Toftekær and J. Høgsberg</i>	
Semi-Active Piezoelectric Tuned Mass Damper for Mitigation of Aerodynamic Vibrations in Aircraft Structures	973
<i>K. Georgopoulos-Bosinas, N. A. Chrysochoidis, C. Rekatsinas, Y. Revalor and D. A. Saravanos</i>	
Stick-slip oscillations in an electromechanical system	985
<i>R. Lima and R. Sampaio</i>	
Suppression of delay-induced instabilities of digital piezoelectric vibration absorbers	991
<i>G. Raze, A. Paknejad, G. Zhao, V. Broun, C. Collette and G. Kerschen</i>	
The development of the model of electric analog for electromechanical systems taking into account mechanical losses	1002
<i>D. Oshmarin, N. Sevodina, N. Iurlova and M. Iurlov</i>	
The use of negative capacitances to improve the vibration attenuation of piezoelectric resonant shunt.....	1014
<i>M. Berardengo, S. Manzoni, O. Thomas and M. Vanali</i>	
Theoretical and experimental study of piezoelectric nonlinear resonators for energy harvesting and vibrations control.....	1025
<i>V. Guillot, A. Givois, M. Colin, O. Thomas, A. Ture Savadkoohi and C. H. Lamarque</i>	
Vibration control of smart composite plates using shunted piezoelectric elements	1037
<i>G.K. Tairidis, K. Marakakis, P. Koutsianitis, G. Foutsitzi, J. F. Deü, G. E. Stavroulakis and R. Ohayon</i>	
Vibration mitigation of multiple nonlinear resonances through an analogous piezoelectric network.....	1046
<i>B. Lossouarn, G. Kerschen and J. F. Deü</i>	

MS11: Smart Design of Periodic Structures

Organized by Christophe Droz, Olivier Bareille, Wim Desmet and Elke Deckers

A multi-scale reinforced sandwich panel for vibroacoustic applications: shear transition effects	1058
<i>R. Palumbo, D. Ivanov, C. Droz, F. Scarpa, O. Bareille and M. Ichchou</i>	
A Wave-Based Methodology for the Optimization of Finite 1D Metamaterials	1066
<i>R. Boukadia, E. Deckers, C. Claeys, M. Ichchou and W. Desmet</i>	
Absorption enhancement in poro-elastic materials by mass inclusion, exploiting the mass-spring effect	1076
<i>S. Ahsani, E. Deckers, T. G. Zielinski, Ł. Jankowski, C. Claeys and W. Desmet</i>	
Band diagram and forced response analysis of periodic and quasi-periodic panels	1085
<i>S. Timorian, M. Ouisse, N. Bouhaddi, S. De Rosa and F. Franco</i>	
Decoupling of energy transmission between subsystems of a complex structure	1096
<i>G. Mazzeo, M. Ichchou, G. Petrone, F. Franco and S. De Rosa</i>	
Elastic Energy Transport Leveraging Tunable Topological Structures	1105
<i>D. E. Quadrelli, E. Riva, G. Cazzulani and F. Braghin</i>	
Investigations about the modelling of acoustic properties of periodic porous materials with the shift cell approach	1112
<i>D. Magliacano, M. Ouisse, S. De Rosa, F. Franco and A. Khelif</i>	
On the effect of distributed embedded resonators in curved sandwich panels loaded by turbulent boundary layer	1124
<i>F. Errico, M. Ichchou, S. De Rosa, F. Franco and O. Bareille</i>	
On the structural characterization through k-space methods: assessments and validations	1136
<i>G. Tufano, C. Droz, M. Ichchou, O. Bareille, A. M. Zine, W. Desmet and B. Pluymers</i>	
On the vibration attenuation properties of finite periodic lattices of impact dampers	1146
<i>V. Dertimanis, S. Masri and E. Chatzi</i>	
Parametric analysis of a triple core periodic unit cell including a middle random core	1157
<i>N. Guenfoud, C. Droz, M. Ichchou, O. Bareille, E. Deckers and W. Desmet</i>	
Uncertainties in wave characteristic of one-dimensional periodic media using the fuzzy wave finite element method	1169
<i>R. P. Singh, M. Ichchou, O. Bareille, F. Franco and S. De Rosa</i>	

Wave-diode effect exploiting discretely modulated phononic waveguides	1183
<i>E. Riva, G. Cazzulani, J. Marconi and F. Braghin</i>	

MS12: Integrated Prognostic and Health Monitoring of Complex Aeronautical Structures

Organized by Nazih Mechbal, Marc Rebillat, Theodoros Loutas and Dimitrios Zarouchas

Composite Plate Automatic Damage Isolation Based on Support Vector Machine Classification of Lamb Wave Signals	1189
<i>R. Santos, P. Souza, N. Inocente-Junior and E. Nóbrega</i>	

Damage quantification method in composite materials based on triangulation	1201
<i>W. Briand, M. Rebillat, M. Guskov and N. Mechbal</i>	

Data-Driven Autoregressive Model Identification for Structural Health Monitoring in Anisotropic Composite Plates	1213
<i>S. da Silva, J. Paixão, M. Rébillat and N. Mechbal</i>	

Investigation of nonlinear Lamb wave/damage interaction: numerical and experimental approaches	1224
<i>X. Li, E. Monteiro, M. Rebillat, M. Guskov and N. Mechbal</i>	

Spatial attenuation prediction of Lamb waves in composite materials. ...	1236
<i>S. Guo, M. Rebillat and N. Mechbal</i>	

Strain-Based Damage Assessment on Single-Stiffener Composite Panels	1248
<i>D. Milanoski and T. Loutas</i>	

Structural state awareness of composite structures by blending passive and active acoustic-based health monitoring methods	1260
<i>D. Zarouchas and M. Saeedifar</i>	

MS14: Magnetorheological Fluids, Devices, and Integrated Adaptive Systems

Organized by Norman Wereley

Experimental study on vibration control of a vehicle semi-active suspension with magneto-rheological damper traversing speed bump	1270
<i>M. Yu, X. Du, J. Fu and C. Huang</i>	

Fuzzy-neural control for a magnetorheological elastomer vibration control system with sinusoidal excitations	1281
<i>J. Fu, J. Bai, Z. Yang, Z. Dai, J. Liu and M. Yu</i>	

Interaction between carrier liquid and iron particles in MR-based sealings	1291
<i>C. Hegger and J. Maas</i>	
Multi-axis Magnetorheological Aircraft Seat Suspension	1300
<i>Y.T. Choi, N. M. Wereley and G. Hiemenz</i>	
The Effect of Mesocarbon Microbeads on the Behavior of Magnetorheological Fluid	1312
<i>R. M. Pierce, Y.T. Choi and N. M. Wereley</i>	

GENERAL SESSIONS

GS1: Smart structures

Acoustic energy focusing and band gap structure of robocast ceramic scaffolds	1319

Key words: programmable matter, self-reconfigurable system, cellular robots

Abstract. Recently, a new approach for cellular robots has been presented. The single elements of the robot are triangular cells, which can change their shape by means of linear actuators at each edge. The novelty concerns the connection of autonomous cells at their edges rather than at the vertices. In this way, unstructured triangular meshes can be formed. The robot can self-reconfigure and thus can reproduce almost arbitrary planar shapes. The self-reconfigurable system shall serve as a basis for programmable matter. The present paper presents ways to assess and to compensate positioning errors of triangular cells. A mechanical model is developed, which considers compliance of links and joints by introducing axial and bending stiffness of according members of the model. In order to enable a fast computation and an integration of the actuators, a simplified discrete model is developed. A calibration and a comparison with accurate motion and force measurements shows the validity of the model. In the future, an extended model shall be used in order to optimize the mechanical parameters.

1 Introduction

Modular self-reconfigurable mechanisms have been investigated since the 1980s [1]. Self-reconfigurable mechanisms which are able to change their shape autonomously are classified as metamorphic robotic systems [2]. Only few such systems are available and they consist mostly of rigid cubical [3] or spherical [4] cells with an active or passive connection mechanism and are able to self-reconfigure by means of moving around on the other cells. However, these systems can only reconfigure, but not additionally change shape after reconfiguration. Since the development of metamorphic robotic systems, researchers improved the single components of the systems such as actuators, connection mechanisms, electronics and algorithms for self-reconfiguration [5]. Furthermore, spherical cells have been proposed for a possible approach to programmable matter [6], but no concrete areas of application have yet been identified [7].

The present paper deals with a simplified model of an extremely versatile cellular, adaptive and reconfigurable robotic system. The Planar Adaptive Robot with Triangular Structure (PARTS)

[8] goes significantly beyond the technology of existing cellular robots and is intended to be used in a wide range of applications. Considering cell sizes in the range from meters to millimeters, possible applications range from large adaptive and self-constructing scaffolds to small adaptive 'material'. One of the disadvantages of the existing system are the six-bar-linkages, which cause a low stiffness of the cells. In order to determine the stiffness, a test rig was designed which allows the determination of a force-displacement curve by means of two orthogonally applied forces. A mechanical model was developed which takes into account the bending stiffness of the six-bar-linkages. The model is highly important for the further development of the self-reconfigurable system, as it aims to predict the size of positioning errors which can be used to estimate possible connection faults. As compared to earlier works on the triangular cells, positioning errors can be predicted qualitatively given the parameters of a single cell only.

2 A planar cellular robot

The recently developed self-reconfigurable mechanism PARTS with adaptive triangular cells (ATC) and active connection mechanism as shown in Figure 1a), can reconfigure itself autonomously. Specifically, this can be achieved with the advantage that general triangular meshes can be exactly recreated. This is possible because the kinematic rotation axes of the vertices are located outside of the assembly space due to the use of six-bar linkages as shown in Figure 1b). Thus, all polygons with according edge sizes and angle limitations can be built with this method. In contrast to all other existing systems, the above mentioned features of PARTS allow that the whole structure can still move and, e.g., grip something, nearly independent of the reconfiguration of the structure. In other words, the programmable structure PARTS combines self-reconfiguration with adaptronics. Furthermore, programmable matter can be realized if using tetrahedral cells [9] together with miniaturization.

In order to transform the self-reconfigurable mechanism from one to another meshed structure, the cells are moving, e.g., along the outer edges of the current structure, cf. Figure 2. However, the real cells show a significant amount of deformation at the realized joints, such that a deviation of the real mesh from the idealized triangular mesh occurs. As the individual ATCs have no sensors for absolute positioning, the error between actual and target positions should be computed from a calibrated model of the deformable mechanism.

3 Positioning accuracy

The main part of the present contribution concerns the modeling of the cells, specifically of the six-bar-linkage joints as shown in Figure 1b) [8], which lead to a deviation of the real cells as compared to the idealized prescribed movements of the underlying triangular mesh due to compliance, bearing clearances and actuator inaccuracies. A first approach to modeling positioning errors due to compliance, clearance and friction has been based on a simplified mechanical model using elastic trusses of the triangular mesh to predict the positioning errors [8]. To get an accurate prediction of the positioning error, the current model is extended, by modeling every six-bar-linkage with elastic trusses and rods (for bending) and the whole self-reconfiguration mechanism resulting as a multibody system with changing constraints. In the present contribution, the modeling of the joints is improved by means of an additional bending related compliance in the six-bar-linkages. Modeling of bending stiffness follows the finite segment method, which

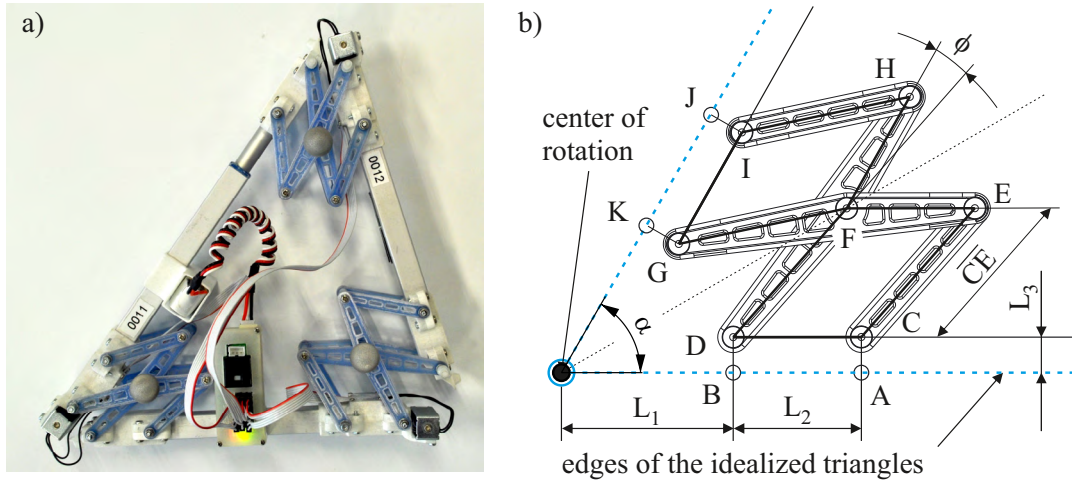

Figure 1: a) Top view of an ATC prototype with six-bar-linkages, electronics and measuring points. b) Schematic representation of a six-bar-linkage with center of rotation outside of the assembly space [8].

Figure 2: Proof of concept of self reconfiguration of PARTS with six ATCs. Steps a) to i) show the reconfiguration of PARTS by adapting the surrounding ATCs and by releasing and connecting the ATCs at the side edges.

Figure 3: a) Schematic of the deflection of a beam. b) Sketch of a linearized three-point torsion-spring.

allows to use only rigid bodies and springs for the whole model [10].

3.1 Deformation of a beam through bending

Bending stiffness has not been considered within the first model of the ATCs [8], which is why the model error becomes very large with the number of added ATCs. The maximum of the elastic deflection, denoted as y_c , of a simply supported beam loaded at a distance a and b from the support, see Figure 3a), is given by

$$y_c = \frac{Fl^3}{3EI} \frac{a^2 b^2}{l^2} \quad (1)$$

with the force F acting on the beam, the young's modulus E , the area moment of inertia of cross section I and the length l of the beam between the supports. The above formula can be rewritten as

$$F = \frac{3EI}{a^2 b^2} y_c. \quad (2)$$

The supporting forces F_A and F_B are calculated as follows

$$F_A = F \frac{b}{l} \quad \text{and} \quad F_B = F \frac{a}{l}. \quad (3)$$

Modeling of bending stiffness follows the finite segment method, which allows to use only rigid bodies and torsion springs for the whole model as shown in Figure 3b). Note that within the finite segment method, small deformation assumptions of the underlying beam are utilized, but the method could even tackle geometrically nonlinear deformations.

The maximum bending moment of the beam shown in Figure 3a), which is collocated with the point of maximum deflection y_c , is given by

$$M(\phi) = \mathbf{F}_F \cdot \mathbf{e}_{13}^\perp \frac{ab}{l} \quad (4)$$

with

$$\mathbf{F}_F = F \mathbf{e}_{13}^\perp \frac{ab}{l} \quad (5)$$

and the unit vector \mathbf{e}_{13}^\perp perpendicular to \mathbf{e}_{13} . The index gives the direction of the unit vector e.g. from node 1 to node 3, see Figure 3b). In the discrete model Figure 3b), a linearized relation between the deflection y_c and the angle ϕ can be derived. Assuming that the distance $a = b$, the maximum deflection is

$$y_c = \frac{\phi l}{4}. \quad (6)$$

Inserting equation (2) in equation (5) and using equation (6), an according bending stiffness can be derived for the discrete model, see Figure 3b), which is given by

$$M(\phi) = \frac{3EI l}{a^2 b^2} \frac{\phi l}{4} \frac{ab}{l} = \frac{3EI l}{4ab} \phi = c_t \phi. \quad (7)$$

Herein, the torsion stiffness parameter is given by

$$c_t = \frac{3EI l}{4ab}. \quad (8)$$

As our nodal-based model does not include rotations, the angle ϕ_F results from flexible bending as given by the relative displacements of the three nodes, reading

$$\phi_F = \arctan \left(\frac{\mathbf{e}_{12}^\perp \cdot \mathbf{e}_{23}}{\mathbf{e}_{12} \cdot \mathbf{e}_{23}} \right). \quad (9)$$

In order to apply a torque M_F due to (flexible) bending,

$$M_F = c_t \phi_F \quad (10)$$

we apply appropriate forces \mathbf{F}_F , \mathbf{F}_{FA} and \mathbf{F}_{FB} . The force \mathbf{F}_F follows from equation (4),

$$\mathbf{F}_F = M(\phi) \frac{l}{ab} \mathbf{e}_{13}^\perp = c_t \phi_F \frac{l}{ab} \mathbf{e}_{13}^\perp \quad (11)$$

and the forces \mathbf{F}_{FA} and \mathbf{F}_{FB} at the supports are calculated as follows

$$\mathbf{F}_{FA} = \mathbf{F}_F \frac{b}{l} \quad \text{and} \quad \mathbf{F}_{FB} = \mathbf{F}_F \frac{a}{l}. \quad (12)$$

The resulting discrete model is used to approximate the bending effect and is denoted as 'new model' in the experimental results.

Figure 4: Truss model with friction to represent the edges of the ATC.

3.2 Modeling of positioning errors due to compliance, clearance and friction

In the ATC the parallel six-bar linkage with the two bars DFH and GFE, see Figure 1b), have been identified as components with high compliance and clearance. Clearance is not considered here, because clearance effects will be significantly reduced in the future design with compliant joints. The basic idea of the current truss model with friction is to represent the edges of the ATCs with trusses as shown in Figure 4. Every actuator is represented by means of a truss with stiffness k_A . The friction in this model is based on a spring element and a Coulomb friction element put into series. The values for the simulation are listed in Table 1. For details on the truss model without bending, see [8].

To get an accurate prediction of the positioning error, the current truss model with friction is extended, by modeling every six-bar-linkage with elastic trusses and rods (for bending) as shown in Figure 5a). The modeling of the joints is improved by means of an additional bending related compliance EI in the six-bar-linkages as described above. For the second moment of area I_0 and the area of the C-shaped profile A , the cross-section of the bar CE as shown in Figure 5b) was used. The resulting stiffness parameters of all truss elements, as given in Figure 5b), are listed in Table 1.

4 Laboratory measurements and experiments

Two laboratory scale experiments have been performed. The first experiment with one triangular cell is used to identify the stiffness of a single cell. In particular, the measurements are used to identify the bending stiffness parameter EI for the model as described in Section 3.

The second experiment is carried out with four connected ATCs and detailed measurements are used to validate the model.

4.1 Experiment to identify the bending stiffness parameter

A test bench has been developed, see Figure 6, which allows the precise application of displacements and forces along almost any direction. Within the present setup, one edge is rigidly connected to a ground plate while the opposite vertex of the ATC can freely move on ground.

Figure 5: a) Extended truss model with elastic trusses and rods. b) Enlarged representation of one edge.

Table 1: Parameters of the truss model.

parameter	value	unit
actuator stiffness k_A (calibrated)	1.048	N/mm
reference length L_0	229	mm
friction normal force F_N	0.597	N
static friction coefficient (ATC/ground) μ	0.18	–
max. friction force $F_{max} = \mu \cdot F_N$	0.107	N
max. friction spring length d_{max}	2	mm
friction spring constant k_{Fr}	0.054	N/mm
young's modulus VisiJet Navy E	735	N/mm ²
second moment of area of C-shaped profile I_0	84.42	mm ⁴
area of C-shaped profile A	17	mm ²
bending stiffness EI_{act}	$8 \cdot EI$	Nmm ²
bending stiffness EI_{con}	$8 \cdot EI$	Nmm ²
axial stiffness EA_{act1}	$8 \cdot EA$	Nmm ²
axial stiffness EA_{act2}	$8 \cdot EA$	Nmm ²

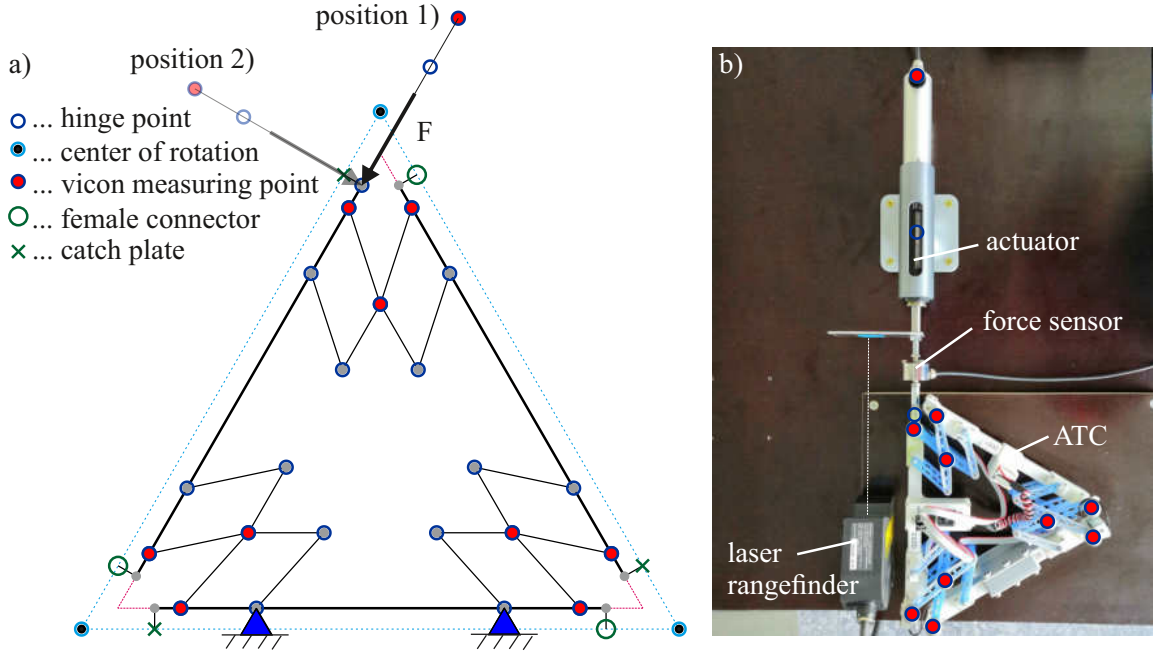

Figure 6: Test bench for measuring force and displacement of an ATC to identify the bending stiffness parameter EI of the model. The actuator is in position 1) in axial direction of the ATC and in position 2) normal to axial direction.

The actuator stroke of the PI 'M-235 High-Resolution Linear Actuator' is prescribed by an according controller with a nominal velocity of 1 mm/s. A force sensor 'U9C' which is attached at the tip of the actuator measures the force along the axis. Note that the center of the actuator can freely rotate using a ball bearing (friction neglected) between the mounting on the base plate and the actuator. The center of gravity of the actuator and the force is carefully balanced such that almost no gravitational force is transferred to the ATC. As the actuator allows no simple synchronization, we measure the actuator displacement with a laser range-finder 'LK-H157'. Two representative orientations of the actuator have been chosen, being the 'axial' direction of the ATC (position 1, tangential to the edge of the ATC) and normal to the first direction (position 2). The diagram of the force path for the two mounting positions is shown in Figure 7a).

Retro-reflective markers were applied to the cells and the relative movements of the markers at given actor strokes were measured with a motion tracking system (Vicon) and compared with the results of the model by an identified force of $f = 14$ N. The location of Vicon measuring points is given in Figure 6a) and also highlighted red in Figure 6b). The error over all Vicon measuring points, which is computed as the distance between measured and computed (model) points, is shown for the two actuator positions in Figure 7b). For model calibration, a factor is used against the nominal bending stiffness EI_0 , which is determined from the material and geometry parameters of the respective arms of the six-bar-linkages. By visual inspection, the optimal bending stiffness parameter is determined as $EI_{opt} = 1.3 EI_0$, which is used in the simulation with the model.

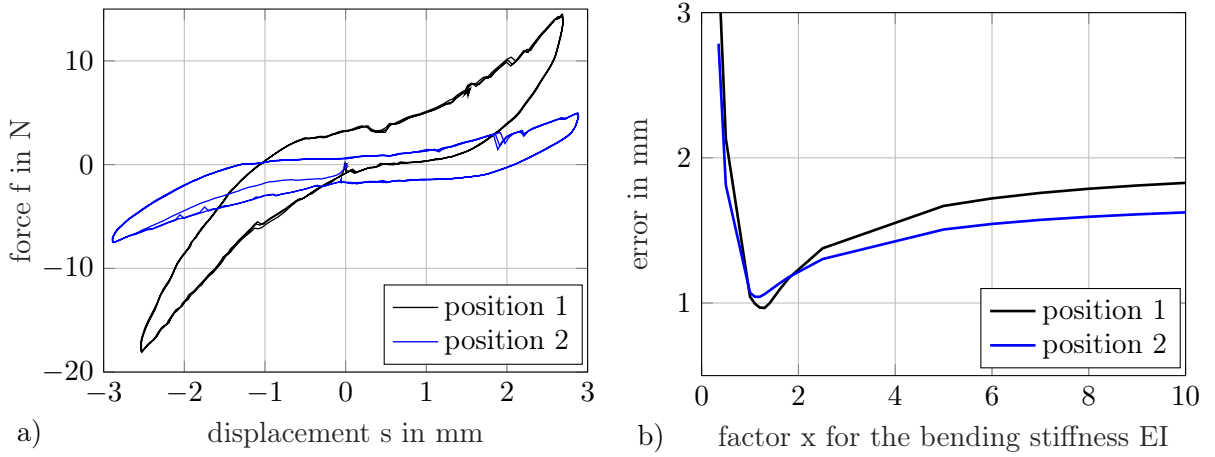

Figure 7: a) Force path diagram for the two measuring positions as shown in Figure 6; b) Error over all measured and calculated points for position 1) (black) and for position 2) (blue).

Table 2: Desired actuator strokes of the first experiment (mm); the strokes are interpolated with 20 mm steps.

step	ATC	act.	stroke	step	ATC	act.	stroke
1)	1	A11	0	4)	1	A11	80
	4	A42	0		4	A42	80
2)	4	A41	80	5)	4	A41	0
3)	1	A13	80	6)	1	A13	0

4.2 Motion tracking experiments

In order to verify the model on a larger scale with four ATCs, the measurement points in Figure 8a) are recorded with the motion tracking system Vicon for every ATC. The desired strokes of the 4 ATC experiment are given in Table 2, which have been prescribed in steps of 20 mm. Figure 8b) shows snapshots of the motion of the real system. The newly developed model is compared against a simpler model [8] in which, however, an adjustment actuator stiffness parameter has been calibrated using the data of the 4 ATC setup itself, while in the present model a reference measurement with one ATC is used. Figure 9b) depicts the distance of the points between measured and desired trajectory and between computed model and desired trajectory. The large deviation between desired (ideal) and real position of point P6 is obviously reduced by the new model. Larger deviations at the beginning of the movement could be attributed to the unknown pre-stress in the system. Concludingly, the model predictions could be used to reduce the positioning errors significantly.

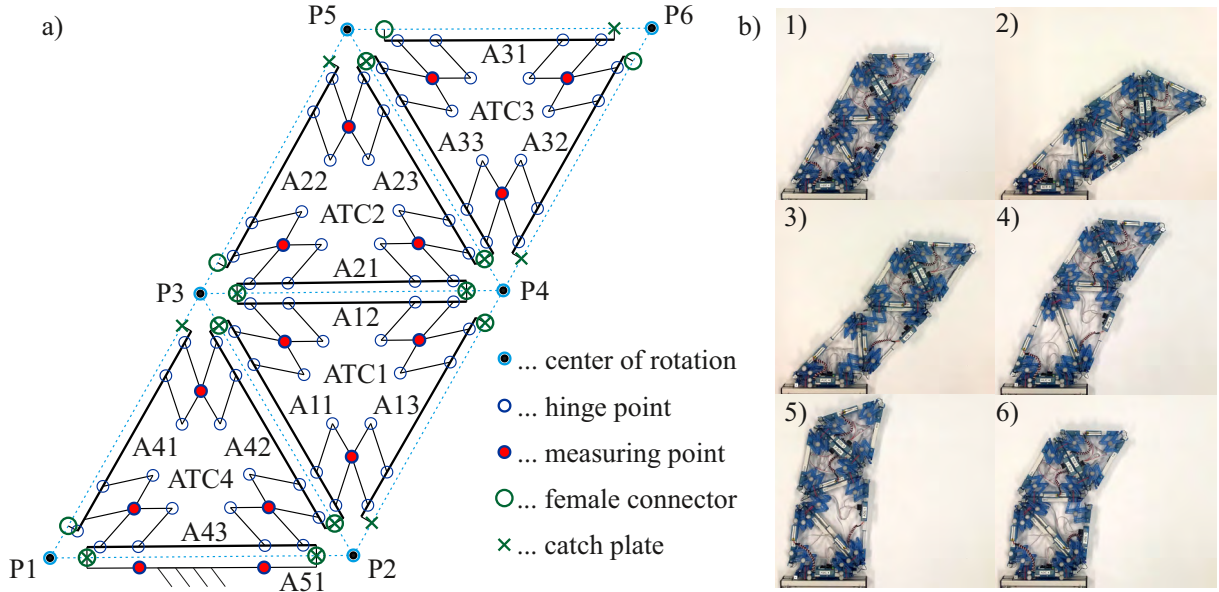

Figure 8: a) Initial position of four ATCs with centre of rotation P1 - P6, parallel six-bar linkages, retroreflective markers (red measuring points), connection mechanism (green) and actuators A11-A51. b) Snapshots of the motion of PARTS for the first experiment, using steps 1) – 6) in Table 2.

Figure 9: a) Results of the first experiment according to Table 2, showing the desired trajectory, the results of the model and the experiment for the position of P6; b) Evaluation of the position P6 in the first experiment (Table 2), showing the distance between measured (experiment) and desired values as well as between model and desired values.

5 Conclusions

The use of simplified models of the real kinematics of the adaptive self-reconfigurable mechanism delivers the possibility to correct the linear actuators to minimize the positioning errors and to directly set the desired triangular shapes. Furthermore, the laboratory setup opens the possibility to optimize the design and to search for kinematic designs with much higher stiffness. Due to the corrections applied, the general triangular structure based on a given network can be easily programmed, which enables the implementation on an embedded system. A self-reconfiguration algorithm of PARTS is currently under development [11]. At the moment only a static model is considered because motion is slow and dynamic effects are small, which should be extended in further research in order to simulate effects during connection and release. The disruptive potential of the presented adaptive robot is dependent on a realization at the micro-scale, leading to a smart material. Even though such a realization is not expected in the near future, the present approach can be seen as a top-down attempt to obtain a fully programmable matter or a self-healing material.

Key words: adaptive engineering structure, moving loads, disturbance compensation, shape optimization, parametric model order reduction

Abstract. This contribution proposes a workflow for simultaneous structural and control design for adaptive engineering structures. It allows to optimize the shape and the control in accordance with each other in order to obtain an overall optimized system. Its main idea is to solve a subordinate optimal control problem in every iteration of a superordinate shape optimization. Additionally, the workflow combines geometrically parameterized finite elements with parametric model order reduction. This allows to conduct the necessary transient simulations during the solution of the optimization problem numerically efficient with models of low order. Next, it enables an efficient sensitivity analysis. An exemplary adaptive engineering structure which diminishes displacements by an actuation is used to illustrate the workflow. In this example, the structure is subjected to a dynamic, moving load. The corresponding actuation is determined by an optimal control law. The objective is to optimize the shape and the control input such that the actuation energy is minimized.

1 INTRODUCTION

The construction sector plays a major role in the worldwide consumption of resources and in the production of emissions, see [9]. In view of limited resources, a decrease of the material consumption and the emissions in the civil engineering sector is, therefore, essential. Adaptive engineering structures are one way to achieve a weight reduction, [11]. It is the idea to combine the actual engineering structure with actuators, sensors, and a control concept to manipulate for example stresses or deformations. Thereby, the load carrying behavior can be improved and a weight reduction of the structure can be achieved.

However, the design of adaptive engineering structures is not a trivial task. It requires to design the structure, the control concept including actuator and sensor placement, see [13], and the control law.

The novel contribution of this paper is a workflow in which both the shape and the control of an adaptive engineering structure are optimized simultaneously. As a result, an adaptive engineering structure is derived in which the shape and the control are optimized in accordance with each other yielding an optimized overall system. Furthermore, the entire simulation and optimization is done using parameterized, reduced order finite element models, see [7]. Including reduced order modeling in the workflow allows very efficient yet accurate reruns of the dynamic, transient simulations and therewith an efficient solution of the simultaneous optimization problem.

This paper is structured as follows. Section 2 describes the adaptive engineering structure used as an illustrative example which is followed by the introduction of the control concept. Simulation results are shown both for the passive and the active structure. Section 3 states the simultaneous shape and control optimization problem and illustrates the proposed optimization workflow. Parametric model order reduction is applied and the optimization problem is solved. The results are interpreted and discussed. The conclusion can be found in Sec. 4.

2 MODELING AND CONTROL OF THE ADAPTIVE ENGINEERING STRUCTURE

This section introduces the adaptive engineering structure which is used as an example in this contribution. The exemplary structure is a simplified model of a bridge. It compensates external loads, for example caused by cars or trains, by an actuation. The structure is first introduced in [12]. For a better understanding, its functionality will be shortly described below.

The structure with material properties and dimensions is illustrated in Fig. 1. The beam-like structure has two supports where the left support constrains displacements in all directions. The right support only constrains displacements in x - and y -direction allowing a horizontal movement of the right support. Two displacement fields, one of the passive, one of the active structure are shown in Fig. 2 for a loading in vertical direction. The passive structure shows clear bending. For the active structure, an actuation force in z -direction is applied at the right support to compensate the bending. It can be seen that the displacement at the loading position is reduced to zero. The displacement along the rest of the structure is also diminished significantly. A more elaborated analysis of this particular adaptive engineering structure including a shape optimization can be found in [7]. However, the authors of [7] only investigate *static* load cases and a *static* compensation. In the following, a *dynamic*, moving load case is considered and transient simulations are conducted. Consequently, the control concept has to be extended to this problem type. First, the governing equations and the modeling of the moving load will be illustrated. Second, an optimal control concept is stated and applied to the structure.

Figure 1: Adaptive structure with pinned nodes (black), the actual element size is two times smaller.

Figure 2: Passive and active structure for an exemplary static loading in y-direction.

2.1 Modeling of the dynamic load case

The structure is discretized with the finite-element-method (FEM), see for example [15], with 5504 hexahedron elements with linear interpolating ansatz functions. This results in a system with 36 200 degrees of freedom. Note that the FEM mesh shown in Figs. 1-2 is a coarse mesh for illustration, the actual mesh size is two times smaller. The dynamic load is modelled as a moving force where its loading position $\eta(t) \in [-21.3\text{ m}, 21.3\text{ m}]$ is a function of time. The load on the structure is written as the product

$$\mathbf{f}_{\text{load}} = \mathbf{e}(\eta(t)) w(t) \quad (1)$$

where the disturbance $w(t) \in \mathbb{R}$ is distributed along the structure with help of the time dependent disturbance input vector $\mathbf{e}(\eta(t))$ as a 1.4 m wide surface load around $\eta(t)$. The control force acting on the right support is written as the product

$$\mathbf{f}_{\text{ctrl}} = \mathbf{b}u(t) \quad (2)$$

with the constant control input vector $\mathbf{b} \in \mathbb{R}^N$ and the control input $u(t) \in \mathbb{R}$. Hence, the governing set of second order differential equations is given as

$$\begin{aligned} \mathbf{M}\ddot{\mathbf{q}}(t) + \mathbf{D}\dot{\mathbf{q}}(t) + \mathbf{K}\mathbf{q}(t) &= \mathbf{b}u(t) + \mathbf{e}(\eta(t)) w(t) \\ y_{\text{disp}}(t) &= \mathbf{e}^T(\eta(t)) \mathbf{q}(t) \end{aligned} \quad (3)$$

where $\mathbf{M} \in \mathbb{R}^{N \times N}$, $\mathbf{D} \in \mathbb{R}^{N \times N}$, $\mathbf{K} \in \mathbb{R}^{N \times N}$ are the mass, damping, and stiffness matrix, respectively. The nodal displacements are described by $\mathbf{q} \in \mathbb{R}^N$. Additionally, system (3) includes the system output of interest $y_{\text{disp}}(t)$ describing the displacement in vertical direction at the time dependent loading position $\eta(t)$. In the following, the disturbance force is set to be constant with $w = 1000\text{ kg} \cdot 9.81\text{ m/s}^2 = 9810\text{ N}$. Two loading position trajectories, a forward and a backward trajectory, are considered where both trajectories

$$\eta(t)^{\text{forw,backw}} = \pm 21.3\text{ m} \pm t 9.7\text{ m/s} \quad (4)$$

describe a linear movement with constant velocity, see Fig. 3. The initial conditions are set to zero with $\mathbf{q}(t=0) = \mathbf{0}$ and $\dot{\mathbf{q}}(t=0) = \mathbf{0}$. From now on, the time dependency of $\mathbf{q}(t)$, $u(t)$, $w(t)$, $\eta(t)$ and $y_{\text{disp}}(t)$ will be only written if there is a benefit for the reader.

Solving system (3) in time for the backward loading position trajectory and $u = 0$ yields the displacement y_{disp} of the passive structure, see Fig. 4. The loading position η is marked for some time steps. The displacement y_{disp} increases as the load moves along the structure since the structure becomes more

Figure 3: Trajectories of loading position.

Figure 4: Displacement at loading position for passive structure over time and corresponding z -coordinates of loading position.

flexible for a loading in the center. In the static case, one would expect the maximum displacement for a loading position directly in the center of the structure at $\eta = 0$ m. However, the moving load excites an oscillation such that the maximum displacement of $y_{\text{disp}} \approx 1.21 \cdot 10^{-3}$ m occurs at $t = 2.43$ s at the loading position $\eta = -2.2$ m. Small displacements can be observed when the moving force is acting over the supports, for example at $\eta = 13.5$ m, as the system is stiffer here.

2.2 OPTIMAL CONTROL DESIGN

Assuming the disturbance is known a priori, the input $u(t)$ which minimizes $y_{\text{disp}}(t)$ over the simulation time can be determined by an optimization. In order to do this, system (3) is rewritten in state space notation and discretized in time as

$$\begin{aligned} \mathbf{x}_{k+1} &= \tilde{\mathbf{A}}\mathbf{x}_k + \tilde{\mathbf{b}}u_k + \tilde{\mathbf{e}}_k w_k, \\ y_k &= \tilde{\mathbf{e}}_k^T \mathbf{x}_k \end{aligned} \quad (5)$$

with

$$\tilde{\mathbf{A}} = e^{\mathbf{A}T_s}, \quad \mathbf{A} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{D} \end{bmatrix} \quad (6)$$

and

$$\tilde{\mathbf{e}}_k = \int_0^{T_s} e^{\mathbf{A}(T_s-\tau)} \begin{bmatrix} \mathbf{0} \\ \mathbf{e}(kT_s) \end{bmatrix} d\tau, \quad \tilde{\mathbf{b}} = \int_0^{T_s} e^{\mathbf{A}(T_s-\tau)} \begin{bmatrix} \mathbf{0} \\ \mathbf{b} \end{bmatrix} d\tau. \quad (7)$$

The initial condition is given by $\mathbf{x}_{k=0} = \mathbf{0}$ and the sample time is T_s . The optimization problem can now be formulated as

$$\min J_{\text{ctrl}} = \mathbf{x}_K^T \mathbf{H}_{xx,K} \mathbf{x}_K + \sum_{k=0}^{K-1} \mathbf{x}_k^T \mathbf{H}_{xx,k} \mathbf{x}_k + u_k H_{uu} u_k, \quad \text{subject to system (5)}. \quad (8)$$

Here, K is the number of time steps considered. This means that the time span over which the input u_k is optimized is given by $t_{\text{ctrl}} = KT_s$.

It can be seen that the cost function J_{ctrl} weights and penalizes both the control input u_k and the deviation of the state \mathbf{x}_k from the equilibrium. The weighting matrix H_{uu} is chosen to be constant. In

order to only penalize the displacement at the actual loading position but not the entire state including velocities, the weighting matrix $\mathbf{H}_{xx,k}$ is written as

$$\mathbf{H}_{xx,k} = \tilde{\mathbf{e}}_k H_{xx} \tilde{\mathbf{e}}_k^T \quad (9)$$

such that

$$\mathbf{x}_k^T \mathbf{H}_{xx,k} \mathbf{x}_k = \mathbf{x}_k^T \tilde{\mathbf{e}}_k H_{xx} \tilde{\mathbf{e}}_k^T \mathbf{x}_k = y_{\text{disp},k} H_{xx} y_{\text{disp},k}. \quad (10)$$

The scalar weighting matrix H_{xx} is chosen to be constant, as well. The optimization problem (8) can be analytically solved by backward iteration as depicted in Alg. 1. A more elaborative derivation can be found in [10].

Algorithm 1 Backward iteration

```

1:  $\mathbf{W}_{xx,K} = \mathbf{H}_{xx,K}$ 
2: for  $k = K - 1$  to 0 do
3:    $\mathbf{G}_{xx,k} = \mathbf{H}_{xx,k} + \tilde{\mathbf{A}}^T \mathbf{W}_{xx,k+1} \tilde{\mathbf{A}}$ 
4:    $\mathbf{G}_{xu,k} = \tilde{\mathbf{A}}^T \mathbf{W}_{xx,k+1} \tilde{\mathbf{b}}$ 
5:    $\mathbf{G}_{uu,k} = H_{uu} + \tilde{\mathbf{b}}^T \mathbf{W}_{xx,k+1} \tilde{\mathbf{b}}$ 
6:    $\mathbf{G}_{x,k} = \tilde{\mathbf{A}}^T (\mathbf{W}_{xx,k+1} \tilde{\mathbf{e}}_k w_k + \mathbf{W}_{x,k+1})$ 
7:    $\mathbf{G}_{u,k} = \tilde{\mathbf{b}}^T (\mathbf{W}_{xx,k+1} \tilde{\mathbf{e}}_k w_k + \mathbf{W}_{x,k+1})$ 
8:    $\mathbf{R}_{ux,k} = (\mathbf{G}_{uu,k})^{-1} (\mathbf{G}_{xu,k})^T$ 
9:    $\mathbf{R}_{u,k} = (\mathbf{G}_{uu,k})^{-1} \mathbf{G}_{u,k}$ 
10:   $\mathbf{W}_{xx,k} = \mathbf{G}_{xx,k} - \mathbf{G}_{xu,k} \mathbf{R}_{ux,k}$ 
11:   $\mathbf{W}_{x,k} = \mathbf{G}_{x,k} - \mathbf{G}_{xu,k} \mathbf{R}_{u,k}$ 
12: end for
    
```

The optimal control problem is now solved with Alg. 1. Afterwards, the complete input signal is obtained by forward simulation along with system (5) using the control law $u_k = -\mathbf{R}_{ux,k} \mathbf{x}_k - \mathbf{R}_{u,k}$. The input signal for the backward loading position trajectory is shown in Fig. 5. The corresponding displacement y_{disp} of the controlled structure is illustrated in Fig. 6. The maximum displacement decreases to $y_{\text{disp}} \approx 1.38 \cdot 10^{-4}$ m. The mean displacement over the entire simulation time is also much smaller compared to the mean displacement of the passive structure. The proposed optimal control strategy seems, therefore, to be appropriate for disturbance compensation in this dynamic load case example.

Figure 5: Control input at right support.

Figure 6: Displacement at loading position for passive and active structure.

3 SIMULTANEOUS CONTROL AND SHAPE DESIGN

This section illustrates the design approach in which the control input and the shape of the adaptive engineering structure are optimized simultaneously. First, the design parameterization and the exemplary optimization problem is stated. Second, parametric model order reduction (PMOR) is applied to enable an efficient computation of the objective function during the optimization. Finally, the simultaneous optimization process will be outlined and numerical results will be shown.

3.1 Formulation of the Optimization Problem

Figure 7 shows the structure where quadratic Bézier curves at the upper part and linear Bézier curves at the supports are added to manipulate its shape. This yields 15 Bézier control points gathered in the parameter vector $\mathbf{p} \in \mathbb{R}^{15}$ which are used to describe the shape parameterization. The objective of this contribution is to optimize the shape of the structure such that the actuator energy for the active control from Sec. 2.2 is minimized. In this particular example, the optimization is conducted for a given loading position trajectory η and a given disturbance w . The actuation energy is both influenced by the control input u and the operating displacement at the right support y_{act} . The latter can be written with the transpose of the control input vector as $y_{\text{act}} = \mathbf{b}^T \mathbf{q}$. The time dependent power output is therefore given as $P(t) = \dot{y}_{\text{act}}(t)u(t)$. It is the goal of this optimization to minimize the integral of the squared power output over the simulation time and thereby to minimize the energy required to run the control. Two loading position trajectories, the forward and the backward trajectory from Fig. 3, are considered to achieve a symmetric load. They are treated in two separate simulations starting with zero initial conditions such that the objective function reads

$$J(\mathbf{p}) = J^{\text{forw}}(\mathbf{p}) + J^{\text{backw}}(\mathbf{p}) = \int_0^{t_{\text{end}}} (\dot{y}_{\text{act}}^{\text{forw}}(t)u^{\text{forw}}(t))^2 dt + \int_0^{t_{\text{end}}} (\dot{y}_{\text{act}}^{\text{backw}}(t)u^{\text{backw}}(t))^2 dt. \quad (11)$$

The optimization problem can therewith be written as

$$\begin{aligned} \min_{\mathbf{p} \in \mathcal{P}} J(\mathbf{p}) &= \min (J^{\text{forw}}(\mathbf{p}) + J^{\text{backw}}(\mathbf{p})) \\ \text{with } \mathcal{P} &:= \{\mathbf{p} \in \mathbb{R}^{15} \mid \mathbf{p}_{\text{lower}} \leq \mathbf{p} \leq \mathbf{p}_{\text{upper}} \mid m(\mathbf{p}) - m(\mathbf{p}_0) \leq 0, c(\mathbf{p}) - c(\mathbf{p}_0) \leq 0\}. \end{aligned} \quad (12)$$

The first nonlinear inequality condition $m(\mathbf{p}) - m(\mathbf{p}_0) \leq 0$ ensures that the mass of the structure $m(\mathbf{p})$ does not exceed the initial mass $m(\mathbf{p}_0)$. The second nonlinear inequality condition $c(\mathbf{p}) - c(\mathbf{p}_0) \leq 0$ guarantees that the mean squared displacement

$$c(\mathbf{p}) = \frac{1}{t_{\text{end}}} \int_0^{t_{\text{end}}} y_{\text{disp}}^2(y) dt \quad (13)$$

at the loading position does not exceed the mean squared displacement at the loading position for the initial geometry. The second inequality $c(\mathbf{p}) - c(\mathbf{p}_0) \leq 0$ is necessary to make sure that the trivial solution with $u(t) = 0$ resulting in a zero actuator energy is excluded from the feasible design space.

Figure 7: Adaptive structure with Bézier curves (red) and Bézier control points.

3.2 Parametric Model Order Reduction

The shape parameterization introduced in Sec. 3.1 and illustrated in Fig. 7 makes the linear, second order system (3) a linear, *parameter-variant*, second order system

$$\begin{aligned} \mathbf{M}(\mathbf{p})\ddot{\mathbf{q}} + \mathbf{D}(\mathbf{p})\dot{\mathbf{q}} + \mathbf{K}(\mathbf{p})\mathbf{q} &= \mathbf{b}u + \mathbf{e}(\eta)w \\ \mathbf{y} &= [\mathbf{e}(\eta), \mathbf{b}]^T \mathbf{q} \end{aligned} \quad (14)$$

since the system matrices clearly depend on the parameterized geometry. Due to the parameter dependency, the system outputs $\mathbf{y} = [y_{\text{disp}}, y_{\text{act}}]$ implicitly depend on the parameter vector \mathbf{p} as well. This means that the parameter dependent system (14) has to be solved in every iteration of the optimization process. However, the large number of degrees of freedom with $N = 36\,200$ makes the subsequent solution of system (14) numerically expensive. This results in very long and unacceptable computation times to solve the optimization problem.

Parametric model order reduction (PMOR) is an efficient way to overcome this problem. PMOR seeks to replace the parameterized, full order system by a parameterized, reduced order system. For that, the solution is approximated as $\mathbf{q} \approx \mathbf{V}\bar{\mathbf{q}}$ in a lower dimensional subspace \mathcal{V} spanned by the columns of the base $\mathbf{V} \in \mathbb{R}^{N \times n}$ with $n \ll N$, see for example [1, 5]. Inserting the approximation into system (14) and left multiplying with \mathbf{V}^T to perform a Galerkin projection yields the parameterized reduced order system

$$\begin{aligned} \mathbf{V}^T \mathbf{M}(\mathbf{p}) \mathbf{V} \ddot{\bar{\mathbf{q}}} + \mathbf{V}^T \mathbf{D}(\mathbf{p}) \mathbf{V} \dot{\bar{\mathbf{q}}} + \mathbf{V}^T \mathbf{K}(\mathbf{p}) \mathbf{V} \bar{\mathbf{q}} &= \mathbf{V}^T \mathbf{b}u + \mathbf{V}^T \mathbf{e}(\eta)w \\ \bar{\mathbf{y}} &= [\mathbf{e}(\eta), \mathbf{b}]^T \mathbf{V} \bar{\mathbf{q}} \end{aligned} \quad (15)$$

with the reduced system matrices

$$\bar{\mathbf{M}}(\mathbf{p}) = \mathbf{V}^T \mathbf{M}(\mathbf{p}) \mathbf{V}, \quad \bar{\mathbf{D}}(\mathbf{p}) = \mathbf{V}^T \mathbf{D}(\mathbf{p}) \mathbf{V}, \quad \bar{\mathbf{K}}(\mathbf{p}) = \mathbf{V}^T \mathbf{K}(\mathbf{p}) \mathbf{V}, \quad \bar{\mathbf{b}} = \mathbf{V}^T \mathbf{b}, \quad \bar{\mathbf{e}}(\eta) = \mathbf{V}^T \mathbf{e}(\eta).$$

This contribution uses so-called interpolatory projection methods, see [2], to derive the base \mathbf{V} . For that, the transfer behavior from the system inputs to the system outputs of system (14) is described in Laplace domain with the frequency response function

$$\mathbf{H}(s, \mathbf{p}) = [\mathbf{b}, \text{span}(\mathbf{e}(\eta))]^T (s^2 \mathbf{M}(\mathbf{p}) + s \mathbf{D}(\mathbf{p}) + \mathbf{K}(\mathbf{p}))^{-1} [\mathbf{b}, \text{span}(\mathbf{e}(\eta))], \quad (16)$$

where $s \in \mathbb{C}$ denotes the Laplace-variable. Choosing the base

$$\text{span}(\mathbf{V}) = \text{span}([\hat{\sigma}^2 \mathbf{M}(\hat{\mathbf{p}}) + \hat{\sigma} \mathbf{D}(\hat{\mathbf{p}}) + \mathbf{K}(\hat{\mathbf{p}})]^{-1} [\mathbf{b}, \text{span}(\mathbf{e}(\eta))] \mathbf{r}) \quad (17)$$

yields a reduced order system with a reduced order transfer function interpolating the full order transfer function at the frequency expansion point $\hat{\sigma}$ and the parameter expansion point $\hat{\mathbf{p}}$ along the tangential direction \mathbf{r} such that

$$\mathbf{H}(s, \mathbf{p}) \mathbf{r} = \bar{\mathbf{H}}(s, \mathbf{p}) \mathbf{r} \quad \text{for } s = \hat{\sigma}, \quad \mathbf{p} = \hat{\mathbf{p}}. \quad (18)$$

It is also possible to construct a base \mathbf{V} such that the gradient of the reduced order transfer function can be matched to the gradient of the full order transfer function. This property is especially helpful in an optimization context as it allows to preserve sensitivity information in a reduced order model and to conduct a meaningful sensitivity computation with reduced order models. The approximation quality of the parameterized, reduced order model can be further improved by concatenating the result of Eq. (17)

for multiple frequency and parameter expansion tuple $[(\hat{\sigma}_1, \hat{\mathbf{p}}_1), (\hat{\sigma}_2, \hat{\mathbf{p}}_2), \dots]$ in one representative base as

$$\mathbf{V} = \text{span} \left[\left(\hat{\sigma}_1^2 \mathbf{M}(\hat{\mathbf{p}}_1) + \sigma_1 \mathbf{D}(\hat{\mathbf{p}}_1) + \mathbf{K}(\hat{\mathbf{p}}_1) \right)^{-1} [\mathbf{b}, \text{span}(\mathbf{e}(\eta))] \mathbf{r}_1, \right. \\ \left. \left(\hat{\sigma}_2^2 \mathbf{M}(\hat{\mathbf{p}}_2) + \sigma_2 \mathbf{D}(\hat{\mathbf{p}}_2) + \mathbf{K}(\hat{\mathbf{p}}_2) \right)^{-1} [\mathbf{b}, \text{span}(\mathbf{e}(\eta))] \mathbf{r}_2, \dots \right] \quad (19)$$

to ensure interpolation conditions at the tuple $[(\hat{\sigma}_1, \hat{\mathbf{p}}_1), (\hat{\sigma}_2, \hat{\mathbf{p}}_2), \dots]$. The reader is referred to [8, 2, 5, 14, 3] for more details concerning interpolatory projection methods for non-parameterized and parameterized systems. The PMOR in this contribution is done using the MOR-toolbox *Morembs*, see [6].

This contribution uses geometrically parameterized finite elements as presented in [7] for discretization. They allow to derive the system matrices for a parameterized geometry in an affine representation. For example the parameterized, full order stiffness matrix can be explicitly written as

$$\mathbf{K}(\mathbf{p}) = \sum_{m=1}^M \theta_m(\mathbf{p}) \mathbf{K}_m \quad (20)$$

with the scalar weight functions $\theta_m(\mathbf{p})$ and the constant and pre-computable matrices \mathbf{K}_m . Combining the parameterized finite elements from [7] and PMOR has several advantages in an optimization context. Instead of solving the full order system, a reduced order system of much smaller dimension can be solved. Second, the affinely parameterized, reduced system matrices from Eq. (20) can be efficiently evaluated as

$$\tilde{\mathbf{K}}(\mathbf{p}) = \mathbf{V}^T \left(\sum_{m=1}^M \theta_m(\mathbf{p}) \mathbf{K}_m \right) \mathbf{V} = \sum_{m=1}^M \theta_m(\mathbf{p}) \mathbf{V}^T \mathbf{K}_m \mathbf{V} = \sum_{m=1}^M \theta_m(\mathbf{p}) \tilde{\mathbf{K}}_m, \quad (21)$$

where the coefficient matrices $\tilde{\mathbf{K}}_m = \mathbf{V}^T \mathbf{K}_m \mathbf{V}$ are precomputable after the reduction step. Finally, the analytic description of the parameterized system matrices allows to differentiate the system matrices with respect to the parameters and, therefore, enables an efficient sensitivity analysis. In this particular work, 100 frequency and parameter expansion tuples are selected yielding a base with $\mathbf{V} \in \mathbb{R}^{36200 \times 100}$. This means that the parameterized system can be reduced from 36 200 to 100 degrees of freedom.

3.3 Simultaneous Optimization Workflow

The optimal control input signal derived in Sec. 2.2 is based on the system model of the structure in its reference shape described by \mathbf{p}_0 . Hence, it is possible that the input signal $u(t, \mathbf{p}_0)$ is not appropriate to compensate the moving load if the shape of the structure is modified during the iterative solution of the shape optimization problem (12). The control and the shape design should be, therefore, conducted simultaneously.

A possible workflow in which both the control and the shape are optimized is illustrated in Fig. 8. First, the system is modelled to obtain the parameterized, full order system. PMOR is applied to derive the parameterized, reduced order system for which the necessary reruns of the simulation can be performed efficiently during the optimization process. The actual optimization starts with the evaluation of the reduced system matrices for the discrete parameter sample $\tilde{\mathbf{p}}$. The resulting reduced system is used to derive the input signal $u(t, \tilde{\mathbf{p}})$. The controlled system is then simulated to derive $y_{\text{disp}}(t, \tilde{\mathbf{p}})$ and $y_{\text{act}}(t, \tilde{\mathbf{p}})$ and the objective function and the nonlinear inequality conditions are evaluated. The sensitivities are computed using the adjoint variable method, compare [4]. The process is repeated until the optimizer converges. To summarize, the underlying optimal control problem from Eq. (12) is solved in every iteration of the superordinate shape optimization. The control input signal is therefore optimized in accordance with the optimization of the shape yielding an optimized overall system.

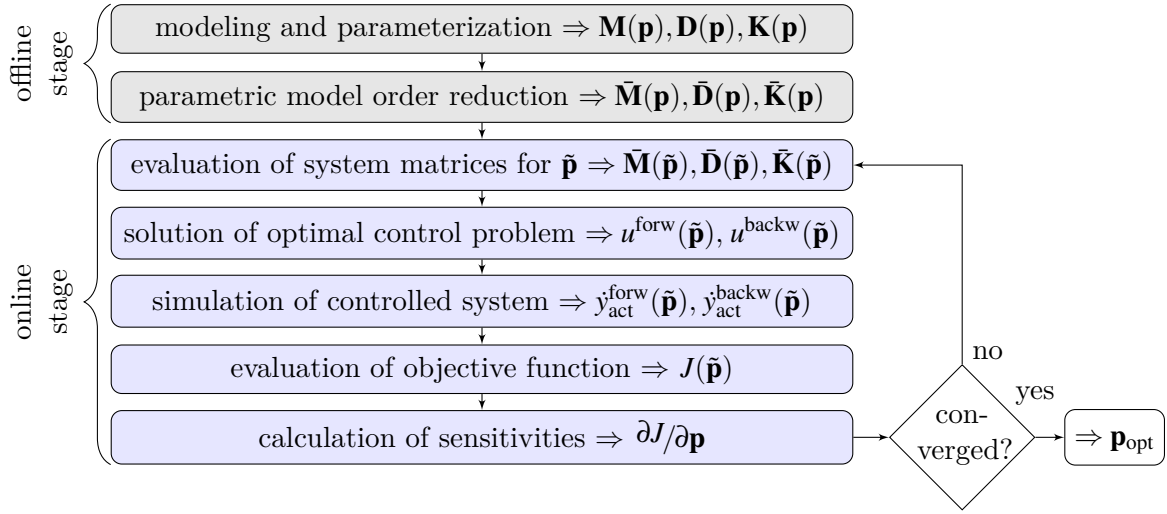

Figure 8: Workflow of simultaneous control and shape optimization.

Note that the workflow in Fig. 8 is separated in two stages. The offline stage (marked grey) covers the model preparation and the reduction. The online stage (marked blue) deals with the actual optimization problem. The computations of the online stage can all be done with the parameterized, reduced order model such that they are numerically cheap to conduct. The computations of the offline part have to be done only once. Therefore, it is possible to re-use the parameterized, reduced order models to solve diverse optimization problems.

3.4 Numerical Results

The optimization problem is now solved according to the previous section with a sequential quadratic programming optimizer. The objective function is $J(\mathbf{p}_0) = 1.06 (\text{Nm})^2/\text{s}$ for the initial design and it is $J(\mathbf{p}_{\text{opt}}) = 0.148 (\text{Nm})^2/\text{s}$ for the optimized design. The corresponding shapes of the structures are shown in Fig. 9. The optimal shape forms a flexible joint in the center. This solid-body like joint allows the structure to act like a kinematic mechanism and to compensate the external disturbances with less activation energy.

The displacements, the optimal control input and the objective function over time are shown in Fig. 10 for the initial and the optimal design for the backward loading position trajectory. In the optimized design, both the mass inequality constraint and the mean displacement inequality constraint are active. The displacements at the loading positions $y_{\text{disp}}^{\text{backw}}$ for the initial and the optimized design show a similar

Figure 9: Outer shape of initial and optimal design.

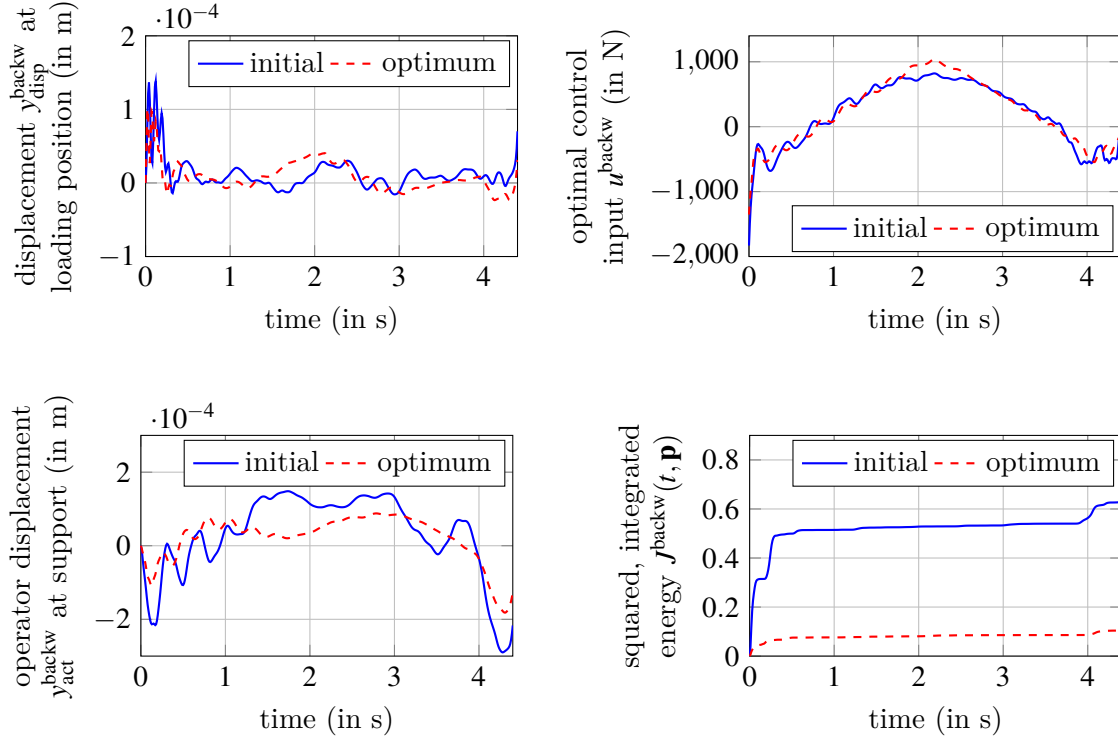

Figure 10: Displacement at loading position and support, control input and objective function over time for initial and optimal design.

behavior confirming that the mean displacement constraint is active. The input signal u^{backw} for the optimized structure shows a similar behavior as for the initial design. In contrast, the required operating displacement $y_{\text{act}}^{\text{backw}}$ is smaller for the optimized design than for the initial design. This is also the reason leading to a much smaller, squared activation energy $J^{\text{backw}}(t, \mathbf{p}) = \int_0^t (\dot{y}_{\text{act}}^{\text{backw}} u^{\text{backw}})^2 dt$.

An interesting fact is that the optimized shape is not symmetric to the y -axis. Instead, the left part of the structure is thinner compared to right part. Conducting the optimization repeatedly for different velocities of the moving load shows that this effect arises less distinct for smaller velocities, see Fig. 11. The smallest velocity of 1.9 m/s describes a more quasi-static load case. Here, the optimal shape becomes almost symmetric to the y -axis. A purely static load case, as in [7], would finally lead to a symmetric optimal shape. It can be shown by investigating the frequency response function, see Fig. 12, that the transfer behavior from the right support to the ends of the structure is indeed symmetric for the static case

Figure 11: Outer shape of optimized design for different velocities of moving load.

Figure 12: Frequency response function from right support to right and left end of structure.

meaning for a zero exciting frequency. However, for non-zero exciting frequencies the transfer behavior from the right support to the ends of the carrier is not symmetric anymore. This causes the non symmetric optimal shape for the dynamic load case problem.

4 CONCLUSIONS

This article demonstrates the application of adaptive engineering structures as a promising approach to improve the load carrying behavior of classical engineering structures. This is useful for example to save resources or to decrease emissions in the civil engineering sector. To this end, a design approach is suggested supporting engineers in the simultaneous shape and control design for adaptive engineering structures. First, the modeling of a dynamic moving load case for an exemplary structure is described. An optimal control strategy is applied which efficiently compensates the disturbance forces in the dynamic load setup. The optimal control concept is combined with a shape optimization where it is the objective to minimize the actuation energy. For that, an optimization workflow is suggested which both considers the control and the shape design. This is meaningful as it yields an overall system in which the control and the shape are optimized in accordance with each other. Due to the large number of degrees of freedom parametric model order reduction is employed. This allows a significant reduction of the degrees of freedom while retaining the parameter dependency and enables an efficient solution of the optimization problem with reduced order models.

Further research could include the investigation of the robustness of the optimized structure or the simulation of more realistic loading position trajectories and loadings. Furthermore, an interesting topic would be the estimation of unknown loads or unknown loading positions.

Keywords: Condition Health Monitoring, Structural Health Monitoring, Damage Detection, Suspension strut mount, EMI Technique, FE coupled simulation.

Abstract.

The suspension strut cap is the major component of automobile, which attaches the suspension strut to the vehicle body. In addition, it insulates the tire noise & vibrations from the vehicle for generated due to rough road profile and speed breakers. The suspension cap is mounted at the top of suspension strut, where one side bolts to the vehicle (i.e. cap is directly attached to the body) and the other side to attached to the steering pivots of wheel. So as the vehicle moves and goes over bumps, the up & down impact pushes and pulls at the mount. The caused vibration can be transmitted into the vehicle if routine inspection has not been done and can cause wear and tear in bearing part of the mount (loosening of bolts). The damaged suspension cap can lead to clunking noises, noisy steering, excessive movement, tire alignment etc. Hence, conditional health monitoring of a suspension strut cap is vital in vehicles. For this study, the utilizations of dual sensing mechanism of piezo sensor has made for Structural health monitoring (SHM) technique i.e. Electro-Mechanical Impedance Technique. Different state of damage has been induced by loosening the bolts to different torque range and compared with pristine stage (when bolts are tightened to highest force). The admittance signature are plotted to verify the damage condition raised due self-loosening. The RMSD plots were drawn to quantify the level of damage. Finally the FE coupled simulation has done for the suspension strut mound with surface bonded PZT patch for different damage levels and results are compared with experimental results. The promising results for this study sets a new paradigm for SHM technologies.

1 INTRODUCTION

A Suspension System is essential in an automobile as it provides steering stability and good handling of the vehicle. It also absorbs and counteracts the vibrational forces or shock caused due to the irregularities on the road surface. It consists of a spring which absorbs the energy caused due to the vibration and a strut which consists of a shock absorber (which is a damping

system) to dissipate the absorbed energy. A shock absorber, basically consists of an oil pump which could be either compressed or extended using a piston arrangement. The upper part of the shock absorber is connected the vehicular frame and the lower part is attached the axle, near the wheel. The piston rod of the shock absorber is connected to the upper strut mount through bolt joints, which in turn is connected to the piston, which sits in a tube filled with hydraulic fluid. The Upper Strut Mount used for this study is of the front suspension of MacPherson type, which is the most widely used front suspension system (Earle S. MacPherson in 1947)

Upper Strut mount, also referred to as bearing plate, is an important linking component in the vehicle as it connects the vehicle's suspension system to the body of the vehicle. Strut mounts have to be flexible enough to handle slight angle changes in order to be able to transfer vehicle load to the spring of the suspension system (Huynh et al., 2018). Due to high impulsive loading, brittle failure or small fractures can be observed on the surface of the upper strut mounts. Due to excessive vibrations experienced due the vehicle travelling on a rough road profile, caused the self-loosening of the bolts, which connects the suspension strut to the vehicular body is also termed as a damage criterion for the suspension system. It must be ensured that the bolts remained tightened and maintain the preload conditions (Wang et al., 2013). Also, Failure to replace a worn upper strut mount will cause it to deteriorate very quickly, which will have a knock-on effect to other components, such as the shock absorbers and even the tyres (Huynh et al., 2018).

From the above detailed study, it can be observed that the continuous monitoring of upper strut mount ensure the reduction in maintenance and more passenger safety and comfort. Hence, the authors attempts to monitor the self-lesening effect of bolts on suspension mount for different level lessening state (different torque moment) using piezo sensor for Electro-mechanical impedance technique. For damage quantification statistical interpretation are done. The experimental details and results are discussed in upcoming section.

The process of implementing a damage detection strategy for a civil, mechanical or aerospace infrastructure is known as Structural Health Monitoring (SHM). The damage is defined as changes to the material and/or geometric properties of these systems, including changes to the boundary conditions and system connectivity, which adversely affects the system's performance (Farrar & Worden, 2006). SHM systems are denoted as a reliable system with the ability to detect and interpret adverse changes in a structure due to damage (Kessler et al., 2002). Typically, such a system consists of sensors, actuators, amplifiers and signal conditioning circuit. There are a large variety of methods and evaluation tools used to implement structural health monitoring on a system. (Bhalla, 2004a and 2004b). These methods can be classified as either global or local methods. Global methods study the structure as a whole whereas local methods are used to detect damages in a localized part of the structure. Condition Monitoring is analogous to Structural Health Monitoring, but it addresses to rotating and reciprocating machinery instead of large infrastructures.

2. BASICS OF EMI TECHNIQUE

In general, SHM or damage detection techniques based on the vibration response of the structure can be classified into two categories: model based (which require a model of the structure to start with) and non model based (in which model is not pre requisite). The impedance-based technique belongs to the non model based category. Most of the current work in the impedance based SHM is focused on adapting the EMI technique for application on real world structures. This involves miniaturization of the data acquisition hardware, combination with wireless telemetry and addressing powering issues including energy harvesting techniques.

The basic concept of the EMI technique for SHM is to monitor the integrity of the structure by measuring the electrical admittance via the PZT transducer bonded on the surface of the monitored structure. Because of the direct and the converse piezoelectric effects, any change in the mechanical impedance of the structure caused by damage modifies the electrical admittance of the PZT transducer bonded to it. Usually, the electro-mechanical admittance signature, comprising of the conductance (real part) and the susceptance (imaginary part) is acquired in the healthy condition of the structure and used as the reference baseline for future decisions on structural integrity. Any occurrence of damage on the structure modifies the admittance signature, thereby providing a signal to the end user. Bhalla and Soh (2004a,b) developed a two dimensional piezo-impedance approach based on the concept of effective impedance to model the PZT-structure interaction manifesting active and passive part of coupled admittance signature. Any damage to the structure will cause these characteristics to change and hence changes the structural impedance ($Z_{s,eff}$), which in turn alters the admittance (\bar{Y}) as given by the following expression

$$\bar{Y} = \frac{\bar{I}}{\bar{V}} = G + Bj = 4\omega j \frac{l^2}{h} \left[\frac{\bar{\epsilon}_{33}^T}{\epsilon_{33}^T} - \frac{2d_{31}^2 \bar{Y}^E}{(1-\nu)} + \frac{2d_{31}^2 \bar{Y}^E}{(1-\nu)} \left(\frac{Z_{a,eff}}{Z_{s,eff} + Z_{a,eff}} \right) \left(\frac{\tan kl}{kl} \right) \right] \quad (1)$$

where ω is the angular frequency, l the half-length and h the thickness of the patch, $\bar{\epsilon}_{33}^T = \epsilon_{33}(1 - \delta j)$ the complex piezoelectric permittivity (δ being the dielectric loss factor), $\bar{Y}^E = Y^E(1 + \eta j)$ the complex Young's modulus (η being the mechanical loss factor), $Z_{s,eff}$ and $Z_{a,eff}$ respectively the effective impedances of the structure and the PZT patch and k the wave number. This equation couples the mechanical impedance of the structure with the electrical admittance \bar{Y} , which means that any damage to the structure (change of $Z_{s,eff}$) will reflect itself as change in \bar{Y} . Furthermore, a continuum approach has recently been developed with rigorous inclusion of the bonding effect on the coupled admittance signature (Moharana and Bhalla, 2014, 2015). Recently, the EMI technique has been increasingly tested on civil and mechanical structures (Varadan and Varadan, 2002; Park et al., 2000a, b; Soh et al., 2000; Bhalla, 2001) as well as aerospace structures (Chaudhary et al., 1995; Giurgiutiu, 2000; Giurgiutiu and Zagari, 2002; Ghoshal et al., 2001). Bhalla and Soh (2004a, b) proposed a damage quantification approach, based on identifying the equivalent system parameters from signatures. This approach utilized both real and imaginary components of the signature and paved way for identifying the system parameter from experimental data, enabling parametric damage quantification.

3. EXPERIMENTAL PROCEDURE

A PZT patch is bonded to the surface of the upper strut mount near the bolt connection using high strength epoxy adhesive as shown in Figure 1. The LCR meter is connected to bonded PZT patch. For EMI technique, the PZT patch is excited with 1.41 volt and coupled admittance response has recorded for 30-300kHz through VEE-PRO software.

Fig.1 Experimental set up (a) Suspension strut sample connected to both system and system (b) Digital torque wrench used for loosening bolts

As per the Hyundai specification sheet for suspension strut systems, the upper strut mount nuts have to be fastened by providing torque of 20 Nm for our sample, i.e, the upper strut mount of a Hyundai Accent. So all the nuts were fastened by applying torque of 20 Nm by using a torque wrench and this is considered as the pristine or undamaged state. Five sets of impedance response signatures were recorded by the using the LCR meter to perform the repeatability test of the pristine state. For inducing damages the bolts are loosened to certain torque value as mentioned in Table-1. The coupled admittance signatures were recorded for damaged sates aand compared with pristine values.

Table 1: Different damage level details for the bolt connections.		
Pristine Condition	All bolts tightened to 20 Nm	Intact
Damage Level 1	Bolt 1 $\Delta T = 5$ Nm	Incipient damage
Damage Level 2	Bolt 1 $\Delta T = 10$ Nm	Moderate damage
Damage Level 3	Bolt 1 $\Delta T = 15$ Nm	Severe damage

Statistical quantification methods can be used to detect the changes of the preload in the bolted connections. Two common methods used to quantify damages in the structures or machines are

Correlation Coefficient Deviation (CCD) and Root Mean Square Deviation (RMSD) indices. (Huynh et al., 2018). The CCD can be computed

$$CCD = 1 - \frac{1}{\sigma_Z \sigma_Z^*} E\{[Re(Z(\omega_i) - Re(\bar{Z}))][Re(Z^*(\omega_i) - Re(\bar{Z}^*))]\} \quad (2)$$

where $E[\cdot]$ is the expectation operation; $Z(\omega_i)$ and $Z^*(\omega_i)$ are the impedance responses at the i th frequency value before and after damage, respectively; \bar{Z} and \bar{Z}^* are the mean values of those responses; and σ_Z and σ_Z^* are the standard deviations of the corresponding impedance responses.

The Root Mean Square Deviation (RMSD) index can be computed as

$$RMSD = \sqrt{\sum_{i=1}^n [Z^*(\omega_i) - Z(\omega_i)]^2 / \sum_{i=1}^N [Z(\omega_i)]^2} \quad (5)$$

where n denotes the number of reading

4. RESULTS AND DISCUSSION

For damage identification, conductance signature is more sensitive and widely used for localised SHM techniques. Hence for this study only conductance plot for sensor reading are studied and analysed. The conductance signatures for suspension mount plotted for 30-300 kHz for baseline and damage state (see Fig 2 and Fig 3). The repeatability of sensor signature towards system identification is quite robust, can be seen from Figure 2.

Fig.2 Plot of Conductance versus Frequency in Pristine State

The is shifting resonance peaks and decrease in conductance values in conductance signature of specimen for damage State-3 and State-4, when bolts are loosened to 10Nm and 15Nm torque (see Fig. 3). For better visibility and clarification, closer views of conductance signature for

selective frequency range has plotted in Figure 4. In Figure 4a to 4f, it can be seen that self-loosening effect (loosened to certain torque value) has significantly changed/ shifted the conductance peak values.

Fig.3 Experimental conductatnce signature (Pristine Vs Damag states)

(a) The frequency range of 70-75 kHz

(b) The frequency range of 95-100 kHz

(c) The frequency range of 190-195 kHz

(d) The frequency range of 230-240 kHz

(e) The frequency range of 208-218 kHz

(f) The frequency range of 268-272 kHz

Fig.4 Experimental impedance signatures under bolt-loosening cases obtained from

From Figure 4, it can be concluded that the impedance peaks tend to shift to downwards to the right as bolts are loosened torque values significantly. So, in order to quantify the measured coupled admittance responses, damage-sensitive features were extracted from the impedance data, the correlation coefficient deviation (CCD) and root-mean-square deviation (RMSD) indices. While the CCD index mainly quantifies the frequency shift of the impedance signatures, the RMSD index quantifies both the frequency and magnitude. Figure 5 presents the RMSD and CCD indices that was plotted according to the torque-loss level for all of the loosening cases of Bolt.

Fig. 5 (a) RMSD Variation for different level of torque loss (b) CCD variation for level of torque loss

The RMSD (%) is plotted against the damage state for clearer understanding of the increasing trend of damage with respect to the preload loss or self-loosening of the bolted connections. The damage progress is plotted against the frequency and the peak conductance value and is shown in Fig.6. We can see that the damage progress is higher at high frequencies and at lower peak conductance values.

Fig. 6 variation in conductance peak value and frequency with respect to damage progress

6. CONCLUSION

The road roughness leads to excessive vibrations of the suspension system which in turn causes the self-loosening of bolts that connects the suspension strut to the vehicular body through the upper strut mount. This paper comprise the SHM of suspension strut using piezo sensor for the Electro-Mechanical Impedance Technique. The conductance signatures were acquired through impedance analyser for pristine state (tightened to highest torque) and damage state (gradual decrease of torque value for self loosening). The experimental results were compared for both pristine and damaged for comparison and it is found that for increase in loss of torque value there is decrease in conductance peak value and shift in frequency. The statistical quantification of damage has done by evaluation of RMSD and CCD. The results were encouraging and imply with nature of piezo impedance based structural health monitoring.

Key words: Smart Buildings, Optimal Control, CFD, Reduced-Order Modeling, Sports Buildings

Abstract. Sports facilities have high energy requirements and therefore, presents a great opportunity for energy savings. In fact, people generate a significant sensible and latent heat because of high activity level and the amount of moisture released through exercising activities and showers. These buildings are more challenging to control because of the specific occupants requirements. In this effort, dynamic control of roof top units subject to external weather predictions is implemented on a case study of a gymnasium. The control model is an an optimal controller based on a reduced order model of CFD simulations of the indoor air, coupled to an envelope model.

1 INTRODUCTION

In 2017, about 40% of total U.S. energy consumption was consumed in residential and commercial buildings [1]. Comprehensive efforts are put in place to optimize the energy use in these buildings. The focus of this paper is on sports facility buildings. This class of buildings features high ventilation rates and cooling power requirements to guarantee the indoor air quality falls within the comfort range of the occupants. Recently, recreational/sports centers have been studied for energy reduction purposes [2, 3, 4, 5].

In sports buildings, adequate control factors like air flow, thermal, and moisture conditions, are crucial since they affect the performance of athletes. These factors are hard to control because of the large spaces. Thus the well-mixed assumption is not realistic because spots may be asymmetric in loading and ventilation. Consequently, a more developed model taking into account the details of the asymmetry in the loads and the provided air is necessary for better control results.

In this work, we investigate the thermal and moisture performance of the HVAC system in a gymnasium for dynamic control purposes. For that, computational Fluid Dynamics (CFD) simulations are performed to capture the thermal fluxes across the building. For that, a linear time-invariant (LTI) model is developed to approximate the input-output behavior observed in computational fluid dynamic (CFD) simulations. Various approaches to couple prediction codes for fluid dynamics and solid conduction have been studied in [6, 7, 8]. Our reduced order model is applied to produce a computationally efficient iterative optimization. Several previous works have used the same method [9, 10, 11].

This modeling approach is now applied to a sports facility where the moisture component is very important. After combining the CFD reduced order model with the envelope model, the Berkeley Library for Optimization Modeling (BLOM) is used to solve the optimization problem of setting the supply RTU temperatures that yield minimum electrical cooling power for the assumed operating conditions. Dynamic control is then implemented to assess the effects of eventual weather variations on the optimal consumed power.

2 CFD MODELING

2.1 Gymnasium geometry and mesh

The gymnasium we studied is located in Knoxville, Tennessee, USA. It is a $30.5\text{ m} \times 22.8\text{ m}$ rectangular area. This open area is cooled using four RTUs, having ceiling-mounted supply vents (at a 6 m height). Each RTU is connected to a wall mounted thermostat placed on the WNW and ESE walls. The short outside wall faces WNW. Other walls of the gymnasium are interior to the building. For the purpose of creating CFD simulations for the space, we define the origin on the floor at the corner of the WNW and NNE walls. 'X' is along the WNW wall, 'Y' is along the NNE wall, and 'Z' is along the ascendant vertical. They are labeled Xmin, Xmax, Ymin and Ymax. For mesh generation, we use the open source software tool, GMSH, developed by C. Geuzaine and J.-F. Remacle [12, 13]. The final geometric configuration of the interior space is described using 310 points, 412 lines, 164 surfaces and 9 volumes. In addition to the three spatial coordinates, each point included a mesh spacing variable that could be used to selectively refine the mesh where needed. The 164 surfaces included the floor, ceiling, and walls but also included a number of internal details such as an elevated track, the entrance doors, 16 diffusers and 4 returns. The final mesh, resulting in approximately 737k tetrahedral cells with 129k vertices (Figure 1), had no cells with worse than a three to one aspect ratio.

2.2 Reduced Order Model

The reduced order model needed for the energy optimization procedure requires the analysis of a specific nominal configuration in which we specify the source terms and the boundary conditions. This nominal configuration is generally chosen based on average operational loads and conditions. The envelope conditions, namely the average wall temperatures, are found from an energy balance taking into account different modes of heat transfer as shown by [7]. The openings to other spaces like the locker and weight rooms are modeled as uniform velocity inlets, with a prescribed temperature and moisture.

Figure 1: A global view of the mesh

The Ymax wall has two entry doorways. These openings are simulated with a pressure outlet boundary condition and have a prescribed gauge pressure according to the appropriate elevation. Concerning the air supply, each RTU controls two round diffusers of about 0.5 m radius and two 0.6 m x 0.25 m rectangular vents. The air supply from all the round diffusers is at 19.0°C temperature, at 8.0g/kg water vapor mass fraction.

Apart from the boundary conditions specified on the above surfaces, source terms are used to account for the occupants, namely the players on the court and the track, and the audience in the bleachers. The heat source corresponds to that generated by 20 players on the basketball court, 8 supporters on the bleachers, and 2 runners on the track. The occupants' sensible and latent produced loads are adopted from ASHRAE Handbook [14].

The system was subjected to fixed boundary and source conditions chosen to represent a mean condition in the space. FLUENT was run in unsteady mode to simulate more than five hours. Figure 2 shows the mass-averaged temperature over the entire gym space. It proves that the nearly steady state flow is established about half an hour of flow time after the simulation was started. We construct a Linear Time Invariant (LTI) model that approximates the perturbed CFD responses generated by FLUENT simulations as done by [9, 10, 11, 15, 7]. The objective is to reduce the complexity of the CFD simulations to save in computational time, and allow for real-time implementation of a model-based control. The LTI model is written as a first-order state space system in the form

$$\dot{x}(t) = -\frac{1}{\tau}x(t) + bu(t) \quad (1)$$

$$y(t) = Cx(t) + Du(t), \quad (2)$$

The coefficients are obtained through 23 CFD simulations, each one is obtained by assigning a step

Figure 2: Average temperature

function to the perturbed input. These 23 inputs consist of the wall temperatures, the RTU temperatures, water vapor fraction and mass flow rates, and the occupancy loads. The reactions to these inputs are stored into 44 outputs consisting mainly of the envelope fluxes, the return properties, thermostats temperatures and averaged thermal quantities over different subvolumes. In the state space system, τ and b are respectively the time constant and the scaling factor.

Figure 3 compares the FLUENT data (raw and filtered) to the ROM response. Here the volume averaged temperature of Court 1, which corresponds to the quarter of the court underneath RTU 1, is responding to a 5°C increase in the RTU 1 supply temperature. The first-order ROM response provides a good approximation to the filtered data.

3 DYNAMIC CONTROL

The LTI model developed above is coupled to the dynamics of the envelope model and used to compute the cost function and the comfort constraints (See Figure 4). The coupled model is represented by a single State Space system. For an optimal operation of the facility, we are controlling the RTU supply temperatures $T_{s|i}$ ($i = 1 : 4$). For every other input, we are applying the nominal value to the weather parameters, supply water vapor fractions, supply mass flow rates, and occupancy loads. The model outputs are the return and zone thermodynamic properties in terms of temperature and moisture. Some are required for the cost function and some others are required to formulate the constraints. The cost function is defined as the total power used to run the space cooling under the condition that each of the zones has a set point temperature of 22°C . The cooling power also includes the ventilation load resulting from mixing the recirculated indoor air with sufficient outdoor air 20%.

Then, the total cooling load at each RTU is divided into sensible $Q_{s|i}$ and latent $Q_{l|i}$ loads as shown in the following equations

Figure 3: Court 1 temperature response to RTU 1 supply temperature

$$Q_s|_i = C_p \dot{m}_s|_i (T_m|_i - T_s|_i), \quad (3)$$

$$Q_l|_i = L(\dot{m}_r|_i \lambda f_r|_i + \dot{m}_{oa}|_i f_{oa} - f_s \dot{m}_s|_i), \quad (4)$$

$$P_t|_i = \frac{Q_s|_i + Q_l|_i}{cop}. \quad (5)$$

The Berkeley Library for Optimization Modeling BLOM 2.0, which is a MATLAB/SIMULINK based tool, is used to solve the optimization problem over a finite horizon $([0, T])$. Since the tool is restricted to discrete-time dynamics, the continuous state space system is discretized. The optimal control formulation needs to take into account the uncertainties due to the dynamics of the model like the occupants' loads, weather, etc. In this study, the focus is on the external temperature variation. A dynamic control procedure is implemented here. For instance, to launch an optimization at a certain point in time, the weather predictions are updated for the whole time horizon. Naturally, the weather data at a point of time is subject to more error as we approach the end of the time interval. Applying the disturbances to the temperatures in the weather signal: the outdoor air temperature, the ground temperature and the sky air temperature for long wave, and using a maximum error of 10%, we compare two cases. We denote by Method 1, our solution to the optimal control problem for a 12 hour horizon resulting in only one optimization, and by Method 2 an algorithm resulting in a total of 12 optimization problems, and correcting the prediction at each time step. Table 1 shows that the dynamic controller is about 3% more precise in calculating the consumed energy than the optimal controller.

4 CONCLUSIONS

To summarize, a LTI model for the indoor-air is created using Fluent simulations and optimization of model parameters. The interior air model is coupled to the exterior envelope model as an approximation of a Dirichlet-to-Neuman dynamic map. Specifically, the envelope model provides surface temperatures (Dirichlet data) as boundary conditions for the interior fluid dynamics, and the interior-air model provides

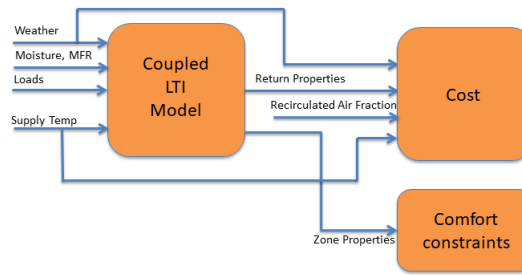

Figure 4: Inputs/Outputs map for control purposes

Table 1: Effects of perturbed weather on total power for a maximum prediction error of 10%.

Weather	error 0	error -10%	error +10%
Method 1 (kJ)	284322	273137	295513
Method 2 (kJ)	284322	283470	285174

resultant wall fluxes (Neuman data) to the envelope. Cooling equipment is also coupled: supply air enters the space at temperature, humidity, flow-rates specified by the equipment (inputs to the indoor-air model) and return air properties are outputs from the model. The output of the reduced-order model is constructed as a nominal steady value plus a perturbation which is realized as a linear time-invariant system. The coupled CFD-ROM/Envelope model is used to study the optimal control problem using BLOM. Dynamic control is also implemented to assess the effects of inaccuracies in weather forecasts.

Key words: Adaptive structures, shape control, actuator placement optimization, non-linear force method, structural sensing, structural optimization

Abstract. Adaptive structures can modify their shape and internal forces through sensing and actuation in order to maintain optimal performance under changing actions. Substantial whole-life energy can be saved with respect to traditional passive designs through well-conceived adaptive design strategies; the whole-life energy comprises an embodied part in the material and an operational part for structural adaptation. Controlled large shape changes allows a significant stress redistribution so that the design is not governed by rare and extreme loadings. A design process based on optimization of the structural geometry and actuator placement has been formulated. A method that considers geometric nonlinearity is employed for shape and force control. Experimental testing on a small-scale prototype adaptive structure produced by this design process is presented. The structure is a planar truss. Shape adaptation is achieved through controlled length changes of turnbuckles that replace some of the elements. Stress redistribution through shape adaptation is in good accordance with numerical values, with a minimum Pearson correlation coefficient of 0.86. Results show that stress homogenization through controlled large shape changes is feasible.

1 INTRODUCTION

Civil structures are designed to meet strength and deformation criteria for extreme and thus rarely occurring loads. Consequently, the structural capacity is not fully utilized for most of the service life of the structure. If the structure can counteract the effect of loads through active control, it can be designed to maintain optimal performance as the external load changes [1]. The potential of using adaptation to design structures with a better material utilization has been investigated [2, 3]. A new design criterion for adaptive structures has been introduced [4], which is ‘whole-life’ energy comprising a part embodied in the material and another part for adaptation. Through the methods formulated in [4], it was shown that adaptive structures are more energy efficient than conventional structures. Instead of relying on passive resistance provided by material and form, strategically placed actuators change the shape and internal forces at the occurrence of strong loadings. This way, material embodied energy is reduced at the cost of a small increase in control operational energy. Whole-life energy savings as high as 70% have been achieved for slender structures [5, 6].

Shape optimization is usually employed to optimize the geometry of structures under worst case loadings [7, 8]. When applied to reticular structures, shape optimization can lead to large modifications of nodal coordinates, so that the internal forces are altered significantly [9]. From this process, shapes resembling arch, catenary and lenticular configurations were found to be efficient in terms of material utilization [7]. However, the geometry obtained through these methods is fixed, the structural capacity is only partially utilized under peak demands.

Shape control involving large shape changes has been studied for deployable and tensegrity structures [10, 11]. In this context, however, large shape changes have been achieved through mechanisms based on moving parts. This often results in increased weight of the joints and control complexity [12]. Shape control of reticular structures, which relies mostly on flexibility, has received little attention both theoretically and experimentally. Shape and force control of a reticular adaptive structure has been successfully tested in [13]; however, geometric nonlinearity was not accounted for. Formulations of geometrically non-linear shape and force control exist [14], nonetheless experimental validation is still lacking.

The efficacy of structural adaptation through large shape changes has been studied numerically [15]; a substantial embodied energy savings with respect to structures that are able to adapt through small shape changes was shown to be possible. Though large geometry reconfiguration, the internal forces can be redistributed effectively and thus, the design is not governed by extreme loading. This paper gives details of the experimental testing of a small-scale prototype adaptive structure produced by the methods formulated in [15]. Shape control is achieved through length changes of turnbuckles that replace some of the structural elements. Element stress and nodal displacements are monitored through strain sensors and optimal tracking respectively. Results will inform future research on larger scale adaptive structures.

2 DESIGN METHOD

The design method consists of two parts: (1) optimization of the geometry, internal forces and element cross-section areas to minimize the embodied energy, (2) optimal actuator placement to control the structure into the shapes obtained in (1) through quasi-static, nonlinear geometric shape and force control. The design process is formulated for reticular structures and this study deals only with such structures. Linear actuators are integrated into the structure by replacing selected elements. Figure 1 gives a schematic flowchart of the design process.

The first step of the design process can be thought of as a mapping between external load and target shapes as well as internal forces that are optimized to minimize the embodied energy of the structure. This process is subject to force equilibrium and stress constraints including element buckling. The design variables include the element cross-section areas, which remain constant during control; as well as optimal forces and target shapes for each load case.

The second step of the design process is to obtain an actuator layout that is optimal to control the structure into the target shapes. This is a combinatorial problem and thus, when the number of structural elements is large, a full enumeration is impossible. Instead, optimal actuator placement is carried out using constrained simulated annealing (CSA) [16]. A heuristic based on a measure of efficacy for each element to contribute towards the attainment of the optimal shapes via its length changes [4] is employed to generate the initial candidate solution and to define the neighborhood structure i.e. the set of feasible solutions ‘close’ to the current solution.

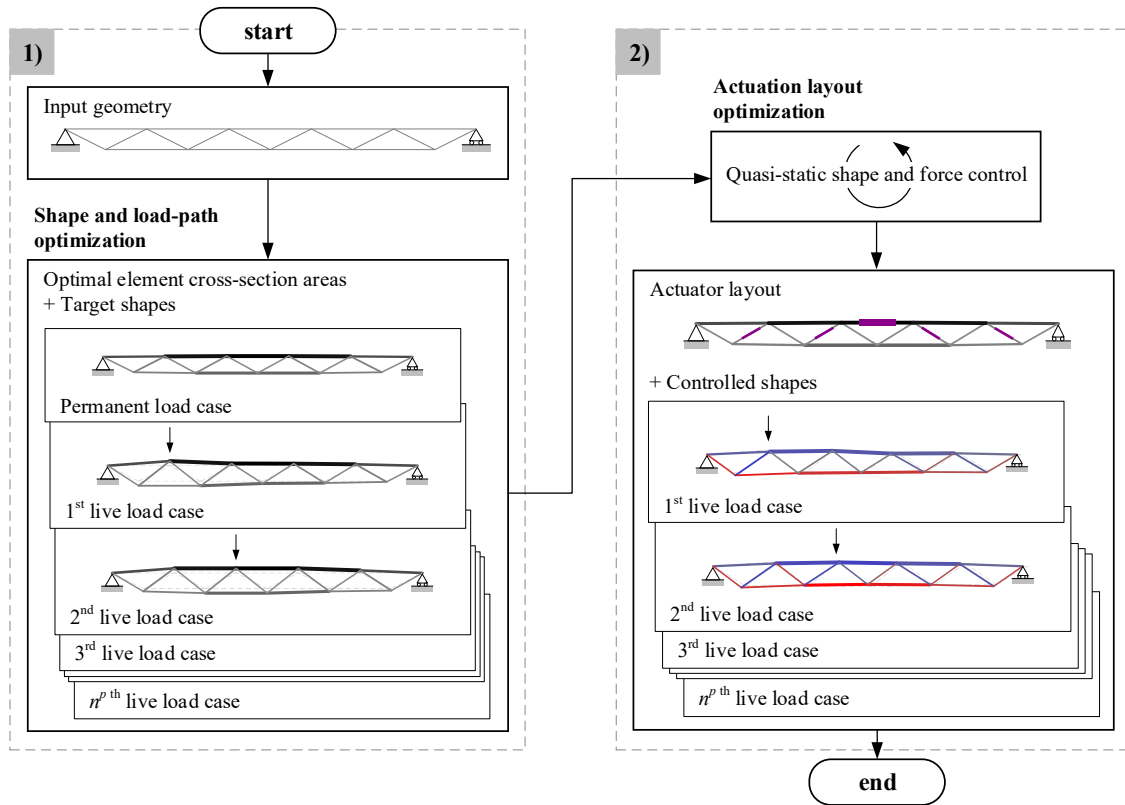

Figure 1: Design method flowchart

The structure has to be controlled through control commands that cause a change of internal forces and nodal displacements which approximate the target ones. Because shape adaptation does not rely on mechanisms with defined kinematics, there are generally infinite solutions to approximate a required shape change through element length changes. A possible strategy is to find the minimum actuator length changes that deform the structure into a required shape. Since large shape changes modify equilibrium conditions, control commands must be computed through an iterative scheme. In this work, shape and force control are implemented using a geometric non-linear force method based on singular value decomposition of the equilibrium matrix [14, 17].

3 NUMERICAL CASE STUDY

The prototype structure tested in this study is a planar simply-supported truss beam which is shown in Figure 2. The truss is thought of as part of a roof system whose lateral stability is assumed to be provided by other means. The structure has a span of 1000 mm and a 20:1 span-to-depth ratio. It consists of 19 elements connected through 11 nodes. All elements have a circular section and are made of aluminum with a Young's modulus of 72.4 GPa.

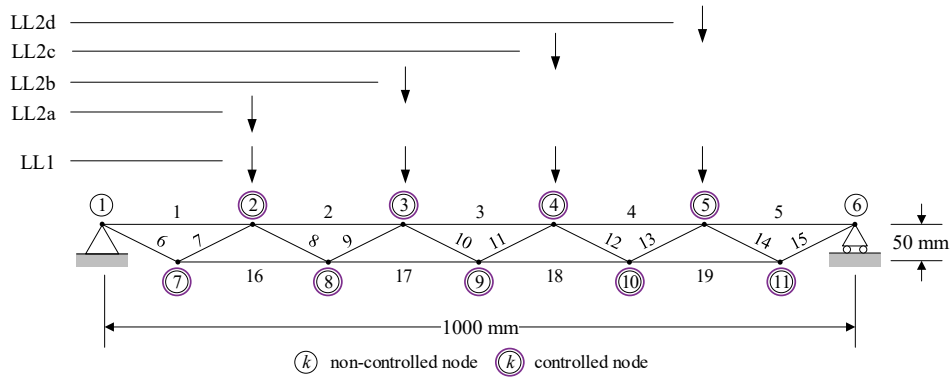

Figure 2: Planar-truss beam

Due to the small scale of this structure, its self-weight is negligible. Two live loads (LL) are considered: (1) a uniformly distributed load of 10 N applied on all top chord nodes (LL1); (2) a moving load of 20 N applied on each node of the top chord in turn (LL2a–LL2d). All nodes except the supports can shift vertically within ± 15 mm. The lower bound for the element radius is set to 1 mm. The first step of the method outlined in Section 2 produces a structure whose embodied energy is reduced by 17% compared to an identical weight-optimized passive structure.

A low number of actuators is generally preferred to reduce monetary cost and control complexity. A minimum number of actuators is determined by applying sequentially the layout optimization process (outlined in Section 2); each time decreasing the number of actuators until no feasible solution can be obtained. Figure 3 shows the layouts obtained for 19, 14, 10, 7, 5 and 4 actuators. No feasible solution (ULS satisfied) can be found for layouts made of less than 5 actuators. The layout shown in Figure 3f is an infeasible solution for 4 actuators; the maximum element demand/capacity ratio is 1.26. With 5 actuators the maximum element demand/capacity ratio is 0.83, and thus this layout was chosen as the optimal actuator layout (Figure 3e). This solution was obtained after 413 iterations at an average of 651 seconds. The global optimality has been verified through a full enumeration (11628 candidate solutions) which has taken approximately 5 hours on an Intel Core i7, 3.60 GHz.

Figure 3: Optimal actuator layouts for 19, 14, 10, 7, 5 and 4 actuators

The optimal shapes obtained in the first part of the design process are shown in Figure 4a. Figure 4b shows the controlled shapes with the element stress mapped onto the geometry. Optimal shapes and controlled shapes are very similar but not identical. There is a maximum distance of 11.8 mm for node 8 between target and controlled shape under LL2b.

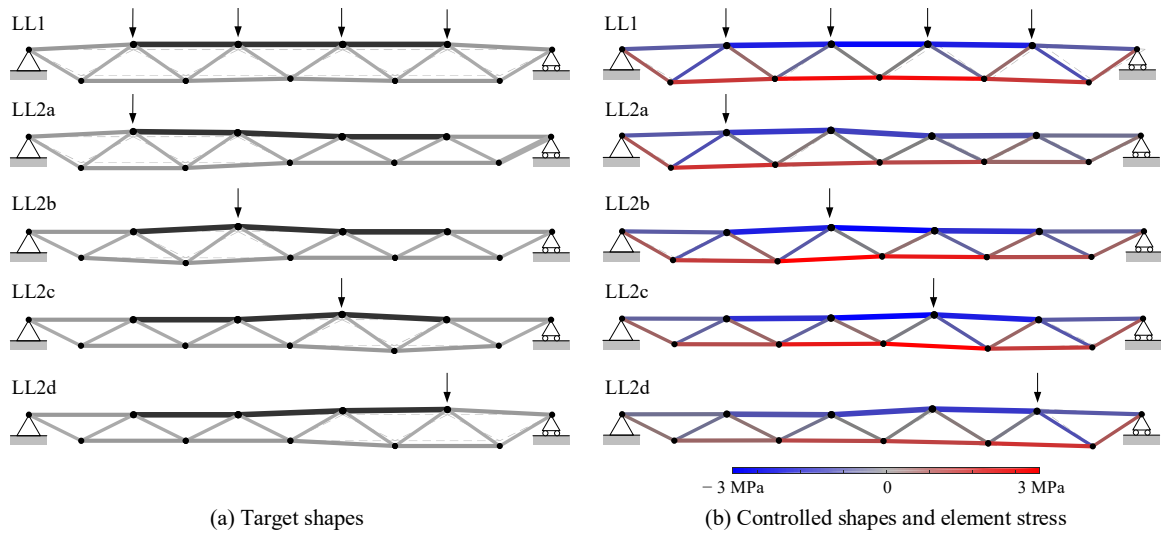

Figure 4: Optimal shapes and controlled shapes

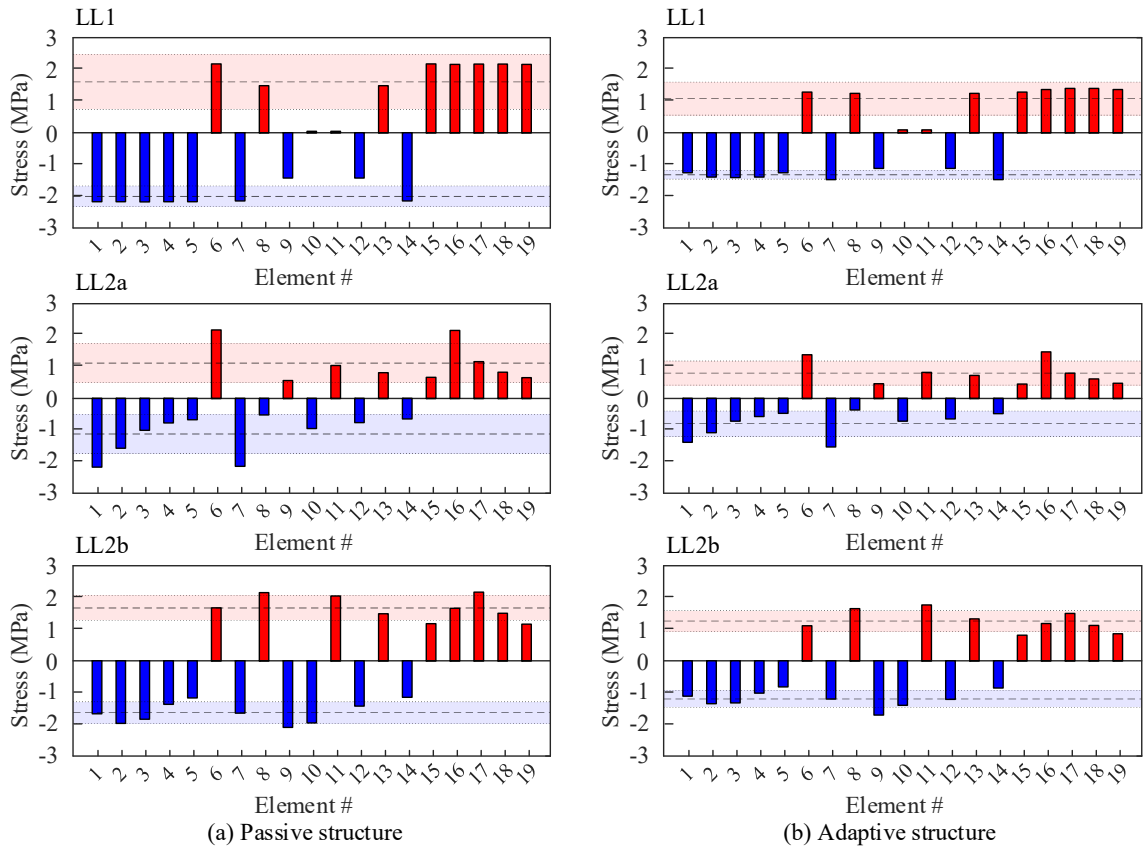

Figure 5: Element stress in passive (a) and adaptive (b) structure

The adaptive solution is compared to an identical weight-optimized passive structure to show stress redistribution through active control. Stress homogenization is understood as a reduction

of magnitude and variability. Figure 5 shows bar charts of the element stress for the passive (a) and adaptive (b) structures. LL2c and LL2d are not shown because they are mirror of LL2b and LL2a. Tensile and compressive stress are indicated in red and blue, respectively. The mean for each data set is shown as a horizontal dashed line. Stress variability is quantified through standard deviation. The width of the shaded band, whose centerline is the mean value of each data set, is twice the standard deviation. The element stress in the adaptive structure is consistently lower than that of the passive structure. The maximum mean reduction for tensile and compressive stress are 33% and 34%, respectively (both in LL1). LL1 and LL2b have the smallest variability through shape control for compressive and tensile stress, respectively. Stress homogenization can be appreciated the most in LL1. The stress of element 8, 9, 12 and 13 remains similar to that of the corresponding elements in the passive structure. However, the stress of element 1~7 and 14~19 decrease. Similarly, in LL2a, the stress of element 6, 7 and 16 decrease significantly while the stress for the other elements remain practically the same. There is no stress reversal between the passive and adaptive structure.

4 EXPERIMENTAL TESTING

A prototype structure was built based on the model described in Section 3. The active elements are five turnbuckles, fitted according to the 5-actuator layout (Figure 4e). The joints are fabricated via additive manufacturing using a polymer-based material with a Young's modulus of 82 MPa. This material was chosen to ease shape reconfiguration, which in this case is manually operated through the turnbuckles.

Figure 6: Prototype and supports

Only 8 out of 19 elements are instrumented with strain sensors, namely element 1, 2, 4, 5, 16, 17, 18 and 19 (Figure 6). It was not practical to install strain gauges on the 5 mm diameter bracing elements and on the turnbuckles. The static response under loading is measured and compared to the numerical predictions obtained in Section 3. Element strains and nodal positions are measured before and after shape control. Table 1a gives the maximum Euclidean distance between the nodes of simulated and measured controlled shapes as well as the norm of the shape difference between simulation and measurement.

Table 1: Discrepancy between measurement and simulation

(a) Nodal coordinates

Load case	No load	LL1	LL2a	LL2b	LL2c	LL2d
Norm difference of measurement and simulation (mm)	19.8	21.9	19.6	22.4	23.5	23.4
Max. node distance (mm)	7.9	10.6	11.5	12.2	11.7	12.1

(b) Change of stress

Load case	No load	LL1	LL2a	LL2b	LL2c	LL2d
Pearson correlation measure	-	0.99	0.86	0.93	0.94	0.90

The measured response under shape control is consistent with the numerical predictions (Section 3); an overall reduction of tensile and compressive stress is observed. The reduction is caused by the increase in depth in proximity of point of application of the external load. Table 1b shows the Pearson correlation between measured and predicted change of stress i.e. change before and after control. There is a strong correlation between measurement and prediction for all load cases.

To implement a control system based on the process outlined in Section 2, the external load has to be sensed. This is because a target shape can be computed only after knowing where the load is applied. To infer the external loading, the internal forces and the shape of the structure have to be known. Since only 8 out of 19 elements are instrumented with strain gauges, the forces in non-instrumented elements are obtained through nodal equilibrium. However, it is not possible to compute the force in element 3 through nodal equilibrium because it connects node 3 and 4 where the external load is applied. Instead, the force in element 3 is inferred through linear regression.

**Figure 7:** External load on node 2 (load case LL2a)

Figure 7 shows the comparison between applied and predicted values for the external load when the structure is subjected to a constant 20 N load on node 2 (LL2a), before and after shape control. Using a linear regression model that considers only internal forces as the independent variables, prediction of the external load was not accurate during and after shape control, with a maximum error of 4 N as shown by the grey scatter plot in Figure 7. Load prediction was more accurate when the length changes were also included in the independent variables in order to obtain the forces in non-instrumented elements. As shown by the black scatter plot in Figure 8, the predicted load is close to the applied one even after shape control with a maximum error of 0.6 N.

5 CONCLUSIONS

The results of this study lead to the following conclusions:

- Experimental testing on a small-scale prototype has demonstrated that stress homogenization through large-shape changes is feasible. This enables an adaptive structure to operate closer to design limits maximizing material utilization and thus saving embodied energy with respect to a passive structure. The maximum mean reduction for tensile and compressive stress are 25% and 32%, respectively.
- The geometrically nonlinear force method offers an efficient way to control the shape of a reticular structure under quasi-static loading as shown by good accordance (Pearson correlation of 0.86) between simulation and measurement.
- Detection of the applied loading is necessary for non-linear shape and force control. The external load was inferred from sparse strain measurements combined by an optical tracking system. The optical system was essential to close the information gap caused by sparse instrumentation, especially in situations where nodal coordinates were varying due to shape control.

Similar conclusions are expected from tests on similar reticular structures designed using the design method outlined in this work. However, it was not possible in this work to appreciate the effect of node stiffness on internal forces and nodal displacements and how this effect behaves with the scale. In addition, the use of machine vision may pose a reliability risk as the monitoring of nodal coordinates may fail when multiple reflective markers are occluded. Future work will involve testing on a larger scale prototype adaptive structure.

Key words: Nonlinear bending, Dielectric plate, Differential quadrature method, Effective-medium theory.

Abstract. This paper investigates the nonlinear bending of graphene platelets (GPLs) reinforced composite (GPLRC) plate with dielectric permittivity. Effective-medium theory (EMT) is adopted to determine tensile modulus and dielectric while rule of mixture is adopted to determine Poisson's ratio. Governing equations for nonlinear bending of the GPLRC plate are established based on first-order shear deformation plate theory and numerically solved through differential quadrature method (DQM). The dependency of the bending behaviors of the GPLRC plates on the attributes of plate geometry, GPL concentration and electrical field are comprehensively investigated. The analysis reveals that by adjusting several parameters the performances of the GPLRC plate can be designed and actively tuned.

1 INTRODUCTION

The current paper will be the first concentration on nonlinear bending behaviours of graphene reinforced composite plate with considering the dielectric property of the composite material. For case study, PVDF and GPL are chosen as constituent components for the composite plate. The top and bottom surfaces of the plate are coated with conductive paste serving as the compliant electrodes to accommodate the applied electrical voltage. Effective-medium theory (EMT) and rule of mixture will be employed to calculate the composite's material properties as required for structural analysis. Parametric study on the bending of the GPLRC plate is conducted through numerically solving the governing equations, which are derived by first-order shear deformation plate theory taking account of von Kármán geometrical nonlinearity.

Figure 1 Schematic configuration of GPLRC plate.

2 EFFECTIVE MATERIAL PROPERTIES OF GPLRC

Rule of mixture could determine the effective Poisson's ratio of GPLRC with random and uniform dispersion, as

$$\nu_e = \varphi_m \nu_m + \varphi_f \nu_f \quad (1)$$

where the subscripts “m”, “f” and “e” denote matrix, reinforcing fillers and effective composite, respectively, and ν and φ refer to Poisson's ratio and volume fraction, respectively. In the current paper, the Poisson's ratio of GPL and PVDF are 0.175 and 0.35, respectively.

In the current paper, effective medium theory (EMT) is employed to evaluate the Young's modulus and dielectric permittivity of GPLRC. After some mathematical derivation, the effective property of graphene reinforced composites could be determined by the following scalar equation as

$$\varphi_m \frac{L_m - L_e}{L_m + (1/3)(L_m - L_e)} + \frac{1}{3} \varphi_f \sum_{k=1}^3 \frac{L_k - L_e}{L_e + S_{kk}(L_k - L_e)} = 0 \quad (2)$$

where L_k ($k = 1, 2, 3$) is the component of concerned moduli tensor and S_{kk} ($k = 1, 2, 3$) is the component of Eshelby's tensor of GPL filler in its local coordinate system.

2.1 Effective dielectric permittivity

The moduli components in Eq. (2) can be complex electrical conductivity components of the effective medium. Substituting the corresponding moduli components, one can have

$$\varphi_m \frac{\sigma_m^* - \sigma_e^*}{\sigma_e^* + (1/3)(\sigma_m^* - \sigma_e^*)} + \frac{1}{3} \varphi_f \sum_{k=1}^3 \frac{\sigma_k^* - \sigma_e^*}{\sigma_e^* + S_{kk}(\sigma_k^* - \sigma_e^*)} = 0 \quad (3)$$

where σ^* is the complex electrical conductivity which contains two parts, i.e. $\sigma^* = \sigma + 2\pi f_{AC} \epsilon j$, wherein σ is the DC (direct current) conductivity and the second imaginary term is the AC conductivity with f_{AC} being AC frequency of electrical field and ϵ the dielectric permittivity of the material.

This theory could be improved by taking the imperfect bonding/interaction between reinforcements and matrix into consideration. This is achieved by introducing an interphase surround the filler. As investigated in [1], the effective electrical conductivity and dielectric permittivity of the coated reinforcing fillers, i.e. $\sigma_k^{(c)}$ and $\epsilon_k^{(c)}$, can be estimated by

$$\sigma_k^{(c)} = \sigma_0^{(int)} \left[1 + \frac{(1 - \varphi_{int})(\sigma_k - \sigma_0^{(int)})}{\varphi_{int} S_{kk}(\sigma_k - \sigma_0^{(int)}) + \sigma_0^{(int)}} \right], \quad \epsilon_k^{(c)} = \epsilon_0^{(int)} \left[1 + \frac{(1 - \varphi_{int})(\epsilon_k - \epsilon_0^{(int)})}{\varphi_{int} S_{kk}(\epsilon_k - \epsilon_0^{(int)}) + \epsilon_0^{(int)}} \right] \quad (k = 1, 2, 3) \quad (4)$$

with $\sigma_0^{(int)}$ and $\epsilon_0^{(int)}$ being the electrical conductivity and dielectric permittivity of the interphase, respectively. All the electrical conductivity and dielectric permittivity of the GPL fillers involved in Eq. (3) should be substituted by the ones in Eq. (4). φ_{int} in Eq. (4) denotes the volume fraction of the interphase in the coated GPL, which is

$$\varphi_{int} = 1 - \frac{\frac{4}{3} \pi \left(\frac{t_{GPL}}{2} \right) \left(\frac{D_{GPL}}{2} \right) \left(\frac{D_{GPL}}{2} \right)}{\frac{4}{3} \pi \left(\frac{t_{GPL}}{2} + t_{int} \right) \left(\frac{D_{GPL}}{2} + t_{int} \right) \left(\frac{D_{GPL}}{2} + t_{int} \right)} \quad (5)$$

where t_{int} is the thickness of the interphase.

D

Choosing GPLs and PVDF as the reinforcing fillers and the polymer matrix, respectively, the EMT model on predicting the dielectric permittivity of GPL/PVDF composites was validated by Xia et al. [2].

2.2 Effective elastic modulus

Replacing the parameters with components of stiffness tensor gives the following equation

$$\varphi_m \frac{E_m - E_e}{E_e + (1/3)(E_m - E_e)} + \frac{1}{3} \varphi_f \sum_{k=1}^3 \frac{E_k - E_e}{E_e + S_{kk}(E_k - E_e)} = 0 \quad (6)$$

where E_e is the elastic modulus of the homogeneous GPLRC. Taking the imperfect bonding between fillers and polymer into account, the effective elastic modulus of coated GPL is

$$E_k^{(c)} = E_0^{(int)} \left[1 + \frac{(1 - \varphi_{int})(E_k - E_0^{(int)})}{\varphi_{int} S_{kk}(E_k - E_0^{(int)}) + E_0^{(int)}} \right] \quad k = 1, 2, 3 \quad (7)$$

with $E_0^{(int)}$ being the elastic modulus of the interphase. E_k in Eq. (7) would be substituted by the elastic modulus of coated GPLs. In the current study, the Young's modulus of the PVDF is 1.44 GPa and the in-plane and out-plane Young's modulus of GPL are 1.01 TPa and 101 TPa, respectively. The thickness of the interlayer is 3 nm and the average thickness of GPLs is 50 nm.

3 PROBLEM FORMULATION

Employing first-order plate theory, the displacement field is given as

$$\begin{cases} U_1(X_1, X_2, X_3) = U_1(X_1, X_2, 0) + X_3 \Phi_1(X_1, X_2, 0) \\ U_2(X_1, X_2, X_3) = U_2(X_1, X_2, 0) + X_3 \Phi_2(X_1, X_2, 0) \\ U_3(X_1, X_2, X_3) = U_3(X_1, X_2, 0) \end{cases} \quad (8)$$

where $U_1(X_1, X_2, 0)$, $U_2(X_1, X_2, 0)$ and $U_3(X_1, X_2, 0)$ are the displacement components of the middle plane in X_1 , X_2 and X_3 directions, respectively, $\Phi_1(X_1, X_2, 0)$ and $\Phi_2(X_1, X_2, 0)$ are cross-sectional rotations in the 103 and 203 planes. For convenience, the following conventions would be introduced

$$\begin{aligned} U_1(X_1, X_2, 0) &\equiv U_1, U_2(X_1, X_2, 0) \equiv U_2, U_3(X_1, X_2, 0) \equiv U_3 \\ \Phi_1(X_1, X_2, 0) &\equiv \Phi_1, \Phi_2(X_1, X_2, 0) \equiv \Phi_2 \end{aligned} \quad (9)$$

The strain field could be given by von Kármán geometrical nonlinearity as

$$\begin{Bmatrix} \varepsilon_{11} \\ \varepsilon_{22} \\ \varepsilon_{33} \\ \gamma_{23} \\ \gamma_{13} \\ \gamma_{12} \end{Bmatrix} = \begin{Bmatrix} \varepsilon_{11}^{(0)} \\ \varepsilon_{22}^{(0)} \\ \varepsilon_{33}^{(0)} \\ \gamma_{23}^{(0)} \\ \gamma_{13}^{(0)} \\ \gamma_{12}^{(0)} \end{Bmatrix} + X_3 \begin{Bmatrix} \varepsilon_{11}^{(1)} \\ \varepsilon_{22}^{(1)} \\ \varepsilon_{33}^{(1)} \\ \gamma_{23}^{(1)} \\ \gamma_{13}^{(1)} \\ \gamma_{12}^{(1)} \end{Bmatrix} = \begin{Bmatrix} U_{1,1} + \frac{1}{2} U_{3,1}^2 \\ U_{2,2} + \frac{1}{2} U_{3,2}^2 \\ 0 \\ \Phi_2 + U_{3,2} \\ \Phi_1 + U_{3,1} \\ U_{1,2} + U_{2,1} + U_{3,1} U_{3,2} \end{Bmatrix} + X_3 \begin{Bmatrix} \Phi_{1,1} \\ \Phi_{2,2} \\ 0 \\ 0 \\ 0 \\ \Phi_{1,2} + \Phi_{2,1} \end{Bmatrix} \quad (10)$$

The stress field could be given as

$$\begin{Bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \tau_{23} \\ \tau_{13} \\ \tau_{12} \end{Bmatrix} = \begin{bmatrix} Q_{11} & Q_{12} & 0 & 0 & 0 & 0 \\ Q_{21} & Q_{22} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & Q_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & Q_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & Q_{66} \end{bmatrix} \begin{Bmatrix} \varepsilon_{11} \\ \varepsilon_{22} \\ \varepsilon_{33} \\ \gamma_{23} \\ \gamma_{13} \\ \gamma_{12} \end{Bmatrix} + \begin{Bmatrix} \varepsilon_{110} \\ \varepsilon_{220} \\ \varepsilon_{330} \\ \gamma_{230} \\ \gamma_{130} \\ \gamma_{120} \end{Bmatrix} - \frac{V^2}{t^2} \varepsilon \begin{Bmatrix} 1 \\ 1 \\ 1 \\ 0 \\ 0 \\ 0 \end{Bmatrix} \quad (11)$$

where $\{\varepsilon_{110} \ \varepsilon_{220} \ \varepsilon_{330} \ \varepsilon_{230} \ \varepsilon_{130} \ \varepsilon_{120}\}^T$ is the prestrain vector, $Q_{ij} (i,j=1,2,4,5,6)$ are the elastic stiffness of the plate given as

$$Q_{11}=Q_{22}=\frac{E}{1-\nu^2}, \quad Q_{12}=Q_{21}=\frac{\nu E}{1-\nu^2}, \quad Q_{44}=Q_{55}=Q_{66}=\frac{E}{2(1+\nu)} \quad (12)$$

The last vector on the right hand side of Eq. (11) denotes the electrostatic stress produced by the voltage due to the dielectric property of the plate. V is the voltage applied across the plate. The voltage applied consists of two parts, i.e. $V = V_{DC} + V_{AC} \sin(2\pi f_{AC} t)$, in which V_{DC} and V_{AC} are the amplitudes of DC and AC voltage, respectively, and f_{AC} is the AC frequency of the voltage in Hertz. Here it should be noted the AC voltage is normally used for actively tuning or periodic excitation and its magnitude is usually much smaller than DC component [3]. Therefore, the magnitude of DC voltage will be used in Eq. (11) to calculate the axial stress.

Integrating the normal and shear stresses over corresponding domains, the internal forces and moment in the plate are derived as

$$\begin{Bmatrix} N_{11} \\ N_{22} \\ N_{33} \\ N_{23} \\ N_{13} \\ N_{12} \end{Bmatrix} = \int_{-\frac{H}{2}}^{\frac{H}{2}} \begin{Bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \tau_{23} \\ \tau_{13} \\ \tau_{12} \end{Bmatrix} dx_3 = \begin{bmatrix} A_{11} & A_{12} & 0 & 0 & 0 & 0 \\ A_{21} & A_{22} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & A_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & A_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & A_{66} \end{bmatrix} \begin{Bmatrix} \varepsilon_{11}^{(0)} \\ \varepsilon_{22}^{(0)} \\ \varepsilon_{33}^{(0)} \\ \gamma_{23}^{(0)} \\ \gamma_{13}^{(0)} \\ \gamma_{12}^{(0)} \end{Bmatrix} + \begin{Bmatrix} \varepsilon_{110} \\ \varepsilon_{220} \\ \varepsilon_{330} \\ \gamma_{230} \\ \gamma_{130} \\ \gamma_{120} \end{Bmatrix} - \begin{Bmatrix} N_{11}^E \\ N_{22}^E \\ N_{33}^E \\ 0 \\ 0 \\ 0 \end{Bmatrix} \quad (13)$$

$$\begin{Bmatrix} M_{11} \\ M_{22} \\ M_{33} \\ M_{23} \\ M_{13} \\ M_{12} \end{Bmatrix} = \int_{-\frac{H}{2}}^{\frac{H}{2}} X_3 \begin{Bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \tau_{23} \\ \tau_{13} \\ \tau_{12} \end{Bmatrix} dX_3 = \begin{bmatrix} A_{11} & A_{12} & 0 & 0 & 0 & 0 \\ A_{21} & A_{22} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & A_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & A_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & A_{66} \end{bmatrix} \begin{Bmatrix} \varepsilon_{11}^{(1)} \\ \varepsilon_{22}^{(1)} \\ \varepsilon_{33}^{(1)} \\ \gamma_{23}^{(1)} \\ \gamma_{13}^{(1)} \\ \gamma_{12}^{(1)} \end{Bmatrix} \quad (14)$$

where A_{ij} and D_{ij} are coefficients determined as

$$\begin{aligned} A_{ij} &= \int_{-\frac{H}{2}}^{\frac{H}{2}} Q_{ij} dX_3 \quad (i, j = 1, 2, 3, 6) & A_{ij} &= \int_{-\frac{H}{2}}^{\frac{H}{2}} k_s Q_{ij} dX_3 \quad (i, j = 4, 5) \\ D_{ij} &= \int_{-\frac{H}{2}}^{\frac{H}{2}} X_3^2 Q_{ij} dX_3 \quad (i, j = 1, 2, 3, 4, 5, 6) & N_{11}^E &= N_{22}^E = N_{33}^E = \frac{V^2}{H^2} \varepsilon t \end{aligned} \quad (15)$$

with k_s being the shear correction factor.

Based on energy method, the governing equations for bending of the plate can be obtained with the following boundary conditions:

CCCC:

$$U_1 = U_2 = U_3 = \Phi_1 = \Phi_2 = 0 \quad (X_1, X_2 = 0, 1) \quad (16)$$

SSSS:

$$\begin{aligned} U_1 = U_2 = U_3 = \Phi_2 = 0, D_{11}\Phi_{1,1} + D_{12}\Phi_{2,2} = 0 \quad (X_1 = 0, 1) \\ U_1 = U_2 = U_3 = \Phi_1 = 0, D_{21}\Phi_{1,1} + D_{22}\Phi_{2,2} = 0 \quad (X_2 = 0, 1) \end{aligned} \quad (17)$$

CCSS:

$$\begin{aligned} U_1 = U_2 = U_3 = \Phi_1 = \Phi_2 = 0 \quad (X_1, X_2 = 0) \\ U_1 = U_2 = U_3 = \Phi_2 = 0, D_{11}\Phi_{1,1} + D_{12}\Phi_{2,2} = 0 \quad (X_1 = 1) \\ U_1 = U_2 = U_3 = \Phi_1 = 0, D_{21}\Phi_{1,1} + D_{22}\Phi_{2,2} = 0 \quad (X_2 = 1) \end{aligned} \quad (18)$$

4 SOLUTION

To normalize the governing equations, the following dimensionless quantities are defined

$$\begin{aligned} \{x_1, x_2\} = \left\{ \frac{X_1}{L}, \frac{X_2}{W} \right\}, \{u_1, u_2, u_3\} = \frac{\{U_1, U_2, U_3\}}{H}, \{\varphi_1, \varphi_2\} = \{\Phi_1, \Phi_2\}, q = \frac{Q\eta L}{A_{110}} \\ \{a_{ij}, d_{ij}\} = \left\{ \frac{A_{ij}}{A_{110}}, \frac{D_{ij}}{A_{110}H^2} \right\}, \eta = \frac{L}{H}, \lambda = \frac{L}{W}, \{n_{11}^e, n_{22}^e, n_{33}^e\} = \frac{\{N_{11}^E, N_{22}^E, N_{33}^E\}}{A_{110}} \end{aligned} \quad (19)$$

where A_{110} and I_{10} are the corresponding values of A_{11} and I_1 of plate made of pure polymer, respectively.

The dimensionless governing equations can be solved numerically with the aid of differential quadrature method (DQM). First, the following displacements of the plate and their derivatives are introduced

$$\begin{aligned} \left\{ \begin{aligned} \{u_1, u_2, u_3, \varphi_1, \varphi_2\} &= \sum_{m=1}^M \sum_{n=1}^N l_m(x_1) l_n(x_2) \{u_{1mn}, u_{2mn}, u_{3mn}, \varphi_{1mn}, \varphi_{2mn}\} \\ \left. \frac{\partial^{k_1}}{\partial x_1^{k_1}} \frac{\partial^{k_2}}{\partial x_2^{k_2}} \{u_1, u_2, u_3, \varphi_1, \varphi_2\} \right|_{x_1=x_{1i}, x_2=x_{2j}} &= \sum_{m=1}^M \sum_{n=1}^N C_{im}^{(k_1)} C_{jn}^{(k_2)} \{u_{1mn}, u_{2mn}, u_{3mn}, \varphi_{1mn}, \varphi_{2mn}\} \end{aligned} \right\} \quad (20) \end{aligned}$$

where $\{u_{1mn}, u_{2mn}, u_{3mn}, \varphi_{1mn}, \varphi_{2mn}\}$ is the displacement vector at position $x_1 = x_{1m}$, $x_2 = x_{2n}$, $l_m(x_1)$ and $l_n(x_2)$ are the Lagrange interpolation polynomials and $C_{im}^{(k_1)}$ and $C_{jn}^{(k_2)}$ are the weighting coefficients of the k_1 th derivative at $x_1 = x_{1m}$ and the k_2 th derivative at $x_2 = x_{2n}$, and M and N are the total numbers of grid points distributed along the x_1 and x_2 directions. In present work, the following expression for the distribution of the grid points are used [4]

$$\begin{aligned} x_{1i} &= \frac{1}{2} \left[1 - \cos \frac{\pi(i-1)}{N-1} \right] \quad (i = 1, 2, \dots, M) \\ x_{2j} &= \frac{1}{2} \left[1 - \cos \frac{\pi(j-1)}{N-1} \right] \quad (j = 1, 2, \dots, N) \end{aligned} \quad (21)$$

Substituting Eq. (20) into dimensionless governing equations will yield the discretized governing equations which could be simplified as the following matrix equation

$$[\mathbf{K}_L + \mathbf{K}_{NL}(\mathbf{d})]\mathbf{d} = \mathbf{q} \quad (22)$$

where \mathbf{K}_L denotes linear stiffness matrix, \mathbf{K}_{NL} denotes the nonlinear stiffness matrix depending on displacement vector expressed as

$$\mathbf{d} = \left\{ \left\{ \text{vec}(u_{1ij}) \right\}^T, \left\{ \text{vec}(u_{2ij}) \right\}^T, \left\{ \text{vec}(u_{3ij}) \right\}^T, \left\{ \text{vec}(\varphi_{1ij}) \right\}^T, \left\{ \text{vec}(\varphi_{2ij}) \right\}^T \right\}^T \quad (23)$$

\mathbf{M} denotes mass matrix and \mathbf{q} denotes force vector expressed as

$$\mathbf{q} = \left\{ \left\{ 0 \right\}_{MN}^T, \left\{ 0 \right\}_{MN}^T, \left\{ q(x_i, x_{2j}) \right\}_{MN}^T, \left\{ 0 \right\}_{MN}^T, \left\{ 0 \right\}_{MN}^T \right\}^T \quad (i = 1, 2, \dots, M, j = 1, 2, \dots, N) \quad (24)$$

Eq. (24) can be solved by direct iteration method for nonlinear bending.

5 RESULTS AND DISCUSSION

5.1 Convergence and validation study

Table 1 validates the results of the current method by comparing with those obtained using other methods from literature for an elastic isotropic homogeneous rectangular plates. The present solution is realized for a quadratic plate, with the following parameters: $L = 1$, $W = 1$, $E = 1$, $Q = 1$, $\nu = 0.3$ and three values for the plate thickness: $H = 0.01$, $H = 0.03$, and $H = 0.1$. It is found that present results agree very well with the results from reference

Table 1 Dimensionless deflections of isotropic homogeneous plates

H	Classic [5]	3-D [6]		Ref [7]	Present
		In mid-plane	Average		
0.01	44360.9000	44384.7000	44383.9000	44383.8400	44383.8765
0.03	1643.0000	1650.9400	1650.6600	1650.6460	1650.6578
0.10	44.3609	46.7443	46.6586	46.6548	46.6594

Table 2 presents dimensionless deflection of GPL/PVDF composite plates with different numbers of grid points and boundary conditions. The concentration of GPL in the composites is 1.5 wt%. The dimensions of the plate are $L = W = 0.01\text{m}$ and $H = 0.0005\text{ m}$, respectively. No electrical field are applied on the plate. The initial prestrain are set to be 0.01 in both 1 and 2 directions. The number of grid points M and N in both 1 and 2 directions increases from 5 to

15. It could be concluded that 15 grid points in both 1 and 2 directions are enough for computational accuracy.

Table 2 Dimensionless deflection of GPLRC plate with various boundary conditions

$M=N$	CCCC		SSSS		CCSS	
	Linear	Nonlinear	Linear	Nonlinear	Linear	Nonlinear
5	0.3094	0.3310	0.3769	0.3635	0.3453	0.3388
7	0.2195	0.2163	0.3516	0.3371	0.2760	0.2693
9	0.2226	0.2201	0.3531	0.3386	0.2774	0.2712
11	0.2226	0.2200	0.3530	0.3386	0.2774	0.2712
13	0.2226	0.2200	0.3530	0.3386	0.2774	0.2711
15	0.2226	0.2200	0.3530	0.3386	0.2774	0.2711

5.2 Parametric study

A simply supported GPL/PVDF plate is considered for parametric study. Unless stated otherwise, the size of the plate are $L = W = 0.01\text{m}$ and $H = 0.0005\text{m}$. The prestrain in the 1 and 2 direction are 0.01. The GPL volume fraction is 1.5 wt%. The properties of PVDF are $E_{\text{PVDF}} = 1.44\text{GPa}$, $\nu_{\text{PVDF}} = 0.35$, $\sigma_{\text{PVDF}} = 3.5 \times 10^{-9}\text{S/m}$, $\varepsilon_{\text{PVDF}} = 5 \times 8.85 \times 10^{-12}\text{F/m}$ and the properties of GPL are $E_{\text{GPL}_1} = E_{\text{GPL}_2} = 1010\text{GPa}$, $E_{\text{GPL}_3} = 1010\text{TPa}$, $\nu_{\text{GPL}} = 0.175$, $\sigma_{\text{GPL}_1} = \sigma_{\text{GPL}_2} = 8.32 \times 10^4\text{S/m}$, $\sigma_{\text{GPL}_3} = 83.2\text{S/m}$, $\varepsilon_{\text{GPL}_1} = \varepsilon_{\text{GPL}_2} = 15 \times 8.85 \times 10^{-12}\text{F/m}$, $\varepsilon_{\text{GPL}_3} = 0.6715 \times 8.85 \times 10^{-12}\text{F/m}$.

The plate geometry affects the bending behaviours of GPLRC plate, as presented in Fig. 2. It is found in Fig. 2 the increase of length-to-thickness ratio and the decrease of length-to-width ratio increase the deformation of the plate. The effect of plate geometry on the deflection also depend on the applied electrical voltage and length-to-width ratio.

Fig. 2. Variation of dimensionless deflection with thickness of GPL/PVDF plate.

Fig. 3 plots the variation of the dimensionless deflection of the GPL/PVDF plate with the GPL concentration. The decrease of the dimensionless deflection is observed when GPL concentration reaches a critical value, i.e. $f_{\text{GPL}} = 1.1$ wt%. When GPL concentration further increases, the deflection becomes highly dependent on the electrical voltage. Similar trend of the dependency of the deflection on GPL weight fraction is found in Fig. 3. In Fig. 3b, the magnitude of DC voltage is fixed as 100 V while the AC frequency varies from 0 Hz to 10^6 Hz. A snap-through phenomenon is observed for the deflection when the GPL concentration exceeds the critical concentration.

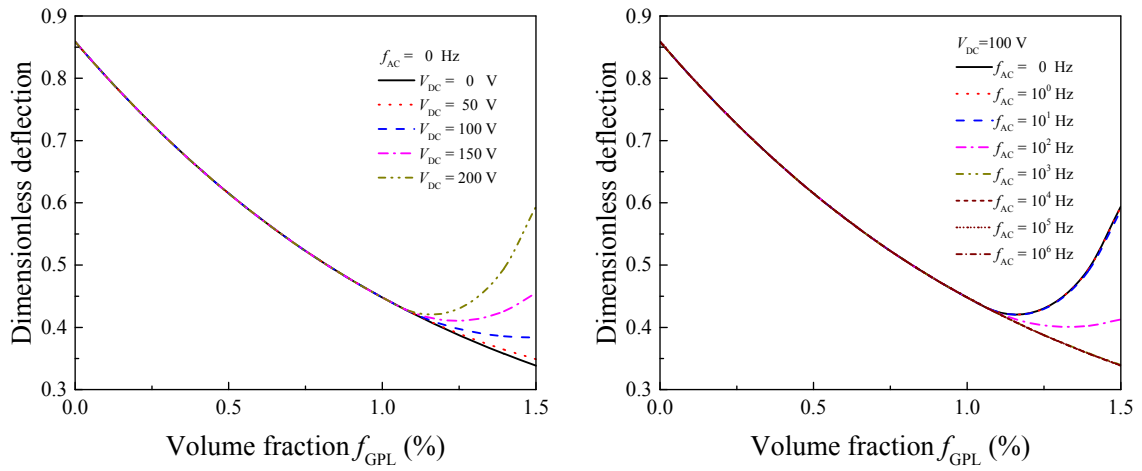

Fig. 3. Variation of dimensionless deflection of GPL/PVDF plate with GPL volume fraction (a) $f_{\text{AC}} = 0$ Hz; (b) $V_{\text{DC}} = 100$ V.

Fig. 4. Variation of dimensionless deflection of GPL/PVDF composite plate with voltage.

Fig. 4 plots the variation of the dimensionless deflection of GPL/PVDF plate with electrical voltage. The dimensionless deflection increases as the electrical voltage grows and the variation of the dimensionless deflection is more evident as the GPL concentration increases. The different of the two figures in figure 4 also indicates that the decrease of AC frequency magnify the effects of DC voltage.

6 CONCLUSIONS

Nonlinear bending of GPLRC dielectric plate are studies by numerically solving governing equations, which are derived based on first-order deformation theory and von Kármán geometrical nonlinearity. The analysis demonstrates that the bending behaviors of the GPL/PVDF plate could be artificially tuned by adjusting several parameters, i.e. plate size, GPL concentration and external electrical field.

Key words: Adaptive civil engineering structure, nonlinear modeling, tension-only elements, feedback linearization

Abstract. Adaptive civil engineering structures aim at saving material and energy in the construction and operation of buildings. Such structures incorporate sensors, actuators and a control unit to instantly adapt their response to external dynamic and static loads to guarantee an optimal material utilization all times. These structures are often modeled using a linear approach, however some nonlinear aspects cannot be neglected, but need to be captured by the governing equations. Tension-only elements can bear tension forces but collapse completely under compression. In this contribution, a nonlinear model of a civil engineering structure incorporating tension-only elements is introduced and a model order reduction by means of proper orthogonal decomposition is conducted. The controller design for this nonlinear system is carried out in two steps. First, the closed loop dynamics are forced to follow a linear target dynamic by applying a nonlinear input transformation including a virtual input. Second, this new input is used to control the linear target dynamic with methods from linear control theory with the aim of oscillation damping. The proposed method is applied to an exemplary adaptive high-rise structure. The results illustrate the effectiveness of the introduced control strategy, due to a strong impact of the nonlinearities on the structure's behavior.

1 INTRODUCTION

The introduction of adaptivity in structural engineering enables a way to build lightweight and sustainable and therefore save material in the construction sector by actively influencing the structure. Adaptive engineering structures guarantee their structural stability by combining sensors and actuators with a control unit [21,32]. Therein, a control algorithm processes sensor signals to provide actuator inputs for compensating static and dynamic loads and ensuring a comfortable usage and a secure functioning of the structure. Research in control of adaptive civil engineering structures goes back to the 1970s [37]. Classification of such structures and control approaches can be looked up in [17,33].

Civil engineering structures often make use of tension-only elements, e.g. ropes used as stiffening elements. If such an element is being compressed it gets slack and (temporarily) loses its load bearing behavior and therefore its function in the structure [2]. A high pretension of these elements can prevent slackness. However, if high pretension forces are applied, additional

Figure 1: Rendering of an adaptive high-rise building (right), which will be built on the site of the University of Stuttgart. The left building is the access and supply tower (source: ILEK).

stress is put on the structure, which is not desirable due to the increased need of material and construction costs, which is contrary to our goal of a sustainable and lightweight construction.

Tension-only elements are state-of-the-art in finite element (FE) tools (e.g. ANSYS), however their use results in a loss of linearity. Nevertheless, many control approaches for such large structures are based on linear equations of motion due to its simplicity and the need of low order design models that can easily be derived for linear systems, e. g. by modal transformation [13,28]. Even though this often results in a reasonable control performance, a large number of nonlinear elements might require a nonlinear modeling and control approach to further improve the closed loop system dynamics. However, this impedes the usage of classical workflows, in which linear FE models are extracted and reduced for control design purposes. State-of-the-art light-weight engineering structures typically incorporate a high number of tension-only elements. Despite these local nonlinearities, some of these structures express an almost linear behavior with respect to the global structural modes. Therefore, a proper orthogonal decomposition can be applied to capture the main components of the nonlinear model and to be able to reduce it for simulation and control design purposes.

A lot of research concerning tension-only elements in civil engineering is directed towards tensegrity structures [31]. These consist of tensioned cables and compressed struts. Using activated struts, a control algorithm that manipulate the eigenfrequencies of the structure to minimize vibrations is proposed by [3], whereas in [8] an optimal controller is designed for a tensegrity structure with actuated cables. However, these systems are different to the system in this contribution because the bars in tensegrity structures do not bear bending moments and high pretension of the cables is required.

Structures relying heavily on cable networks can be found in suspension bridges, cable roofs, and transmission lines [19]. The more general concept of tension systems, in addition to cable systems, also includes membranes [5,23]. For modeling and control of single cables, slackness is considered in many contributions [1,14], often in the context of hybrid systems [7]. Hybrid systems are not applicable for the high number of tension-only elements typically found in civil engineering structures, due to the combinatorial explosion of the number of discrete states.

For control of nonlinear system equations, a linearizing input transformation renders the closed-loop dynamics into an integrator chain, an established method in the context of flat systems [11]. The applied control concept is a linearizing input transformation [15,22] forcing

the nonlinear system to the dynamics of a target system. The nonlinear system can then be controlled by controlling the target system with common linear control theory.

To demonstrate the research concerning adaptive civil engineering structures, an experimental adaptive high-rise building will be installed on the site of the University of Stuttgart (see Fig. 1 and details in [36]). A simplified model of this structure's geometry is presented in section 5.1 and used to illustrate the nonlinear effects of tension-only elements and the proposed algorithm.

The main contribution of this article is the modeling and control of nonlinear effects of tension-only elements in the context of adaptive engineering structures, where possibly a high number of tension-only elements can be available. Furthermore, a linearizing input is stated, transforming the nonlinear system into a desired closed-loop target dynamics, which can be controlled with linear control theory.

In the following, the linear model equations are stated in section 2 as the basis for including nonlinear tension-only elements. A nonlinear model order reduction is conducted by means of POD in section 3 and a model for control purposes is derived. In section 4, a linearizing input transformation, which is applied to the nonlinear system, forces the closed-loop system onto a desired target dynamic. Simulation results for the application of the introduced methodology to a numerical high-rise structure are given in section 5.

2 SYSTEM MODELING

This section concerns modeling of linear and nonlinear effects in mechanical structures arising in special civil engineering structures. In the following, the linear equations of motion are introduced as a basis for further nonlinear modeling and for the sake of evaluation and comparison of both model types and the selection of a target system in section 5.

2.1 Linear Equations of Motion

A common technique to model mechanical structures is the application of the finite element method (FEM). This framework discretizes the infinite number of degrees of freedom (DOFs) of flexible structures. The resulting equations of motion with the DOF vector $\mathbf{q}(t) \in \mathbb{R}^n$ are described by the second order differential equation

$$\overline{\mathbf{M}}\ddot{\mathbf{q}}(t) + \overline{\mathbf{D}}\dot{\mathbf{q}}(t) + \overline{\mathbf{K}}\mathbf{q}(t) = \overline{\mathbf{F}}\mathbf{u}(t), \quad t > 0, \quad \mathbf{q}(0) = \mathbf{q}_0, \quad \dot{\mathbf{q}}(0) = \mathbf{q}_1 \quad (1)$$

with the positive definite matrices for mass $\overline{\mathbf{M}} \in \mathbb{R}^{n \times n}$, stiffness $\overline{\mathbf{K}} \in \mathbb{R}^{n \times n}$ and damping $\overline{\mathbf{D}} \in \mathbb{R}^{n \times n}$. Manipulation of the system can be realized by actuator forces $\mathbf{u}(t) \in \mathbb{R}^m$ on the right side of (1). The input matrix $\overline{\mathbf{F}} \in \mathbb{R}^{n \times m}$ distributes these forces among the DOFs. The mass and stiffness matrix are directly obtained by an FE analysis of the underlying structure, whereas the damping matrix is chosen as Rayleigh damping in the following form:

$$\overline{\mathbf{D}} = \alpha_1 \overline{\mathbf{M}} + \alpha_2 \overline{\mathbf{K}}. \quad (2)$$

The coefficients α_1 and α_2 can be determined by experimental identification or from literature. Rayleigh damping is classified as proportional damping, which is accompanied by the advantage that eigenmodes of the model remain unchanged [26, 29].

2.1.1 Modal Analysis

A modal analysis is a powerful tool to characterize and reduce – solely – linear models. Therefore, the harmonic solution $\mathbf{q}(t) = \boldsymbol{\varphi}_i \exp(j\omega_i t)$ is plugged in the undamped system, which

leads to the generalized eigenvalue problem $(\mathbf{K} - \omega_i^2 \mathbf{M})\boldsymbol{\varphi}_i = 0$. The n eigenvalues ω_i represent the oscillation frequencies of the i^{th} eigenmode and the eigenvectors $\boldsymbol{\varphi}_i$ collect the respective mode shape. Equation (1) can be transformed by $\mathbf{q}(t) = \mathbf{\Phi}\boldsymbol{\eta}(t)$ with $\mathbf{\Phi} = [\boldsymbol{\varphi}_1, \dots, \boldsymbol{\varphi}_n]$, where $\boldsymbol{\eta}(t)$ represent the modal amplitudes. This along with left multiplying of (1) by $\mathbf{\Phi}^\top$ yields the modal dynamics:

$$\ddot{\boldsymbol{\eta}}(t) + \mathbf{D}_\eta \dot{\boldsymbol{\eta}}(t) + \mathbf{K}_\eta \boldsymbol{\eta}(t) = \mathbf{F}_\eta \mathbf{u}(t), \quad t > 0, \quad \boldsymbol{\eta}(0) = \mathbf{\Phi}^{-1} \mathbf{q}_0, \quad \dot{\boldsymbol{\eta}}(0) = \mathbf{\Phi}^{-1} \dot{\mathbf{q}}_1. \quad (3)$$

The eigenvector matrix $\mathbf{\Phi}$ is unique besides a scaling factor and therefore normalized such that $\mathbf{\Phi}^\top \mathbf{M} \mathbf{\Phi} = \mathbf{I}$, where \mathbf{I} is the identity matrix. The modal stiffness matrix $\mathbf{K}_\eta = \text{diag}([\omega_1^2, \dots, \omega_n^2])$ is diagonal and includes the squared eigenfrequencies on the main diagonal. Model order reduction can be conducted by applying the transformation above with a reduced set of eigenvectors $\mathbf{\Phi} = [\boldsymbol{\varphi}_1, \dots, \boldsymbol{\varphi}_{n_r}]$.

2.2 Model with Tension-only Elements

In order to model the tension-only elements properly, an adaption of the linear equations of motion is necessary. A qualitative description of the system's behavior shall make the reader comfortable with the effect before the corresponding equations are given. If tension is applied to a tension-only element of the structure, a linear force-displacement relation is assumed (see Fig. 2) and the system can be described as in 2.1. If a tension-only element is at its initial length (or potentially below), the contribution of this element to the stiffness of the structure vanishes. A two-dimensional visualization is given in Fig. 3. The stiffness k of the i^{th} diagonal element for $i = 1, \dots, n_t$ with n_t tension-only elements is given by

$$k_i(\mathbf{q}(t)) = \begin{cases} k_i, & \Delta l_i(\mathbf{q}(t)) \geq 0 \\ 0, & \Delta l_i(\mathbf{q}(t)) < 0 \end{cases} \quad i = 1, \dots, n_t. \quad (4)$$

The absolute length $\Delta l_i(\mathbf{q}(t))$ of a tension-only element i is calculated via the distance of the two nodes the element is attached to. These nodes are referred to as endpoint nodes 1,2. The initial length of a tension-only element equals the initial distance between these nodes: $l_{i,0} = \sqrt{\Delta \mathbf{q}_{i,0}^\top \Delta \mathbf{q}_{i,0}}$ with $\Delta \mathbf{q}_{i,0} = \mathbf{q}_{i,1,0} - \mathbf{q}_{i,2,0}$, where $\mathbf{q}_{i,1,0}$ and $\mathbf{q}_{i,2,0}$ are the initial positions of the endpoint nodes. In the equation of motion, the DOFs $\mathbf{q}(t)$ represent a relative motion around the equilibrium state. The absolute position of a node is given by $\tilde{\mathbf{q}}_{i,1}(t) = \mathbf{q}_{i,1,0} + \mathbf{q}_{i,1}(t)$ and analogously $\tilde{\mathbf{q}}_{i,2}(t) = \mathbf{q}_{i,2,0} + \mathbf{q}_{i,2}(t)$. The relative displacements of the endpoint nodes are a subset of the DOFs vector $\mathbf{q}_{i,1}(t) \subset \mathbf{q}(t)$, respectively $\mathbf{q}_{i,2}(t) \subset \mathbf{q}(t)$. After determining the absolute position of the endpoint nodes, the direction vector between the two nodes is $\Delta \mathbf{q}_i(t) = \tilde{\mathbf{q}}_{i,1}(t) - \tilde{\mathbf{q}}_{i,2}(t)$. The distance between the nodes equals the absolute length of the tension-only element and can be calculated via the scalar product. Subtracting the initial length yields $\Delta l_i(\mathbf{q}(t)) = \sqrt{\Delta \tilde{\mathbf{q}}_i^\top(t) \Delta \tilde{\mathbf{q}}_i(t)} - l_{i,0}$ for evaluating the inequality conditions in (4). Tension-only elements under small pretension can be treated by adjusting $l_{i,0}$ according to the pretension value.

Based on (4), the stiffness matrix is state-dependent and changes to $\mathbf{K}(\mathbf{q}(t))$. The tension-only elements contribute to the stiffness matrix according to the orange graph in Fig. 2 as opposed to a linear stiffness behavior (Fig. 2 gray). Therefore, the stiffness matrix is reassembled in the FE toolchain every time a tension-only element changes in the sense of (4) [6, 30]. The equation for the model with tension-only elements changes to

$$\mathbf{M} \ddot{\mathbf{q}}(t) + \mathbf{D}(\mathbf{q}(t)) \dot{\mathbf{q}}(t) + \mathbf{K}(\mathbf{q}(t)) \mathbf{q}(t) = \mathbf{F} \mathbf{u}(t), \quad t > 0, \quad \mathbf{q}(0) = \mathbf{q}_0, \quad \dot{\mathbf{q}}(0) = \dot{\mathbf{q}}_1, \quad (5)$$

Figure 2: The force in a tension-only element is depicted over the element length (orange). The element force is zero for the element under compression, and linearly increasing with slope k under tension; linear element for comparison (gray).

Figure 3: 2D-Sketch with tension-only elements in orange and common linear elements in black. a) Undisplaced structure and b) structure displaced by a force F , which leads to a tension-only element under compression, marked with a dashed line.

with the damping matrix $\mathbf{D}(\mathbf{q}(t)) \in \mathbb{R}^{n \times n}$. It is derived according to (2), where the state-dependency is inherited by $\mathbf{K}(\mathbf{q}(t))$. As can be seen in (5), the mass matrix is equivalent to the linear version because tension-only elements still contribute inertia to the structure. Any effects of a changed mass distribution are assumed to be small and therefore negligible.

3 Proper Orthogonal Decomposition and Model Order Reduction

The kind of systems, introduced in section 2.2, incorporate many local nonlinearities in form of tension-only elements. However, looking at the overall system, almost linear oscillation behavior is observed that motivates the application of proper orthogonal decomposition (POD) for model order reduction and generation of a model for control design. POD is a method to achieve a low-dimensional approximation of a high dimensional space [4]. After the theorem of Eckart-Young-Mirsky, POD is the best low-rank approximation [9, 25] for this task. It is also referred to as Karhunen-Loeve transformation or principal component analysis and is well-established in statistical analysis [24].

The POD is realized by the singular value decomposition, also referred to as the generalization of the eigenvalue problem (see 2.1.1) for rectangular matrices. Performing the singular value decomposition, a general matrix $\mathbf{A} \in \mathbb{R}^{n_1 \times n_2}$ is factorized in three matrices

$$\mathbf{A} = \mathbf{V} \mathbf{\Sigma} \mathbf{W}^* \quad (6)$$

where $\mathbf{V} \in \mathbb{R}^{n_1 \times n_1}$ is a unitary matrix and the columns are the left eigenvectors of \mathbf{A} . $\mathbf{\Sigma} \in \mathbb{R}^{n_1 \times n_2}$ is a diagonal matrix with non-negative real numbers $[\sigma_1, \sigma_2, \dots, \sigma_{\min(n_1, n_2)}]$ on the diagonal, called the singular values of \mathbf{A} . $\mathbf{W}^* \in \mathbb{R}^{n_2 \times n_2}$ is the conjugate transpose matrix of the unitary matrix \mathbf{W} and the column vectors of \mathbf{W} are the linear independent right eigenvectors of \mathbf{A} . If \mathbf{A} is quadratic, the singular values are equal to the squared eigenvalues.

The singular values quantify the importance of a corresponding POD vector for the data set. Therefore, the column vector corresponding to the highest singular value has highest share in the approximation. Selection of $n_r < n$ eigenvectors in the orthonormal POD basis to transform the nonlinear system can be quantified by $\sum_{k=1}^{n_r} \sigma_k^2 / \sum_{k=1}^n \sigma_k^2 > \kappa$, where κ is a defined tolerance. This fraction is referred to as the cumulative energy captured by n_r modes [34]. A physical

interpretation of the POD modes, specifically for mechanical systems, can be found in [10, 20].

POD is a method in model order reduction and can be applied to nonlinear systems. Often, simulation of nonlinear systems is computationally intensive, leading to long simulation times which is even worse in online evaluations for control application. A requirement for the application of POD is the availability of a data set representing the dynamics of a system. In turn, this points out the need of proper data recording. Using the dimensions such that n_2 equals the number of simulation steps and $n_1 = n$, the number of DOFs, the transformation matrix yields $\mathbf{V}_r = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_{n_r}] \in \mathbb{R}^{n \times n_r}$. A POD is conducted on simulated data set of the nonlinear model (5) which leads to a POD basis \mathbf{V} . The system is reduced by means of a reduced POD basis \mathbf{V}_r under the transformation law $\mathbf{q}(t) = \mathbf{V}_r \boldsymbol{\zeta}(t)$, followed by a left multiplication with \mathbf{V}_r^\top , which yields

$$\begin{aligned} \mathbf{M}_r \ddot{\boldsymbol{\zeta}}(t) + \mathbf{V}_r^\top \mathbf{D}(\mathbf{V}_r \boldsymbol{\zeta}(t)) \mathbf{V}_r \dot{\boldsymbol{\zeta}}(t) + \mathbf{V}_r^\top \mathbf{K}(\mathbf{V}_r \boldsymbol{\zeta}(t)) \mathbf{V}_r \boldsymbol{\zeta}(t) &= \mathbf{F}_r \mathbf{u}(t), \quad t > 0, \\ \boldsymbol{\zeta}(0) &= \mathbf{V}_r^{-1} \mathbf{q}_0, \quad \dot{\boldsymbol{\zeta}}(0) = \mathbf{V}_r^{-1} \mathbf{q}_1. \end{aligned} \quad (7)$$

The coordinates of the nonlinear reduced order model are $\boldsymbol{\zeta}(t) \in \mathbb{R}^{n_r}$. The reduced POD basis \mathbf{V}_r is normalized such that $\mathbf{M}_r = \mathbf{V}_r^\top \mathbf{M} \mathbf{V}_r \approx \mathbf{I} \in \mathbb{R}^{n_r \times n_r}$, with the unit matrix \mathbf{I} . Furthermore, the reduced order input matrix is $\mathbf{F}_r = \mathbf{V}^\top \mathbf{F} \in \mathbb{R}^{n_r \times m}$. As can be seen in (7), the nonlinear evaluation is not eliminated by the transformation and must still be conducted in the original dimensions. For reduction of computation time, the model order reduction with a POD basis is useful despite.

3.1 Design Model for Control

For control design, models of usually low dimension are used, such that the main characteristics of the system can be controlled. Therefore, the complexity in control design and the computation effort remain acceptable. In linear control theory, a modal controller is designed based on the primary modes as can be derived from section 2.1.1 [13]. Higher order modes can be neglected due to a high natural damping of these modes and a limited bandwidth of actuators. However, the selection of the primary modes is delicate and is done based on experience as well as practical relevance and the control engineer must be aware of effects like spillover [16, 28]. This model for control design for the nonlinear system is generated similarly to the reduced order model (7), but a different transformation matrix $\mathbf{V}_c \in \mathbb{R}^{n \times n_c}$ is chosen, where $n_c < n_r < n$ and the transformation law $\mathbf{q}(t) = \mathbf{V}_c \boldsymbol{\zeta}(t)$. The input affine system for control design is now written in general state space form with the state $\mathbf{x} = [\boldsymbol{\zeta}, \dot{\boldsymbol{\zeta}}]^\top$

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t)) + \mathbf{g}(\mathbf{x}(t))\mathbf{u}(t), \quad t > 0, \quad \mathbf{x}(0) = \mathbf{x}_0, \quad (8)$$

$$\mathbf{f}(\mathbf{x}(t)) = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{V}_c^\top \mathbf{K}(\mathbf{V}_c \boldsymbol{\zeta}(t)) \mathbf{V}_c & -\mathbf{V}_c^\top \mathbf{D}(\mathbf{V}_c \dot{\boldsymbol{\zeta}}(t)) \mathbf{V}_c \end{bmatrix} \mathbf{x}(t) \quad \text{and} \quad \mathbf{g}(\mathbf{x}(t)) = \mathbf{g} = \begin{bmatrix} \mathbf{0} \\ \mathbf{F}_c \end{bmatrix}. \quad (9)$$

4 CONTROL

A similar behavior between the linearly modeled structure and the nonlinear system is observed. To control nonlinear systems, feedback linearization can be applied, which transforms the system such that a chain of integrators is resulting [11], of which control is fairly simple. This would be an option for the introduced system with tension-only elements, however, due to similarities to linear systems the following approach is proposed. A linearizing input transformation is performed, where the target system is modeled by linear second order equations

of motion. Therefore, the control effort to linearize the system can be kept low because the dynamics of original and target system are similar. The target system is chosen that the desired properties are achieved. A control strategy is applied to the nonlinear system (5) based on the nonlinear model for control design (8).

4.1 Linearizing Input Transformation

In order to control the nonlinear system, a nonlinear input transformation is conducted, which forces the nonlinear system to follow the dynamics of the target system. Under the assumption of local controllability of system (8), a general target system is

$$\dot{\mathbf{x}}(t) = \mathbf{f}_d(\mathbf{x}(t)) + \mathbf{g}_d(\mathbf{x}(t))\mathbf{w}(t), \quad t > 0, \quad \mathbf{x}(0) = \mathbf{x}_0, \quad (10)$$

where a new virtual input $\mathbf{w}(t) \in \mathbb{R}^m$ for the linear target system is defined. For $\mathbf{w}(t) = \mathbf{0}$ the system is required to be stable and show desired decay properties. The target system incorporates desired dynamics and system properties, which are parameters in design. A clever selection of the target system simplifies further control design, e.g. if a linear target system is chosen. The dynamics of the general nonlinear control system (8) are set equal to the dynamics of the target system (10). Solving for the input $\mathbf{u}(t)$ of control system, yields

$$\mathbf{u}(t) = \mathbf{g}^+(\mathbf{x})\left(\mathbf{f}_d(\mathbf{x}(t)) - \mathbf{f}(\mathbf{x}(t))\right) + \mathbf{g}^+(\mathbf{x})\mathbf{g}_d(\mathbf{x}(t))\mathbf{w}(t). \quad (11)$$

If $\mathbf{g}(\mathbf{x})$ is quadratic, the Moore-Penrose pseudo inverse [27] $\mathbf{g}^+(\mathbf{x})$ will be the inverse. This is the case for an equal number of inputs and states, which is generally not valid. Plugging (11) into (8) makes the nonlinear closed-loop system follow the dynamics of the target system. The quality of this approach is highly depending on the pseudo-inverse of $\mathbf{g}(\mathbf{x})$.

4.2 Target System for Mechanical Structures

For the application in structural dynamics, the desired system (10) is chosen as linear second order system in state space form

$$\dot{\mathbf{x}}(t) = \mathbf{f}_d(\mathbf{x}(t)) + \mathbf{g}_d(\mathbf{x}(t))\mathbf{w}(t), \quad t > 0, \quad \mathbf{x}(0) = \mathbf{x}_0, \quad (12)$$

$$\mathbf{f}_d(\mathbf{x}(t)) = \mathbf{A}_d\mathbf{x}(t) = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{K}_d & -\mathbf{D}_d \end{bmatrix} \mathbf{x}(t) \quad \text{and} \quad \mathbf{g}_d(\mathbf{x}(t)) = \mathbf{B}_d = \begin{bmatrix} \mathbf{0} \\ \mathbf{F}_d \end{bmatrix} \quad (13)$$

with $\mathbf{f}_d(\mathbf{x}(t)) \in \mathbb{R}^{2n_c}$ and $\mathbf{g}_d(\mathbf{x}(t)) \in \mathbb{R}^{2n_c}$, where the system still shows the structure of a second order mechanical system and \mathbf{A}_d consists of a desired stiffness and damping matrix $\mathbf{K}_d \in \mathbb{R}^{n_c \times n_c}$ and $\mathbf{D}_d \in \mathbb{R}^{n_c \times n_c}$. The structure of system matrix \mathbf{A}_d is Hurwitz [18] and is therefore stable. For control of the linear target system a linear quadratic (LQ) controller is applied as a state feedback [12, 28].

5 NUMERICAL RESULTS

The introduced methodology is applied to an exemplary high-rise structure. The order reduction over the POD basis is evaluated and the POD modes are interpreted physically. A reduced order simulation model is stated and the performance of the control strategy is illustrated.

Figure 4: Sketch of the high-rise building with tension-only elements (orange) and the DOF for depiction of results (light blue).

Description	Formula sign	Value	Unit
Density	ρ	7850	kg/m ³

Width	w_{vd}	0.15	m
Height	h_{vd}	0.012	m

Table 1: Geometry and material parameters of the structure.

5.1 High-rise Structure

To illustrate the proposed modeling and control strategy, an adaptive high-rise structure is introduced. This structure (Fig. 1) will be built on the site of the University of Stuttgart and consists of 12 stories, which are summarized in 4 modules comprising 3 stories each. The diagonal bracings are tension-only elements spanning over one module, two on each side, which leads to a total amount of 32 such elements (4 modules with 8 diagonals each). The tension-only elements are realized with flat steel. A sketch of the structure is given in Fig. 4 with tension-only elements in orange. All other elements can withstand compression and tension. The columns in the corner of a story are modeled as beams that are connected by horizontal links on the joints. The horizontal ceilings are approximated by links connecting diagonally opposing nodes. All geometry and material parameters can be taken from Tab. 1. The system incorporates 24 actuators, 8 actuators are in the columns of the lower two modules and the remaining actuators are placed in the diagonal bracings. All diagonals in the first module are equipped with actuators and in the second and third module 4 diagonals elements each [16, 35]. For the linearizing input transformation and the control, the actuators in the columns are used because the effect of the nonlinear bracings is examined in this contribution without interference of actuation. This results in a model with $n = 288$ DOF which are distributed over 48 nodes with 6 DOF each. The DOF at the 4 boundary nodes at the bottom are fixed.

5.2 POD Modes

For the determination of the POD modes by means of (6), the 24 actuators are activated successively with a white noise signal to excite the dynamics of system (5). The POD modes are

Figure 5: DOF of node 45 at the top left in x -direction of the original nonlinear model (dashed gray) and reduced order (blue) system.

Figure 6: The POD modes of the nonlinear model (blue) are compared to the linear modal modes (gray). a) 1. order torsion mode, b) 1. order bending mode, c) 2. order bending mode.

analyzed regarding their shape with decreasing singular values. The first POD vector represents a first order torsion mode, followed by two first order bending modes. The two bending modes are reasoned in the symmetry of the structure, where one goes in x -direction and the second one in y -direction. The fourth POD vector is the second order torsion mode before two second order bending modes. The shape of the POD modes already indicates similarities to the linear modal analysis. Therefore, the identified POD modes of the nonlinear system are compared to the modal modes of the structure, modeled as a linear system according to (1), where all diagonals are modeled as links, which can bear tension and compression. The comparison results are depicted in Fig. 6, where the frequencies corresponding to the POD modes are determined by fast Fourier transform from the simulation data. Sorting the eigenmodes by increasing frequencies the order of the linear system's modal modes differs from that of the POD modes. In the linear model, both first order bending modes correspond to the lowest eigenfrequencies, followed by the first order torsion mode, two second order bending modes, two third order bending modes and the second order torsional modal mode. The different order regarding mode shapes and frequencies can be explained by the drastically reduced stiffness of the nonlinear model concerning torsional motions. Due to the ineffectiveness of the stiffness component of the tension-only elements under compression, torsion modes get more important, which is captured by the simulation of the nonlinear model. A comparison of the corresponding normalized mode shapes, however, shows high alignment of the POD modes and the modal modes (Fig. 6). Depicted are a) the first order torsion and b) the first and c) second order bending modes in x -direction. As expected, the alignment decreases for higher mode order. However, the good alignment motivates the application of the introduced control approach with linearizing input.

5.3 Reduced Order Simulation Model

The reduced order simulation model is composed of $n_r = 18$ POD modes. This leads to $\kappa = 99.08\%$, which means that the residual modes contribute less than 1% to the cumulative energy with respect to the data set used for the POD analysis. The approximation quality is

illustrated in numerical results in Fig. 5, where the simulation is conducted with a non-zero initial condition. The time series is depicted for node 45 at the top left in x -direction, which is marked in Fig. 4. This node is selected because the largest displacements are found at the top of the building. The data of the full model is depicted in dashed gray needing 49.9s simulation time and the reduced order model in blue with 7.6s. The reduced order model approximates the dynamics of the full model with high accuracy, thus justifying its use to drastically save simulation time of 84%.

5.4 Control Performance

In a first step, the linearizing input (11) is applied to the nonlinear system with the target system (12) as described in section 4. The eight actuators in the columns of the first and second module are used for the linearizing input and control. The model for control design is of order $n_c = 4$, where the first and the second order bending modes are captured in \mathbf{V}_c . The torsional modes are left out because they are not controllable with the selected set of actuators. This selection is justified due to the specific investigation of the nonlinear effect concerning the tension-only elements and the torsion mode is not excited in this numeric experiment.

The target system's matrix \mathbf{A}_d is chosen such that the desired stiffness matrix $\mathbf{K}_d = \frac{1}{4}\mathbf{K}(\mathbf{V}_c\mathbf{0})$ is equal to a quarter of the nonlinear system's stiffness matrix evaluated at zero. The damping matrix is chosen equivalently to $\mathbf{D}_d = \mathbf{D}(\mathbf{V}_c\mathbf{0})$ with increased coefficients in the Rayleigh damping of $\alpha_{1d} = 0.1$ and $\alpha_{2d} = 0.01$. The target input matrix \mathbf{B}_d is set to \mathbf{g} from (9) since there is no nonlinearity in the input and the input affinity of the system can be preserved. The result is illustrated in Fig. 7, where the reduced nonlinear system is shown in dashed gray and the effect of the uncontrolled linearizing input in dark blue, where both times the same initial condition is applied. The system with linearizing input shows an altered oscillation behavior with a decreased oscillation frequency. Due to the increased damping coefficients of the linear target system, the nonlinear system with linearizing input already express a higher damping rate. According to the chosen target matrix, the frequency of the system with linearizing feedback is not a quarter of the original system's frequency because the nonlinearity already leads to decreased oscillation frequencies. Compared to simulating purely the linear target system, small deviations are visible due to the residual modes. With application of the LQ controller the damping of the system is increased further which proofs the effectiveness of the linearizing input transformation. The control algorithm as described in section 4 transforms the nonlinear system to a desired target system with the designed closed-loop dynamics. Thus, control design is simplified drastically through the nonlinear input transformation of such nonlinear systems.

6 CONCLUSION

In this contribution, the nonlinear equations of motion for tension-only elements were derived. A POD was conducted, which captures the main characteristics of the nonlinear system. Properties were compared to the nonlinear system evaluated at zero, where similar behaviors were discovered. The mode shapes of the POD and the eigenmodes are almost equal, whereas the frequencies have changed. The nonlinear system was reduced to achieve acceptable calculation times with high model accordance at the same time. The effect of nonlinearities from tension-only elements have high impact on the systems behavior and need to be considered in modeling. A low dimensional model for control and a linearizing input transformation for the nonlinear model were derived, which drives the system states according to the dynamics of a

Figure 7: The input-transformed nonlinear system with LQ-controller (light blue) in comparison to the input-transformed nonlinear system without additional feedback control (dark blue) and the original open-loop nonlinear system (gray). The displacement in x -direction of node 45 at the top left is depicted.

linear target system. With this linearizing input, the nonlinear system can simply be controlled by controlling the linear target system, where the wide methods of linear control theory can be applied. The results promise applicability to structures with tension-only elements.

For further research, any other target system or controller can be chosen to achieve a different closed-loop behavior. An integration of actuators in the tension-only elements can be useful to further generalize this method. After construction of the experimental high-rise structure is finished, the presented algorithm will be applied.

Key words: Smart Structures, Wind Energy, Bend-Twist-Coupling, Flaps, Slats

Abstract. Within the frame of the Smart Blades and the SmartBlades2 projects, different technologies for developing smart rotor blades for wind turbines have been developed and are still being studied and tested. These cover the three following technologies: bend-twist coupled rotor blades; rotor blades with trailing edge flaps and rotor blades with leading edge slats. In addition, cross-technology topics that need to be considered for successfully implementing all three technologies as well as for evaluating their performance within a wind turbine system are being studied.

This paper will present an overview of the results of the project focusing in the following:

- Rotor blades with geometrical Bend Twist Coupling (BTC): summary of the blade design and manufacturing processes, summary of the results of modal tests, and selected preliminary results of field tests (on a turbine) with an introduction of a specially developed blade tip sensor for the measurement of the torsional deformation angle at the blade tip.
- Rotor blades with trailing edge flaps: summary of the concept and design of the demonstrator as well as fatigue tests, summary and highlights of the controller design activities, overview of the possibilities for upscaling as well as for developing alternative concepts.
- Rotor blades with leading edge slats: summary of three different concepts and the available results regarding wind tunnel tests as well as controller development with an emphasis on an active and a passive concept.
- Introduction to the evaluation method that will be used for evaluating the different technologies.

1 INTRODUCTION

The use of renewable energies is constantly growing and one of the fastest expanding sectors is wind [1]. In order to satisfy the resulting demand, the tendency in the wind energy sector is going towards building larger rotor blades [2], since the electrical power output that can be generated by a turbine is proportional to the square of the blade's radius. However, increasing the blade's size also means rapidly increasing their weight, proportional to the cube of the blade's radius, and substantially increasing the critical loads at the blade's roots [3].

The Smart Blades and SmartBlades2 projects, funded by the German Federal Ministry for Economic Affairs and Energy (BMWi), explore three different approaches for alleviating these loads increments: using bend-twist coupled rotor blades, using trailing edge flaps and, finally, using leading edge slats. This paper presents an overview of the proposed concepts as well as selected results of the first tests.

2 BEND-TWIST-COUPLED ROTOR BLADES

The first concept focuses on a passive principle that uses geometrical bend-twist coupling. The geometry of the blades allows them to bend and simultaneously twist increasingly across their span when strong wind and loading conditions are present, such as during gusts. This reduces the wind exposed area and angles of attack of the blades, leading to an overall loading reduction. This helps to prevent damage while keeping a high energy yield [4].

2.1 Design and manufacturing

One method for reducing loads along a rotor blade is sweeping. Local sweep variations can decrease heterogenic aerodynamic loading conditions caused by higher loads from effects such as gusts. A parametric study of the blade geometry for an 80 m blade was realized during the Smart Blades project, aiming to achieve an optimal sweep for bend-twist coupling. The parameters taken into account were the vertical displacement of the tip to the pitch axis, the distance of the sweep starting point from the blade root and the projected length of the blade at the pitch axis (Figure 1–Top). Aeroelastic simulations under quasi-static inflow conditions were performed in a discretized blade model (Figure 1–Bottom) to investigate the coupling behavior. A section coupling coefficient calculated by dividing the torsional moment over the flapwise bending moment was introduced to account for the structural coupling effects [5].

Figure 1: Top: Parameters for the determination of sweep; Bottom: Discretized model of the straight and swept blade [5]

The results were scaled down to a 20 m blade design and focused on manufacturability [6]. At the end of Smart Blades and based on the new design, a Glass Fiber Reinforced Plastic (GFRP) mold with an integrated heating system was built and, during SmartBlades2, used for the production of four blades. The manufacturing process based on a prefabrication concept and followed a semi-shell sandwich construction method: two half shells were individually produced and then fused together to form each blade. Some internal components, such as the spar, consist of sandwich panels that were manufactured separately in a vacuum infusion process and then cut to the designed shapes. Other components, such as the flange, are made of GFRP. For their manufacturing each inlay was pre-cut using a CNC cutter and manually laid in and infused in the appropriate area of the shell tool. For ensuring positioning precision and monitoring the infusion, a laser and a thermographic system were respectively used. The half shells were produced once the prefabrication components were ready. The flange inlays were positioned first and then the two layer outer laminate was laid up. The spar caps and sandwich material, consisting of balsa wood and foam, were then integrated. Once the inner laminate of the blade, which also comprised two layers, had been laid up, the blade halves were vacuum-infused. The final prefabricated part, the base, was then positioned in the shell of the suction

side. In a final step, the pressure and suction sides were bonded to form the finished rotor blade [4].

2.2 Modal tests overview

Once manufactured, all blades were subjected to modal testing and their eigenfrequencies and damping were determined under two different boundary conditions: clamped to a test rig (blade #1) and free-free, hanging on elastic suspensions (all blades). In addition, the modal shapes were measured using a high sensor density array attached to the blades' surfaces. The acquired data is being used for updating self-developed finite element models. To choose an appropriate distribution of the measurement points and excitation locations, a pretest analysis incorporating an FE shell model was carried out. During the modal tests, response signals were recorded via uniaxial accelerometers and force input was provided either by an impulse hammer or through electrodynamic shakers. Table 1: summarizes the eigenfrequency and damping values resulting from the two different test scenarios. Global modes are sorted from lower to higher frequencies as they appear for a clamped rotor blade. The structural dynamic similarity of the three blades can be recognized in the free-free tests results. Furthermore, local eigenforms illustrating cross-sectional vibrations attributed to the deflection of the blade shells could also be identified. Compared to the global results, the local modes correlate poorly with FE predictions [7]. In the forthcoming progress of the project the acquired data will serve as a basis for updating the FE model towards modal parameters.

Table 1: Eigenfrequencies and damping values of blade #1 being clamped to a test rig and arithmetic averages of blades #2 - #4 from free-free tests.

no.	mode description	test rig		free-free		
		eigenfrequency in Hz	damping in %	eigenfrequency in Hz	damping in %	coefficients of variation in %

2.3 Wind turbine tests

In addition to the modal tests, test rig tests (not within the scope of this paper) were performed and turbine tests are being performed. The test rig tests covered extreme loading

testing for different static and dynamic conditions, including fatigue, and were accomplished successfully. The results allowed proceeding towards the turbine tests. The main goal of these is to measure the behavior and performance of the rotor blades under real conditions. Several sensors have been integrated in the blades' structure and on their outer skin to measure their behavior in detail, including strain gauges, torsion sensors, digital image correlation (DIC) foils and a Light Detection and Ranging (LiDAR) system. The Controls Advanced Research Turbine 3 (CART 3) [8] and the National Wind Technology Center (NWTC) [9] site of the National Renewable Energy Laboratory (NREL), where the tests are being performed, are also equipped with a wide range of sensors, allowing obtaining more detailed measurements of the turbine itself as well as of the surrounding environmental conditions.

2.4 Tip pitch Sensor

Even though the blades are instrumented with strain gauges and equipped with an optical deformation measurement system using a stereo camera system, detecting torsion deformation near the tip remains challenging. Strain gauges only detect local strains. Connecting them in Wheatstone bridges and proper calibration allows the measurement of bending and torsion moments at discrete radial positions. To derive the torsion deformation at the tip (θ_{tip}), the moment distribution ($M_t(x)$) needs to be inter- and extrapolated from the discrete measurement locations, divided by the distribution of torsional stiffness ($GI(x)$) and then integrated over the length of the blade - equation $\theta_{tip} = \int_{x_{root}}^{x_{tip}} \frac{M_t(x)}{GI(x)} dx$

(1).

$$\theta_{tip} = \int_{x_{root}}^{x_{tip}} \frac{M_t(x)}{GI(x)} dx \quad (1)$$

This procedure is prone to uncertainties and needs several measurement points as well as a very precise a priori knowledge of the stiffness distribution to deliver accurate results. The optical deformation measurement system installed within the blades cannot measure along the whole length either. The taper of the inner cross section and the elastic deformation of the blades limit the optical markers observability and restrict the measurement range. To solve these problems, an additional sensor capable of detecting torsional motion was developed and placed near the blade tip. The solution is based on a concept developed for active twist helicopter rotor blades [10][11] and was adapted to wind turbine rotor blades.

The new sensor detects rotational accelerations around one rotation axis. An inertia mass is connected to the blade tip via a flexible element. Under acceleration, the mass generates inertia moments that deform the flexible element. The flexible structure is soft in torsion and stiff for all other deformations. The deformation of the flexible element is captured by semiconductor strain gages, which are connected in a Wheatstone bridge that compensates for

temperature and suppresses sensor signals due to unintended deformations (e.g. bending). A tailored design of the inertia mass in combination with static accelerations in the centrifugal field of the rotor allows the detection of static pitch angles. The concept uses the propeller moments that occur in the centrifugal field (Figure 2).

The mass connected to the flexible element at point P consists of two punctual masses m . When the rotor spins with the frequency f_{rotor} , the force F is necessary to counteract the centrifugal force. F has two components: one parallel to the blade, F_{parallel} , and one orthogonal to the blade, $F_{\text{orthogonal}}$. If the pitch angle of the inertia mass, θ_{mass} , is zero, both mass points lie on a plane that is orthogonal to the rotor axis. Consequently, the orthogonal components of the forces do not generate any moment around P. However, if θ_{mass} increases, the mass points move out of the plane that is orthogonal to the rotor axis and contains P, the $F_{\text{orthogonal}}$ components generate a moment around P. This propeller moment deforms the flexible element even in case of static pitch angles.

Figure 2: Formation of propeller moments

The location of the sensor near the blade tip brings an increased risk for lightning strike, meaning an electrical conductive connection between the sensor and the blade root needs to be avoided. To fulfill this requirement the sensor was connected with both a fiber optical data and energy transmission system. The system consists of a class 4 laser that couples 2 W of optical power into a fiber optic cable. At the other end of the cable a photovoltaic power converter delivers approx. 500 mW of electrical power, sufficient to operate the sensor and the module that transmits the data to the blade root. Figure 3 shows the major components of the sensor as CAD model and during installation.

Figure 3: Sensor and its components (left), sensor during integration (right)

The flexible element (1) connects the mass (2) with the blade tip. To protect the sensor from foreign objects, the sensor is capsuled in a housing (3). The photovoltaic power converter (4) provides the power supply for the circuit board that drives the sensor (5) and the data transmission module (6). The latter two are capsuled by the electronic box (7).

3 TRAILING EDGE FLAPS

The second smart blades concept focuses on using trailing edge flaps for active flow control. The flaps function in a similar way to aircraft ailerons, components used to control the aircraft's movement. Even though the aerodynamic effects of trailing edge flaps are very similar, it is important to consider other design aspects for wind turbine rotor blades, such as the rotational operating conditions, maintenance and the environment at low altitudes [3].

3.1 Design concept and demonstrator

A flexible trailing edge structure design was chosen as a solution for the trailing edge flap and was developed during the Smart Blades project. The concept uses a rib like structure with a central support (Figure 4). By pushing or pulling, as the forces F_1 and F_2 show, the structure can be deformed and the desired flap deflection can be achieved, which allows to influence the airflow [3].

Figure 4: Flexible trailing edge concept [3]

Since the structure is flexible and is destined to morph under aerodynamic loads, the effect of aerodynamic pressure acting on the flap's surface needs to be considered in the structural design phase. An iterative process covering structural and aerodynamic factors was followed. The first step consisted on the creation of a structural model, followed up by the calculation of the actuation induced deflections. Once this done, the aerodynamic pressure distribution of the deflected flap was calculated and input back to the structural model to recalculate loading. The structure was then re-evaluated and optimized. The process stopped when the deflection values remained constant, reaching structural and aerodynamic stability [3].

3.2 Testing of the trailing edge

Three types of tests of the trailing edge flaps have taken place: laboratory tests to analyze its general behavior, fatigue tests and rotational test-rig tests.

The main goal of the laboratory tests was to validate the developed FE models and to demonstrate that the structure could achieve the desired deflection. Angles between -8° and $+12^\circ$ could be measured via DIC. The differences between the deflections expected from the simulations and the experimental results are small (Figure 5 – left). A similar behavior was measured for strain values (Figure 5 – right) [3].

Figure 5: Left: Comparison of simulated and measured trailing edge deflection angle; Right: Comparison of simulated and measured strains [3]

To test the behavior of the structure under realistic conditions, a second demonstrator was designed and built for a measurement campaign on the rotational test bed of the Technical University of Denmark (DTU) (Figure 6). Several sensors were implemented on the demonstrator, including accelerometers, strain gauges and pressure taps. The demonstrator was installed on an adapter airfoil section which was then mounted on DTU's rotational test bed. The goal of the campaign was to measure aerodynamic performance, as well as relevant environmental effects, such as turbulences and centrifugal loads [3]. The measurement campaign was successful and the aerodynamic effects of the flap could be measured. The

results of these tests are not within the scope of this paper.

Figure 6: Left: Trailing Edge mounting on Airfoil Section; Right: DTU's rotational test bed with demonstrator mounted [3]

3.3 Flap Controller design and tests

To study control mechanisms for the flap, a model of a movable trailing edge with a 10 m spanwise length was introduced on the blades of a generic three-bladed 7.5 MW wind turbine model with 80 m blades [12]. The chord length of the trailing edge flap is 25 % of the blade's chord length, with 5% flexible and 20% rigid. Deflection angles vary between $\pm 10^\circ$, with a maximum angular rate of $20^\circ/\text{s}$. The pitch angular rate is limited to $3^\circ/\text{s}$ for Individual Pitch Control (IPC). Due to the rotational sampling effect, the blade samples inhomogeneous wind fields with a frequency determined by the rotor speed and the dynamic blade loads are concentrated at multiples of the rotational frequency. IPC is capable of reducing once per revolution (1P) loads [12].

A feedforward-feedback control structure based on the H^∞ loop shaping method [14] was chosen for the study, with a special focus on uncertainty quantification and a robust control performance [15]. Since the flap/blade area ratio is small, the operation is close to the actuator limits and needed to be considered in the controller structure [16]. A series of algorithms with the same baseline controller (REF) for collective pitch and torque control were developed. All additional control loops used flapwise blade root bending moments as a feedback signal: a) individual pitch control acting on 1P (IPC 1P), b) individual flap control acting on 1P (IFC 1P), c) individual flap control acting on 2P (IFC 2P), d) individual flap control acting on 1P and 2P (IFC 1P 2P), and e) individual pitch control acting on 1P and individual flap control acting on 2P (IPC 1P IFC 2P). Time domain simulations were carried out between cut-in wind speed (3 m/s) and cut-out wind speed (25 m/s), using the high fidelity aero-elastic simulation code HAWC2 [17] with the ATEFlap dynamic stall engineering model[18]. The turbulent wind conditions were chosen in accordance with [19], where the turbulence intensity is 41%

at 3 m/s and 15% at 25 m/s. Wind shear and tower shadow were also taken into account and no yaw misalignment was considered. For each wind speed, six 10-minute simulations were carried out, each under different turbulent wind speeds. 1 Hz damage equivalent loads (DEL) were calculated. The obtained DEL were weighted with the Rayleigh probability function with an average wind speed of 10 m/s to determine the lifetime damage equivalent loads.

The power spectral density (PSD) of the flapwise blade root bending moment for the hub height mean wind speed of 13m/s is plotted in Figure 7 (left). It can be seen that 1P and 2P harmonics are the most dominant load components and that all control algorithms are capable of reducing the desired frequencies. Furthermore, the highest load reduction at 1P is achieved with individual pitch control, since it can influence the entire blade. Active flap control only influences parts of the blade and achieves lower reductions at 1P. However, due to its higher dynamics, it is more suitable for reduction of 2P load components. Because of the limited surface and the actuator limitations, the active flap control targeting both 1P and 2P load components (IFC 1P 2P) does not lead to any satisfactory load reductions. The best results can be achieved with IPC targeting 1P loads and individual flap control targeting 2P loads (IPC 1P IFC 2P). The same is valid for the reduction of lifetime damage equivalent loads. Figure 7 (right) summarizes these results for blade root flapwise bending moment, hub yaw and tilt moments and tower top and tower bottom fore-aft and side-side bending moments.

Figure 7: Left: PSD of the flapwise blade root bending moment under different algorithms. Right: Reduction of lifetime damage equivalent loads

3.4 Upscaling Flaps

The SmartBlades2 project is also investigating flap upscaling concepts for their application in larger wind turbines. Different simulation models have been developed and cover overall blade simulation as well as structural optimization. They are also capable of integrating the flap structure and perform sizing and analysis processes. One of the goals of these simulations, as an example, is to find a concept that enables load transmission around the flap

cutout. Some results with this focus are presented in Figure 8. As it can be seen, in comparison to the reference blade [12], the second main spar is shifted in trailing edge direction to the cutout and serves as a connection spar for the flap. The flap cutout lays between 66 m and 75 m in spanwise direction and has a 30% profile depth. Even though the total blade weight increases from 21,7 t to 24,5 t under this configuration, the flap-wise deflection and the induced twist decrease respectively from 11.06 m to 9.95 m and from $0.65^\circ/2.09^\circ$ to $0.61^\circ/-1.54^\circ$. The diminishing values can be explained by the spar cap's area enlargement in blade tip direction. By shifting the rear spar towards the rear edge flap, the chordwise position changes from 40% to 65% of the chord. The absolute spar cap area is therefore increased, leading to a higher flapwise and torsional stiffness and an increment in the overall blade mass. Since the present study does not consider flap aerodynamic forces and moments and the role of the flap is to reduce aerodynamic loads, the total weight could be reduced by considering the complete set of loads.

While this study focuses on the structural aspects, aspects such as costs need to be considered for further development: the total cost of the flap itself and its control mechanism must be lower than the cost reduction that can be achieved by material and weight savings.

Figure 8: Blade design for the 80m Smart Blade (IWT 7.5 MW) with flap cut-out

3.5 Alternative multistable flap concept overview

Recently, there has been an increased interest in multistable structures. These structures are characterized by two or more stable states with distinct geometrical shapes [20][21] and can remain in these states without requiring any external energy or force input. Force or energy is only required to snap from one shape to another.

A rectangular bistable plate capable of yielding a curved and a flat shape was designed as

an alternative concept for a morphing flap based on [22][23]. The design ensures that the edges of the two stable shapes remain as flat as possible in order to facilitate the flap's embedding. Two sets of actuators were placed on top and bottom of the plate to enable snap-through and snap-back. A nonlinear FE analysis was performed to simulate the proposed concept and a multi-objective non-gradient based optimization was carried out to find the optimal location of the actuators. The objectives were to minimize the snapping voltages while maximizing the curvatures in order to maximize the morphing action. A separate FE analysis was carried out on the optimized rectangular plates to introduce thermal residual stresses. As the plate cools down, it displays a curved stable shape generated by the residual stresses. This curvature defines the flap's deflection angle. The cooled structure can be embedded in its curved form as a deflected flap. Once the voltages are applied to the actuators, strains develop on the plates and they snap to the neutral configuration. When voltage is removed, the flap maintains its new shape. The main advantage of this multi-stability approach is that it obviates the need for a continuous power supply, which is often required in conventional actuation methods.

4 LEADING EDGE SLATS

The third approach for load reduction being investigated within the projects is the use of leading edge slats, particularly for their influence on the aerodynamic behavior of the blades under turbulent inflow conditions. Since turbulences happen at small time scales and because of the large inertia of the blade, turbulences cannot be handled by common pitch control systems. When implemented, these devices allow the airfoil to operate at higher angles of attack, improving its aerodynamic performance compared to an unequipped wind turbine and also help the turbine system to react better against sudden wind changes [24]. Three approaches for this kind of system are being considered: an active, a passive and a rigid one. The active leading edge, as the name says, is actively controlled by a motor. The motor can move the slat in or outwards according to the wind conditions and so change the angle of attack experienced by the blade. The passive concept automatically moves from its retracted to its deployed position by only using the present aerodynamic loads. Finally, the rigid concept stays in a constant rigid position. The gap between the blade and the slat is what allows improving the overall flow conditions.

4.1 Slat controller design and tests

Turbulent wind tunnel tests of a deformable active slat were performed to study the effects of the slat on the blade damage equivalent load due to fast local inflow angle fluctuations [25]. The gap size between the slat trailing edge and the main body of the airfoil could be varied by moving the slat. The aim of the work was to characterize the active slat and to

gauge its initial capabilities under the influence of sinusoidal inflow conditions. It was observed that varying the gap size has an influence on the aerodynamic polars of the airfoil: different aerodynamic coefficients for the same angle of attack could be achieved by moving the slat to different positions and modifying the gap size (Figure 9).

Figure 9: Static lift coefficients C_L for laminar inflow with $Re = 0.6 \times 10^6$ for different gap sizes g_s compared to the clean airfoil without slat [25].

The airfoil was exposed to an inflow with sinusoidal variation of the angle of attack at 5Hz. The amplitude of the inflow angle variation was of 3° . A “TIM control” (Timed Inflow-angle-coupled Motion control) strategy was developed to reduce the resultant fluctuating load. This involved the synchronized variation of the gap size with the wind tunnel’s active grid motion. Measurements for different phase shifts between slat motion and inflow angle fluctuations were performed and as much as 20% of the standard deviation of lift force fluctuation could be reduced compared to the case where the slat wasn’t deployed (Figure 10).

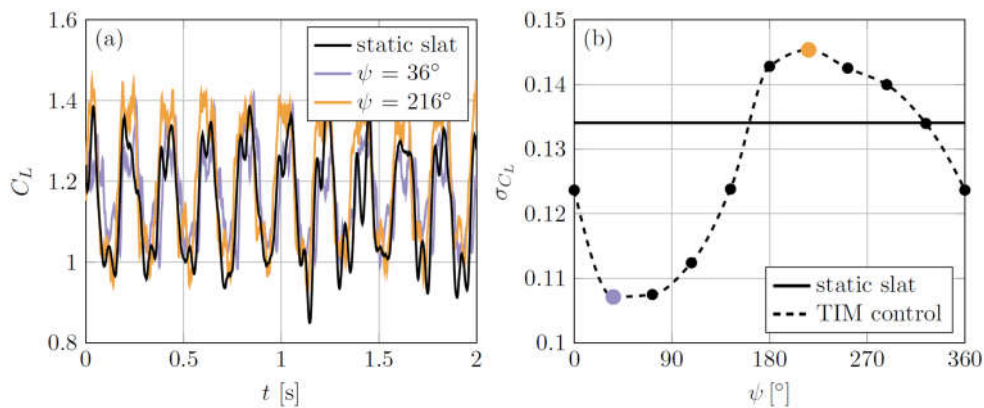

Figure 10: Lift coefficients C_L time series for static slat and TIM controlled slat with phase shifts $\psi = 36^\circ$ and 216° (a) and standard deviation of lift coefficient σ_{C_L} of static slat and TIM controlled slat for different ψ with inflow angle fluctuations (b) [25]

5 TECHNOLOGIES' EVALUATION CONCEPT AND PERSPECTIVES

To compare the performance of the different smart blades technologies, a detailed evaluation is being carried out throughout the project and an economical and a technical assessment according to VDI 2225 [26] is being performed.

The economic performance (P_e) of a technology is based on a comparison of the leveled cost of energy. The included projected costs are calculated using detailed cost models for the reference rotor blade, technology add-ons and the reference wind turbine itself. This way additional material, labor and investment costs as well as differences in annual energy production are taken into account for each technology. Furthermore cost differences occurring from altered operation and maintenance schemes are estimated and implemented in the cost model.

The evaluation of the technical performance (P_t) is done in a utility analysis consisting of 44 criteria, e.g. load reduction, rotor blade mass and reliability. The assessment of the criteria is conducted using customized functions which correlate the respective result with a specific utility value. The resulting utility value is weighted, whereat the weight and the assignment of utility values to certain results are based on a questionnaire handed out to all project partners.

In order to compare the economic and technical performance of the technologies visually P_e and P_t can be normalized and plotted in a diagram as shown in Figure 11.

Figure 11: Exemplary visualization of the technical performance, P_t , and economical performance, P_e , of a technology.

So far, each technology has proven its potential within the expected range of the numerical models. In the meantime, validation experiments, such as a field test at the NREL CART3 wind turbine (Section 2.3), are carried out to confirm the results.

11 CONCLUSIONS

Three different approaches for reducing loads in wind turbine blades are being investigated: bend twist coupling, trailing edge flaps and leading edge slats. All three approaches have proven their potential at different scales and under different testing scenarios, such as in test rigs or wind tunnel tests, however further concept development and larger scale tests still need to be performed in order to be able to provide an accurate evaluation of the technologies, especially concerning factors relevant to the industry, such as costs and upscaling. Future work will focus on the detailed results of the projects' tests as well as on the concepts' detailed evaluation based on these results.

AKNOWLEDGEMENTS

Abstract. Tensegrity structures are self-stressed frameworks composed of elements in compression and elements in tension. Their stability is attributed to a state of self-equilibrium in the system. Tensegrity structures are thus statically indeterminate. Many tensegrity systems are also kinematically indeterminate including motions other than the rigid-body motions that can occur without changes in their element lengths (infinitesimal mechanisms). Since not change in element lengths are required, infinitesimal mechanisms have been identified as advantageous control paths. Although tensegrity systems have been proposed for active applications in science and engineering, existing form-finding and design methods do not address or provide any insight regarding sensor and actuator placement in tensegrity structures. In this paper, self-stress and infinitesimal mechanisms are investigated through cellular morphogenesis to identify appropriate sensor and actuator placement strategies.

1 INTRODUCTION

Tensegrity describes a system composed of elements in tension (cables) and compression (struts) in stable state of self-equilibrium [1-2]. Although the concept originates from art work of Kenneth Snelson, it quickly found applications in science, engineering and architecture [3-6]. Tensegrity structures are materially and mechanically efficient structures that can integrate sensors and actuators within their structural elements [2]. They are thus especially advantageous for active applications. However, in most applications, sensors and actuators are placed in tensegrity systems based on engineering judgement resulting to solutions that are closely related to specific applications and contexts. Sensory applications have employed both dynamic and static measurements for structural identification and damage identification in tensegrity structures [7-10], while adaptive application using both active struts and active cables have been proposed [11-13]. Active struts allow tensegrity structures to be stiff for a limited range of configurations, while active cables enable them to remain stable and stiff throughout large shape transformations [14]. Moreover, shape transformations along the directions of infinitesimal

mechanisms (displacements that can occur without changes in the element lengths) have been identified as ideal motion-control paths as no element deformation is required [15]. This paper explores cellular morphogenesis, a bio-inspired generative process for the combined topology identification and form finding of tensegrity structures, as a strategy for identifying advantageous sensor and actuator placement solutions in active tensegrity structures.

2 CELLULAR MORPHOGENESIS

De Guzman and Orden [16] proved that tensegrity structures can be decomposed into elementary units (cells) defined as the complete graphs on $d+2$ nodes with d being the space dimension. Figure 1 illustrates the topology of three-dimensional tensegrity cells. Tensegrity cells have one self-stress state and no infinitesimal mechanism. Aloui et al. [17-18] analytically described the self-stress of tensegrity cells based on their topology and nodal coordinates. Tensegrity structures can thus be seen as multicellular organisms composed of tensegrity cells. Furthermore, in an analogy with biological organisms, starting from a tensegrity cell more complex tensegrity structures can be generated through the multiplication mechanisms of cellular adhesion and fusion. Aloui et al. [17-18] studied the effects of adhesion and fusion on the self-stress of a tensegrity structure being generated through cellular multiplication. They showed that a basis of the self-stress space can be analytically constructed based on the cell topology. Moreover, they showed that with adhesion that represents the gluing of two cell graphs along one or more shared edges and vertices, the number of self-stress states in the composing structure increases, while with fusion which is the removal of one or more of the shared elements between the two cells the number of self-stress states in the composing structure decreases. Consequently, the resulting basis reflects a vector collection of the self-stress states of the constitutive cells and stable sub-structures resulting from their interaction having thus a direct physical interpretation with each state reflecting the contribution of a sub-system of the structure.

Figure 1: Three-dimensional tensegrity cells

The Simplex (or Triplex) is perhaps the most well-known three-dimensional tensegrity structure. The structure includes 6 nodes, 9 elements in tension and 3 elements in compression in an equilibrium configuration geometrically described by a twisted prism consisting of two equilateral triangular bases rotated by $\frac{\pi}{6}$. Figure 2 illustrates the cellular morphogenesis of the

Simplex as the fusion of tensegrity cells ABCDE and BCDEF, and the removal of elements BD and CE. The combination of the two cells results first into a structure with two self-stress states and no infinitesimal mechanisms which with the removal of elements BD and CE leads to the Simplex structure. The removal of elements BD and CE decreases the number of self-stress states to one creating also one infinitesimal mechanism. The self-stress in the Simplex can thus be obtained through cellular multiplication by identifying a combination of self-stress components that set the self-stress in the elements to be removed equal to zero [19].

Figure 2: Cellular morphogenesis of a Simplex (dashed lines illustrate removed elements)

The removal of the edges BD and CE during the fusion of the two cells that compose the Simplex introduces an infinitesimal mechanism (Figure 3). This non-trivial infinitesimal mechanism can be described by a direction that is orthogonal to the trivial mechanisms. For a Simplex with unitary height and a triangular base with edge length of $\sqrt{3}$, the direction of the infinitesimal mechanism is described by the nodal displacements:

$$\begin{aligned} \vec{d}_A &= \begin{bmatrix} 0 \\ 1 \\ -0.5 \end{bmatrix} & \vec{d}_B &= \begin{bmatrix} -\sin(\frac{2\pi}{3}) \\ \cos(\frac{2\pi}{3}) \\ -0.5 \end{bmatrix} & \vec{d}_C &= \begin{bmatrix} -\sin(\frac{4\pi}{3}) \\ \cos(\frac{4\pi}{3}) \\ -0.5 \end{bmatrix} & \vec{d}_D &= \begin{bmatrix} \sin(\frac{\pi}{6}) \\ -\cos(\frac{\pi}{6}) \\ 0.5 \end{bmatrix} & \vec{d}_E &= \begin{bmatrix} \sin(\frac{\pi}{6} + \frac{2\pi}{3}) \\ -\cos(\frac{\pi}{6} + \frac{2\pi}{3}) \\ 0.5 \end{bmatrix} & \vec{d}_F &= \begin{bmatrix} \sin(\frac{\pi}{6} + \frac{4\pi}{3}) \\ -\cos(\frac{\pi}{6} + \frac{4\pi}{3}) \\ 0.5 \end{bmatrix} \end{aligned} \quad (1)$$

Figure 3: Illustration of the nodal directions of the infinitesimal mechanism in a Simplex

3 SENSOR PLACEMENT AND SELF-STRESS IDENTIFICATION

Structural identification and thus sensor placement in tensegrity systems starts with self-stress identification. The self-stress w in a tensegrity structure corresponds to a solution of the equilibrium in the absence of external loads:

$$Aw = 0 \quad (2)$$

where A is the equilibrium matrix [20]. The set of possible solutions to equation (1) is given by the nullspace of A . The vectors of the basis given by the nullspace of A reflect the self-stress states of the structure and can be grouped to compose the self-stress matrix $= [w_1 \ w_2 \ \dots \ w_s]$ that is by definition full rank. The self-stress in the structure is always a linear combination of the self-stress states. This gives:

$$w = W\alpha \quad (3)$$

where α is a vector of s real coefficients and s is the dimension of self-stress space. Since matrix W is full rank, determining the vector α requires minimum s self-stress values. Consequently, the number of sensors required to characterize the self-stress in a tensegrity structure corresponds to its number of self-stress states s . Following the principles of structural morphogenesis, this number corresponds also to the minimum number of constitutive unicellular sub-structures (cells and stable sub-structures resulting from their interaction) composing the structure as each cell and sub-system composing the structure have one self-stress state. Consequently, for the Simplex, one sensor is enough to characterize its self-stress assuming that the nodal positions are known. The method can be extended for structural identification and damage assessment [21].

4 ACTUATOR PLACEMENT AND CONTROL

Tensegrity structures can be actuated through the integration of active elements (struts and/or cables) with the actuation configuration (number and placement) depending on the topology of the system and the desired change in shape or behavior. However, for applications that require large changes in the length of the elements (large nodal displacements), cable actuation is typically preferred [14]. With cable actuation, a given set of nodal displacements in tensegrity structure can be obtained through a set of cable-length changes applied on different groups of cables. De Guzmán and Orden [16] proved that a node in a tensegrity system in general position can be in a state of self-equilibrium if and only if it has at least four incident members. Consequently, nodal displacements can be expressed as a combination of the change in length of a set of three incident elements with independent directions, which according to de Guzmán and Orden [16] is always satisfied for a system in self-equilibrium. This confirms that to generate any nodal motion in a tensegrity structures, each controlled node should be attached to minimum three active elements.

Let P be a node in a tensegrity structure with PP_1 , PP_2 and PP_3 three incident members to P with independent directions. The displacement at P can be expressed as:

$$\vec{d}_P = \alpha_1 \vec{PP_1} + \alpha_2 \vec{PP_2} + \alpha_3 \vec{PP_3} \quad (4)$$

where α_1 , α_2 and α_3 are real coefficients reflecting the motion of the node in each member direction. The displacement of the node in each member direction can be calculated through the projection of d_P in the basis $\beta_P(PP_1, PP_2, PP_3)$. Let M_P be the non-singular matrix described β_P . Then, the coefficients α_1 , α_2 and α_3 can be calculated by:

$$\begin{bmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{bmatrix} = M_P^{-1} \vec{d}_P \quad (5)$$

Assuming n nodes P_1, P_2, \dots, P_n are moving in the structure with assigned displacements $d_{P_1}, d_{P_2}, \dots, d_{P_n}$ and the basis matrices $M_{P_1}, M_{P_2}, \dots, M_{P_n}$, the displacements of the nodes along the active elements can be calculated as:

$$\begin{bmatrix} \alpha_{P_1} \\ \alpha_{P_2} \\ \vdots \\ \alpha_{P_n} \end{bmatrix} = \text{blkdiag}(M_{P_1}^{-1}, M_{P_2}^{-1}, \dots, M_{P_n}^{-1}) \begin{bmatrix} d_{P_1} \\ d_{P_2} \\ \vdots \\ d_{P_n} \end{bmatrix} \quad (6)$$

where α_{P_i} is a 3×1 vector of projection coefficients of the displacement d_{P_i} on the basis β_{P_i} and $\text{blkdiag}()$ is the function forming a block diagonal matrix from a set of square matrices. Consequently, any displacement in space including the advantageous paths given by the infinitesimal mechanisms [15] can be decomposed in element-length changes. For a cable-actuated Simplex with only rigid body motions restrained and a desired change in the height of 0.01m, the changes in the length to be applied correspond to:

Cable	Change in length [m]
AB	0.0089
BC	0.0089
AC	0.0089
AD	-0.1000
BE	-0.1000
CF	-0.1000
DE	0.0000
DF	0.0000
EF	0.0000

(7)

5 CONCLUSIONS

Although tensegrity systems have been employed for active applications, there are no widely accepted design guidelines regarding sensor and actuator placement. In this paper, sensor and actuator placement is discussed through cellular morphogenesis highlighting that:

- the number of sensors required to characterize the self-stress in a tensegrity structure corresponds to its number of self-stress states
- the number of sensors required to characterize the self-stress is also given by the minimum number of constitutive unicellular sub-structures composing the structure
- the number of actuators required to control a tensegrity structure depends on the configuration and the desired change in shape or behavior
- nodal displacements can be expressed as a combination of the change in length of a set of three incident elements with independent directions.

The aforementioned statements imply that for an active tensegrity Simplex one sensor and 9 actuators are sufficient.

Key words: Adaptive Building Design, Inflatable Membrane Facades, Ultra Light Weight Buildings, ETFE

Abstract. The high thermal mass of conventional buildings is an important factor for maintaining comfortable indoor conditions. The building itself serves as a heat storage and damps the effects of changing outdoor temperatures or varying solar loads. Moving away from heavy-weight to ultra-light-weight buildings allows to rethink the conventional design of facades as sole thermal or noise insulation. Intelligent facade structures with integrated capability for thermal actuation can be used to control indoor conditions in order to reduce the energy demand. Inflatable membrane facades allow for a variation of heat capacity by introducing air and thus increasing the thermal mass of a facade element. This can be used to control the heat exchange between the building interior and the environment depending on the outside conditions. Furthermore, introducing connections between adjacent wall elements enables the transport of thermal energy from one side of the building to another. This allows for intelligent distribution of solar loads by transferring heated air from the south- to the north-facing side of the building.

In this work, a thermal network model of a building using inflatable membrane wall elements is developed. The numerous couplings of element-specific mass and temperature dynamics introduce various effects on the thermal conditions and the related energy demand. The theoretical potential of this type of actuation is determined through a detailed simulative study. Recordings of the temperate climate in Germany are combined with a geometrical solar irradiation model to determine the environmental disturbances. Subsequently, an analysis of different operational conditions is performed to identify the energy saving potential of rewarding use cases. While the energy demand rather depends on system design parameters (e.g. solar absorption), the reduction of radiant temperature asymmetry and demand-oriented heat transfer from unoccupied to occupied zones are promising applications.

1 INTRODUCTION

The growth of the world population creates the need for an increasing amount of living space. This need clashes with the goal of reducing our environmental footprint: today, the European building sector makes up about 50 % of the resource consumption and 42 % of its energy demand [1]. A large portion of the energy that is consumed over the lifecycle of a building is embodied energy. Therefore, one of the primary approaches to both resource and energy consumption reduction is lightweight construction using sustainable materials. The public acceptance of such significant changes constrains their implementation where one driving factor is the occupant's comfort. Hence, it is mandatory for novel building constructions to maintain or even improve the quality of the internal thermal environment compared to conventional building types while reducing the environmental footprint.

The superior indoor comfort of conventional heavy building structures compared to passive lightweight construction is well known, particularly in climates with large daily temperature variations [2, 3]. The lower thermal capacity of light-weight buildings incorporates faster dynamics and results in a more extreme reaction to outside conditions. This leads to a higher energy demand of the heating, ventilation and air conditioning system to ensure the thermal comfort of the occupants. Researchers have devised a number of ways to overcome this limitation, one of which is adaptation of the building's facade to changing environmental conditions. An overview can be found in [4].

Membrane facades are a type of lightweight construction that gained popularity in the past years. They usually consist of fabric or ethylene tetrafluoroethylene (ETFE) films [5]. Membranes made of ETFE can consist of one or more layers and have high light and UV permeability. ETFE offers low soiling due to the smooth surface and low surface tension. Dust and other particles can adhere poorly [6]. It has a low weight and is stable in extreme climatic conditions. A number of exemplary buildings using ETFE cushions are described in [7].

Various efforts have been made to take advantage of the elasticity and durability of membrane materials by introducing adaptivity into the structures. Cardoso et. al. proposed using an electrochromic layer to locally adapt a cushion facade's opacity based on touch-feedback from occupants [8]. Adaptive shading may also be provided by adjusting the inflation of printed multi-layer cushions as described in [5]. Shading and power generation are combined in membrane-integrated photovoltaics, as proposed in [9]. An approach for adaptive membrane facades that is inspired by the human thermoregulatory system are water-filled cushions for active thermal control [10].

In this work, a novel building facade system comprised of inflatable membrane elements is introduced. The facade consists of membrane cushions filled with air. The cushions can be actively inflated or deflated and air can be exchanged between facade elements to achieve varying thermal mass and resistance for each wall and to transport thermal energy. This allows for intelligent distribution of solar loads, e.g. by transferring heated air from the south- to the north-facing side of the building to equalize thermal conditions or transport energy through the building envelope. The following work analyzes the saving potential of this kind of actuation regarding its energy demand for maintaining comfortable conditions. The effect of the inflation state on the building dynamics, the sensitivity to system parameters as well as the impact of air circulation through the facade elements are evaluated for the identification of a meaningful system design and future applications.

Table 1: List of Symbols

Symbol	Description	Value	Unit
A_i	Surface area of i -th wall element	-	m^2
C_{floor}	Heat capacity of floor elements		kJ/K
c_p	Specific heat capacity of moist air	1.020	kJ/kgK
c_a	Specific heat capacity of dry air	1.004	kJ/kgK
c_w	Specific heat capacity of water vapor	1.860	kJ/kgK
d_{mem}	Thickness of membrane	0.5	mm
d_{wall}	Thickness of wall (= inflation state)	1	m

2 MODEL DESCRIPTION

In the following section, the simplified thermal network model is derived based on heat and mass balance equations. The goal is to achieve a quantitative description of the thermal, hygrothermal and energetic effects within the system that allows conclusions about the energy saving potential of the proposed approach. At the same time, the description is kept as simple as possible to achieve a low complexity for the analysis and numerical simulation as well as good interpretability.

2.1 System Description

A schematic representation of the building is given in Figure 1. The sketched two story building is considered in the following analysis where each level consists of one zone which is enclosed by four inflatable wall elements (light shaded). The intermediate floor that separates two zones is considered as ceiling for the lower level and as floor for the upper level simultaneously. The need for a stabilizing floor layer is ignored for simplicity. Each external facade element can be in- or deflated, either by outside air or by exchanging air with adjacent elements. This allows for arbitrary heat transport over the whole building structure. Zones and floors have a constant mass (dark shaded) to avoid a change of the interior volume and consequent implications for the occupants.

Through the described adaptivity, the properties of the membrane facade can be changed. Heat flows can be used selectively to increase the air permeability of the facade to adjust interior

Figure 1: Sketch of inflatable building design for variable insulation state and heat transfer by mass exchange.

surface and room air temperatures. For the following analysis, the material properties of the membrane facade are set based on an exemplary ETFE film as stated in [11] and given in Table 1. It is assumed that a facade element consists of 5 membrane layers with a thickness of 0.2 mm which are cumulated to an inner and outer surface for a simplified reference model. Hence, the total thickness results in $d_{\text{mem}} = 0.5 \text{ mm}$. For further simplification, an opaque membrane without solar transmission is considered.

2.2 Physical Modeling

The dynamic equations to represent the building dynamics are obtained by the heat and mass balance of the facade and zone elements [12] under the assumption of well mixed conditions within the zones and wall components. Each element can be modeled as an air cushion with a temperature T , a mass m and a relative humidity RH . For simpler equations, relative humidity RH is substituted by the mass fraction of water $X_{\text{H}_2\text{O}} = \frac{m_w}{m_w + m_a}$. The temperature and inflation are defined by the heat and mass balance

$$c_p(T, X_{\text{H}_2\text{O}})(m\dot{T} + \dot{m}T) = \sum_{i=1}^{n_{\text{adj}}} \frac{T_i - T}{R_i(T, T_i, \dot{Q}_{\text{sol}})} + \sum_{j=1}^{n_{\text{flow}}} \dot{H}_j + \dot{Q}_{\text{demand}} \quad (1a)$$

$$\dot{m} = \sum_{j=1}^{n_{\text{flow}}} \dot{m}_j \quad (1b)$$

$$\dot{X}_{\text{H}_2\text{O}} = \frac{\dot{m}_w - \dot{m}X_{\text{H}_2\text{O}}}{m} \quad (1c)$$

where c_p is the specific heat capacity of moist air, \dot{H}_j denotes the enthalpy flow due to the mass transfer from or to an adjacent element j , \dot{Q}_{sol} defines the effective solar load and \dot{Q}_{demand} represents the required heating or cooling demand to maintain comfortable indoor temperatures. The j -th enthalpy flow between adjacent wall elements is defined by [13]

$$\dot{H}_j = \dot{m}_j \left(c_a T_j (1 - X_{\text{H}_2\text{O}}) + X_{\text{H}_2\text{O}} \left(c_w T_j + 2501 \frac{\text{kJ}}{\text{kg}} \right) \right), \quad (2)$$

Figure 2: Thermal resistance of the membrane.

where \dot{m}_j denotes the corresponding mass flow and T_j depends on the direction of the flow. The effective solar heat load depends on the sun position as well as direct and diffuse solar radiation:

$$\dot{Q}_{\text{sol}} = F_{\text{sol}} I_{\text{dir}} + I_{\text{dif}}. \quad (3)$$

The view factor F_{sol} is calculated based on the wall's facing angle, the azimuth and elevation of the sun and the absorptivity α as stated in Table 1. Besides mass exchange, heat is transferred by a combined effect of conduction, convection and radiation. These are summarized in the non-linear thermal resistance R_i that is calculated by [14]

$$R_i = \sum_{k=1}^2 \frac{R_{ik}^{\text{conv}} R_{ik}^{\text{rad}}}{R_{ik}^{\text{conv}} + R_{ik}^{\text{rad}}} + R_i^{\text{cond}}, \quad (4)$$

where

$$\begin{aligned} R_i^{\text{cond}} &= \frac{d_{\text{mem}}}{\lambda_{\text{mem}} A_i} \\ R_{ik}^{\text{rad}} &= \frac{1}{h_k^{\text{rad}}(T_{\text{mem}}, T_k) A_i} = \frac{\frac{1}{\epsilon_1} + \frac{1}{\epsilon_2} - 1}{\sigma A_i (T_{\text{mem}}^2 + T_k^2)(T_{\text{mem}} + T_k)} \\ R_{ik}^{\text{conv}} &= \frac{1}{h_k^{\text{conv}}(T_{\text{mem}}, T_k, \dot{Q}_{\text{sol}}) A_i} \\ h_k^{\text{conv}} &= \begin{cases} 1.31 |T_{\text{mem}} - T_k|^{\frac{1}{3}} & \text{for a vertical wall} \\ 1.52 |T_{\text{mem}} - T_k|^{\frac{1}{3}} & \text{for } (\text{floor} \wedge T_{\text{mem}} < T_k) \vee (\text{ceiling} \wedge T_{\text{mem}} > T_k) \\ 0.76 |T_{\text{mem}} - T_k|^{\frac{1}{3}} & \text{for } (\text{floor} \wedge T_{\text{mem}} > T_k) \vee (\text{ceiling} \wedge T_{\text{mem}} < T_k) \end{cases} \\ T_{\text{mem}} &= \frac{R_1(T_{\text{mem}}) R_2(T_{\text{mem}})}{R_1(T_{\text{mem}}) + R_2(T_{\text{mem}})} \left(\frac{T_1}{R_1(T_{\text{mem}})} + \frac{T_2}{R_2(T_{\text{mem}})} + \frac{\alpha}{A_i} \dot{Q}_{\text{sol}} \right). \end{aligned}$$

The convective heat transfer coefficient h_k^{conv} is computed based on the TARP algorithm [15, 16].

The building dynamics are highly influenced by external conditions due to the thin membrane layers without additional insulation. The main impacting factors are outside temperature T_{out} and direct and diffuse solar radiation, I_{dir} and I_{dif} respectively. Solar energy is absorbed by the facade cushions and can either be used as heat source or needs to be removed depending on the required indoor conditions. Although relative humidity changes the heat capacity of the air, simulations showed that the thermal impact is rather low within the occurring humidity range.

3 SIMULATIVE ANALYSIS

The building dynamics are analyzed for different initial inflation states. Multiple simulations based on typical weather conditions in Stuttgart are compared in relation to their energy demand for maintaining comfortable conditions. The applied weather data are taken from the German Weather Service [17]. The desired operative temperature is set to a constant value of $T_{\text{op}}^{\text{des}} = 24^\circ\text{C}$ for simplicity and comparability. This corresponds to a reasonable compromise between comfortable conditions during winter and summer time as well as different clothing levels [18]. The required operative and mean radiant temperature are approximated by [19]

$$T_{\text{op}} = \frac{T_{\text{air}} + T_{\text{mr}}}{2}, \quad T_{\text{mr}} = \frac{\sum_i^{n_{\text{walls}}} A_i T_i}{\sum_i^{n_{\text{walls}}} A_i}. \quad (5)$$

The considered building has a floor area of 10 m by 10 m and a room height of 3 m. The northern facade faces directly to the north such that the building has a clear north (N), east (E), south (S) and west (W) facade which are referred to by the corresponding letter and story number (e.g. N1). The thermal capacity of the floor elements is increased compared to the purely air-filled facade cushions to account for potential interior equipment. Table 2 summarizes the applied system parameter changes that are discussed in the following.

First, the impact of different wall thicknesses is evaluated for typical winter and summer conditions to demonstrate the possible effects and dynamics. The results are given for a period of 48 h and depicted in Figure 3. Comparing the required, time-dependent cooling or heating power for three different inflation states ($d_{\text{wall}} = \{0.1\text{ m}, 1\text{ m}, 10\text{ m}\}$) reveals the potential of changing wall volumes. Generally, a fast response to varying outside conditions and a strong dependency on solar influences can be noted for all setups. Furthermore, the upper zone has a significantly higher energy consumption compared to the lower zone. This is due to the larger external wall area and consequently an increased energy loss through the ceiling/roof. The larger external wall area also implies a lower/higher mean radiant temperature in winter/summer and consequently affects the operative temperature directly. However, only a negligible difference between a wall thickness of 0.1 m and 1 m can be noted on an hourly scale. A notable change of the building dynamics can only be achieved by a high (but presumable physically infeasible) increase to 10 m. The corresponding daily and annual energy demand

$$Q_{\text{demand}}^I = \int_I |\dot{Q}_{\text{demand}}(t)| dt \quad (6)$$

over the examined time interval I is listed in Table 2 and supports the outcome of the graphical analysis. The energy consumption for the first two setups is almost identical. The higher thermal capacity of the walls in setup 3 slows down the building's response and can make better use of the internally stored heat or cold. This effect is even more beneficial during the summer than the winter time due to the damped impact of solar radiation. The lower wall temperatures reduce the zonal mean radiant temperature and hence the impact on the operative temperature as described in (5).

However, instead of increasing the external wall capacity, an opposite change of the internal characteristic, thus decreasing the internal heat capacity, can lead to a similar reduction of the energy consumption. In setup 4, the wall thickness d_{wall} is again set to 1 m while the thermal capacity of the interior is reduced by factor 10 (which corresponds to an air-filled floor element with $d_{\text{wall}} = 1\text{ m}$). Comparing the energy demand of setup 2 and 4 directly shows that heating

	$Q_{\text{demand}}^{\text{year},Z2}$	MWh	24.33	24.33	24.31	24.31	23.82	23.67	24.31	24.03
	$Q_{\text{demand}}^{\text{year},Z1+Z2}$	MWh	36.90	36.90	36.87	36.85	36.06	35.84	36.85	37.57

but particularly cooling power is lowered as a result of the smaller internal heat storage. This results in faster dynamics and less required power to keep the desired temperature as shown in Figure 4. Although small variations can be noted, the energy demand is comparable for all facade widths that are within a building-physically meaningful range due to the equal stationary system behavior. Therefore, the impact of other system parameters is further analyzed.

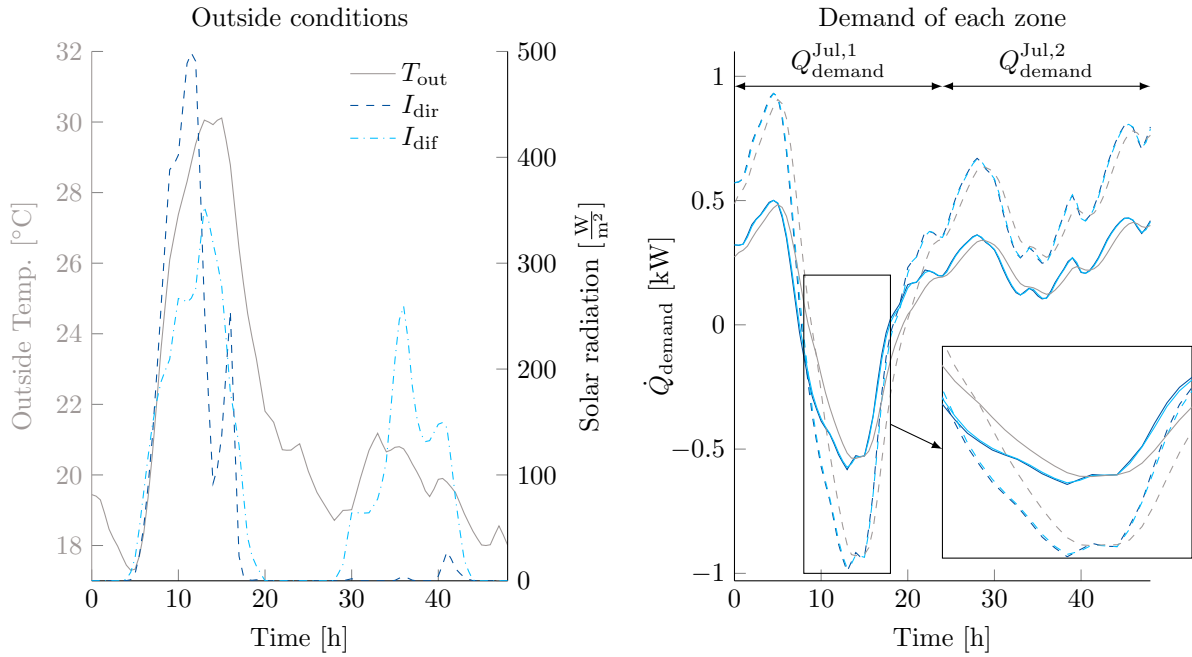

Since solar radiation is a main contributor to the thermal conditions of the light-weight building structure, a higher solar absorption coefficient α leads to a more significant change. The impact of radiation on the operative temperature is clearly demonstrated by the temperature difference between the two zones as shown in Figure 4. Wall temperatures below the desired set-point increase the required air temperature while higher wall temperatures involve lower interior air temperatures. As a consequence, the low wall temperatures during the winter result in a higher temperature set-point ($> 1^\circ\text{C}$) for upper zone (Figure 4a). The smaller temperature differences during the summer time reduce this effect (Figure 4b). Hence, an increase of α to 0.8 according to configuration 5 results in a significant impact on the cooling demand in Figure 4b. The upper zone acts like a greenhouse and requires a very high cooling power due to the considerable temperature increase of the air-filled walls. However, this effect can be beneficially used during winter time to reduce the heating demand by a higher mean radiant temperature and thus operative temperature. This lowers the annual energy consumption because of the higher heating demand on a yearly basis of the considered building location.

For the given modeling assumptions, insulation is only provided by the membrane. Increasing its thickness d_{mem} (or number of layers) directly amplifies the conductive resistance. The resulting system dynamic for $d_{\text{mem}}^{\text{new}} = 10 \cdot d_{\text{mem}}^{\text{old}}$ is also pictured in Figure 4. In particular during the winter time (Figure 4a), the larger insulation is visible as a reduced heating demand due to a smaller heat loss and hence allowing lower wall temperatures. For warmer periods, when the air temperature difference between indoor and outdoor conditions is relatively small, the additional insulation does not result in a notable change of the building dynamics.

So far, only stationary system configurations were analyzed where no mass exchange was

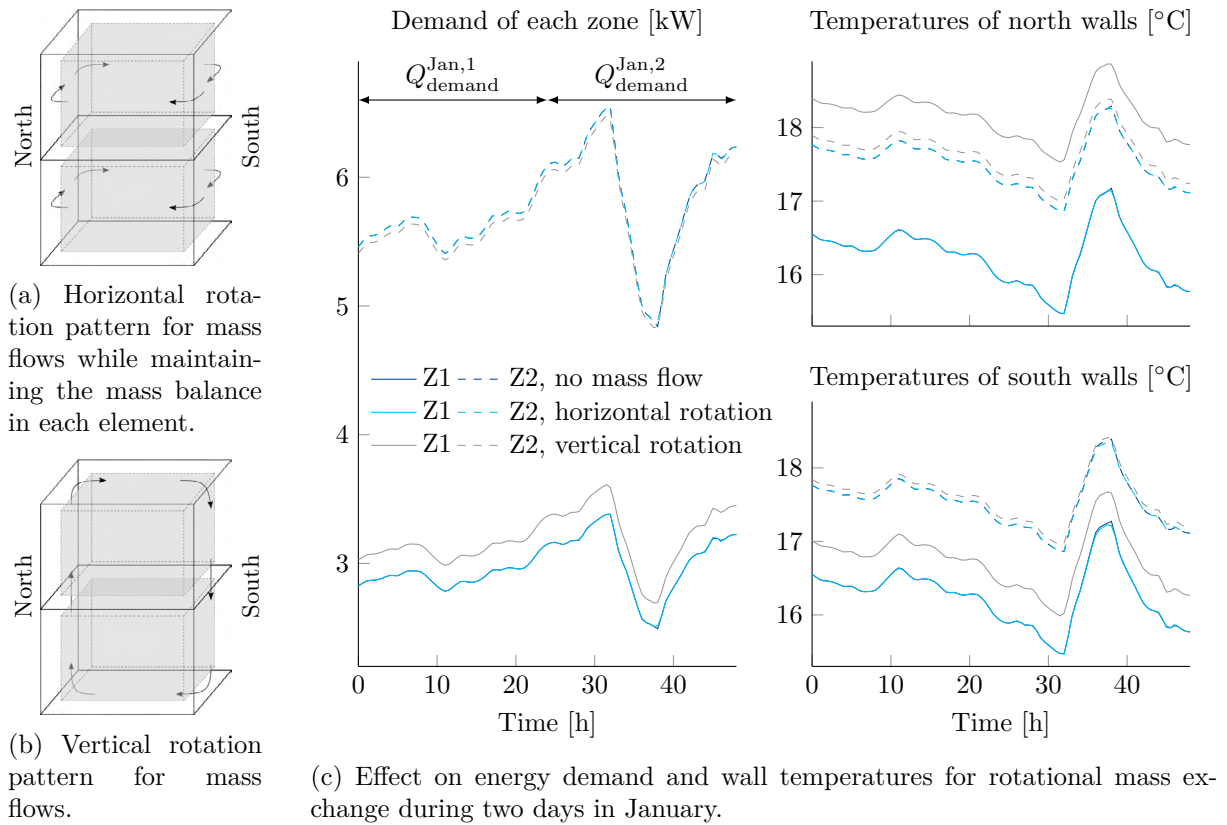

Figure 5: Analysis of the effect of mass exchange between adjacent facade elements.

involved. The impact of air circulation is exemplary analyzed based on two rotational patterns as sketched in Figure 5a and 5b. The resulting power consumption and wall temperatures are shown in Figure 5c. The horizontal mass exchange (Figure 5a) does not change the building dynamics noticeable. Due to the small floor area of the considered building with one zone on each level surrounded by external walls only, the temperature differences between the walls are already relatively small such that an additional mixing does not lead to a significant change. However, a small reduction of the overall energy demand can be achieved.

A larger impact is obvious for the vertical rotation, as pictured in Figure 5b. The rotational mass flow around the building results in an energy exchange between the first and second floor as well as the north and south facade. The air is heated by circulating through the floor and then cooled down on its way around the building. Consequently, the wall N1 is the warmest and S2 the coldest for the simulated winter conditions. The heat transfer from the first to the second level results in a small reduction of the required heating power of the upper zone Z2. However, the consumed heating power of Z1 is increased by a larger amount. This results in a higher energy demand of the building, as stated in Table 2. The detailed results for July are not shown due to smaller effects originating from the lower temperature differences compared to the heating period during winter. Nevertheless, a similar tendency can be noticed for the corresponding energy consumption. In particular the annual demand emphasizes the previous observations. While the consumption of zone 2 can be lowered by approx. 2%, zone 1 requires 8% more energy which leads to a total increase of about 2%.

4 LIMITATIONS AND POTENTIAL

The previous results point to some limitations that are introduced by model assumptions and simplifications. The model approach uses the assumption of perfect mixing within the zones and wall elements. While this is a common assumption for medium-sized spaces, it can entail characteristics which diminish the insulation property of an inflatable facade structure. The perfect-mixing assumption leads to equivalent stationary behavior for all inflation states. A multilayer design, that separates the air volume in several thinner air layers, can reduce convective effects such that the insulation property of air can be used more efficiently. Particularly for the stationary case with still air, conduction should be more dominant and a larger air volume could improve the building's insulation remarkably. As shown by simulation setup 6, this property will have a significant impact on the energy demand.

Moreover, the facade is assumed to be opaque and transmission is completely neglected for the presented results. Using ETFE as facade material allows for bright indoor conditions without adding large-scale glazing. Including this property to the model also changes solar impacts and can lead to lower heating demand during the cold period as indicated by the results for increased solar absorption in setup 5.

Modified results are also possible when internal disturbances, like occupancy, lightning and electrical devices, are considered in the analysis. The prerequisite that all zones must maintain comfortable conditions 24 h per day, is often not necessary and changing occupancy can introduce a great potential. Although the results for vertical mass circulation showed that heat transfer between zones entails energy losses, it could be efficiently used for transferring conditioned air from an unoccupied zone to occupied building sections. A mass exchange can be even more advantageous when considering a larger building with multiple zones on one level, where solar influences have a more local effect on thermal conditions.

Another potential benefit originates from a reduction of radiant temperature asymmetry to improve thermal comfort [19]. Circulating the air and thus equalizing wall temperatures reduces asymmetric conditions and enhances thermal comfort.

5 CONCLUSION

The presented analysis revealed potential but also some problems regarding the use of inflatable membrane facades. While pure inflation does not change the building dynamics significantly, greater impact can be achieved by mass exchange and intelligent selection of system parameters during the design phase. The right choice for a final building setup depends strongly on the building type, utilization and the corresponding occupancy and internal disturbance profiles.

Therefore, further work will analyze the impact of transmission, internal disturbances and varying occupancy as well as different building configurations. Interpreting thermal comfort not only as an operative temperature implies additional potential of this approach.

ACKNOWLEDGMENT

The work described in this paper was conducted in the framework of the Collaborative Research Centre 1244 "Adaptive Skins and Structures for the Built Environment of Tomorrow" funded by the German Research Foundation (DFG - Deutsche Forschungsgemeinschaft). The authors are grateful for the generous financial support and wish to express their gratitude therefor.

e-mail: zhangxiaopeng@dlut.edu.cn

Keywords: Topology optimization, Active control, Piezoelectric material structure, Smart structure.

Abstract. Smart structural systems with piezoelectric actuators and sensors are considered as an effective manner to reduce structural vibration for avoiding possible damage of a structure or degradation of system performance. Piezoelectric actuators are often used for providing active damping in the active vibration control system. It is clear that the active control effect can be promoted by optimizing the numbers and positions of piezoelectric actuators. Topology optimization of piezoelectric smart structures has also received increasing attention.

This study presents a topology optimization formulation for optimizing the piezoelectric actuator and sensor layout optimization to suppress the structural dynamic response under active vibration control. The structure is excited by an external harmonic load. For controlling the dynamic response, each sensor patch is connected to a charge amplifier, and the CGVF control algorithm is adopted to convert the sensor output to feedback control voltage in the corresponding actuator patch. Here, the control effect can be treated as active damping of the dynamic system. The structure is discretized with finite element model, and the structural response is evaluated with a time-integration method. In the optimization model, an integral-type performance function in a given time interval is to be minimized. The pseudo-densities of piezoelectric elements (sensor and actuator) with penalization for indicating the presence or absent are taken as design variables. The sensitivity analysis scheme is derived with the adjoint-variable method and the optimization problem is solved with a gradient-based mathematical programming algorithm.

1 INTRODUCTION

Since large vibrations are harmful to structural safety and functionality, many studies have been devoted to the control of structural vibration. According to the control mechanisms, structural vibration control methods can be divided into three categories: active control, passive control, and semi-active control. Herein, the active control approach focuses on reducing the structural vibration by arranging control transducers in the vibrating structure. Active control strategies have been proved effective in reducing the structural vibration level. Many studies on active vibration control of thin-shell structures focus on arranging the spatial distribution of control transducers (e.g. piezoelectric actuator/sensor patches). To achieve the best control

performance, however, finding the optimal layouts of the piezoelectric actuators/sensors patches in accordance with the employed control algorithms becomes highly important.

Optimization of piezoelectric smart structures has received increasing attention. Genetic algorithms^[1], particle swarm optimization algorithms^[2] or other heuristic algorithms^[3], have been used to seek the optimal size and location of piezoelectric actuators. In addition, more and more scholars use the method of topology optimization to study the layout of piezoelectric materials(e.g. Kögl and Silva^[4], Carbonari et al.^[5], Kang et al.^[6], Luo et al.^[7] and Kang and Tong^[8]). Some authors also considered topology optimization of piezoelectric structures under active control. For example, Wang et al.^[9] optimized the distribution of piezoelectric actuators/sensors for suppressing the structural vibration with classical constant gain velocity feedback(CGVF) control and genetic algorithms. Drenckhan et al.^[10] proposed the piezoelectric actuators distribution optimization method in a beam structure. Donoso and Sigmund^[11] studied the mechanism of the piezoelectric bimorph actuators and proposed a parametric optimization method for optimizing the thickness and width profile of the piezoelectric layers.

This paper mainly studies the optimal layout of the piezoelectric sensor layer and actuator layer, which aims at reducing the vibration level of the structure under external harmonic excitation. The classical CGVF control algorithm is adopted as the active control algorithm. The topology optimization problem with the structural dynamic compliance response at the specified harmonic excitation is considered. Numerical examples are given to verify the accuracy and effectiveness of the proposed method.

2 ESTABLISHMENT OF FINITE ELEMENT MODEL

Here, the piezoelectric actuator layer and the sensor layer are attached to the top and bottom surfaces of the host structure (as shown in Figure 1).

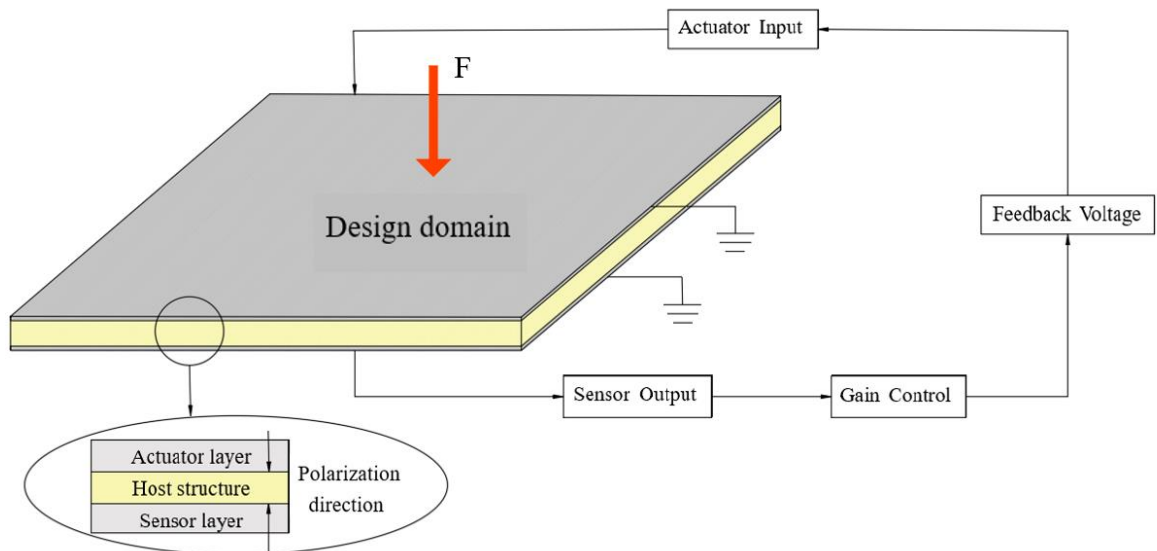

Figure 1: Schematic diagram of active control of laminate structure with surface-attached piezoelectric sensor layer and actuator layer

The mechanical properties of the sensor layer, the actuator layer, and the host layer are considered to be linear elastic. Thus, the constitutive equation for the piezoelectric layer can be written as^[12] $\boldsymbol{\sigma} = \mathbf{D}^E \boldsymbol{\varepsilon} - \mathbf{e}^T \mathbf{E}$. Here, $\boldsymbol{\sigma}$ and $\boldsymbol{\varepsilon}$ are the mechanical stress vector and the mechanical strain vector, respectively; \mathbf{D}^H and \mathbf{D}^E are the elasticity matrices of the host layer and piezoelectric layer, respectively. \mathbf{e} is the piezoelectricity matrix, \mathbf{E} is the vector of electric field.

The electric potential functions are assumed to have linear variations across the thickness of the piezoelectric actuator and sensor layers. The electric voltage in the actuator layer $\boldsymbol{\Phi} = \{\Phi^1, \Phi^2, \dots, \Phi^{N_e}\}^T$. In the active vibration control of plate with piezoelectric layer, the voltage is applied only in the thickness direction. We assume that the electric potential varies linearly across the actuator layer. Thus the electric field vector for the i th actuator patch $\mathbf{E}^i = \{0, 0, -\Phi^i/h\}^T$ ($i=1, 2, \dots, N_e$), h is the thickness of the actuator layer.

We consider the optimal layout of a given volume of piezoelectric material in the actuator and sensor layer. The governing equation of piezoelectric laminate based on finite element discrete can be given as:

$$\mathbf{M}\ddot{\mathbf{y}}(t) + \mathbf{C}\dot{\mathbf{y}}(t) + \mathbf{K}\mathbf{y}(t) = \mathbf{F}(t) + \mathbf{F}_a(t) \quad (1)$$

where $\mathbf{M} \in \mathbf{R}^{n \times n}$, $\mathbf{C} \in \mathbf{R}^{n \times n}$ and $\mathbf{K} \in \mathbf{R}^{n \times n}$ (n is the number of degree of freedom) are the mass matrix, the damping matrix and the stiffness matrix of the whole structure, respectively; $\mathbf{F}(t) = \mathbf{f}e^{i\theta t}$ is the vector of excitation force with a frequency θ and amplitude \mathbf{f} . $\mathbf{F}(t)$ is the vector of time-varying equivalent nodal forces of the piezoelectric actuator that can be express as $\mathbf{F}_a(t) = \mathbf{K}_{u\Phi} \boldsymbol{\Phi}_a(t)$. Here, $\boldsymbol{\Phi}_a(t)$ is the actuator voltage vector and depends on the sensor voltage $\boldsymbol{\Phi}_s(t)$ of the sensor layer; $\mathbf{K}_{u\Phi} = \int_{\Omega} \mathbf{B}_{uu}^T \mathbf{e}^T \mathbf{B}_{u\Phi} d\Omega$ is the structural electromechanical matrix of the actuator layer. \mathbf{B}_{uu} and $\mathbf{B}_{u\Phi}$ are the strain-displacement matrix and the matrix relating the electrical field with the actuation voltage, respectively; and they depend on the geometry of the actuator layer.

3 ACTIVE CONTROL MODEL BASED ON CGVF CONTROL ALGORITHM

In this study, the CGVF control algorithm is adopted to convert the sensor output to feedback control voltage in the corresponding actuator patch. Therefore, the actuator voltage vector $\boldsymbol{\Phi}_a(t)$ can be obtained by using the output sensor voltage $\boldsymbol{\Phi}_s(t)$ as:

$$\boldsymbol{\Phi}_a(t) = -\mathbf{G}_a \boldsymbol{\Phi}_s(t) = -\mathbf{G}_a \mathbf{G}_s \mathbf{K}_{\Phi u} \dot{\mathbf{y}}(t) \quad (2)$$

where \mathbf{G}_a is a constant gain diagonal matrix.

The system equations with active damping can be obtained as:

$$\mathbf{M}\ddot{\mathbf{y}}(t) + (\mathbf{C} + \mathbf{C}_A) \dot{\mathbf{y}}(t) + \mathbf{K}\mathbf{y}(t) = \mathbf{F}(t) \quad (3)$$

where $\mathbf{C}_A = \mathbf{K}_{u\Phi} \mathbf{G}_a \mathbf{G}_s \mathbf{K}_{\Phi u}$ is the active damping matrix.

It is noted that the active damping matrix \mathbf{C}_A is not positive definite and is not symmetric. Thus the damping matrix $(\mathbf{C} + \mathbf{C}_A)$ of the structure is still not a positive definite matrix.

4 TOPOLOGY OPTIMIZATION PROBLEM FORMULATION

We consider the optimal topological layout of the piezoelectric actuator layer and the piezoelectric sensor layer in a piezoelectric laminate structure as shown in Figure 1 with a given volume fraction. Thus, the topology optimization problem can be expressed as:

$$\begin{aligned}
 \min_{\mathbf{x}} \quad & f(\mathbf{x}) = c = \sqrt{(\mathbf{F}^T \mathbf{Y}^R)^2 + (\mathbf{F}^T \mathbf{Y}^I)^2} \\
 \text{s.t.} \quad & (-\theta^2 \mathbf{M} + i\theta(\mathbf{C} + \mathbf{C}_A) + \mathbf{K}) \mathbf{Y} = \mathbf{F} \\
 & \sum_{e=1}^{N_e} x_e V_e - f_v \sum_{e=1}^{N_e} V_e \leq 0 \\
 & 0 < \underline{x} \leq x_e \leq 1 \quad (e = 1, 2, \dots, N_e)
 \end{aligned} \tag{4}$$

Here, the objective function is the dynamic compliance defined by Ma^[13] et al. The vector $\mathbf{x} = \{x_1, x_2, \dots, x_{N_e}\}^T$ collects the element-wise density design variables used to describe the material layout of the piezoelectric actuator layer and sensor layer, N_e denotes the total number of finite elements in the design domain. The symbol f_v denotes the volume fraction ratio, and V_e is the volume of the e th element. The lower bound of the relative density \underline{x} is set as 10^{-6} in this study.

A penalization $p > 1$ on the piezoelectric property is needed to be introduced, the choice of the penalization factors in piezoelectric material topology optimization has been discussed in many studies. Following the suggestion of Noh and Yoon^[14], we set $p = 3$. With this penalization the piezoelectric coefficient matrix of piezoelectric materials and active damping matrix can be written as:

$$\mathbf{e}^{\text{piezo}}(x_e) = x_e^p \mathbf{e} \tag{5}$$

$$\mathbf{C}_A = \sum_{e=1}^{N_e} (x_e)^p \mathbf{K}_{u\Phi}^e \mathbf{G}_a^e \mathbf{G}_s^e \mathbf{K}_{\Phi u}^e \tag{6}$$

5 NUMERICAL EXAMPLES

The optimization program is implemented on the MATLAB platform, and the optimization problem is solved with the globally convergent method of moving asymptotes (GCMMA) for treating highly nonlinear behavior functions in the considered dynamic optimization model.

In all numerical examples, we consider the composite plate as shown in Fig. 1. Here, the host structure (aluminum) has Young's modulus $E^h = 6.9 \times 10^{10} \text{ N/m}^2$, Poisson's ratio $\nu^h = 0.3$, and the mass density $\rho^h = 2700 \text{ Kg/m}^3$; and the properties of the piezoelectric material (PZT) are $E^{\text{piezo}} = 7.1 \times 10^{10} \text{ N/m}^2$, $\nu^{\text{piezo}} = 0.35$ and $\rho^{\text{piezo}} = 5000 \text{ Kg/m}^3$. The

piezoelectric stress coefficients are $e_{31} = e_{32} = -5.2 \text{ C/m}^2$, $e_{33} = 15.1 \text{ C/m}^2$ and $e_{15} = e_{25} = 12.7 \text{ C/m}^2$. The damping coefficients of the host structure are $\alpha = \beta = 5 \times 10^{-4}$. The gain value of the current amplifier is $G_c = 1 \times 10^6 \text{ V/A}$, and the negative feedback control gain is $G_a = 50$.

We first consider the topology optimization of the piezoelectric actuator and sensor layers attached to a cantilever laminate plate, the geometric properties of the plate are $a = 1.5 \text{ m}$, $b = 1 \text{ m}$ and $t_h = 4 \times 10^{-3} \text{ m}$ as shown in Figure 2. The sensor layer and the actuator layer, both with the thickness $t_s = t_a = 0.5 \times 10^{-3} \text{ m}$, are attached to the bottom surface and the top surface of the host structure, respectively. A time-harmonic external force $f(t) = Fe^{i\theta t}$ (with $F = 200 \text{ N}$, $\theta = 2\pi f_p$ and $f_p = 37 \text{ Hz}$) is applied at the midpoint of the free edge. The design domain is discretized by 75×50 uniform-sized four-node Mindlin shell elements.

Figure 2: A cantilever plate excited by a time-harmonic load

In the optimization model, the volume fraction ratio of the piezoelectric material in the design domain is restricted by $f_v = 0.5$, and only the first 40 eigenmodes are considered in the computation. The optimization program converges after 65 steps, and its iteration history is shown in Figure 3. The optimal layout of the piezoelectric material is shown in Figure 4. In addition, the active control actuation voltage amplitude applied to the structure is as shown in Figure 5. It can be found that the actively controlled actuation voltage is almost zero in the region without the piezoelectric material.

Figure 3: Iteration histories of objective function value and volume fraction ratio

Figure 4: Optimization result of actuator/sensor distribution.

Figure 5: Actuator voltage amplitude distribution for the optimal configuration

To further examine the dynamic performance of the optimized design, we perform the calculation of the structural dynamic compliance for the initial design and optimal design in the excitation frequency range 29-60 Hz, as shown in figure 6. It can be found that, in the excitation range [33, 40] Hz, the dynamic compliance value of the optimal design under active control is

significantly smaller than the value of the initial design, which proves the effectiveness of the proposed optimization model.

Figure 6: Dynamic compliance sweep in a specified excitation frequency range for the initial design and the optimal design

The effect of volume fraction ratio on the optimization results is also examined. Here we select the same structure and boundary conditions as the previous example, but the volume fraction ratios are taken as $f_v = 0.3, 0.35, 0.4, 0.45$. The optimization results under different volume fraction ratios are shown in Figure 7. It can be seen that as the increasing of the volume fraction ratios, more areas the piezoelectric material occupies, but the shape of the optimization results does not change so much and the topology of the design changes very little.

Figure 7: Optimization results for actuator/sensor layers obtained under 37 Hz excitation with different volume fraction ratios. (a) $f_v = 0.3$; (b) $f_v = 0.35$; (c) $f_v = 0.4$; (d) $f_v = 0.45$; (e) $f_v = 0.5$

6 CONCLUSIONS

This study mainly studies the optimal topological layout of piezoelectric laminate based on active control under harmonic excitation. The globally convergent method of moving asymptotes (GCMMA) is employed as the optimizer. In the optimization problem, an artificial piezoelectric material model that simultaneously punishes the piezoelectric material stiffness and the piezoelectric effect are proposed, and dynamic compliance is taken as the objective function in the optimization model. The validity and accuracy of the proposed method are verified by numerical examples. At the same time, it can be found that the dynamic compliance under harmonic excitation can be effectively reduced by topology optimization.

Key words: Neutral Equilibrium Mechanism, Time Delay, Critical Differential Gain, Critical Proportional Gain

Abstract. Earthquake is an inevitable natural disaster. How to improve the seismic resistant capacity of structures is an important issue in the field of seismic engineering research. In this study, a new type of control mechanism, the neutral equilibrium mechanism, is proposed for buildings with insufficient seismic resistance. The neutral equilibrium mechanism is formed by connecting an unstable balance mechanism and a stable balance mechanism in series to achieve the effect of the power amplifier. This mechanism provides a reliable and efficient structural shock absorption with virtually no additional energy supply. This study proposes a prototype of a neutral balance control mechanism and passes functional verification. The experimental results show that the neutral balance mechanism only needs to exert a force of 1/500 of its output force when changing its output size and direction, and does not need to increase the force acting distance, so its power amplification rate has reached 500. With the neutral balance mechanism as the source of control, we then explore how to effectively use this mechanism to control the deformation of structures. Because this mechanism can achieve excellent energy-saving effects, we do not need to consider additional control laws that take into account energy consumption and control effects, such as the optimal control. This study intends to use the PID controller commonly used in automatic control technology because it has good tracking performance and stability. In this study, numerical analysis is used to investigate the effects of Gain coefficient of displacement and Gain coefficient of velocity on control effects and control stability. The analysis results show that the structure will not cause the acceleration amplification effect of the structure when it is subjected to the earthquake force after the installation of the mechanism. In addition, when the velocity gain coefficient and the displacement gain coefficient are larger, the structural displacement response is smaller. However, when the amount of time-delay increases, it may cause divergence of control. The last focus of this paper is to explore the convergence interval of the above two gain coefficients. We found the dimensionless parameters corresponding to these two parameters. When using

the dimensionless parameter, regardless of the mass, natural frequency and damping ratio of the structure, and regardless of the amount of time delay, the convergence interval has its consistency. The mechanism can provide a stable control effect by accurately providing the appropriate speed gain coefficient and displacement gain coefficient. In the future, the mechanism can increase the predictive control to achieve better control effects.

1 INTRODUCTION

The frequency and intensity of earthquakes have gradually increased in recent years. For example, on December 26, 2004, a large earthquake of magnitude 9.0 occurred in Sumatra, Indonesia, which caused a tsunami in South Asia, killing more than 200,000 people. Then, on March 11, 2011, an earthquake occurred in the north-eastern part of Japan, near the Pacific Ocean. With an intensity of 9, it was the most violent earthquake in the past years, causing a severe tsunami that exceeded 10 meters of high waves. A large amount of seawater flooded into coastal areas and washed away a lot of buildings. The number of deaths and missing persons exceeded 20,000, and the economic losses were heavy. Then on September 24, 2013, the magnitude 7.7 earthquake occurred in Pakistan, because the buildings were not earthquake-resistant, causing many buildings to fall, killing 825 people and injuring more than 700 people. In April 2015, a massive earthquake with a magnitude of 7.8 was observed in Nepal. In May of the same year, the 7.3 aftershocks of the earthquake occurred again, causing many casualties. In 2016, there were major earthquakes in Japan's Kumamoto and Fukushima offshore and the Great New Zealand earthquake.

Taiwan is located in the Pacific seismic belt and is at the junction of the Eurasian plate and the Philippine sea plate. There are quite many earthquakes that occur every year. A strong earthquake of 7.3 in the central part of Taiwan occurred 20 years ago, causing buildings and bridges located near the Chegongpu fault that stretched for more than 100 kilometers[1,2]. The Ministry of Science and Technology also announced the "earthquake hazard potential map" in Taiwan. In the next 30 years, the probability of earthquakes with a magnitude of 6.5 or higher in South Taiwan is as high as 64%, and that in East Taiwan is about 20% [3]. Therefore, the threat of earthquakes cannot be ignored. How to improve the earthquake resistance of a large number of old buildings is a subject that must be actively faced.

The basic concept of structural seismic design is: under the premise of not endangering life safety, as long as it meets the principles that the building is easy to repair by small earthquakes, and does not collapse by severe earthquake, some degree of damage is allowable. After the earthquake, some buildings need to be reinforced as soon as possible, so as to avoid more serious damage to the structure or collapse caused by aftershocks after a strong earthquake. How to quickly reinforce components and improve the seismic capacity of such buildings is the main goal of this study. Structural control is an emerging structural reinforcement technology for nearly three decades. Structural control can be divided into passive control (isolation, shock absorption and energy dissipation [4-5]), active control [6-8], and semi-active control [9-11]. This study proposes a new state control mechanism, Neutral Equilibrium Mechanism NEM, which can be applied to active control methods. The mechanism is connected in series with an unstable balance system and a stable balance system to obtain a neutral balance mechanism. This structure, through a cleverly matched connecting rod, spring, and guide rail system, can generate powerful control forces with little energy supply to control the deformation of the

structure under earthquake action.

Firstly, based on the theoretical analysis of the neutral equilibrium mechanism, this paper deduces the design parameters of the mechanism, and designs the prototype of the neutral equilibrium mechanism according to the design parameters, and then verifies the change of the mechanism after the force is applied. By real-time active control, the control force of the mechanism is determined by the displacement, velocity, acceleration and other factors of the structure. Therefore, the neutral equilibrium mechanism is equipped with a PID controller, but the PID controller is subjected to influence of the Gain coefficient of displacement and the Gain coefficient of velocity. Therefore, the dynamic analysis of the structure of the structure is performed to investigate the relationship between the gain coefficients and the damping effect of the neutral equilibrium mechanism. The correlation of the critical Gain coefficient of displacement and velocity and the time delay are also studied.

2 DESIGN CONCEPT OF NEUTRAL EQUILIBRIUM MECHANISM

2.1 Neutral Equilibrium Mechanism

The neutral balance mechanism includes an unstable mechanism, one that has potential energy and releases energy when it loses balance, and a stable spring that stores energy by deformation. In order to maintain the balance of energy, the parameters of the mechanism must be skillfully matched. Based on this, the neutral equilibrium mechanism as shown in Fig. 1 was designed.

Fig.1 Construction of the Neutral Equilibrium Mechanism

This figure shows the interaction between the mechanism and the structure, and the linear spring element can satisfy this concept. If the linear spring is pressed, it is in an unstable state. Therefore, the structure can be retrofitted with the above unstable mechanism in a statically

stable state, and is connected in series with the structural bracing. When the bracing is under stress, the unstable balance of the linear spring element is broken to exert a force on the structure, and the force can be used to offset the diagonal brace force generated by the deformation of the brace.

The free-body-diagram of the joint B and C in Fig.1 are shown in Fig. 2.

Fig.2 Free-Body Diagram of Joint A and B of NEM in Fig.1.

Take the spring-link free body diagram as shown in Figure 2(a), (b), and take the static balance of point B and C to get the following formula:

For Joint B:

$$\sum F_y = 0 \quad R - F_L \sin \theta = 0 \quad (1)$$

$$\sum F_x = 0 \quad F_L \cos \theta - F_s = 0 \quad (2)$$

Where,

F_L is the axial force of rigid link, F_s is the spring force, and R is the reaction force.

After rearranging the equations,

$$F_s = F_L \cos \theta \quad (3)$$

For joint C:

$$\sum F_y = 0 \quad F_e + 2F_L \sin \theta - F_b = 0 \quad (4)$$

By substituting equation (3) into equation (4) yields:

$$F_e = F_b - 2F_s \tan \theta \quad (5)$$

Where,

F_b is the bracing force in idea state, that no structural displacement exists.

F_e is the actuating force to balance F_b and F_s , the smaller the value, the better, and ideally close to zero.

Assuming θ is equal to 90° , the springs S_1 and S_2 just return to the original length L , that is, when $\theta = 0^\circ$, the compression of the spring is exactly equal to the length L' of the rigid link. So for any angle, θ

$$L' = (L - L_0) \sec \theta \quad (6)$$

Substituting equation (6) into equation $F_e = K_b L' \sin \theta - 2K_s (L - L_0) \tan \theta$ yields,

$$F_e = (K_b - 2K_s) L' \sin \theta \quad (7)$$

When the stiffness of the bracing is exactly two times of the stiffness of springs, as following

$$K_b = 2K_s \quad (8)$$

Then the required actuating force F_e equals to zero. No power supply is required for driving the joint C.

Therefore, a set of parameter values that make the neutral equilibrium mechanism true can be obtained:

- I. The bracing stiffness is equal to 2 times the spring stiffness;
- II. The spring is in an unstressed state when the internal angle θ of the mechanism is equal to zero.

2.2 Force balancing states of the NEM

The change of the force balance of the neutral equilibrium mechanism can be explained by the change of the force behavior in Fig. 3: (1) The horizontal spring reaches the horizontal state, at which time the vertical spring is not deformed and the horizontal spring reaches the maximum compression, but the horizontal resultant force is zero and the vertical spring has no force, so the node driving force is zero, as shown in Figure 3(a); (2) The horizontal spring is deformed and the deformation of the left and right sides is the same and so as the angle, and the vertical spring is deformed. Therefore, the combined force of the horizontal and vertical directions on the node is zero, so the node driving force is still zero, as shown in Fig. 3(b); (3) the horizontal spring reaches the original length without deformation, and the vertical spring reaches the maximum amount of compression. However, because of the angle of the links is perpendicular to the guide of horizontal springs, the resultant force at the intermediate node is zero, so the node driving force is still zero, as shown in Fig. 3(c).

Fig.3 Changing of the equilibrium states

Therefore, to change the output of the vertical spring, it only needs to be based on the magnitude of the seismic force, without the need to provide any driving force to achieve the effect of shock absorption. That is to say, in an ideal state, the control force can be arbitrarily changed without exerting actuating force.

3 CONTROL LAW OF THE NEM ACTUATOR

An active control with NEM can use the common active control law, and this NEM can be said that it does not need to consume a large amount of control energy. Therefore, it is not necessary to pay attention to the control force expenditure, and the deformation of the structure should be minimized, that is, the displacement between the structure and the NEM should be as near to the minimum as possible. Therefore the PID controller is used in the NEM controlled system. That is, using the PID control law to determine the reaction force of the stiffening element, the displacement signal of the structure can be used as the error signal, and the following formula determines the reaction force that the stiffening element should generate, and determines the amount of push/pull displacement of the micro actuator.

3.1 PID Controller

The magnitude of the control force is determined by the displacement, velocity, acceleration, etc. of the structure. The common relationship is as follows:

$$u(t) = G_p x(t) + G_I \int_0^t x(t) dt + G_D \dot{x}(t) \quad (9)$$

Where, $u(t)$ is the control force exerted by bracing, $x(t)$ is the displacement of structure, and G_p, G_I, G_D are the proportional, integral and differential gain respectively.

Changing the gain factor (G_p, G_I, G_D) can change the structural control effect. A relatively large coefficient can achieve a better damping rate, but it can lead to loss of control. The main reason for the loss of control is the “time delay”. The time when the control force occurs always lags behind the time when the control force should occur. The difference between the two is the “time delay”.

This study explores the impact of time delay on NEM and can be modeled using the GENDYN program which is developed in our lab.

The control parameters of the PID controller can be divided into three parts: proportional part P, integral part I, and differential part D. Where: (1) Proportional control term P = error value multiplies with positive constant G_p . When the proportional control gain value increases, there will be a larger output under the same error amount, but if the proportional control gain value is too large, it will make the system unstable. Conversely, if the proportional control gain value is small, the output is small at the same amount of error, so the controller is less sensitive. When external disturbances occur, the control signal may not be large enough to quickly correct the effects of external interference. (2) Integral control term = past error multiplies with positive constant G_I . There are problems such as unavoidable friction and minimum starting command value in the system, causing a residual error to be eliminated by the comparison control. The integral control term is used, and the error is added up to generate a larger control command value, which can eventually eliminate small errors. (3) Differential control term = derivative of error multiplies with positive constant G_D . While the proportional control will cause the system to oscillate back and forth around the predetermined value, applying differential control can eliminate oscillation and improve system stability. When the system parameters are adjusted properly, PID control can be very good, but when the parameter is not carefully adjusted, the

effect will be very poor. The impacts of changes on shock absorption benefits induced by G_p , G_D are discussed in this study.

3.2 Influence of the proportional and differential gain on the displacement of structure

3.2.1 Motion equation

Author's affiliation should be written centered, in 11pt Roman, 12pt below the list of authors. A 12pt space should separate two different affiliations.

A SDOF structure equipped with an active control system can be expressed as the following equation:

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = p(t) + u(t) \quad (10)$$

Where, x is structural displacement, m is the mass, c is the damping coefficient, k is the stiffness, $p(t)$ is external force and $u(t)$ is the control force.

When the control force is determined based on PID controller with considering a time delay, the control force $u(t)$ can be expressed as,

$$u(t) = -G_p x(t - \Delta t) - G_D \dot{x}(t - \Delta t) \quad (11)$$

Where, G_p is the proportional gain, G_D is the differential gain and Δt is the time delay.

In case of free vibration, equation (1) can be transformed as,

$$m\ddot{x}(t) + c\dot{x}(t) + G_D \dot{x}(t - \Delta t) + kx(t) + G_p x(t - \Delta t) = 0 \quad (12)$$

3.2.2 Linearized equation of motion

When the amount of time delay is not large, the motion during time interval Δt can be considered as constantly accelerated, and the terms $\dot{x}(t - \Delta t)$ and $x(t - \Delta t)$ can be rewritten as follows:

$$\dot{x}(t - \Delta t) = \dot{x}(t) - \ddot{x}(t) \cdot \Delta t \quad (13)$$

$$x(t - \Delta t) = x(t) - \dot{x}(t) \cdot \Delta t - 0.5\ddot{x}(t)\Delta t^2 \quad (14)$$

Substitute equation (13) and (14) into equation (12), the equation of motion becomes

$$(m - G_D \Delta t - 0.5G_p \Delta t)\ddot{x}(t) + (c + G_D - G_p \Delta t)\dot{x}(t) + (k + G_p)x(t) = 0 \quad (15)$$

It can be seen from equation (15) that the effective mass of the structure is reduced and the structural damping is increased by the differential gain G_D , while the effective mass of the structure and the damping of the structure are reduced by the proportional gain G_p , the stiffness of the structure is increased by G_p . Overall speaking, the effective mass of the structure is reduced and the stiffness of the structure is increased, and the structural damping has the effect of time delay in addition to the influence of G_D and G_p , and does not necessarily increase or decrease. From the results of the above derivation, it can be found that: (1) When G_D and G_p are extremely large, the effective mass of the structure may approach zero, and the frequency

of the structure increases and tends to be unstable. (2) When the time delay is too large, or G_D is too large to reduce the effective mass of the structure and increase the structural frequency, equation (13) and (14) is not applicable, so the above inference is not valid.

4. RESULTS AND DISCUSSIONS OF NUMERICAL SIMULATIONS

When the mechanism proposed by the research institute is used for the damping control of the structure, it is affected by the amount of time delay and the displacement gain coefficient and the speed gain coefficient of the neutral equilibrium mechanism. To explore the effects of these parameters, a numerical simulation of over one million parameter combinations was performed in this study.

In addition to verifying the correctness of the numerical model derived from the equation of motion, this study responds to the corresponding relative displacements of different structural frequencies, damping ratios, frequencies and time delays, and discusses the critical G_D and critical G_p to understand the critical G_p and critical G_D relationship.

4.1 Analysis results

In order to investigate the influence of structural characteristics, time delay, proportional and differential gain on the displacement response of the shear building equipped with NEM, some characteristic responses should be defined. The Displacement response ratio is defined as follows:

$$\text{Displacement Response Ratio} = \frac{\text{The Maximum Relative Displacement of Building under PID Control}}{\text{The Maximum Relative Displacement without Control}}$$

Selected analysis results are shown in Fig.7~8.

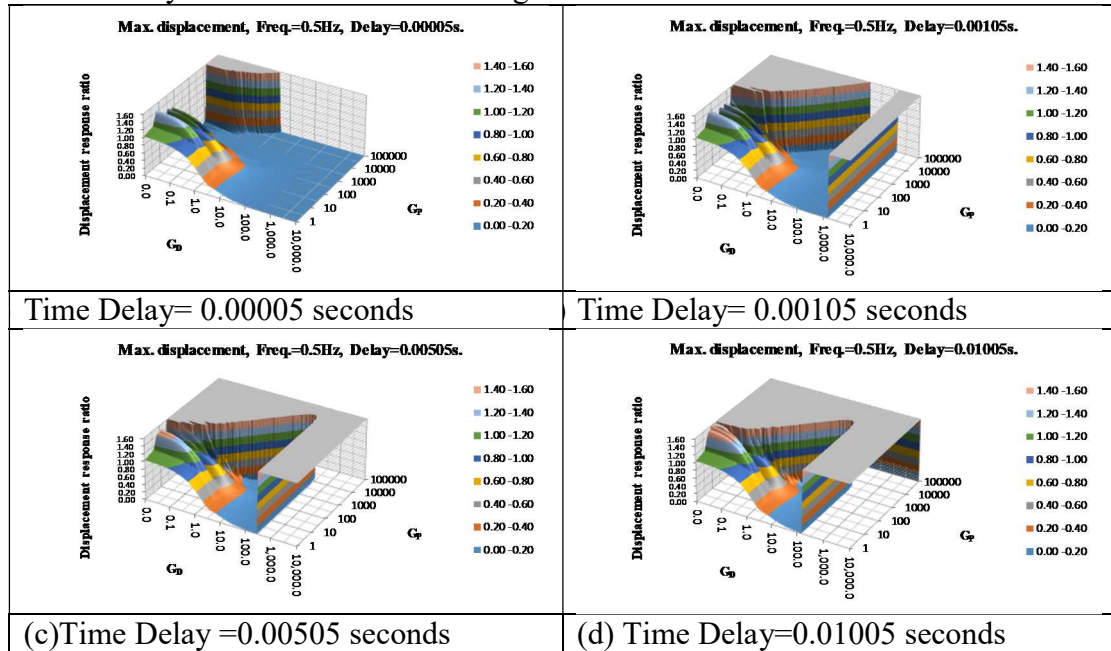

Figure 7. Analysis results of $\xi_0=0.02$, $\omega_n=0.5$ Hz with various time delay and control gains

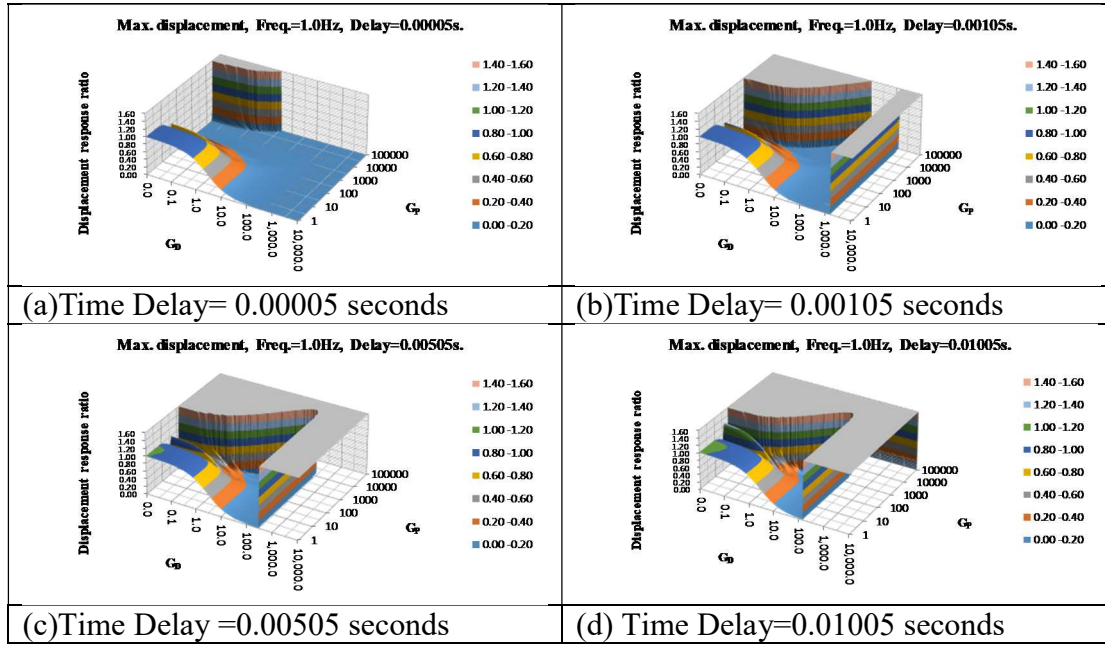

Figure 8. Analysis results of $\xi_0=0.05$, $\omega_n=1.0$ Hz with various time delay and control gains

4.2 Discussion

4.2.1 Performance of reduction of vibration and acceleration response

Comparing the trends in Fig. 7~8, it can be clearly found that when the amount of time delay increases, the interval of G_p and G_d which contribute good damping effect decreases, and even some of the intervals produce amplification benefits, that is, the mechanism fails. The damping ratio of the frame can improve the damping efficiency of the mechanism; when it is known from Fig. 7(a)~8(a) that the time delay is low, as long as the differential gain G_d reaches about 10 or more, the displacement damping effect is very good. But as the natural frequency of the structure increases, the G_d also increases to achieve a good damping effect. If the differential gain coefficient G_d is less than 10, the proportional gain coefficient G_p must be higher than 1000~10000. Comparing Fig. 7 with Fig. 8 it can be found that the damping effect is affected by the time delay when the 1st modal frequency is the same.

The following conclusions can be summarized from Figures 7 and 8:

- (1) When both of the differential gain G_d and the proportional gain G_p are large, the displacement response is small. But when the value G_d and G_p are large and the amount

of time delay increases, it is easy to cause divergence. Therefore, it is necessary to pay attention to the value G_D and G_p to avoid divergence.

- (2) If only the differential gain coefficient is used, i.e. $G_p=0$, the relative displacement of the structure can be effectively reduced. But if the time delay can be precisely controlled, and the simultaneous use of G_D and G_p can achieve better results;
- (3) If G_D exceeds a certain value, it will unconditionally diverge, and this critical value will decrease with the increase of time delay;
- (4) As the differential gain G_D increases, the value G_p can be larger and larger, and good shock absorption can be achieved without causing divergence.

4.2.3 Regression relation of critical G_D and critical G_p

G_p , G_D and time delay are three factors that influence the stability of the system. In this section, we will explore the interaction of the three on the stability interval of the control system. Here, we have a structure with a natural frequency of 1 Hz and a damping ratio of 0.02 as a controlled structure. When the time delay is 0.01005 seconds, the relationship between the critical proportional gain and the differential gain is shown in Fig. 9.

Fig. 9 Relationship of critical proportional gain and critical differential gain for structure with natural frequency = 1.0Hz and damping ratio = 0.02

According to the linear regression results of the effective critical G_p , the regression line formed by the critical G_D and critical G_p has a slope of about $\frac{1}{\Delta t}$ and the intercept is about $\frac{c}{\Delta t}$. The deviations are caused by numerical resolution. The theoretical analysis shows that the

value G_p should also be dimensionless, $\hat{G}_p = \frac{1}{m}(G_p \Delta t^2 - c \Delta t)$, so that the relationship critical G_D and critical can be clearly understood.

After the differential gain and the proportional gain are dimensionless, we find that the relationship between the critical differential gain and the proportional gain of all the analysis results coincides, regardless of structural damping, structural frequency, and time delay. Fig. 10 shows the above relationship.

Fig.15 Relation of critical dimensionless proportional and differential gain

5 CONCLUSION

This study uses theoretical and experimental verification and numerical analysis to explore the theoretical assumptions of NEM. The relationship between the critical differential gain and the critical proportional gain is also discussed. The results of the experiment and analysis are summarized as follows:

1. According to theoretical derivation and experimental verification, the condition of this mechanism is that the stiffness of the diagonal bracing is equal to 2 times the spring stiffness; the spring is in an unstressed state when the internal angle θ of the mechanism is equal to zero;
2. By introducing the dimensionless proportional gain, $\hat{G}_p = \frac{1}{m}(G_p \Delta t^2 - c \Delta t)$, and differential gain, $\hat{G}_D = G_D \cdot \frac{2 \cdot \Delta t}{\pi \cdot m}$, all relation curves of the control coincide, regardless of structural mass, stiffness, damping coefficient and among of time delay.
3. NEM can be considered as a power amplification mechanism. When it is mounted on a structure, it can exert shock absorbing efficiency without generating acceleration amplification benefits.
4. NEM is susceptible to the amount of time delay. Stable control effects can be achieved by

accurately providing the appropriate speed gain factor and displacement gain factor. In the future, this organization can increase the predictive control mechanism to achieve better control effects.

Key words: Torsional beam vibrations, structural dynamics, warping, active control, position feedback, finite element method.

Abstract. This paper considers damping of torsional beam vibrations by active control of the axial warping displacements. A beam element with active positive position feedback (PPF) is set up with an additional flexibility parameter. This arises from partial restraining of warping caused by discrete actuators. The flexibility lowers the frequency associated with an infinite actuator gain and thereby the attainable damping ratio. It is shown how it furthermore affects the stability limit. Results are compared with three-dimensional finite element results, with multiple actuators acting on an end cross-section of the beam. The accuracy of the beam model is justified by an example which shows that substantial damping ratios may be achieved by active warping control.

1 INTRODUCTION

Slender structures like long bridge decks, aircraft wings, wind turbine blades and general thin-walled beams may be prone to vibrations due to loads like wind, traffic etc. If the loads act with an eccentricity relative to the shear center or if the cross-section lacks double symmetry, torsional vibrations may be induced. For some structures the aerodynamic instability phenomenon flutter may occur where flexural and torsional vibrations couple. To potentially avoid flutter or to reduce fatigue stresses, structural mass or accelerations, supplemental damping may be required.

Torsion of thin-walled beams generates out-of-plane, axial warping displacements that are often significant at the boundaries of beams with open cross-sections. Thus, for these types of thin-walled beams the restraining of warping results in an often considerable increase in the natural frequency and change in vibration characteristics as described by Gere [1]. The localized effect of restrained warping is used in [2] to introduce a substantial amount of supplemental damping by applying an energy dissipating boundary condition. In [3] discrete viscous dampers constituting a pure bimoment are placed on the beam cross-section of a three-dimensional finite element model, showing convincing agreement with the governing transcendental equation.

For beams with closed cross-sections or when torsion couples with flexure, viscous dampers may not be sufficient or even practically applicable. Thus, in the present work an active damping concept is used for damping of pure torsional vibrations. A positive position feedback (PPF) [4] signal is passed by a sensor through a simple linear filter to an actuator which produces an active force. The damping

Figure 1: a) beam with degrees-of-freedom and b) thin-walled cross-section with coordinate system.

concept is applied with a beam element and compared with a full three-dimensional finite element (FE) analysis. In an actual structure the actuators are placed as discrete actuators on a beam cross-section, thus only partially restraining the warping. This is associated with an additional flexibility that lowers the frequency obtained when the actuators completely lock - which in control theory typically is referred to as a zero - and thereby also the maximum damping ratio determined as the relative imaginary part of the natural frequency. This flexibility is incorporated into the beam element as a Maxwell-type boundary condition, and is calibrated by dedicated finite element results. The system is solved in state-space form and it is shown that substantial damping ratios may be obtained for the lowest torsional mode. For the position feedback the control gain is limited by stability yielding a gain as derived in [5]. At a certain point the actuator will eliminate the structural stiffness at the location of the actuator and the response becomes unbounded. This limit, however, is based on a static condition and it is shown how the additional flexibility from restraining warping partially affects this limit.

2 STRUCTURAL EQUATIONS

In this section the governing structural equations are presented. First the differential equation governing pure torsion is presented and then the beam is discretized with beam elements, resulting in the governing multi-degree-of-freedom equations.

2.1 Uncoupled torsional vibrations

Consider the beam in Fig. 1a with length ℓ , longitudinal axis z and transverse axes $\{x_1, x_2\}$. For a cross-section like the one in Fig. 1b with double symmetry, the elastic and shear centers coincide and the torsional and flexural vibrations thereby uncouple. The rotation with respect to the shear center is denoted $\theta(t, z)$ and the warping intensity is the spatial derivative of the rotation $\theta'(t, z)$. The differential equation governing pure torsional vibrations may be derived as [1, 3, 6],

$$EI_\psi \theta''''(t, z) - GK\theta''(t, z) - \rho I_\psi \ddot{\theta}(t, z) + \rho J \ddot{\theta}(t, z) = 0 \quad (1)$$

where E is Young's modulus, G is the shear modulus, ρ is the mass density, I_ψ is the warping moment of inertia, K is the torsion stiffness parameter, $(\cdot)' = \partial(\cdot)/\partial z$ denotes partial differentiation with respect to z and $(\cdot) = \partial(\cdot)/\partial t$ denotes partial differentiation with respect to t . The third term is the inertia associated with the axial warping [6] and is often neglected due to its limited importance.

2.2 Discretization with beam elements

The torsion problem is now implemented in a finite element setting and the structure is discretized with beam elements. As pure torsional vibrations are considered the beam element only contains the two torsional degrees-of-freedom as depicted in Fig. 1a, that is the rotation and warping intensity. The four degrees-of-freedom for the beam element are interpolated as,

$$\boldsymbol{\theta} = \mathbf{N} [\boldsymbol{\theta}_A, \ell \boldsymbol{\theta}'_A, \boldsymbol{\theta}_B, \ell \boldsymbol{\theta}'_B]^T \quad (2)$$

where the displacement interpolation array \mathbf{N} contains the Hermitian shape functions,

$$\mathbf{N} = [2s^3 - 3s^2 + 1, s(s-1)^2, -2s^3 + 3s^2, s^2(s-1)] \quad (3)$$

where $s = z/\ell$ is a local element coordinate. The element stiffness matrix \mathbf{K} and mass matrix \mathbf{M} are associated with the elastic and kinetic energy respectively. Setting up the energies and assuming a prismatic beam element leads to the explicit expression for the stiffness matrix

$$\mathbf{K} = EI_\Psi \ell^{-3} \begin{bmatrix} 12 & & & \\ 6 & 4 & & \\ -12 & -6 & 12 & \\ 6 & 2 & -6 & 4 \end{bmatrix} + GK \ell^{-1} \frac{1}{30} \begin{bmatrix} 36 & & & \\ 3 & 4 & & \\ -36 & -3 & 36 & \\ 3 & -1 & -3 & 4 \end{bmatrix} \quad (4)$$

with contributions from homogeneous and inhomogeneous torsion through GK and EI_Ψ respectively. The mass matrix takes a similar form,

$$\mathbf{M} = \rho J \ell \frac{1}{420} \begin{bmatrix} 156 & & & \\ 22 & 42 & & \\ 54 & 13 & 156 & \\ -13 & -3 & -22 & 4 \end{bmatrix} + \rho I_\Psi \ell^{-1} \frac{1}{30} \begin{bmatrix} 36 & & & \\ 3 & 4 & & \\ -36 & -3 & 36 & \\ 3 & -1 & -3 & 4 \end{bmatrix} \quad (5)$$

The first term in (5) contains the torsional inertia and the second term contains the warping inertia. The latter is usually of limited importance and often discarded but may in this format easily be implemented through the submatrices. The local elements are easily assembled and transformed to a global structure [7].

2.3 Multi-degree-of-freedom system

As the model is discretized with beam elements the equations of motion are given in terms of the displacement vector $\mathbf{q}(t)$ of the linear system and the corresponding stiffness matrix \mathbf{K} and mass matrix \mathbf{M} from Section 2.2. Neglecting any inherent structural damping the system has the general form,

$$\mathbf{M} \ddot{\mathbf{q}}(t) + \mathbf{K} \mathbf{q}(t) = -\mathbf{w} B_d(t) \quad (6)$$

where $B_d(t)$ represents the effect of the external actuator on the system in the form of a bimoment [6]. The corresponding connectivity vector \mathbf{w} identifies the point on the structure connected to the actuator for the beam with a single actuator. The vector has the structure $\mathbf{w} = [0, \dots, 1, \dots, 0]^T$ with the single entry defining the degree-of-freedom associated with the actuator.

The actuator is assumed linear and collocated and may be formulated by a frequency transfer function $H(\omega)$ and gain g in the form

$$B_d(t) = g H(\omega) \mathbf{w}^T \mathbf{q}(t) \quad (7)$$

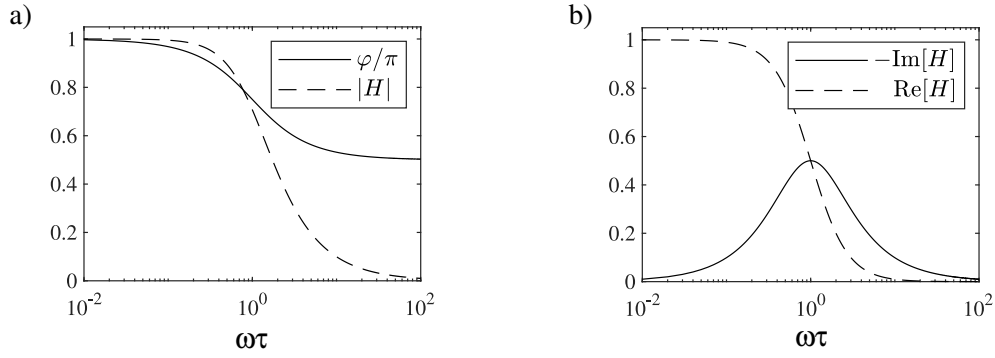

Figure 2: a) magnitude and phase angle and b) real and imaginary part of the transfer function $H(\omega)$.

The frequency function may take several different forms based on the particular control law. By introducing (7) in (6) the equations of motion may be written in the frequency domain as

$$(-\omega_n^2 \mathbf{M} + \mathbf{K} + gH(\omega) \mathbf{w} \mathbf{w}^T) \tilde{\mathbf{q}}_n = \mathbf{0} \quad (8)$$

where $\tilde{(\cdot)}$ indicates the amplitude. If $g = 0$ the actuator does not influence the structure and the solution to the eigenvalue problem in (8) will give real-valued solutions in form of the undamped natural frequencies $\omega_{0,n}$. If, on the other hand, $g \rightarrow \infty$ the actuator will lock and prohibit displacement at its location, whereby the solution to the eigenvalue problem provides the infinitely damped frequencies $\omega_{\infty,n}$, associated with infinite gain. The frequencies ω_0 and ω_∞ are typically denoted pole and zero respectively within control theory.

3 Active control by position feedback

Active control is now introduced by a positive position feedback. The control system detects the axial warping displacement at the end cross-section during the torsional motion, passes it through a simple linear first order filter and feeds it positively back to the structure. The position feedback is deemed appropriate as the warping displacements are small and easily measured by e.g. a piezoelectric sensor or a laser device. The filter is mathematically formulated as [8]

$$B_d(t) + \tau \dot{B}_d(t) = g \theta'_g(t) \quad (9)$$

where $\theta'_g = \mathbf{w}^T \mathbf{q}$ is the displacement at the actuator which in this case constitutes the warping intensity, B_d is the actuator force constituting a bimoment which is energy conjugate to the warping intensity and τ is a filter constant which defines the cut-off frequency at $1/\tau$. Based on the displacement $\theta'_g(t)$ the equivalent actuator force $B_d(t)$ is fed back to the system. The transfer function for the filter in (9) is hereby obtained as

$$gH(\omega) = \frac{g}{1 + i\omega\tau} \quad (10)$$

The corresponding phase angle and magnitude are determined as

$$\tan \varphi = -\omega\tau \quad , \quad |H| = \frac{1}{\sqrt{1 + (\omega\tau)^2}} \quad (11)$$

The phase angle and magnitude are seen in Fig. 2a. This specific filter ensures large damping in the low-frequency range below the cut-off frequency, while attenuating noisy high-frequency components

Figure 3: a) quarter cross-section discretized with isoparametric elements and with local actuators and b) altered cross-sectional warping.

which may be badly represented. By the punctured curve in Fig. 2a it is evident that this is achieved as the magnitude of the transfer function vanishes above the cut-off frequency. The major benefit of active control is the possibility of greater damping performance when the actuator leads velocity with a phase angle $\varphi > \pi/2$. Especially in the low-frequency range this filter exhibits a phase angle close to π as indicated by the solid curve, and therefore has a force component in phase with negative stiffness. In order for the actuator to dissipate energy and not amplify the vibrations, it is required that $\text{Im}[gH(\omega)] > 0$. In Fig. 2b the solid curve represent the imaginary part of the transfer function. As this is negative, it means that $g < 0$.

3.1 Warping-restrained flexibility

In practice warping control may be realized by axial actuators, acting on the cross-section as shown in Fig. 3a. In a situation with concentrated axial actuators applied at a cross-section the actuators will only fully restrain the warping displacements at the location of the actuators. At infinitely high gain, i.e. when $g \rightarrow \infty$, the axial movement at the actuator location will be completely prevented. However, the cross-section may still be able to warp in between the actuators and leave an altered warping function as illustrated in Fig. 3b. This is associated with an additional flexibility compared to a fully restrained cross-section [3]. At vanishing damping ($g = 0$) the additional flexibility must however disappear. This additional flexibility may therefore be modelled as a spring in series with the actuator, as seen in Fig. 4. The warping works through the gradient of the angle of twist and therefore so does the spring. It is, however, an artificial spring as it is not physically present, but merely describes the additional flexibility due to the partial warping of the cross-section for $g > 0$. Thereby it may conveniently be modelled as a Maxwell-type boundary condition. The total gradient of the angle of twist, θ'_d , is the sum of the contribution from the actuator and spring as seen in Fig. 4,

$$\theta'_d(t) = \theta'_k(t) + \theta'_g(t) \quad (12)$$

where it works through the actuator bimoment B_d . The bimoment produced by the spring is

$$B_k(t) = k\theta'_k(t) \quad (13)$$

and the bimoment produced by the actuator is given by (9). Introducing (9) and (13) into (12) yields the modified control equation, to be used for calibration of g and identification of the stability limit,

$$\left(\frac{1}{g} + \frac{1}{k}\right) B_d(t) + \frac{\tau}{g} \dot{B}_d(t) = \theta'_d(t) \quad (14)$$

Figure 4: Maxwell-type boundary condition with an active element with gain g in series with a spring with stiffness k .

The determination of k requires in this case knowledge about the actual structure either from a full three-dimensional finite element model, from experiments or from real measurements. The stiffness k in the flexibility format reduces the infinitely damped frequency ω_∞ as the cross-section is now able to warp in between the actuator locations. However, due to the active nature of the actuator there will be a stability limit, see Section 3.3, where the response becomes unbounded. In the complex plane, however, the root locus will trace towards the correct infinitely damped frequency, as the controller equation (14) in the limit describes only the additional flexibility,

$$\left(\frac{1}{g} + \frac{1}{k}\right) B_d(t) + \frac{\tau}{g} \dot{B}_d(t) = \theta'_d \quad \rightarrow \quad B_d(t) = k\theta'_d \quad \text{for } g \rightarrow \infty \quad (15)$$

This means that the structural equations are merely supplemented with a spring, incorporated in flexibility format, when establishing the state-space equations in the following section. The stiffness k is calibrated in the unstable situation where $g \rightarrow \infty$, but this is equivalent with a situation where the actuators are replaced with supports and may thus be used for calibration.

3.2 State-space formulation

The properties of the dynamic system with damping is conveniently demonstrated in the frequency domain. The equations of motion are therefore set up in a state-space format including the feedback force from (14). With the state-vector $\mathbf{z}(t) = [\mathbf{q}(t), \dot{\mathbf{q}}(t), B_d(t)]^T$ the system is

$$\frac{d}{dt} \begin{bmatrix} \mathbf{q}(t) \\ \dot{\mathbf{q}}(t) \\ B_d(t) \end{bmatrix} = \begin{bmatrix} \mathbf{0} & \mathbf{I} & \mathbf{0} \\ -\mathbf{M}^{-1}\mathbf{K} & \mathbf{0} & -\mathbf{M}^{-1}\mathbf{w} \\ g/\tau\mathbf{w}^T & \mathbf{0} & -g/\tau\left(\frac{1}{g} + \frac{1}{k}\right) \end{bmatrix} \begin{bmatrix} \mathbf{q}(t) \\ \dot{\mathbf{q}}(t) \\ B_d(t) \end{bmatrix} \quad (16)$$

where \mathbf{I} is the identity matrix. The presence of the actuator leads to generally complex-valued solutions of ω ,

$$\omega_n = |\omega_n| \left(\sqrt{1 - \zeta_n^2} + i\zeta_n \right) \quad (17)$$

where n denotes the various eigensolutions. The damping ratio is given by the imaginary part of (17) as

$$\zeta_n = \frac{\text{Im}[\omega_n]}{|\omega_n|} \quad (18)$$

The mode shapes obtained from (16) are in general also complex, with the real part representing the physical vibration form and the imaginary part representing the spatial phase shift due to the presence of the energy dissipating actuator.

Figure 5: Root locus and indication of the stability limit when the purely imaginary eigenvalue becomes negative.

3.3 Stability and gain limit

When solving (16) varying the gain in the interval $g \in [0; \infty[$ the damped frequency will trace a root locus in the complex plane between the undamped frequency ω_0 and the infinitely damped frequency ω_∞ as shown in Fig. 5. However, as mentioned in Section 3.1 after a certain gain the response becomes unbounded. With a single actuator present, a single eigenvalue will be purely imaginary. Instability occurs when this eigenvalue becomes zero. In order for the response not to become unbounded the stability of the system must therefore be considered. This is mainly to set a limit for the gain g . The stability of the system may be checked with the Routh-Hurwitz criterion. For larger systems this typically requires determination of the Routh arrays and may not be convenient to determine an explicit limit for the gain. An alternative is to write the full system consisting of the structural equations (6) and the controller equation (14) in a block format. The structural equations and controller equation are pre-multiplied with $-gv^{-1}$ where $v = (1 + \frac{g}{k})$, and the original structural displacement vector \mathbf{q} is replaced by the modified set of variables in $\mathbf{q}^* = -gv^{-1}\mathbf{q}$. The equations then take the form

$$\begin{bmatrix} \mathbf{M} & \mathbf{0} \\ \mathbf{0} & 0 \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{q}}^* \\ \ddot{B}_d \end{bmatrix} + \begin{bmatrix} \mathbf{C} & \mathbf{0} \\ \mathbf{0} & -gv^{-2}\tau \end{bmatrix} \begin{bmatrix} \dot{\mathbf{q}}^* \\ \dot{B}_d \end{bmatrix} + \begin{bmatrix} \mathbf{K} & -gv^{-1}\mathbf{w} \\ -gv^{-1}\mathbf{w}^T & -gv^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{q}^* \\ B_d \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ 0 \end{bmatrix} \quad (19)$$

It is noted that if $|g| < k$ then $v > 0$. The mechanical energy is defined by the first and last matrix. The equivalent mass matrix is always positive semi-definite, and as $\tau > 0$ the equivalent damping matrix will be positive definite if the original structure has positive definite damping and is otherwise positive semi-definite. The stability is therefore entirely governed by the equivalent stiffness matrix and the corresponding reduction in stiffness caused by the actuator with the added warping-restrained flexibility. The potential energy associated with the stiffness matrix can be expressed as

$$V_e = \begin{bmatrix} \mathbf{q}^{*T} & B_d \end{bmatrix} \begin{bmatrix} \mathbf{K} & -gv^{-1}\mathbf{w} \\ -gv^{-1}\mathbf{w}^T & -gv^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{q}^* \\ B_d \end{bmatrix} \quad (20)$$

After some rearranging it takes the form

$$V_e = \frac{1}{2}\mathbf{q}^{*T} [\mathbf{K} + gv^{-1}\mathbf{w}\mathbf{w}^T] \mathbf{q}^* + \frac{1}{2} \left(B_d (gv^{-1})^{1/2} - (gv^{-1})^{1/2} \mathbf{w}^T \mathbf{q}^* \right)^2 - B_d gv^{-1} B_d - \mathbf{q}^{*T} gv^{-1} \mathbf{q}^* \quad (21)$$

The time derivative of this functional is given by the second matrix in (19) as

$$\dot{V}_e = -[\dot{\mathbf{q}}^{*T} \mathbf{C} \dot{\mathbf{q}}^* - \dot{B}_d g v^{-2} \tau \dot{B}_d] \leq 0 \quad (22)$$

The second term in (21) is a quadratic form and thus always positive, while the third and fourth terms are also positive as $g < 0$. Stability is therefore governed by the first term of which the matrix must be positive definite for the combined system to be stable. If the matrix becomes singular it corresponds to the stiffness component of the actuator eliminating the structural stiffness at the location of the actuator and instability occurs. This corresponds to the requirement

$$\det(\mathbf{K} + g v^{-1} \mathbf{w} \mathbf{w}^T) > 0 \quad (23)$$

Thus the matrix in the parentheses must be invertible and the limit of the gain, g_{stab} , may be found by considering the invertibility of the matrix. The result follows from the Sherman-Morrison formula [9] as

$$(\mathbf{K} + g v^{-1} \mathbf{w} \mathbf{w}^T)^{-1} = \mathbf{K}^{-1} - g v^{-1} \mathbf{K}^{-1} \mathbf{w} (1 + g v^{-1} \mathbf{w}^T \mathbf{K}^{-1} \mathbf{w})^{-1} \mathbf{w}^T \mathbf{K}^{-1} \quad (24)$$

When rigid body motion is accounted for, the stiffness matrix will be fully positive definite. Thus, if the term in the parenthesis on the right side of (24) becomes zero, the term may not be inverted. This determines the gain limit as

$$\frac{1}{g_{\text{stab}}} = -\mathbf{w}^T \mathbf{K}^{-1} \mathbf{w} - \frac{1}{k} \quad (25)$$

The above expression leaves a direct way of determining the maximum gain, which is at the same time seen to be negative. A gain that exceeds the above limit will result in an unbounded response.

4 Comparison with a 3D FEM model

The beam model is compared with a full three-dimensional FE model with isoparametric elements. The elements used are bi-cubic-linear elements for flange parts and bi-linear-cubic elements for corners and junctions. For details on the elements and discretization of the beam see [3]. The beam is discretized with 30 length-wise elements, half of them being concentrated over $\ell/25$ of the beam near the end, and a single bi-cubic-linear element per flange part as in Fig. 3a. In the three-dimensional model, actuators are applied in the corners as in Fig. 3a, and as they are placed asymmetrically they are balanced according to [3, 10]. Thus, m actuators are present and the feedback filter now contains several equations written in vector format as

$$\mathbf{f}_d + \tau \dot{\mathbf{f}}_d = \mathbf{G} \mathbf{W}^T \mathbf{q} \quad (26)$$

This equation resembles (9) but without the flexibility k . In order not to damp other modes than those associated with torsion, each connectivity vector \mathbf{w}_j contains contributions from exactly four actuators constituting a pure bimoment. These four actuators are placed symmetrically in the corners with respect to the principal axes of the cross-section in Fig. 1, and thus only one of the four actuators in each corner as indicated in Fig. 6b enters each connectivity vector. Thus the structure is $\mathbf{w}_j = [0, \dots, -\sqrt{1/4}, \sqrt{1/4}, -\sqrt{1/4}, \sqrt{1/4}, \dots, 0]^T$. The collective array $\mathbf{W} = [\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_{m/4}]$ contains $m/4$ connectivity vectors and $\mathbf{G} = \text{diag}[g_1, g_2, \dots, g_{m/4}] = g^{3D} \text{diag}[\alpha_1, \alpha_2, \dots, \alpha_{m/4}]$ is a diagonal matrix with all gains. The actuators are in this case not balanced equally due to the asymmetric location of the actuators in Fig. 6. Balancing factors α_j are therefore introduced according to [3] and g^{3D} is a common gain. The stability requirement is derived in the same way as for the beam model with

Figure 6: a) 'simple-simple' beam with damping treatment at $z = \ell$ and b) order of actuator gains at cross-section corner.

a single actuator, but the final condition is not an explicit expression for the gain. The following matrix may be derived,

$$\mathbf{H} = \mathbf{G}^{-1} + \mathbf{W}^T \mathbf{K}^{-1} \mathbf{W} \quad (27)$$

which is $m/4 \times m/4$ and will be negative definite for small values of g^{3D} and thereby have all negative eigenvalues $\lambda_i < 0$. Instability occurs exactly when the first eigenvalue of \mathbf{H} becomes positive. As the beam model and three-dimensional model are inherently different, the gain at instability will not be the same as the actuators are tuned differently. However, by setting up the virtual work produced by the actuator in the beam model and the actuators in the three-dimensional model, a conversion factor can be derived as

$$g^{3D} = \frac{g}{\sum_j^m \alpha_j \psi_j^2} \quad (28)$$

where ψ_j is the sector-coordinate of the j 'th actuator. In the next section it will be shown that instability occurs at the same frequency and damping ratio in the two models.

5 Damping of a 'simple-simple' beam

The accuracy of the beam model is now demonstrated by investigating the damping properties of the lowest torsional mode of the 'simple-simple' beam with length ℓ as shown in Fig. 6a. The support conditions restrain rotation but allow warping. The cross-section of the beam is shown in Fig. 1 and has thickness $t = a/40$, Young's modulus $E = 210$ GPa, Poisson's ratio $\nu = 0.3$ and density $\rho = 7850$ kg/m³. The ratio between the cross-section height and the length of the beam is $\ell/a = 30$ and $a = 1$ m, for which the inherent distortion of the cross-section is minimal [3]. The beam model is compared with results from a three-dimensional finite element analysis. In this finite element model four actuators are placed at each corner as shown for a single corner in Fig. 6b, and balanced according to Table 1. This is done in order to avoid unnecessary distortion of the cross-section. For the beam model the first objective is to adjust the infinitely damped frequency ω_∞ to account for the partial restraint of the warping at $z = \ell$. This is done by performing a real analysis of the 3D FE model by solving the full system in (16) with $g \rightarrow \infty$ and afterwards calibrating the flexibility parameter k by a numerical search routine to ensure that the frequency locus terminates at the correct frequency. To create the root locus the gain is varied in the interval $g \in [0; g_{\text{stab}}[$ where the stability limit is given by (25) or (27) for the beam and 3D model respectively.

The root loci for both models are seen in Fig. 7a. The solid line with black circles ($\text{---}, \circ$) are results from the beam model, the red markers ($+$) are results from the 3D model and the blue box marker (\square) indicates the stability limits. Furthermore, the punctured line indicates results for the beam model with $k = \infty$ associated with complete restraint of the warping of the entire cross-section. For comparison,

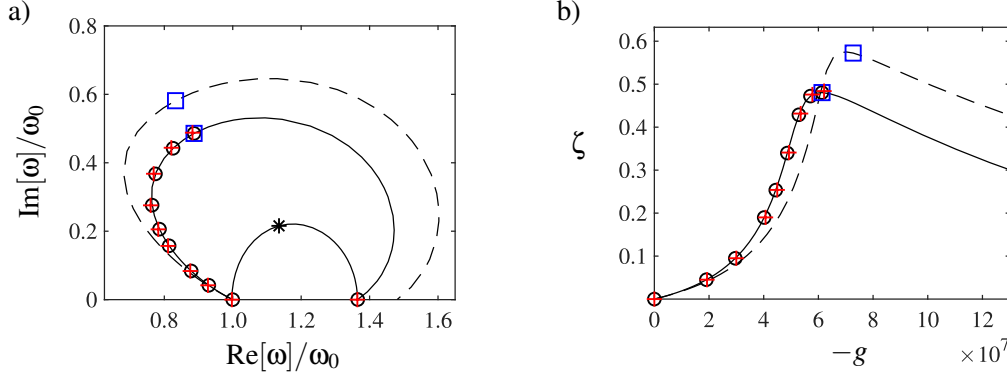

Figure 7: a) root locus and b) damping ratio for the beam analysis (—,○), FE analysis (+), gain limit (□) and $k = \infty$ (---).

the smaller half-circular root locus is with pure viscous damping, and the asterisk (*) indicates optimal tuning. Clearly the partial restraint of the warping associated with the flexibility parameter k given in Table 2 results in a significant difference, lowering the relative frequency increment $(\omega_\infty - \omega_0)/\omega_0$ from 0.481 to 0.365 and the damping ratio at instability from 0.572 to 0.480 for the beam model. The damping ratio as may be seen in Fig. 7b also indicates large damping. The damping ratios at instability and the frequency increments for the two models are very similar as seen in the table, and the small deviation is due to distortional effects in the 3D model, which causes slightly different undamped frequencies ω_0 . Due to the different nature of the two models and actuator configurations, the limit gains g_{stab} and g_{stab}^{3D} are not identical. The factor between these two is $g_{\text{stab}}/g_{\text{stab}}^{3D} = 50.4$ as seen in the table, and this is approximated well with (28) as seen in the last column in the table. Lastly it may be observed that the gain limit for the beam model is higher if not taking the partial warping restraining into account. This may wrongfully lead to instability.

6 CONCLUSION

In this paper a computationally efficient way of investigating the properties of damping the torsional vibrations in a simple beam with active control is considered. A beam element is set up with a single actuator acting on the warping degree-of-freedom. The actuator consists of a simple linear filter in the form of positive position feedback (PPF). It acts on the axial warping displacements, and is on an actual structure placed discretely as a set of actuators constituting a pure bimoment. This partially restrains the warping and allows for an additional flexibility in the beam model. This flexibility lowers the infinitely damped frequency and correspondingly reduces the gain limit at the point of instability. The beam model is compared with a full three-dimensional finite element model which has a set of actuators applied at discrete locations, all constituting pure bimoments. In this way only torsional modes are damped. The system equations are similar to the beam model, and instability is determined by the gain which makes the combined stiffness matrix singular. Considering a simple-simple beam as an example and plotting the root loci and damping ratios, very similar results between the two models are obtained. Only minor

Table 1: Balancing factors.

	g_a	g_b	g_c	g_d
α_j [—]	1.0	7.5	70.0	141.4

Table 2: Results of analysis.

	k	$(\omega_\infty - \omega_0)/\omega_0$	ζ_{stab}	g_{stab}	$g_{\text{stab}}/g_{\text{stab}}^{3D}$	$\sum_j^m \alpha_j \psi_j^2$
Beam model	∞	0.481	0.572	$-7.27 \cdot 10^7$	—	—
	$3.89 \cdot 10^8$	0.365	0.480	$-6.13 \cdot 10^7$	50.4	51.0
3D model	—	0.368	0.484	$-1.22 \cdot 10^6$		

differences are observed, which may be corrected by accounting for the inherent distortion of the three-dimensional model. It is furthermore demonstrated, that the flexibility k is necessary for the beam model to reflect the 3D model. If not included, a gain exceeding the gain limit may wrongfully be chosen. The gain at instability is inherently different in the two models, but may easily be estimated considering the position of the discrete actuators. The benefits with the active filter is clear, as the beam is damped effectively, with a damping ratio of almost $\zeta = 0.5$.

Key words: First mode shapes, Damage Detection, Shear-type buildings, Damage localization.

Abstract. Damage of structures can raise concerns about safety issues to users. Minor damage in structures may not be critical to structural safety; however, users may not exactly know the severity of damage in structures. Thus, structural health monitoring (SHM) becomes a strategy that can estimate current performance and safety of structures. Users can be informed regarding the levels and locations of damage in structures before the damage has been turned into a serious problem. To achieve this goal, dynamic characteristics such as natural frequencies and mode shapes can be employed to derive associated damage indices that inform structural integrity. These characteristics are typically obtained from vibrational measurements of structures through operational modal analysis. Then, damage of structures can be diagnosed from mode shapes. Therefore, the objective of this study is to assess multiple mode shapes based methods for the capability of detecting damage levels and locations. First, mode shapes of buildings are numerically calculated. Because the first mode shape is mostly available from operational modal analysis, the mode shape is then employed in all of mode shapes based damage detection methods. The damage detection methods considered in this study include the mode shape curvature method, the bending energy damage index method, the strain energy damage index method, the continuous wavelet transform method based on mode shape curvatures, and the method of changes in the first mode shape slopes. The capability of these methods for damage location detection is investigated, while the sensitivity of damage levels from these methods are also studied to understand the relationship between the derived damage indices and damage severity. Some modifications are made to the existing methods for better representing damage levels. Moreover, multiple damage locations are considered in this study, and these damage locations are assumed to sequentially occur. A detailed comparison among these methods is

carried out. As seen in the numerical results, second derivatives of mode shapes (i.e., mode shape curvatures) can well represent damage of buildings in terms of damage locations and levels.

1 INTRODUCTION

Damage of structures can raise concerns about safety issues to users. Minor damage in structures may not be critical to structural safety; however, users may not exactly know the severity of damage in structures. Thus, structural health monitoring (SHM) becomes a strategy that can estimate current performance and safety of structures. Users can be informed regarding the levels and locations of damage in structures before the damage has been turned into a serious problem.

One of the commonly seen methods in the field of SHM is to regularly obtain dynamic characteristics of structures through operational modal analysis. These dynamic characteristics include natural frequencies, damping ratios, and mode shapes over a number of vibrational modes. If structures suffer some damage or have some defects, these dynamic characteristics will have some changes. These changes provide a source to determine and localize the damage or defects. For examples, cracks which occur in a structure result in decreased stiffness. The decreased stiffness lowers natural frequencies in the first few modes. The mode shapes would have corresponding variations as compared to those of the undamaged structure. If features can be extracted from these changes in natural frequencies and mode shapes, the damage in a single or multiple spot(s) can be determined and localized.

In this research, six mode shapes-based damage detection methods are investigated. The objective of this study is to exploit these methods for damage detection by means of the first mode shapes only. For example, Pandey *et al.* (1991) employed mode shape curvatures to successfully localize damage regions of a structure [1]. Stubbs *et al.* (1995) utilized mode shapes to derive strain energy and computed the energy ratio of a structure before and after the occurrence of damage [2]. This energy ratio can identify the locations of damage [3]. Allemang and Brown (1982) applied mathematical approach to analyzing the relationship between the mode shapes of a structure before and after the occurrence of damage [4]. Lieven and Ewins (1998) advanced this mathematically comparative approach and proposed a coordinate modal assurance method that can improve the accuracy of damage detection using mode shapes [5]. Mallat (1998) facilitated the wavelet transform to find the singular points in mode shapes that can identify damage locations [6]. Zhu *et al.* (2011) found that use of first mode shapes can directly locate damage of a structure by means of the dynamic characteristic equation. All the aforementioned methods are numerically explored in this study for damage detection in terms of occurrence and localization. This numerical example consists of a ten-story shear-type building with two damage scenarios. In each scenario, the damaged story has three levels of reductions in stiffness. By comparing the successfulness, the six damage detection methods are evaluated.

2 DAMAGE DETECTION METHODS

This section briefly introduces six mode-shape based damage detection methods including the mode shape curvature (MSC) method, bending energy damage index (BEDI) method, the

modal assurance criterion (MAC) method, strain energy damage index (SEDI) method, continuous wavelet transform (CWT) method, and the method of changes in the first mode shape slopes (CFMSS).

2.1 Mode shape curvature

The variations of mode shape curvatures are correlated with damaged regions of a structure because curvatures are associated with the bending stiffness of the structure [1]. A mode shape curvature can be presented by

$$\phi''(x) = \frac{M}{E(x)I(x)} = \frac{\phi(x+h) + \phi(x-h) - 2\phi(x)}{h^2} \quad (1)$$

where $\phi''(x)$ denotes the curvature calculated from the mode shapes $\phi(x)$ at location x ; M is the bending moment; $E(x)$ is the Young's Modulus at location x ; $I(x)$ is the moment of inertia; h is the height of each story. If the building has damage, the reduction of $E(x)I(x)$ will result in changes of the mode shape curvatures. The changes can be indicated by

$$MSC_j = \sum_{i=1}^N |\phi''_{i,j}^* - \phi''_{i,j}| \quad (2)$$

where $\phi''_{i,j}$ and $\phi''_{i,j}^*$ are the mode shapes before and after the occurrence of damage; i and j indicates the i -th mode and j -th location in a structure; N is the number of modes of interest.

2.2 Bending energy damage index

The bending energy damage index method calculates a damage index based on the mode shape curvatures [2]. This index can be represented by

$$BEDI = \sum_{i=1}^N \frac{(\sum_{j=1}^m (\phi''_{i,j}^*)^2 + (\phi''_{i,j})^2) \sum_{j=1}^m (\phi''_{i,j})^2}{(\sum_{j=1}^m (\phi''_{i,j})^2 + (\phi''_{i,j}^*)^2) \sum_{j=1}^m (\phi''_{i,j}^*)^2} \quad (3)$$

where $\phi''_{i,j}$ and $\phi''_{i,j}^*$ are the mode shapes before and after the occurrence of damage; i and j indicates the i -th mode and j -th location in a structure; N is the number of modes of interest.

2.3 Modal assurance criterion

The modal assurance criterion is a method to present the correlation between two mode shapes, and this criterion can also provide the information of damage existence [4]. To further detect damage locations, the coordinate modal assurance criterion (COMAC) can be employed [5]. Thus, both MAC and COMAC indices are written by

$$MAC_{i,k} = \frac{|\sum_{j=1}^m (\phi_{i,j} \cdot \phi_{k,j}^*)|^2}{(\sum_{j=1}^m \|\phi_{i,j}\|^2) (\sum_{j=1}^m \|\phi_{k,j}^*\|^2)}, \quad COMAC_j = \frac{|\sum_{i=1}^N (\phi_{i,j} \cdot \phi_{i,j}^*)|^2}{(\sum_{i=1}^N \|\phi_{i,j}\|^2) (\sum_{i=1}^N \|\phi_{i,j}^*\|^2)} \quad (4)$$

where \cdot indicates the dot product of two vectors; i and k represents the i -th and k -th modes; j denotes the j -th locations; m is the total number of stories; N is the number of modes of interest. Moreover, $MAC_{i,k}$ represents the i -th mode shape of the undamaged structure and the k -th mode

shape of the damaged structure. $COMAC_j$ indicates the j -th location with respect to damage levels.

2.4 Strain energy damage index

The strain energy damage index generates the damage index based on the strain energy variations before and after the occurrence of damage in a structure. The stiffness matrix is formed by a shear-type structure, then the strain energy damage index can be derived as

$$\beta_j = \frac{([\phi_i^*]^T [U_j] [\phi_i^*] + \sum_{i=1}^N [\phi_i^*]^T [U_j] [\phi_i^*]) [\phi_i]^T [U_j] [\phi_i]}{([\phi_i]^T [U_j] [\phi_i] + \sum_{i=1}^N [\phi_i]^T [U_j] [\phi_i]) [\phi_i^*]^T [U_j] [\phi_i^*]} \quad (5)$$

where U_j denotes the j -th local stiffness contribution (i.e., the j -th story) with respect to the global stiffness matrix.

2.5 Continuous Wavelet transform

The continuous wavelet transform can present instant frequency components over time [6]. This wavelet transform can be applied to the difference of mode shape slopes before and after the occurrence of damage in a structure such as

$$W\phi'_i(u, s) = \langle \phi'_i, \psi_{u,s} \rangle = \frac{1}{\sqrt{s}} \int_{-\infty}^{+\infty} \phi'_i(x) \psi\left(\frac{x-u}{s}\right) dx \quad (6)$$

where ψ is the mother wavelet function. This position-frequency representation of the difference of the i -th mode shape slopes shows the discontinuousness in high frequencies. To highlight this discontinuousness, a marginal spectrum can be used by accumulating the amplitudes in Eq. (6) over frequencies.

2.6 Changes in the first mode shape slopes

The method of changes in the first mode shape slopes exploits the dynamic characteristic equation to verify that the first mode shape slopes can be a good indication of structural damage [7]. The mode shape slopes are given by

$$CFMSS = \left(\frac{\phi_{1j}^* - \phi_{1(j-1)}^*}{h_j} \right) - \left(\frac{\phi_{1j} - \phi_{1(j-1)}}{h_j} \right) \quad (7)$$

where $\Delta\phi'_{1j}$ represents the difference of the first mode shape slopes at the j -th location. This method is only valid for a cantilever-type structure.

3 NUMERICAL EXAMPLE

In this research, a ten-story shear-type building is employed to evaluate six mode shapes-based damage detection method. For all these methods, only the first mode shape are taken into account to examine performance of damage detection. This building consists of a 100-kg mass, 1 m high, and 15,800-N/m stiffness per story. Two scenarios are considered: a) only the second story has damage and b) both second and fifth stories have damage. Structural damage is mimicked by a stiffness reduction, and three levels of reductions are considered including 15%, 45%, and 75%. Fig. 1 illustrates the damage locations in simulation.

Figure 1: Illustration of two damage scenarios in the ten-story shear-type building

To determine damage locations, each method has a different criterion. The MSC method needs to be normalized by

$$(MSC)_n = MSC / \max(|MSC|) \quad (8)$$

where $\max(MSC)$ denotes the maximum entry in the difference vector of the first mode shape curvatures. When $(MSC)_n$ exceeds 0.5, the damage is viewed to be detectable. In the BEDI method, the building is damaged if the index is greater than 1. In the MAC-COMAC method, if the MAC is lower than 0.7, the structure is viewed to be damaged. Meanwhile, the COMAC is employed to determine the damage locations. The SEDI method assesses damage by the same approach as the BEDI method. In the CWT method, the marginal spectrum is normalized by a norm. Then, the damage location is determined by the normalized marginal spectrum exceeding 0.5. The CFMSS method detects damage when the ratio of the first mode shape slopes is greater than 0.

3.1 Single damage location

As seen in Fig. 1, the single damage location is at the third floor and the fifth floor. Table 1-2 shows the damage detection results for the two scenarios of the single damage location. In this table, 1 means that damage has been detected by the method, while blanks mean that no damage is detected. Most of damage detection methods used in this study is capable of identifying the damage locations except for the MAC-COMAC method. Moreover, the MSC and BEDI methods introduced some faulty detections in the first floor.

Table 1: Damage detection results of a single damage location (3F): 15%, 45%, and 75% stiffness reduction from top to bottom

3.2 Multiple damage locations

When the building has two damage locations at the third and seventh floors, the results are presented in Table 3. Similarly, 1 means that damage has been detected by the method, while blanks mean that no damage is detected in this table. As seen in the results, the MSC and BEDI methods introduce some faulty detections of damage, while the SEDI, CWT, and CFMSS methods can exactly locate the damage. Therefore, this numerical investigation concludes that the SEDI, CWT, and CFMSS methods are applicable for damage detection of shear-type

buildings based only on the first mode shapes.

4 CONCLUSIONS

This study investigated six mode shape-based methods for damage detection of a shear-type building. All these methods included the mode shape curvature method, bending energy damage index method, the modal assurance criterion method, strain energy damage index method, continuous wavelet transform method, and the method of changes in the first mode shape slopes. These methods derived associated indices based on the 1st mode shapes or their derivatives. A shear-type building with two damage scenarios were introduced to evaluate effectiveness of these damage detection methods. As found in the results, most of the methods were able to identify the damage existence and to locate the damage. The SEDI, CWT, and CFMSS methods were capable of providing an accurate indication of damage when only a single damage location occurred. For multiple damage locations, the CWT and CFMSS methods had better performance because other methods could introduce some faulty detections.

Key words: Damage Experiment, Local Damage, Steel Plate Girder Bridge, Structural Health Monitoring, Thermal Expansion.

Abstract. This study is intended to investigate how the local damage and varying temperature affect changes in modal frequencies of a steel plate girder bridge. A damage experiment on an actual bridge was conducted, and acceleration responses of the bridge under vehicle loading were monitored. Artificial fatigue cracks were introduced to the lower flange and the web plate near the base plate in the damage experiment. The longitudinal displacement of the bridge at supports were also monitored to investigate structural behaviors of supports under local damage and the varying temperature. Observations showed that frequency of the 1st bending mode increased due to artificial damage though frequencies of the 2nd bending mode and 3rd bending mode decreased. On a finite element model, changes in stiffness of spring which models the cantilever steel pivot bearings at support due to the damage as well as temperature change are considered to examine the reason why the frequency of the first bending mode increased while those of the second and third bending modes decreased. A sensitivity analysis to investigate influences of the changes in the stiffness of the girders and the stiffness of the spring at the support. The sensitivity analysis demonstrated that the changes in the stiffness of the spring at the support resulted in the increase of the first bending frequency.

1 INTRODUCTION

Vibration-based structural health monitoring (SHM) has been developed as one of the efficient ways for maintenance of civil infrastructures including bridges. Many studies for damage detection by means of SHM examined the change in modal parameters of bridges such as frequency, damping ratio and modal shape since changes in these modal parameters are

Table 1: The environmental condition during each damage scenario

Damage Scenario	Time and Date	Weather	Temperature of bridge
INT	17:45-18:45 28th August 2017	Cloudy	28°C
DMG1	13:30-14:30 29th August 2017	Clear	38°C
DMG2	14:45-15:45 29th August 2017	Clear	43°C

relevant to damage or deterioration of bridges [1-3]. One of the typical modal parameters of bridges is the frequency. Modal parameters are identified from vibrations of the bridge.

This study investigates the feasibility of the vibration-based SHM to detect damage on an actual steel plate girder bridge. Especially, changes in frequencies due to fatigue cracks in steel girder near the base plate of supports are examined. Stochastic subspace identification (SSI) is used as a modal identification method [4].

In the finite element (FE) model, an eigenvalue analysis for the bridge is also conducted. For the eigenvalue analysis, structural parameters were calibrated by the model-updating using the identified modal parameters. By comparing the frequencies identified from the vibration responses between the undamaged bridge and damaged bridge, this study investigates the feasibility of damage detection by means of the vibration-based SHM. In addition, the eigenvalue analysis results are also compared to system identification results from experimental data so as to confirm the feasibility of the FE model for the eigenvalue analysis. Reasons of changes in modal parameters for each damage scenario are discussed utilizing results from eigenvalue analysis and sensitivity analysis.

In order to clarify possible reasons for the disagreement in the frequency for the first bending mode between the FE analysis and the field experiment, changes in the structural behaviour associated with each damage scenario are discussed using the displacement and temperature obtained from the field experiment.

2 FIELD EXPERIMENT

The field experiment was conducted on an actual steel plate girder bridge shown in Figure 1, whose span length was 40 m long and width was 4.0 m wide. Figure 1 also shows sensor deployment during the field experiment. Ten accelerometers were installed on the lower flanges of the bridge to measure vertical vibrations. Longitudinal displacements at the both ends of the bridge were measured utilizing displacement sensors. Artificial fatigue cracks (hereafter called artificial damage) at the girder end near the base plate of supports are considered in the experiment by severing the lower flange and the web plate by an Oxyacetylene cutting torch. The location of the artificial damage is on the main girder near the support of upstream-side on Ab1 abutment as shown in Figure 1. The artificial damage comprises two damage levels. One is the lower flange cut (hereafter called DMG1) and the other is the web plate cut (hereafter called DMG2) as seen in Figure 2. The bridge condition before the artificial damage was assumed as the intact condition (hereafter called INT). Types of supports at Ab1 and Ab2 are shown in Figure 3: the Ab1 abutment adopted a line bearing, and the Ab2 abutment adopted a cantilever pivot bearing. It should be noted that the line bearing at the Ab1 abutment was fixed due to corrosion.

Modal parameters of the bridge were identified from the accelerations of the bridge for each bridge condition. The vehicle used for the moving vehicle test was a passenger car and the

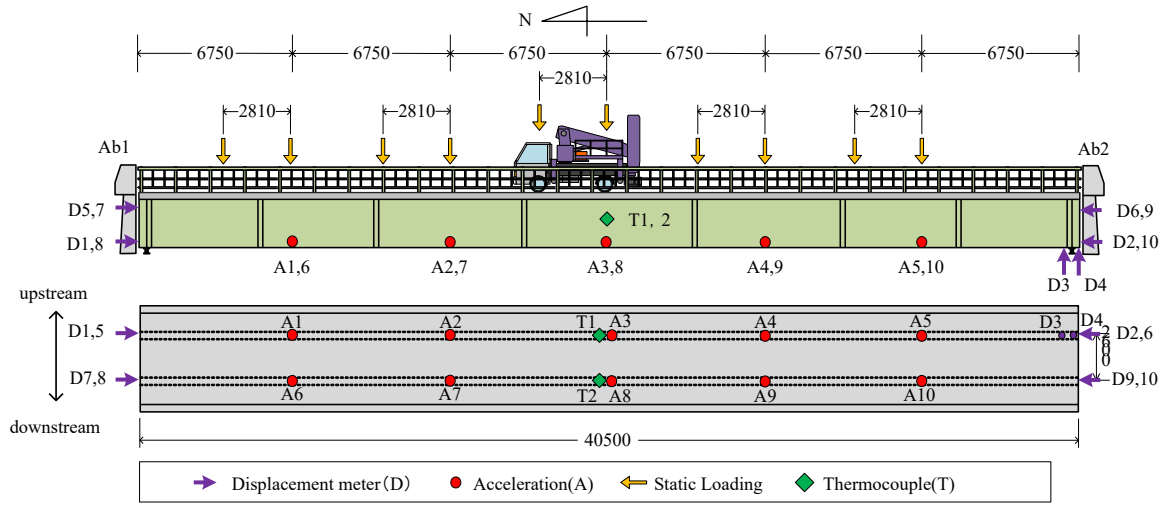

Figure 1: Observation bridge and sensor deployment.

Figure 2: Artificial damage location and each damage scenario.

speed of the car was about 20km/h. The moving vehicle test was conducted 30 round trips for the intact condition, and 15 round trips per damage condition. Sampling rate and length of the vibration data set were 200Hz and 15s, respectively. The environmental condition during the field experiment is summarized in Table 1. Temperatures measured from the thermocouples installed at the center of the plate girder were 28°C, 38°C and 43°C during INT, DMG1 and DMG2 experiments, respectively.

The mechanical properties of the bridge were also examined through static-loading test. The loading was given by a large sized vehicle whose axle weight on front and rear axles were 21.66kN and 54.88kN, respectively. In the loading test, the loading vehicle entered from Ab2 side, and located the rear axle with 6750mm intervals. The loading test was operated two times for each scenario, and each of the displacement was also measured twice. Hereinafter, the averaged displacement is used in discussions.

3 FE MODEL ANALYSIS

To investigate the dynamic characteristics of the bridge, the eigenvalue analysis using the FE model of the bridge was conducted utilizing ABAQUS 6.14. The bridge model, shown in Figure 4, was built based on the documents of periodic inspection and information obtained

Figure 3: Types of bearing at each support.

Figure 4: Finite element model.

from the field experiment as the original design documents of this bridge are not available. The concrete deck, main girder, vertical stiffener and horizontal stiffeners were modelled with shell element, and cross frame and lateral bracing were modelled with beam element. According to the results obtained from the static loading test which will be mentioned in Section 4.1, the boundary conditions were given as follows: fixed boundary condition for the Ab1 abutment, and boundary condition with roller supports with elastic longitudinal springs for the Ab2 abutment. As shown in Figure 3, the supports at Ab2 abutment are the cantilever-like steel pivot support which deforms elastically and act as if springs in the longitudinal direction, which is the reason why the longitudinal spring was introduced at the Ab2 in the FE model as seen in Figure 4.

Specific gravities of steel and concrete were assumed as 7.85 and 2.40 respectively. Young's moduli of steel and reinforced concrete were assumed as 210 GPa and 22.02 GPa, respectively.

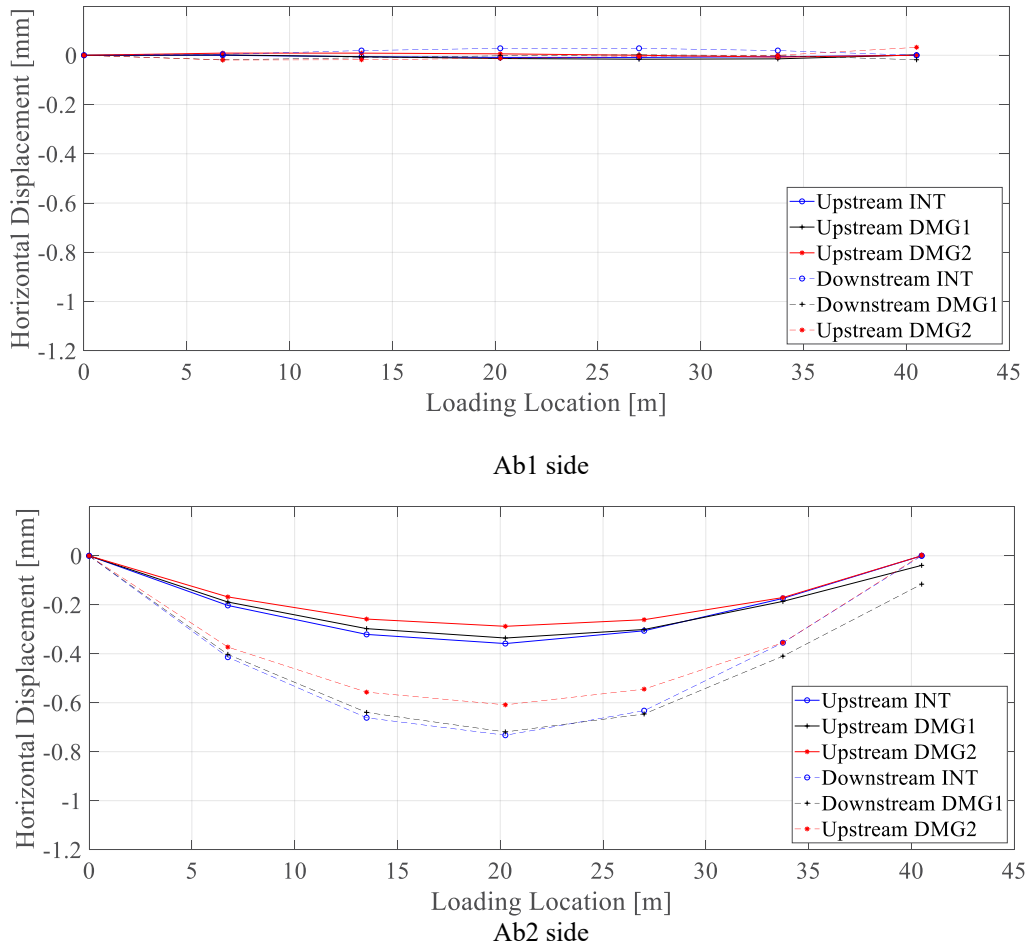

Figure 5: Horizontal displacement of bridge girder at each point.

However, since the bridge model has some differences from the actual bridge due to deterioration and differences between design and construction and so on, the bridge model needs a model updating to calibrate structural parameters of the FE model. The cross entropy (CE) method was applied to update the bridge model so that the eigen frequencies of the FE analysis are fit to those monitored from the actual bridge [5]. The spring constant which idealizes the cantilever steel pivot bearing on Ab2 abutment was also calibrated by means of the model update. The artificial damage was modelled as pseudo cracks in the FE model to realize damage scenarios. This crack was created by removing the connection of elements. The eigenvalue analysis was conducted for each of the damage scenarios. It is noteworthy that, in the model calibration, using the experiment data of INT scenario as reference, the initial finite element model is tuned towards frequencies.

The static longitudinal displacement at the supports is also investigated utilizing the updated FE model for each of the damage scenarios. For the FE analysis, the thermal expansion is evenly considered on each of the elements in the FE model for each damage scenario considering temperature in Table 1. The thermal conductivity of steel and reinforced concrete was assumed

Table 2: Frequency (Hz) and MAC obtained from eigen value analysis (MAC value is in the parenthesis)

	INT	DMG1	DMG2
1 st bending mode	3.13 (-)	3.13 (1.000)	3.11 (0.990)
1 st torsional mode	5.03 (-)	4.97 (1.000)	4.65 (0.989)
2 nd bending mode	9.36 (-)	9.33 (1.000)	9.23 (0.985)
2 nd torsional mode	10.69 (-)	10.66 (0.998)	10.45 (0.917)
3 rd bending mode	22.06 (-)	22.00 (0.999)	21.82 (0.896)

as $45\text{W/m} \cdot \text{K}$ and $1.6\text{W/m} \cdot \text{K}$, respectively. Thermal expansion coefficient of steel and reinforced concrete was assumed as $1.0 \times 10^{-5}/\text{K}$.

4 RESULTS AND DISCUSSION

4.1 Static loading test

To examine static responses of the bridge under vehicle loadings, longitudinal displacements from the static-loading test were examined. Figures 5a and 5b show longitudinal displacements measured at each of the upstream and downstream sides of the girder on Ab1 and Ab2 abutments, respectively. The horizontal axis represents the loading position from the Ab2, and the vertical axis shows the relative displacements taken from the static deformation under the dead load. The displacements adopted in the curves are obtained from the displacement sensors installed nearby the lower flange of each girder at supports (see Figure 1). For each damage scenario, the vehicle loading tests were performed twice, and average displacements are shown in Figure 5.

Figure 5a shows that the supports on Ab1 abutment allows little displacement, while Figure 5b shows that the supports on Ab2 abutment allows longitudinal displacements of the bridge girder. The downstream-side girder showed larger displacements than that of the upstream-side. Focusing on damage scenarios, the relative displacement due to the vehicular loading from the static deformation gets smaller when the damage propagates. This observation will be discussed again in Section 4.3 to clarify why the relative displacement gets smaller when the damage propagates.

4.2 Identified modal properties

The three bending modes and the two torsional modes were stably identified by means of SSI. Histograms of the identified frequencies for each of bridge conditions are shown in Figure 6 with normal distribution fits, where the bin width was chosen as 0.01Hz. The histogram was created utilizing 30 samples of the identified frequencies. The statistical distributions show that frequencies for the 2nd and 3rd bending modes and the 2nd torsional mode tend to decrease as the damage becomes severe, i.e., in the order of INT, DMG1 and DMG2. This result indicates the decrease of bending stiffness of the plate girder due to the artificial damage. However, the frequencies of the 1st bending mode and the 1st torsional mode tend to increase as damage becomes severe. The reasons why the frequencies of these two modes were increased will also be discussed in Section 4.3.

In addition, temperature change on the plate girder is taken into consideration. As shown in Table 1, temperature change was 10°C from INT to DMG1 and 5°C from DMG1 to DMG2

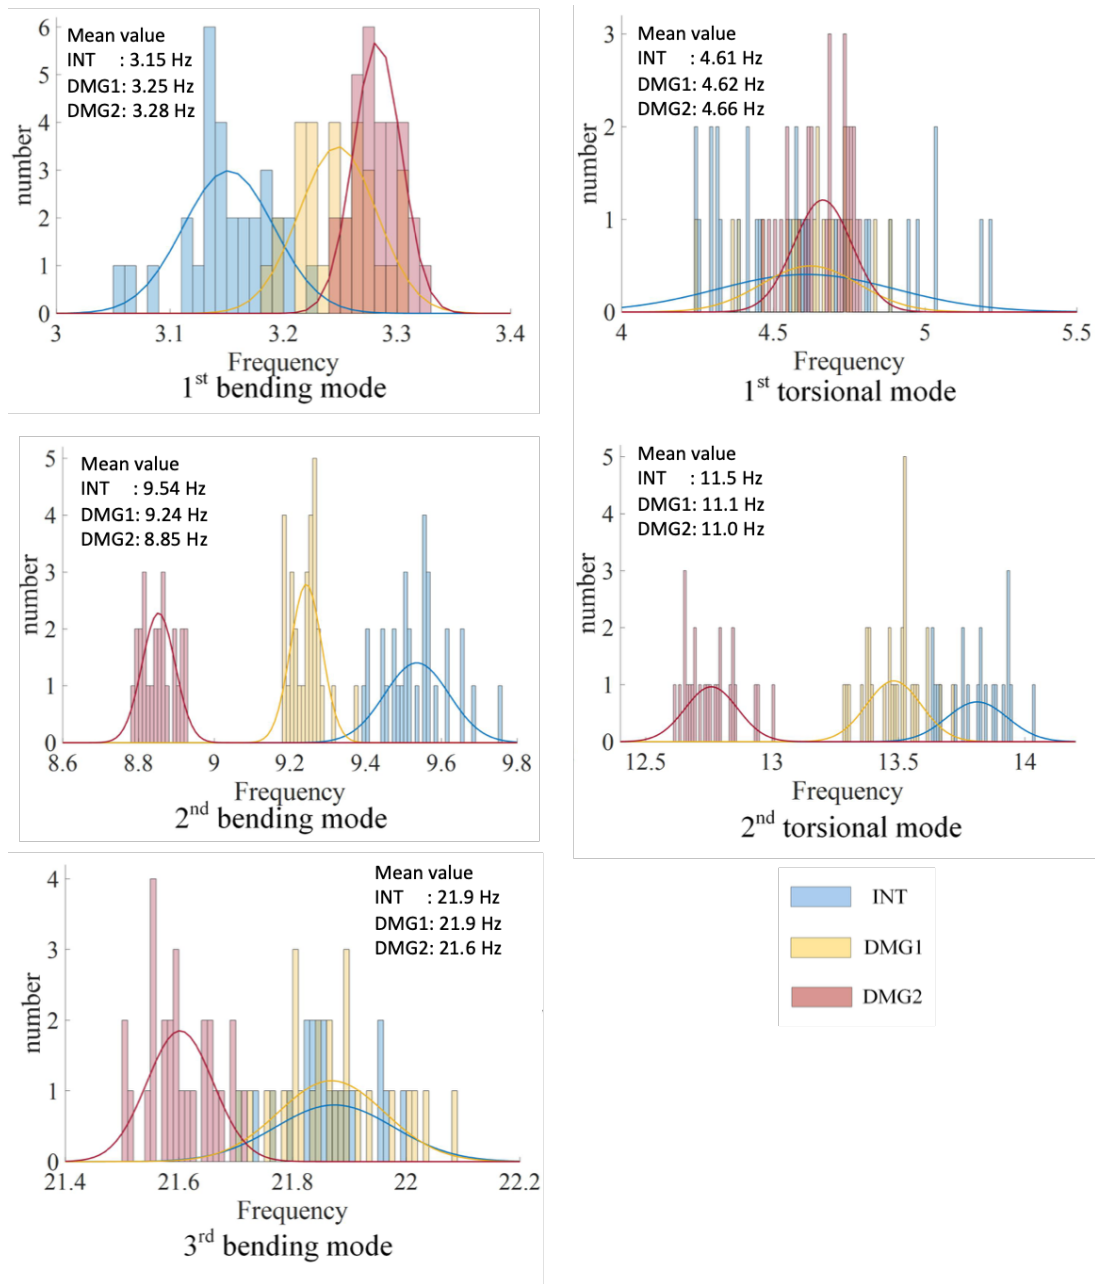

Figure 6: Histograms of identified frequencies associated with bridge condition.

during the field experiment, respectively. However, temperature change was not considered in the eigenvalue analysis in this study.

4.3 Comparison between FE analysis and field experiment

Frequencies and mode shapes from the eigenvalue analysis utilizing the calibrated FE model are compared to those identified from monitoring data. Frequencies obtained from the eigenvalue analysis with the pseudo cracks and values of modal assurance criterion (MAC) are

summarized in Table 2. The spring constant at Ab2 supports was also calibrated referring the frequencies identified in INT. The calibrated FE model of the bridge led to eigen-frequencies of 3.13Hz, 9.36Hz, 22.06Hz, 5.03Hz and 10.69Hz for the 1st, 2nd and 3rd bending modes and 1st and 2nd torsional modes, respectively as shown in Table 2.

MAC values between mode shapes from the eigenvalue analysis and those identified from experimental data were 0.96 for the 2nd torsional mode and more than 0.99 for the other modes. This result means that the mode shapes from the eigenvalue analysis and ones from the experiment were comparable with each other. The frequencies for all modes of the FE analysis decreased as the damage gets severe. The decrease of the 1st bending frequency was much less than the frequencies of the other modes. MAC values for these modes in Table 2 also decreased as the damage gets severe. Changes in the frequencies due to the damage obtained from the eigenvalue analysis showed similar tendency as ones from experiment data except the 1st bending and torsional modes.

Considering the observation of smaller relative longitudinal displacement due to severer damage as seen in Figure 5b that, it can be said that elastic behavior of the pivot bearing becomes stiffer as the damage propagates. In other words, the spring at the support on Ab2 becomes stiffer associate with damage condition. This means the damage might cause not only stiffness reduction on the bridge girder, but also increase stiffness of the spring at the support, so called stiffness hardening effect occurred. However, it should be noted that between damage experiments such as between INT and DMG1 scenarios and DMG1 and DMG2 scenarios temperature changes were observed. Therefore, both damage and temperature should be considered in the discussion for the stiffness hardening effect occurred at the pivot bearing on Ab2 abutment.

To investigate the relationship between the boundary condition and the modal parameters, a sensitivity analysis is performed utilizing the FE model for INT scenario. Figure 7 shows the results of the sensitivity analysis, in which the horizontal axis represents the spring constant for

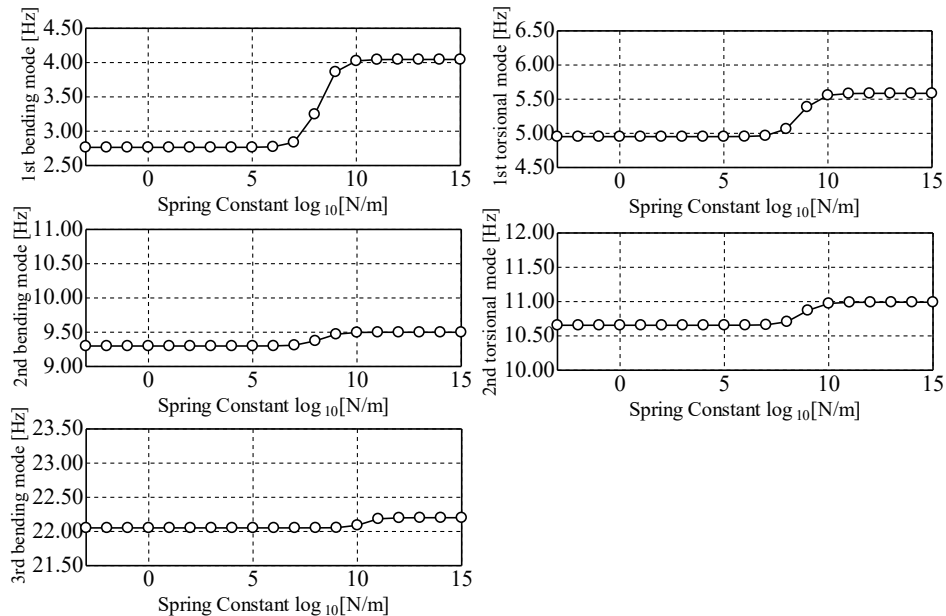

Figure 7: Sensitivity analysis for spring constant at support.

the pivot bearing, and the vertical axis represents each of the modal frequencies. Observations from the sensitivity analysis demonstrated that the spring constant has stronger influences on the change in frequencies of the 1st bending and torsional modes than on the other frequencies. On the other hands, the other modes were strongly influenced by changes in the stiffness of the girder rather than increase of stiffness of the spring at the support. According to the above discussions, the 1st bending and torsional modes were strongly influenced by changes in the boundary condition, rather than changes in stiffness of the girder.

4.4 Structural behavior in longitudinal direction

In this section, longitudinal displacements at girder ends are examined. The relative longitudinal displacements between INT and DMG1 scenarios and DMG1 and DMG2 scenarios are shown in Figure 8 where “D” indicates displacement sensor shown in Figure 1.

Observations from the upstream girder showed that the upper flange elongated due to DMG1 in comparison with the longitudinal displacement under INT condition. Similar trends were observed between DMG1 and DMG2 conditions in the upstream girder. For the downstream girder, a similar trend with that of the upstream girder was observed between INT and DMG1 conditions. However, under the DMG2, the lower flange of the downstream girder on Ab2 abutment was largely elongated than that on the upper flange.

In general, when a damage is propagated on a plate girder, dead load of the bridge increases the deflection of the girder as the stiffness of the girder decreases. Therefore, the upper flange of the girder is expected to compressed when a damage is propagated. Different behaviors were observed in the bridge. One reason might be elongation due to temperature change during the experiment which will be discussed in Section 4.5. For the elongation of the lower flange of the downstream girder on Ab2 abutment under the DMG2, it might be caused by torsional behavior of the bridge under the severe damage DMG2.

Figure 8: Changes in longitudinal behavior of plate girder bridge associate with damage scenarios.

Figure 9: Correlation between temperature and displacement obtained from D2 sensor.

4.5 Thermal expansion

As discussed in Section 4.4, those structural behaviors of the bridge in the longitudinal direction under propagation of damage might be caused by thermal expansion due to the temperature change. There were non-negligible temperature changes between INT scenario and DMG1 scenario as well as between DMG1 scenario and DMG2 scenario as summarized in Table 1. According to the long-term monitoring for this bridge, displacement obtained from D2 sensor showed about 2.5mm changes in the longitudinal direction by changing 5°C as shown in Figure 9. The red line in Figure 9 indicates the linear regression line between temperature change and longitudinal displacement.

In order to investigate the thermal expansion of the bridge, an FE analysis is conducted. In this analysis, temperature changes were 10°C from INT to DMG1 and 5°C from DMG1 to DMG2, and artificial damage for each damage scenario was also considered. The deflection of the bridge from the FE analysis is shown in Figure 10, which shows deflection in upward direction as observed from the field experiment. It is noted that the analytical deflection shapes under the different temperature changes and damage scenarios showed same configuration as seen in Figure 10. This result demonstrated that the thermal expansion affects the structural behavior of the bridge. In addition, the shape after thermal expansion is similar to the end girder shape in Figure 8a, so thermal expansion due to temperature change has more effect on the structural behavior at supports than the artificial damage during DMG1 experiment. However, compared with the end girder shape in Figure 8b, the shape in Figure 10 is so different from the shape in Figure 8b. When it comes to the severe damage such as DMG2, the girder should be much more affected by artificial damage rather than by thermal expansion. Thus, the girder can twist as shown in Figure 8b. On the other hand, such behavior cannot be observed in the FE analysis when DMG2 is propagated. One possible reason for the failure of simulating the structural behavior under DMG2 is that the FE model is not able to simulate different structural

Figure 10: Change in structural behavior due to thermal expansion and artificial damage.

behaviors of the upstream and downstream girders observed in the experiment.

5 CONCLUSIONS

This study investigated feasibility of damage detection of an actual steel plate girder bridge utilizing identified modal parameters from vehicle induced vibrations of the bridge. Especially, the frequency was considered as damage sensitive features of the bridge. In addition, the cause of the frequency changes is considered using results of the static-loading test.

Frequencies identified from the experimental data were changed due to the artificial damage. Frequencies of the 2nd and 3rd bending modes and 2nd torsional mode decreased as the damage gets severe. However, the frequency of the 1st bending and torsional modes increased due to damage.

The FE model is constructed using the results of the static-loading test and the model updating based on the observed frequencies. The eigenvalue analysis utilizing the FE model showed that frequencies for three bending and two torsional modes decreased due to the artificial damage. Tendency of changes in the frequency due to the artificial damage obtained from the eigenvalue analysis were similar to ones from experiment data except the 1st bending and torsional modes.

Observations from this study showed that the 1st bending and torsional modes were strongly influenced by stiffness hardening effect in the cantilevered pivot bearing rather than changes in stiffness of the girder. On the other hand, the other modes were strongly influenced by changes in the stiffness of the girder rather than influence of stiffness hardening effect in the cantilevered pivot bearing.

To investigate the stiffness hardening effect in the cantilevered pivot bearing due to damage, FE analysis adopting spring element as the cantilever pivot bearing and considering thermal expansion was conducted. Comparison of the deflection configurations from FE analysis with

those from the experiment showed that one of the main reasons of the stiffness hardening effect in the cantilevered pivot bearing is thermal expansion due to temperature changes between damage experiments. However, it was unsuccessful to simulate the static behavior under the most severe damage scenario (DMG2) that might be caused by torsional behavior.

The next step for this study is to clarify the static behavior under the most severe damage scenario (DMG2).

ACKNOWLEDGEMENTS

This study is partially sponsored by a Japanese Society for the Promotion of Science (JSPS) Grant-in-Aid for Scientific Research (B) under project No.19H02225, which is greatly appreciated.

Key words: Continuous Dynamic Monitoring, Operational Modal Analysis, Data Acquisition Systems, New Generation of Measurement Systems.

Abstract. This paper describes the work developed by CONSTRUCT – ViBest research group in the area of new solutions of instrumentation of Civil Structures aiming its long term dynamic monitoring. It identifies the main challenges in this area, and focus the discussion around power options and data transmission solutions. The architecture of the developed measurement systems is described, and a few practical examples of monitoring of bridges is presented.

1 INTRODUCTION

The continuous dynamic monitoring of structures is an area that has lately assumed great importance in Civil Engineering. The main reason is related to the subject of Operational Modal Analysis (OMA), which aims to identify the modal parameters of a structure in operating conditions (particularly with regard to natural frequencies, damping ratios and mode shapes) taking into account the measured ambient vibrations at critical points.

In these cases, the measurement of vibrations is performed without disturbing the normal functioning of the structures, which may be implemented in buildings, bridges (railway, roadway, highway), dams and offshore structures. Given the importance of this subject, the Laboratory of Vibrations and Structural Monitoring FEUP (ViBest) has carried out consistent work in this area, both in the development of numerical tools for identifying modal parameters and in the continuous measurement of vibrations in actual structures (see www.fe.up.pt/vibest).

Parallel to this area, ViBest has also developed and implemented vibration measurement techniques that enable to solve specific problems of current systems and to evolve toward a new generation of measurement systems. In particular, the difficulties that are to be overcome include: a) excessive cost of traditional measurement systems; b) excessive dependence on external power supply; c) frequent failures in data acquisition attributed to heavy operating systems; d) difficulty in being physically integrated into structures, taking up too much space and being barely manageable, and; e) when using cables, the number of sensors is limited due to the exponential complexity of the acquisition system.

In contrast, data acquisition systems based microcontrollers and MEM sensors offers the following advantages: a) cost attractive; b) enable wireless solutions; c) autonomous and small size (easily integrated into structures); d) possibility of installation of high number of sensors; e) low power consumption (can run on batteries or solar panels); f) simplicity of functioning and robustness; g) low maintenance, and; h) may be easily customized.

In this context, this paper intends to divulge the instrumentation solutions that have been used by CONSTRUCT - ViBest in the continuous dynamic monitoring of some structures using this technology. The architecture of the developed sensors is described, as well as the power solutions used to guarantee long periods of measurement. In order to illustrate the efficacy of these solutions, a few practical examples of monitoring of bridges is presented.

2 CONTEXT OF THE RESEARCH

The interest of the research in the area of measurement systems emerged from the technological evolution of the last decades in the topic of sensors and data acquisition systems based on microcontrollers. This was encouraged by the easy access to this technology and by the easy access to information available in the internet. In fact, the quantity of tutorials and blogs around this topic is immense.

At same time, researchers who work in actual structures with data acquisition systems, often face many challenges and problems. The lack of robustness of some traditional instrumentation solutions is one of these difficulties. The failure of these systems when working for long periods is not the only cause of that lack of robustness. Sometimes there also external causes like power failures and adverse weather conditions, beyond to other causes of diverse origin. Some data acquisitions systems are also too complex, involving too many cables and connections. The high cost of measurement systems is another factor that hinders the widespread use of these systems in common Civil Structures.

In this context, the objective of the research in this area is to develop instrumentation that meets the following characteristics: i) wireless and compact size, for easy integration and installation in structures; b) robust, allowing the functioning of the system for long periods with no crashes; c) long autonomy; d) flexible, by allowing a variety of different sensors in several mounting schemes; e) accurate, and; f) cost attractive.

The role of these systems is not certainly to substitute the traditional systems. However, there are many applications where these instruments have the same effectiveness as the traditional ones, with additional advantages. In fact, they can simplify the process of installation and operation; they can be custom-made, including the use of 3D printing; maintenance and replacement is facilitated, and; more interesting, their attractive cost may allow the generalization of dynamic monitoring systems in Civil Structures.

Nevertheless, the implementation of these new data acquisition systems also raises some challenges. Particularly with regard to the following issues: a) power supply; b) data transmission; c) reduced energy consumption; d) miniaturization of the systems, and; e) reliability. In this paper, special attention is given to the issue of power supply and data transmission solutions.

Probably the main question about these new systems, most of them base on distributed sensor networks, is how to power them. If they need external electrical energy materialized by a cable, then the wireless functionality do not make any sense. In this case, the power and data

transmission are provided by the physical connection. If they are fully wireless, they need to have a power supply. It's worth to mention that sleep modes in dynamic monitoring are not useful, since the frequency rates are usually high. In addition, many energy-harvesting solutions do not provide enough power for continuous measurement systems.

In parallel to this issue, it is necessary to consider how and how often data is transmitted. It is generally accepted that Civil Engineering structures do not need continuous online observation, with the exception of special cases. Therefore, the continuous data transmission maybe is not useful in the most applications. This will save a lot of energy and will increase autonomy and the robustness of the system. So, it is suggested that data may be accessed by several ways. Probably the most interesting is to access data physically by visiting the structure periodically, say, every 3 or 4 months. This visit is generally needed for inspection of the condition of the whole monitoring system. Data also may be transmitted wirelessly, but in this case it should be selected a limited period of the day to do that. In this case, the wireless connection is established, the data is transmitted, and in the end the wireless is disconnected. This means that the transmission only work for a few minutes each day, saving a lot of power. Another possibility is saving data locally and program the system to send a daily message with some reference parameters in order to check if the acquisition system is functioning properly.

3 DEVELOPED INSTRUMENTATION

In the context of what was said in the previous section, during last years the CONSTRUCT – ViBest research group at FEUP, developed some instrumentation for dynamic monitoring of structures. There are basically two kinds of sensors: those that are powered by batteries, and those that are powered by solar energy.

The earliest developments were based on portable battery-powered devices. In figure 1a) is shown the system here designated by “Portable 1” which was used for the first measurements in 2014, in particular to measure the “lock-in” effect in Luiz I bridge over Douro River in Porto. This device is a little bigger than the size of a credit card, being possible to adapt it to metal structures by powerful magnets. It incorporates a unidirectional MEM accelerometer, antialiasing filters, a 16-BIT ADC and a micro-sd card for saving data. All this hardware is controlled by a 5-V microcontroller powered by one 9-V battery which ensures run time of about 6 hours.

In order to improve system autonomy, another compact system, designated by “Portable 2” was used to measure simultaneously vertical and horizontal vibrations at same section (see Figure 1b). This device, a little smaller than the previous one, also comes with magnets. This model comprises a tri-axis MEM accelerometer, antialiasing filters, independent 16-BIT ADCs and a micro-sd card to save data. Here, the microcontroller is 3.3 V logic level and works with 3 AA batteries allowing the system to work continuously for close to a month. This model is clearly geared to higher periods of measurements.

More recently, these battery-powered devices evolved to a more reduced energy consumption system (“Portable 3”), incorporating a much better tri-axial MEM accelerometer. It uses 3D printing to optimize the shape and space occupied by the device. Figure 2a) represents a very compact model endowed with magnets for fixation to structures, which has an autonomy of 15 days using a battery of 2500 milliamps. The autonomy of these systems may be increased

by adding more batteries. For instance, Figure 2b) represents a model with an autonomy of 6 months using 9 batteries of 3400 milliamps of capacity.

Aiming long periods of data acquisition for enabling the long-term dynamic monitoring of structures, two solar-powered solutions were developed and implemented. The first one (“Solar 1”), was installed in two structures in 2014. It comprises a 10-W 40×28-cm solar panel which

Figure 1: Battery-powered devices: a) “Portable 1” ; b) “Portable 2” measurement system

Figure 2: Battery-powered “Portable 3” devices: a) 15 days autonomy ; b) 6 months autonomy

Figure 3: Solar-powered devices: a) “Solar 1” ; b) “Solar 2”

is also used to cover and protect the system against weather conditions (See Figure 3a). The solar controller manages the power to the 5-V acquisition system and, during the daytime, charges $3 \times 12\text{-V}$ batteries to maintain the system working during the night and on cloudy days. The data is acquired by a system integrating a tri-axis MEM accelerometer and is processed using the pieces of hardware described in the other previous devices.

However, “Solar 1” has some issues that needed to be improved upon: i) external dimensions are relatively high, which hinders its integration in the structure; ii) it is inefficient in terms of power consumption because it is based on a 5-V logic level and is powered by 12-V batteries, and; iii) there is no way to check if the system is working properly without being physically accessed. For these reasons, a new version of a solar powered device was developed (“solar 2”). This one is significantly smaller than the previous one (11×14 cm plan view) and the panel has a power of 2W that feeds a 3.3-V system (Figure 3b). The solar controller allows charging a lithium-polymer battery that can run for as much as one week on a single charge. This device consists of a digital tri-axis MEM accelerometer integrating programmable antialiasing filters and programmable ADC frequency rates, and a micro-sd card to save data. In order to monitor the functioning of the acquisition system, this particular model periodically sends a report to an RF serial receiver including the following information: i) device ID; ii) current date and time; iii) current file name; iv) total number of files; v) temperature inside the box, and; vi) battery voltage. This information may be collected locally, for instance, using a smartphone, and allows checking if the system is working properly. Access to the data is only available using a physical connection.

4 EXAMPLES OF MONITORING OF BRIDGES

The first two significant implementations of the developed instrumentation in actual structures are based on solar-powered systems, aiming the long term monitoring of vibrations. One of these structures is a pedestrian bridge located in Porto (Figure 4). It comprises two spans of 30m each, simply supported at the ends with hinges and at mid-length by means of a concrete column. The deck is 3.5 m wide and has an inclination of 6% starting with a lower elevation at the green park and ending in the Transparent Building at a higher level. The cross-section is composed of two lateral steel girders type IPE600, 600 mm high, connected by a secondary steel structure which, in turn, gives support to a wood floor.

Figure 4: General view of the footbridge

Given the “lively” behavior of the structure when subjected to pedestrian loads, it was decided to install a dynamic monitoring system in order to characterize the levels of vibration experienced by this structure during long periods of time [1]. One sensor was adopted and positioned at the mid-span close to the green park at the south-west side. This way, it was possible to install a solar-powered acquisition system similar to “Solar1” described before, by means of a solar panel installed on the outside of the lateral girder (see Figure 5a). The other pieces of hardware are inside a box, which may be accessed using the bridge itself (see Figure 5b). The system produces data files lasting 10 minutes, which results in 144 files or 16.1 MB per day of information, considering a sampling frequency of 40 Hz.

In order to evaluate the autonomy of the solution, Figure 6 shows the periods where valid data exist or do not exist. The horizontal axis represents the total period of 178 days from 5th October 2014 to 31st March 2015, and the vertical axis represents one day divided into 144 intervals of 10 minutes. The failures (dark spots) occurred exclusively due to power issues, especially during the night or on dark days. No problems were detected in the acquisition system itself. This shows that the system worked 90.5% of the time, corresponding to a very good performance of hardware solution, specially taking into account that the acquisition included the winter period.

Figure 5: Data acquisition system: a) Solar panel; b) Box with microcontroller, battery and solar controller

Figure 6: Failures on the signal acquisition detected for 6 months

The data collected by this system allowed characterizing the levels of vibration of the footbridge over time. For instance, Figure 7 shows a map of the amplitude of vibrations during 6 months. It can be seen that the maximum vibration levels induced by pedestrians often reach values between 0.5 and 1.5 m/s^2 approximately, which highlights the “lively” behavior of the structure. In more specific cases, the structure may experience vibration levels higher than 2.5 m/s^2 attributed to intentional resonant loads, inducing intolerable vibrations from the human comfort point of view.

For that reason, it was decided to install two Tuned Mass Dampers (TMDs) to control vibrations of the first vibration mode of the footbridge. The solar-powered system was then updated to include the measurement of four accelerometers and two displacement sensors. Two accelerometers measure the vibration of the footbridge at each side of the deck, and the other two measure the acceleration of the TMD masses. The displacement sensors measure the relative motion between the structure and the TMD masses. By using this instrumentation, it was possible to evaluate the efficiency of the control devices in reducing the vibrations of the structure. Figure 8 represents the maximum vibration levels of the deck before and after the installation of TMDs, where it is clear that TMDs reduced significantly the vibrations associated with the first vibration mode of the structure.

Figure 7: Maximum vibration levels during 6 months

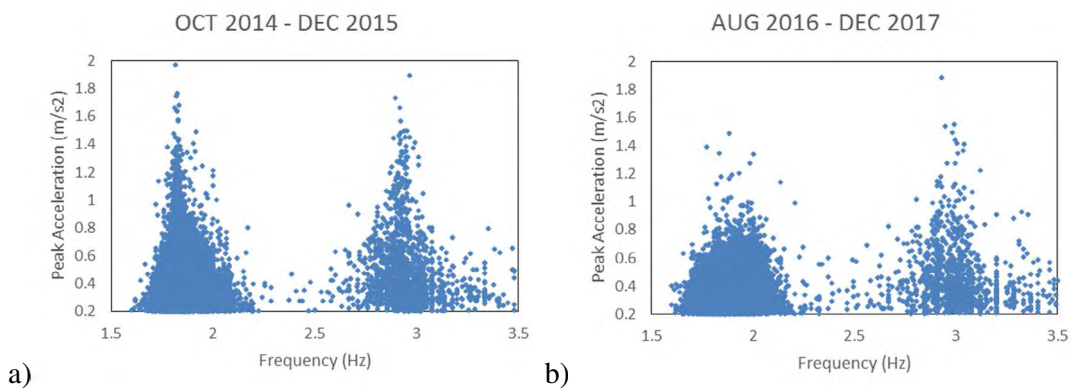

Figure 8: Maximum vibration levels of the footbridge: a) before TMDs; b) after TMDs

The second example of the implementation of solar-powered systems is related to the work developed at Luiz I bridge (Figure 9), which is extensively described in reference [2]. This structure is frequently subjected to extreme events, including crowds of pedestrians walking along the lower and upper deck, as well as pedestrians in athletic races. In the first case, vibrations are lateral and are triggered by a phenomenon known as “lock-in”, characterized by a situation in which a pedestrian crowd, with frequencies randomly distributed around an average value and with random phase shifts, will gradually coordinate at a common frequency (that of the bridge) and enter in phase with the structure motion [3]. In the case of athletic races, the vibrations are essentially vertical, and occur due resonance phenomena between the frequency of the vertical loads directly applied by pedestrians to the pavement and the structure’s natural frequencies.

Because of the unusual levels of vibrations occurred in those situations, there was great interest in installing a dynamic monitoring system in order to quantify those phenomena. Although battery-powered systems have been installed in certain periods, like “Portable 2” devices, this structure has been monitored mainly using solar-powered systems. In particular, “Solar 1” system was used from December 2014 to May 2018, having two “Solar 2” devices measured the vibrations since June 2018.

As an example, figure 10a) shows a time signal of lateral accelerations recorded at mid-span of the lower deck by “Solar 1” system during the feast of St. John 2015. The maximum vibration level reached 0.89m/s^2 , which is which is substantially greater than the recommended maximum value of 0.10m/s^2 . Regarding vertical direction, Figure 10b) shows the measurements made by a “Solar 2” system installed at the lower deck of the bridge. In this case, vibrations reached a maximum value of 3.54 m/s^2 , which is clearly excessive regarding human comfort.

Figure 9: General view of Luiz I bridge

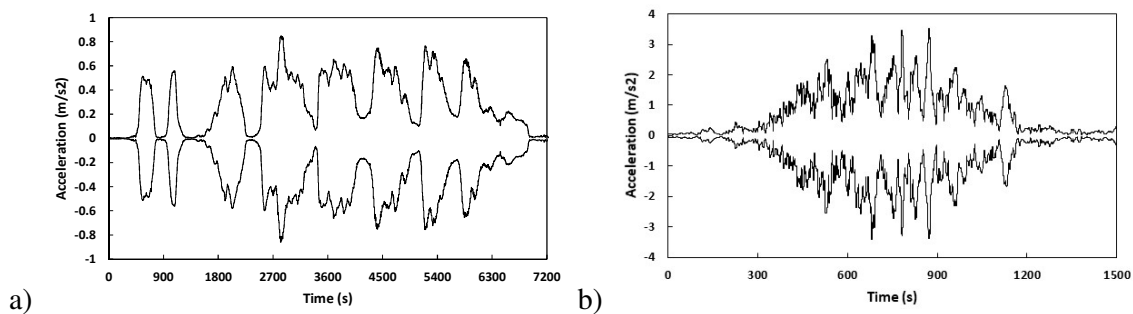

Figure 10: Examples of measurements during extreme events: a) Lateral direction; b) Vertical direction

The use of battery-powered devices in the long term monitoring of structures is relatively more recent. This is because the development of the solution of type “Portable 3” was only finished in 2017. Figure 11a) shows the Arrabida Bridge over Douro River in Porto. It is an arch concrete structure located just down the Luiz I bridge. Since December 2017, two “Portable 3” devices (Figure 11b)) are acquiring dynamic data at Sections S1 and S2 marked in Figure 12. These devices are programed to acquire data in lateral and vertical directions at 60 Hz frequency rate. The batteries allows a continuous functioning for 2 months, which is a period that is adequate to check regularly the condition of the system.

This bridge was studied in past in the context of a rehabilitation that took place in 2003 [4], and since then no dynamic studies were developed. The implementation of this monitoring system is useful to collect data that allow the long term behavior of the structure, as well as to identify modal parameters after the mentioned rehabilitation.

For instance, in Figure 13 the waterfall diagram containing the spectra calculated during one month at section S2 in vertical direction is represented. The natural frequencies can be clearly identified, and the daily variation of some of them, probably due to temperature effects, may be observed. The variation of the traffic intensity may also be noted, which is dependent on the day of the week and the night or day period.

Figure 11: Arrabida Bridge: a) General view; b) Sensor at one measurement section

Figure 12: Location of measurement sections over the deck

Another interesting application is the case of the dynamic monitoring of the Ferradosa Railway bridge (Figure 14). Located in Douro, in the north of Portugal, this structure was also submitted to a recent rehabilitation of its concrete piers. The data collected by two “Portable 3” measurement systems located at points 6 and 14 (see Figure 15), will allow understanding how the dynamics of the bridge changed since the previous measurement campaign occurred in 2016 [5].

5 CONCLUSIONS

This paper describes the work developed at CONSTRUCT – ViBest research group located in FEUP, on the topic of a new generation of dynamic monitoring systems applied to Civil Structures. It was pointed out that some traditional systems have some drawbacks, particularly related to the lack of robustness, complexity, and high cost. In the other hand, simpler systems based on microcontrollers may substitute that classical systems in certain applications, offering some advantages like the ease of installation and operation, less maintenance and attractive cost.

In this context, this document presents several generations of measurement devices based on battery-powered solutions and solar-powered solutions. In any case, the concern in minimizing the power consumption of the systems is always present, aiming longer autonomies. Therefore, the data transmission process needs to be adequate, depending on the objectives of the monitoring.

Some examples demonstrates the utility and the feasibility of using such systems in actual structures. In many practical situations, the results obtained with these systems can be comparable to those obtained with traditional systems.

Abstract. In the last few decades, strong research efforts have been devoted to the continuous structural condition assessment for the civil engineering infrastructure. Structural Health Monitoring (SHM) traditionally refers to the process of implementing monitoring systems to measure structural responses in real-time and to identify anomalies and/or damage at early stages.

Within the field of strengthening of reinforced concrete (RC) structures with fiber reinforced polymer (FRP) composite materials, some previous studies have been devoted to the identification of damage at their earliest stages on externally bonded (EB) FRP reinforcement. However, until now, to the knowledge of the authors, no previous SHM work was focused on the near surface mounted (NSM) technique using FRP. In the NSM-FRP methodology, the FRP reinforcement is installed into slits cut into the concrete cover using cement mortar or epoxy as bonding materials. Its use has several advantages over the EB FRP technique such as protection, improved bond, better aesthetics and surface preparation; because of it, it has become an attractive method as an effective alternative for strengthening RC structures.

In this work, some relevant cluster-based methods and their adaptation to electromechanical impedance (EMI) based damage detection in NSM FRP strengthened structures SHM are developed.

1 INTRODUCTION

Over the last years, extensive research has been conducted on the strengthening of reinforced concrete (RC) structures using externally bonded fiber-reinforced polymer (FRP) laminates; the technology has also been implemented in a large number of practical projects world-wide and different structural health monitoring (SHM) approaches to identify prematurely the more critical brittle failure modes have also been proposed [1, 2]. More recently, near-surface

mounted (NSM) FRP reinforcement has attracted an increasing amount of research as well as practical applications [3]. In the NSM method, grooves are first cut into the concrete cover of an RC element and the FRP reinforcement is bonded therein with an appropriate groove filler (typically epoxy paste or cement grout). NSM FRP reinforcement has a number of advantages over externally bonded FRP reinforcement, such as more reduced risk of debonding and damage due to accidental impact and vandalism. However, although debonding failures are less likely a problem with NSM FRP compared with externally bonded FRP, they may still significantly limit the efficiency of this technology and, therefore, the implementation of SHM techniques able to detect bar-concrete interfacial debonding at their earliest stages results crucial to avoid catastrophic failures.

SHM based on the electromechanical impedance (EMI) provided by piezoelectric ceramic (PZT) sensor-actuators has been used in numerous applications to detect damage [4-7]. The electrical impedance of the PZT can be directly related to the mechanical impedance of the host structural component where the PZT transducers are attached. Since the structural mechanical impedance will be affected by the presence of structural damage, comparisons of admittance (inverse of impedance) spectra at various times during the service period of the structure can be used as damage indicator. Any change in the spectra might be an indication of a change in the structural integrity. This technique appears to be very interesting for our application since the electrical impedance is measured at high frequencies which means high sensitivity to minor damage as desired for our purpose. Additionally, due to their size and lightness PZT sensors are non-intrusively attached and do not affect the performance of the structure.

Therefore, impedance signatures changes captured with PZTs might be used for debonding identification in NSM FRP reinforcement. The use of different statistical metrics, such as the root mean square deviation (RMSD), might be applied to characterize damage from changes of the impedance signatures. However, the use of a single type of metric for EMI based identification has some limitations regarding damage location and severity. Clustering is an interesting technique within the domain of unsupervised learning which can become very useful for anomaly detection. By using a clustering approach, data points that are similar tend to be grouped in different subsets in such a way that the normal condition of a structure is characterized as clusters and the damage detection strategy is based on an outlier detection approach. Hierarchical clustering analysis has been explored in this work as a tool for debonding detection in RC beams with NSM FRP using the EMI technique.

2 IMPEDANCE-BASED STRUCTURAL HEALTH MONITORING

PZT patches are used as high-frequency actuator/sensors in SHM. Electrical signals from the sensor attached to structure are measured using the coupling effect between the electrical and mechanical impedance of system. Any change in the stiffness of the structure such as damage, material properties, modifies mechanical impedance of structure and consequently affects the electrical impedance of sensor. Therefore, by monitoring the variation of the electrical impedance of the PZT patch, information about the damage of the structure can be obtained.

The impedance signature (or admittance Y) at each sensor is obtained using the one-dimensional analytical model proposed by Liang et al. [8] as follows

$$Y(\omega) = j\omega \frac{b_{PZT} l_{PZT}}{e_{PZT}} (\bar{\epsilon}_{33}^T - \frac{Z_s(\omega)}{Z_s(\omega) + Z_a(\omega)} d_{31}^2 \bar{Y}_{11}^E) \quad (1)$$

where ω is the frequency, d_{31} is the piezoelectric strain constant between the z and x directions at zero stress, $\bar{Y}_{11}^E = Y_{11}^E(1 + \eta i)$ is the complex Young's modulus of the PZT in the 1-1 (x) direction, η denotes the mechanical loss factor $\bar{\epsilon}_{33}^T = \epsilon_{33}^T(1 - \delta j)$ is the complex electric permittivity of the PZT at constant stress, δ is the dielectric loss factor, j is the imaginary unit and b_{PZT} , l_{PZT} and e_{PZT} are the length, the width and the thickness of the PZT sensor, respectively. Furthermore, $Z_a(\omega)$ and $Z_s(\omega)$ represent the mechanical impedances of the PZT and the host structure. The first one depends mainly on the PZT properties. Besides, the mechanical impedance of the structure is computed as follows [6]

$$Z_s(\omega) = j \frac{E_p b_{PZT} d_{31}^2 V(\omega)}{\omega u_s(\omega)} \quad (2)$$

where the axial displacement, $u_s(\omega)$, of the structure in frequency domain is obtained numerically.

Such as observed in Eq.(2), mechanical impedance of a structure is related to the mode functions and natural frequencies of the structure.

Eq.(1) corresponds to a 1D model of PZT and cannot be applied or generalized for all cases. Therefore, we will restrict our study to simplified 1D models.

Conventionally, SHM based on EMI assesses the integrity of a mechanical structure by observing some of the changes in the electromechanical impedance of the PZT between two different stages. For it, a scalar metric such as the root mean square deviation (RMSD) is used

$$RMSD(\%) = \sqrt{\frac{\sum_{i=1}^n [\text{Re}(Z_0(\omega_i)) - \text{Re}(Z_1(\omega_i))]^2}{\sum_{i=1}^n \text{Re}(Z_0(\omega_i))^2}} \cdot 100 \quad (3)$$

where $Z_0(\omega_i)$ is the impedance of the PZT measured at the healthy condition of the structure and $Z_1(\omega_i)$ is the corresponding value at a subsequent stage, which might agree with a post-damage stage, at the i th frequency point; n is the number of frequency points. From Eq.(3), the larger the difference between the baseline reading and the subsequent reading, the greater the value of the RMSD index denoting changes of structural dynamic properties which can be due to damage.

3 CLUSTERING ANALYSIS

Different alternatives exist to perform the clustering. In this work, we will use a hierarchical clustering. By using a hierarchical clustering approach, each one of the different observations is initially treated as a single cluster. Subsequently, using an iterative procedure nearby observations are merged into a new bigger cluster; then, successively, new nearby points are added to the nearest group and so on. In this sense, the algorithm uses a bottom-up or agglomerative strategy. The goal of this strategy is to generate a hierarchy of clusters organized into different levels of membership [9] by using the average-linkage method [10]. The steps to follow with this algorithm are:

- i. Find the similarity or dissimilarity between every pair of objects in the data set. This

- is done by computing the distance between objects.
- ii. Group the objects into a binary, hierarchical cluster tree using their distance as criterion. The clusters generated previously are then linked again by pairs under the same criterion, forming a new hierarchical tree. The procedure is continuously repeated until all the dependencies are established.
 - iii. Cut the hierarchical tree into clusters. A threshold is assigned to each branch of the tree, so that all the objects below that threshold are grouped into the same cluster, which creates a partition of the data.

In the first step, there are several ways to calculate the distances between every pair of objects. In this work, the Euclidean distance has been used

$$d_{st}^2 = (\tilde{x}_s - \tilde{x}_t)(\tilde{x}_s - \tilde{x}_t)' \quad (4)$$

where \tilde{x}_s and \tilde{x}_t are vectors containing different data sets.

4 APPLICATION

4.1 Description of the experimental test

An experimental study was carried out on one NSM-FRP RC specimen. In the test programme performed, the strengthened beam was subjected to a series of four-point increasing static load tests with the purpose of gradually introduce deterioration into the specimen (Figure 1). The material properties were assigned as follows: (a) for concrete, the elastic moduli and the compressive strength were taken to be $E = 26$ GPa and $f_c = 30$ MPa; (b) for steel reinforcement, the elastic moduli and elastic limit were taken to be $E = 210$ GPa and $f_y = 510$ MPa; (c) for the reinforcement, one CFRP bar with $E = 170$ GPa and tensile strength of 2500 MPa was inserted into the concrete cover.

Impedance measurements were captured from an array of eight PZT transducers once the beam has been unloaded after each static test and before loading it again. Two different transducers' types and technologies of integration into the test specimens were applied. Two P-876.A12 DuraAct Patch transducers of dimensions 61 mm x 35 mm x 0.5 mm and six P-876.SP1 transducers of dimensions 16 mm x 13 mm x 0.5 mm, both made by Piceramic, were used [11]. P-876.A12 transducers (PZT1 and PZT2) were bonded directly to the external face of concrete beam (Figure 2). Additionally, from the six smaller transducers, two were attached to the concrete surface (PZT3 and PZT4) while the other four were embedded into the structure by bonding them directly on the FRP bars/laminates (PZT6 to PZT9).

Impedance tests were performed by sweeping a wide frequency band of 10–100 kHz. From the healthy initial stage (D0), five different loading stages were considered (D1 to D5). Before measuring the impedances, the beam was previously unloaded after each loading stage.

4.2 Results

Figure 3 shows the hierarchical trees obtained with the hierarchical clustering analysis for the eight sensors. From this figure, it is clear that, considering their performance during the analysis, five groups of sensors might be defined, PZT1+PZT2, PZT3+PZT4, PZT6+PZT9,

PZT7 and PZT8. The first group, PZT1+PZT2, corresponds to the bigger sensors which are located more distant to the loading points. The variability of these two sensors according to the different damage stages is due to the appearance and growth of the external cracks in the concrete surface. For the second group, PZT3+PZT4, damages D3 and D4 are linked together and clearly distinguished from the remaining damage stages. which means they are identified with a similar severity. It is due the growth of a long crack near to these two sensors in the last two loading stages. For sensors 6 and 9, D5 is distinguished from the previous stages and the remaining damages in this region; additionally, D0 and D1 stages are clustered together and independently of D2, D3 and D4. Big cracks were identified in D5 very close to these sensors. Close to sensor 7, from the second load step, some cracks concentrate and grow progressively with the subsequent load steps. Failure was originated from this area. The area surrounding sensor 8 is, in general, little damaged.

5 CONCLUSIONS

A clustering approach has been proposed to detect brittle debonding in NSM FRP-strengthened RC beams. The approach extracted information from the electromechanical impedance spectrum measured with PZT sensors distributed in different locations of the

inspected beam. The measured information from the entire frequency range is used as the input to a clustering algorithm in order to identify subtle differences between the normal signals and distorted ones. These differences can be associated to abnormal behaviours derived of the appearance of minor damage or debonding. With this method, the evolution of the damage in a complex structure as that used in this work can be tracked in a fast and visual way.

Key words: Least-squares reverse time migration, ultrasonic imaging, flaw characterization.

Abstract. Accurate detection and characterization of flaws are very important in the assessment of structural integrity of critical structures in aerospace and nuclear industry. In this paper, an effective ultrasonic imaging technique based on least-squares reverse time migration (LSRTM) is developed for imaging flaws. Reverse time migration (RTM) is a powerful wave-equation-based approach and it has the ability to account for rapid spatial velocity variations and to utilize all wavefront information. It is based on cross-correlating the forward wavefield with the back-propagated wavefield scattered from flaws. To achieve images with better quality, the solution can be obtained by iteratively finding an image generating the modeled data which can best match the measured data in a least-squares sense, i.e. least-squares migration (LSM). Combining RTM and LSM, the LSRTM algorithm is applied to the measured data from the virtual experiment and the physical laboratory experiment, and the results show high-quality reconstructed images for flaw identification.

1 INTRODUCTION

Reliable inspection of flaws is very important in the assessment of structural integrity of critical parts in aerospace and nuclear industry. The type, size and shape of the flaw can assist with the prediction of the remaining life of the parts. A lot of ultrasonic non-destructive evaluation techniques have been shown to be useful for characterising flaws [1].

There are different ultrasonic sizing techniques, e.g. amplitude, temporal, inversion and imaging, which have been reviewed in detail in [2]. In this paper, only imaging methods are presented. Ultrasonic imaging is usually based on ultrasonic arrays, which can be operated by using physical beam forming or full matrix capture (FMC), where the data obtained from all source-receiver pairs is captured [3]. With the FMC data, beam forming or focusing can be used in post-processing [4]. For example, the popular post-processing methods can be used to size an embedded flaw with a regular shape by measuring the distance between two tips in a focused image [5], or specular reflections from the surface of the surface-breaking flaw [6]. However, characterizing irregularly shaped flaw remains challenging as singly-scattered, refraction and diffraction waves from the flaw have to be considered.

In this paper, the least-squares reverse time migration (LSRTM) proposed in geophysics [7] is introduced in ultrasonic imaging to size the flaw with irregular shapes. Reverse time migration (RTM) technique is based on a two-way wave equation, which forward extrapolates the wavefield from the source and backward extrapolates the scattered wavefield from the receiver. Extrapolating the time-reversed scattered wavefields by using the finite difference method focuses the wave energy toward damaged regions. With the cross-correlation imaging condition [8], the flaw image can be formed via extrapolation. To reduce the artifacts and improve the quality of the image, least-squares migration (LSM) is proposed to match the amplitudes of the modeled data with the measured data via an iterative inversion scheme [9]. Compared with conventional methods based on the signal diffracted from the flaw tip, the LSRTM algorithm uses the full wavefield with correct amplitude and phase information, and thus it is capable to characterize irregular-shaped flaws.

This paper is organized as follows. The theory of the LSRTM algorithm based on the acoustic approximation is described in Section 2. Finite element modeling and experimental procedures are presented in Section 3. In Section 4, the LSRTM algorithm is applied to the measured data from a virtual experiment as well as a physical laboratory experiment. Conclusions are summarized in Section 5.

2 LEAST-SQUARES REVERSE TIME MIGRATION

The process of reverse-time migration (RTM) contains three steps: (1) the forward wavefield extrapolation from the source, (2) the extrapolation of time-reversed scattered wavefield from the receiver, and (3) imaging using cross-correlation. Details of the three steps are included in [10]. To improve the image quality, the least-squares migration (LSM) is used to match the amplitudes of the modeled data with the measured data. Combining RTM and LSM, the LSRTM algorithm based on 2D acoustic equation in frequency-domain with the constant density is presented in this work.

The forward Born modeling can be compactly given by a matrix-vector multiplication [11]

$$\mathbf{d} = \mathbf{L}\mathbf{m}, \quad (1)$$

where \mathbf{L} is the forward Born modeling operator which linearly relates the reflectivity model \mathbf{m} to the measured scattered data \mathbf{d} . Here, each element of the reflectivity model \mathbf{m}_v can be defined as

$$\mathbf{m}_v(\mathbf{x}) = \frac{\delta v(\mathbf{x})}{v_0(\mathbf{x})}. \quad (2)$$

The migrated reflectivity model \mathbf{m}_{mv} can be calculated by using the adjoint \mathbf{L}^T of the forward Born modeling operator to the measured data \mathbf{d} [12]

$$\mathbf{m}_{mv} = \mathbf{L}_v^T \mathbf{d}, \quad (3)$$

where the adjoint \mathbf{L}_v^T is the migration operator related to velocity.

The aim of LSM is to obtain the reflectivity model \mathbf{m}_v by minimizing the difference between the forward modeled data $\mathbf{L}_v \mathbf{m}_v$ and the measured data \mathbf{d} in a least-squares sense

$$f(\mathbf{m}_v) = \frac{1}{2} \|\mathbf{L}_v \mathbf{m}_v - \mathbf{d}\|^2. \quad (4)$$

The minimum of $f(\mathbf{m}_v)$ is achieved when the reflectivity model \mathbf{m}_v satisfies

$$\mathbf{m}_v = (\mathbf{L}_v^T \mathbf{L}_v)^{-1} \mathbf{m}_{mv}, \quad (5)$$

Table 1: Conjugate gradient approach for solving $\mathbf{H}\delta\mathbf{m}_{v0} = \mathbf{m}_{mv}$.

1. Starting from initial $\delta\mathbf{m}_{v0}$ and setting the residual vector $r_0 = \mathbf{H}\delta\mathbf{m}_{v0} - \mathbf{m}_{mv}$, initial search direction q_0 is set as r_0 , i. e. $q_0 = -r_0$ and $k = 0$.
2. The scalar $\alpha^{(k)}$ is calculated by using the relationship $\alpha^{(k)} = \frac{r^{T(k)}r^{(k)}}{q^{T(k)}\mathbf{H}q^{(k)}}$.
3. The calculation of $\delta\mathbf{m}_v^{(k+1)}$ is expressed as $\delta\mathbf{m}_v^{(k+1)} = \delta\mathbf{m}_v^{(k)} + \alpha^{(k)}q^{(k)}$.
4. Then, the next residual vector $r^{(k+1)}$ is expressed as $r^{(k+1)} = r^{(k)} + \alpha^{(k)}\mathbf{H}q^{(k)}$.
5. The next step is to compute $\beta^{(k+1)}$, which is used to search the next direction $\beta^{(k+1)} = \frac{r^{T(k+1)}r^{(k+1)}}{r^{T(k)}r^{(k)}}$.
6. The next search direction $q^{(k+1)}$ is obtained by using this scalar $\beta^{(k+1)}$, $q^{(k+1)} = -r^{(k+1)} + \beta^{(k+1)}q^{(k)}$.
7. Then, $k = k + 1$, the next scale $\alpha^{(k+1)}$ is computed by using the obtained search direction $q^{(k+1)}$ and this process is repeated.

where $\mathbf{L}_v^T \mathbf{L}_v$ is the migration Green's function (or Hessian matrix \mathbf{H}). The Hessian matrix of $\mathbf{L}^T \mathbf{L}$ or \mathbf{H} is usually not an identity matrix, and the main diagonal elements are nonuniform and the off-diagonal elements are nonzero [13].

Directly solving equation (5) needs to explicitly store the Hessian matrix and calculate its inverse, which is memory-consuming and computationally expensive. Equivalently, \mathbf{m}_v can be iteratively obtained by solving

$$\mathbf{H}\mathbf{m}_v = \mathbf{m}_{mv}, \quad (6)$$

using a conjugate gradient approach. The implementation flowchart is shown in Table 1. In this paper, implementing the frequency domain LSRTM algorithm with constant density depends on the improved scattering-integral method [11]. The forward Born modeling and the adjoint migration model are based on matrix-vector multiplications, which are carried out by accumulating decomposed vector-scalar products without explicitly constructing or storing matrices.

3 TESTING APPROACH

3.1 Finite element simulation

As a first step for validation of the approach instead of a physical experiment, a 'virtual' experiment is conducted. To this end, 2D finite element simulations implemented in ABAQUS are performed in an aluminum sample (longitudinal wave velocity=6190 m/s, density=2700 kg/m³ and Poisson's ratio=0.33) with the dimension of 200 mm \times 50 mm, as shown in Figure 1. Four-node plane strain elements with the size of 0.1 mm are used in the mesh. A flaw with V shape is modeled by removing elements from the mesh. The linear array with 64 elements is placed on the top surface, which are spaced at a fixed pitch of 1.5 mm. A 2-cycle Hann-windowed tone-burst signal with a centre frequency of 2 MHz is excited by the array. The FMC data are collected from this sample.

In this case, the signals from the scattering of the flaw will overlap with the reflection from the backwall, and therefore likely to be shadowed. In the virtual experiment, one possible way of extracting scattered field from the flaw is to obtain the backwall reflection from a flaw-free sample and then subtract it from the overall signal, which is often called the baseline subtraction. However, this way is not practical in real case, and thus another method will be described in the real physical experiment in Section 3.2. It

Figure 1: The configuration of an array and a V shaped flaw. The unit is mm.

should be noted that only longitudinal waves are considered in this work, and they can be easily gated from time of arrivals.

3.2 Experimental setup

As a second step for validation a physical experiment is investigated. The experimental setup is shown in Figure 2. The real physical experiment was carried out in a 25 mm thick aluminum block with the height of 50 mm and the width of 200 mm. A V shaped flaw with the width of 1 mm and the through-wall extent of 6 mm was machined in the block, as shown in Figure 2. The ultrasonic array with a central frequency of 2 MHz manufactured by Guangzhou Doppler Electronic Technologies Co., Ltd was used to generate and measure signals. A 5-cycle Hann-windowed tone-burst signal centered at the frequency of 2 MHz was generated from a phased array controller (Lecoeur Electronique, France).

In real inspection, the method of baseline subtraction is not practical because it is not possible to obtain a flaw-free copy of the structure. Therefore, FMC subtraction developed by Zhang *et al.* [14] is used to remove the backwall reflections when flaw signals overlap with backwall reflections. In FMC subtraction, when the element pairs are with the same lateral separation, the length of ray paths of backwall reflections are the same but ray paths of flaw signals are different (see Figure 4(a) in [14]). This means that signals from the backwall have the same arrival time and amplitude compared with the ones from the flaw. Therefore, by subtracting the estimated backwall reflection from the total field, the signal scattered from the flaw can be extracted. Figure 3(a) shows a typical contour plot of the displacement signals measured over all receivers in the aluminum block with the flaw in the physical laboratory experiment. The scattering of longitudinal waves caused by the flaw is separated from the measured signals by removing Rayleigh waves with the gating function and by eliminating backwall reflections with FMC subtraction, as shown in Figure 3(b). The extraction of the flaw signals (see Figure 3(b)) achieved by gating function and FMC subtraction is used in the LSRTM technique to directly image the structure.

Figure 2: Experimental setup.

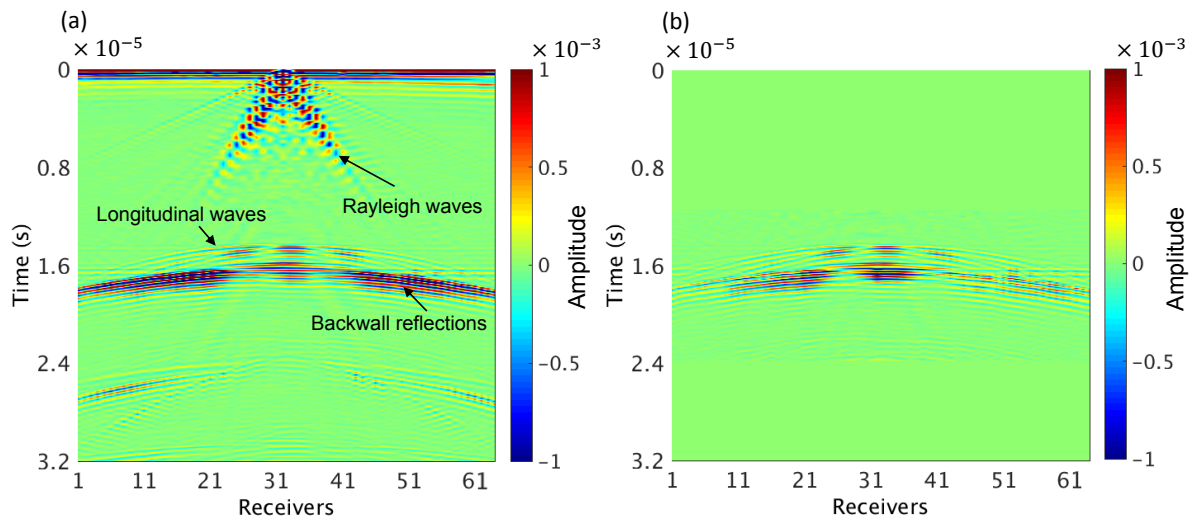

Figure 3: (a) Contour plot of measured displacement excited in the array element 32 shown in Figure 2. (b) Scattered signals caused by the V shaped flaw after time gating and backwall subtraction.

4 RESULTS

The sample with a V shaped flaw is considered in this work, as shown in Figure 1. Post-processing of the LSRTM images after 10 iterations is done by Laplacian filtering, which is applied to suppress low-wavenumber artifacts. Figures 4(a) and (b) show final images obtained from the virtual experiment and the physical laboratory experiment, respectively. The LSRTM algorithm is performed for 15 frequencies from 0.6 MHz to 3.4 MHz in the virtual experiment, and for 8 frequencies from 1.3 MHz to 2.7 MHz in the physical laboratory experiment, with a frequency interval of 0.2 MHz. The forward model is built by using homogeneous background.

Figure 4: LSRTM images of a V shaped flaw from (a) the virtual experiment and (b) the physical laboratory experiment.

It can be seen from figures that high-quality images are achieved by using LSRTM algorithm, with good reconstruction of the location and the shape of the V shaped flaw in both cases. A clear image is obtained in the virtual experiment, however, the reconstructed width of the flaw is slightly wider than the true model. The reason could be that scattered signals which overlap with mode conversions cannot be accurately separated by using time gating and mode conversions are not considered in the LSRTM algorithm based on the acoustic approximation in this work. In the physical laboratory experiment, the LSRTM image shows a good agreement with the image based on virtual experiment, although some artifacts and wider flaw width are observed. Besides the reason mentioned above, the main reason is the difference between the input waveform used in the LSRTM algorithm and the actual excited waveform in the real physical experiment, which would produce some artifacts to the image. The remaining discrepancy there can be attributed to less frequencies used in the LSRTM imaging from the real physical experiment compared to that from the virtual experiment.

The V shaped flaw was produced in the controlled laboratory environment and have nominal through-

wall extents of 6 mm. The through-wall extent is determined by measuring the vertical distance between the tip and the root of this flaw and is found to be 6.1 mm in the virtual experiment. The through-wall extent is measured to be 6.3 mm from the LSRTM image obtained from the real physical experiment, as shown in Figure 4(b).

5 CONCLUSIONS

In this paper, the least-squares reverse time migration (LSRTM) algorithm is investigated for characterizing irregularly shaped flaw. This algorithm is a two-way wave-equation-based approach and attempts to find the best fit reflectivity model by minimizing the mismatching between the measured and modeled data. The LSRTM has been successfully used in the measured data from the virtual experiment as well as the physical laboratory experiment, and the results have shown good accuracy in determining the size, location and shape of the V shaped flaw.

Key words: Trajectory Identification, Moving Load, Inverse Problem, Structural Health Monitoring, Multicriterial Optimization.

Abstract. This contribution presents an approach for indirect identification of the 2D path of a moving load. A multicriterial formulation is proposed, where one objective function quantifies the mismatch between the measured and the simulated structural response. The second objective function expresses the natural expectation that the paths of moving loads are continuous and relatively smooth, and it expresses thus a certain spline-based measure of the geometric regularity of the path. The Pareto front is determined in a local evolutionary search and used to strike the balance between the response fit and the geometric regularity of the path. The approach is tested in a laboratory experimental setup of a plate loaded by a line-follower robot. It is found that the implementation of the smoothness-based objective has a regularizing influence on the identification results: it reveals and emphasizes the actual geometrical character of the identified paths.

1 INTRODUCTION

This contribution is devoted to the problem of indirect identification of a moving load based on the measured mechanical responses of the loaded structure. In general, such a problem belong to the class of load identification problems, which is an inverse problem that has been intensively studied, and with a certain number of published reviews [1–4]. Load identification problems are typically characterized by

- a very large number of the structural degrees of freedom that can be excited by the moving load and
- a limited number of sensors that are used to measure the response.

In effect, the naïve formulation based on minimization of the norm of the response residuum is underdetermined (that is, there are much more unknowns than equations), and the corresponding identification problem has an infinite number of exact solutions. Therefore, in order to guarantee the uniqueness of the solution, it is typical to limit the generality of the load being considered by assuming that the trajectory of the moving load is known (most often, the problem is reduced to the case of a single vehicle moving over a 1D bridge at a constant velocity [5–7]) and that only the magnitude of the load is a subject to identification.

In contrast, our aim is to identify more general loads, and in particular loads that are freely moving on 1D structures like beams and on 2D structures like plates. In an earlier approach [8],

we have used the sparsity-based optimization [9,10], constrained using the l_1 norm, which guarantees the uniqueness of the solution. It has been found that it is possible to reliably identify the trajectory of transient loads moving on a 1D structure (beam), including its timing (decelerations, stops, accelerations, etc.). For related research, see also [11,12].

In this contribution, the aim is to qualitatively identify the trajectory of a single moving load that excites a 2D structure. To limit the generality of the search space, we notice that 2D trajectories of such loads are expected to be relatively smooth. Therefore, in analogy to the object tracking approaches developed in the computer vision community [13], we use the assumption of smoothness in a multicriterial-type optimization, which weights the norm of the measurement residuum vs. a certain spline-based measure of the smoothness of the interpolated trajectory. Such a formulation allows the apriorical knowledge to be included in the identification process in order to

1. limit the sensitivity of the solution to measurement and modelling errors, and/or
2. account for a limited instrumentation.

In experimental investigations, we have used a 1 m x 1 m plate, loaded by a line follower robot, and instrumented with a limited number of strain gauges. Due to the relatively slow motion of the robot, the quasi-static case is assumed, which allows the computationally costly deconvolution to be avoided.

2 EXPERIMENTAL SETUP

The laboratory experimental setup consists of a pointwise supported, 1 m x 1 m steel plate of 0.5 mm thickness, see Fig. 1. The plate is loaded vertically by a line-follower robot (approx. 0.3 kg) that moves at a constant velocity of approximately 10 cm/s and follows one of the three closed-loop trajectories marked with thick black lines: a square, a circle and a triangle. The mechanical response of the plate is measured with a set of 8 strain gauges (sensors No 2, 3, 5, 6, 8, 9, 11 and 12, as shown in Fig. 1). The sampling frequency of 50 Hz is used.

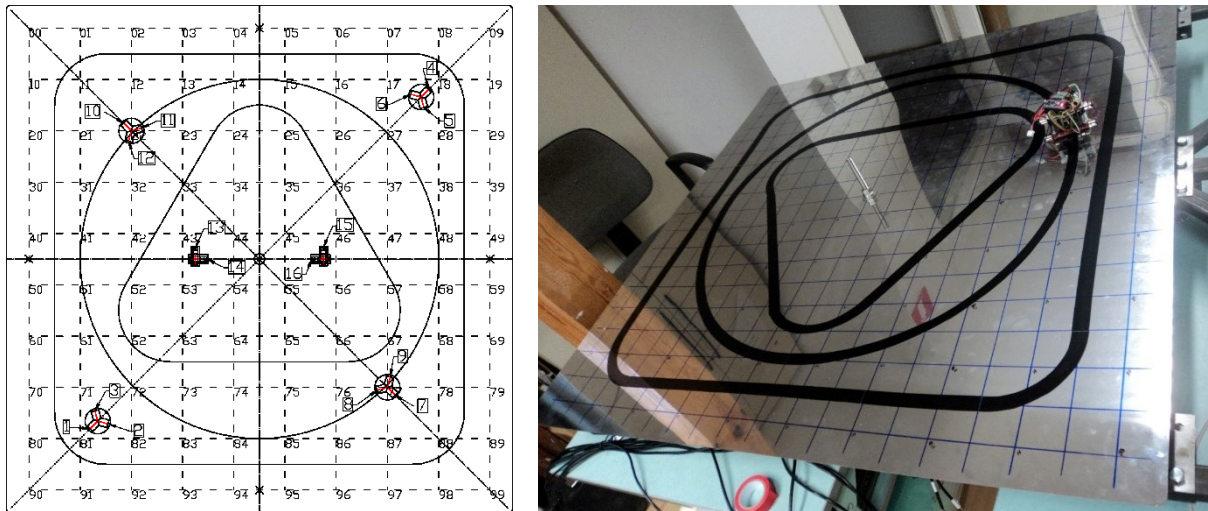

Figure 1: Scheme of the plate (left). The experimental setup (right).

The raw recorded measurements are shown in Fig. 2. As clearly seen from the plots, each path is followed by the robot two times, that the robot follows the respective line approximately two times around the plate.

Figure 2: Measurements of the eight strain sensors for the three considered robot paths (top to bottom : the square, the circle, and the triangle).

3 THE INVERSE PROBLEM

Typical formulations of the inverse problem of load identification rely on minimization of the norm of the residuum, which amounts to finding the best fit between the measured response of the structure and its simulated response to the load being identified. Such a structural, response-based objective function is employed also here and described in Section 3.1. However, approaches that are exclusively based on such a formulation suffer often from two problems:

1. *Nonuniqueness of the solution*, which is related to *insufficient instrumentation*: in most practical scenarios there are much more potentially loaded points than sensors, so that the inverse problem has more unknowns than equations and is thus underdetermined.

2. *Ill-conditioning*, that is a large sensitivity of the results to the inaccuracies of the input data, which arise due to inevitable measurement errors and model errors (for example, possible nonlinearities of the sensors in a linear formulation).

Here, the first problem is addressed by the assumption of load sparsity, which is formulated as the requirement that in each time instance the “ l_0 norm” of the load vector equals exactly one, that is that in each time instance the load vector has only one nonzero element. Effectively, it corresponds to the assumption that a single load is being identified. The second problem is addressed by employing a certain apriorical knowledge in a regularization-like approach. Namely, it is noted that the 2D paths (trajectories) of the moving loads are expected to be relatively smooth. A respective, spline-based objective function is proposed to quantify the smoothness of the trajectory, and it is used concurrently with the response-based objective function in a multiobjective optimization problem. These two objective functions are used to form the Pareto front and find the moving load path that strikes the balance between the response fit and the expected characteristics of moving loads.

3.1 Measurement-based objective function

The measurements shown in Fig. 2 are relatively smooth and do not exhibit any apparent transient effects. It suggests that the considered problem has a quasi-static character. Therefore, the response analysis is decoupled with respect to time: the impulse response functions degenerate to points and the operation of deconvolution reduces to a series of simple time point by time point multiplications:

$$\boldsymbol{\varepsilon}(t_i) = \mathbf{B}\mathbf{f}(t_i), \quad i = 1, 2, \dots, N_t \quad (1)$$

where $\boldsymbol{\varepsilon}(t)$ is the 8-element vector of the responses of the strain gauges, as recorded in time instance t , the matrix \mathbf{B} is a compliance matrix reduced to the strain sensors and potential load positions that correspond respectively to its rows and columns, and N_t is the number of the considered time steps. The path of the moving load is discretized to the 100 points numbered 00 to 99 in Fig. 1 (left), and the vector $\mathbf{f}(t)$ collects the corresponding vertical loads in the time instance t . Notice that the elements of the vector $\mathbf{f}(t)$ can be assumed to be nonnegative.

Given the matrix \mathbf{B} and the measurement vectors $\boldsymbol{\varepsilon}(t_i)$, the structural objective function quantifies (in the logarithmic scale) the fit between the expected response and the measurements, as expressed in terms of the squared norm of the residuum vector,

$$F_1(\mathbf{f}) = \ln \sum_{i=1}^{N_t} \|\boldsymbol{\varepsilon}(t_i) - \mathbf{B}\mathbf{f}(t_i)\|^2. \quad (2)$$

3.2 Smoothness-related objective function

The second objective function is employed to enforce the assumption that the paths of the moving load is expected to be smooth. Due to the assumption of sparsity, the vector $\mathbf{f}(t_i)$ for each time instance t_i has only one nonzero element, which corresponds to one of the points numbered 00 to 99 in Fig. 1 (left). Therefore, each point \mathbf{f} of the search space defines a certain 2D path $\mathbf{x}(t_i)$ on the plate, discretized to the time instances t_i and the plate points 00 to 99. The proposed objective function quantifies the smoothness of this path by: (1) calculating a continuous, spline-based interpolation $\mathbf{x}(t) = (x_1(t), x_2(t))$ of the path; (2) computing the

following weighted sum of two terms:

$$F_2(f) = \alpha \int_{t_1}^{t_{N_t}} \ln \left(1 + \frac{(\dot{x}_1 \ddot{x}_2 - \dot{x}_2 \ddot{x}_1)^2}{10^{-3} + (\dot{x}_1^2 + \dot{x}_2^2)^2} \right) dt + \beta \frac{\sqrt{\int_{t_1}^{t_{N_t}} (\|x\| - \int_{t_1}^{t_{N_t}} \|x\| dt)^2 dt}}{\int_{t_1}^{t_{N_t}} \|x\| dt}, \quad (3)$$

which respectively quantify the variability of the angular velocity of the path and the (normalized) variability of its linear velocity. The weights α and β are selected to equalize the mean magnitudes of both terms on a random sample of several hundreds of paths that are near-optimal according to F_1 .

3.3 The optimization procedure

A multiobjective optimization problem is considered, in which both objective functions are minimized concurrently by means of the Pareto front. In the first step, the starting path is determined by minimizing only the structural objective function F_1 . Then, an evolutionary local search is performed: the operation of mutation is defined and extensively used to generate iteratively new search points. In this way, the neighborhood of the starting point is probabilistically explored. In comparison to genetic algorithms, the operation of cross-over is neglected due to the intended local character of the search: a meaningful load path should be relatively smooth, but it must also provide a certain fit to the measurements, and therefore it must be placed in a certain vicinity of the starting point. The employed operation of mutation shifts a small, randomly selected, number of points of the discretized path to their randomly selected neighboring points (for example, point 23 can be shifted to point 34) or a point that provides a slightly better/worse value of the objective function F_1 .

5 EXAMPLE RESULTS

Since the considered case has a quasi-static character, the measurements have been downsampled to one point per 2 seconds, which corresponds to the distance of approximately 20 cm between successive path points and 34, 25 and 29 points for the three considered paths. Figures 3–5 show the computed Pareto fronts and the load paths corresponding to its few selected points, respectively for the three considered paths: the square, the circle and the triangle. The actual paths are shown in Fig. 1 (left).

The results confirm that the proposed smoothness-based objective function has a regularizing influence on the identified load path. In all three cases, the geometric regularity and smoothness of the path are considerably improved. The trajectories that are identified based on the response fit only (case A in each figure) clearly illustrate the detrimental effect of data inaccuracies: even though the considered problem is not underdetermined, the identified paths are highly noisy, which is especially pronounced in case of Fig. 5. Implementation of the smoothness-based objective reveals and emphasizes the actual geometrical character of the identified paths.

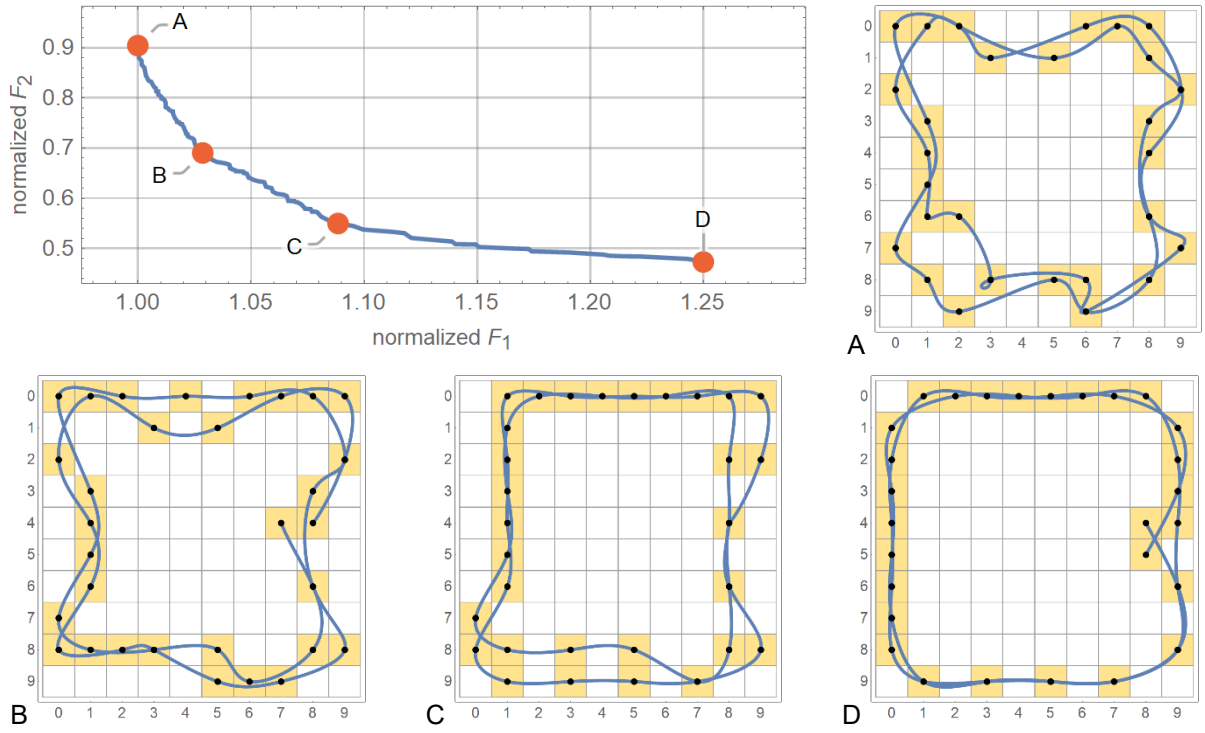

Figure 3: Example identification results: the Pareto front and the identified paths that correspond to its few selected point. The actual path is the square shown in Fig. 1 (left).

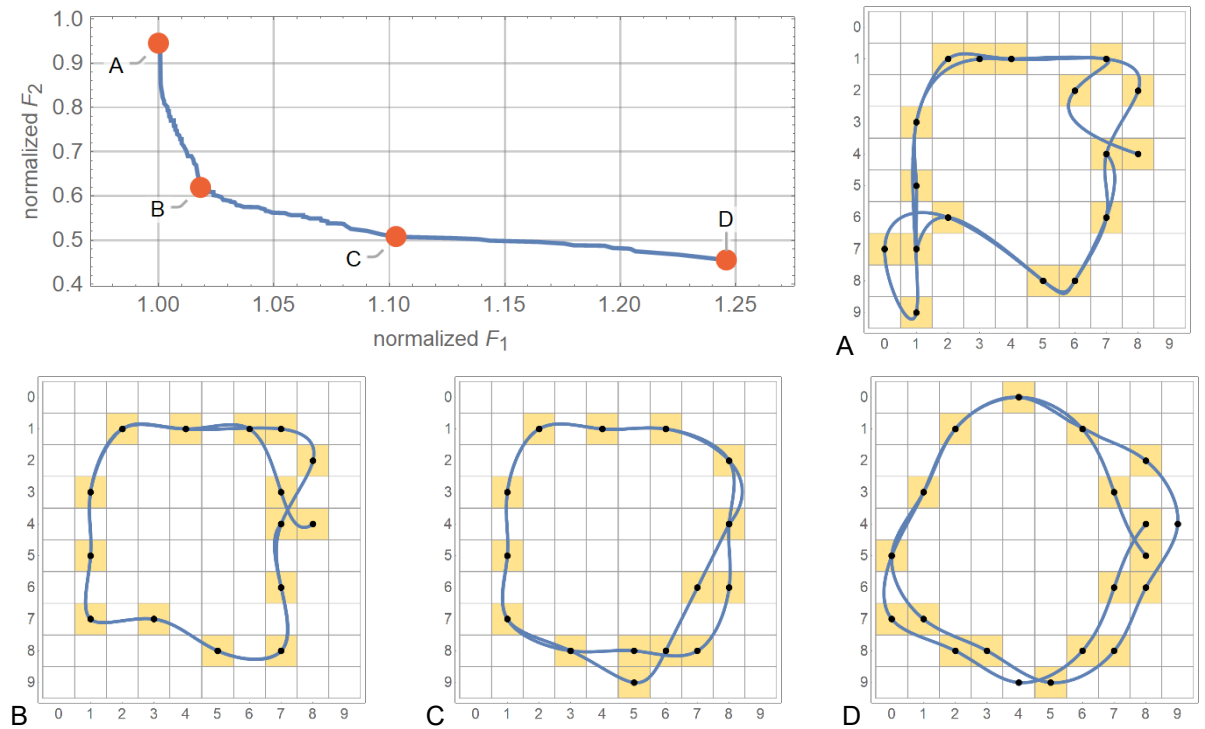

Figure 4: Example identification results: the Pareto front and the identified paths that correspond to its few selected point. The actual path is the circle shown in Fig. 1 (left).

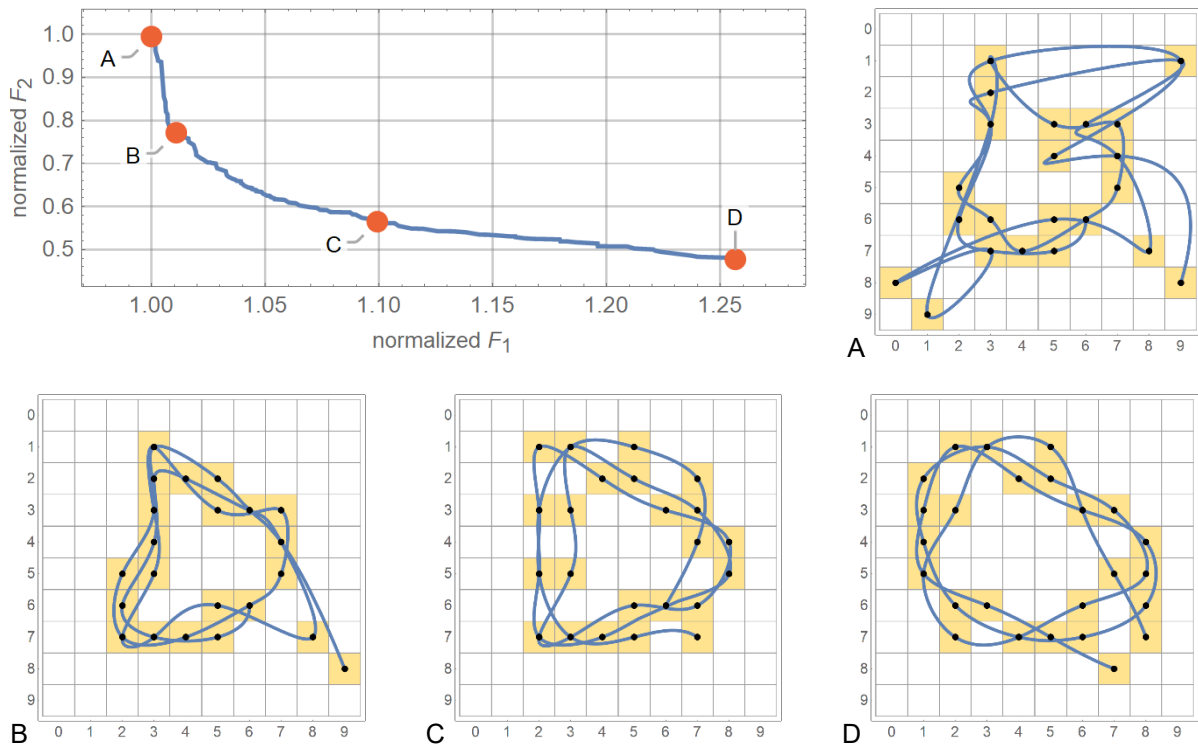

Figure 5: Example identification results: the Pareto front and the identified paths that correspond to its few selected point. The actual path is the triangle shown in Fig. 1 (left).

6 CONCLUSIONS

This contribution proposed a multiobjective approach to indirect identification of 2D paths of moving loads. The formulation employs two objective functions: one is response-based and the other quantifies the geometric regularity of the path. The approach is successfully tested in a laboratory example of a 1 m x 1 m plate loaded by a line-follower robot. The research is ongoing to (1) increase the spatial resolution of the identified paths, to (2) consider multi-load cases, and to (3) automatize the determination of a proper segment on the Pareto front.

Key words: Electro-Mechanical Impedance Technique, Rocks, Structural Health Monitoring, Acoustic Emission.

Abstract. The inspection and maintenance of underground structures built in rocks poses difficulties to the concerned engineers due to the complex behaviour of rocks. Some of the underground regions are inaccessible for the inspection team or might warrant special clearing arrangement, leaving the structure out of service. The complexity of their design, construction and the conditions encountered during service life necessitate the deployment of a dedicated structural health monitoring (SHM) system. It is very crucial to identify the damage in the surrounding rocks in its incipient stage to prevent its further propagation and safeguard the structure built over it. The damage detection in rocks require an efficient SHM system which can monitor them on a regular basis. In the present study, lead zirconium titanate (PZT) patches are used to monitor the condition of rocks under various forms of loadings using electro-mechanical impedance (EMI) technique together with Acoustic Emission (AE) technique. In EMI technique, the vibrations generated by the actuation of PZT patch are sensed by the same PZT patch and is recorded in the form of conductance and susceptance signatures. These signatures can be quantified using root mean square deviation (RMSD) method. The same smart sensors were checked for their potential to be used for AE monitoring of rocks. The AE technique is demonstrated for monitoring acoustic events happening within the rock specimens under uniaxial compressive loading. The study clearly establishes the potential of the EMI and AE technique in detecting and quantifying load induced damages in rocks surrounding the underground structures, opening avenues for its applications in real-life situations.

1 INTRODUCTION

The monitoring of the structures built on rocks or soils requires a timely inspection with the aid of instruments and expert judgment [1]. A structure constructed in rocks or rock mass can fail due to unforeseen geological and weathering conditions or seismic activities. Hence, a continuous systematic health monitoring system is required for timely detection of insipient damages. These damages can be rectified in time instead of letting them progress into a catastrophic failure. Rocks may either fail spontaneously after excavation or may take significant time to fail depending upon its type and surrounding conditions, like overburden pressure.

Health monitoring is a continuous process which is needed at the time of construction and after the operational starting of the structure. A monitoring system should be simple in deployment, should take less time in instrumentation and should cover both accessible and inaccessible areas of the structure. The monitoring methods available are classified into surface and sub-surface methods.

Piezo based sensors are studied extensively for condition monitoring of metallic and concrete structures. However, its applications for SHM of rocks around the underground structures is unexplored yet. The present research aims to explore the potential of piezo sensors in the field of SHM of rocks. The use of smart sensors in condition monitoring of rocks and underground structure has a great possibility. In near future, a smart integrated system can be developed for the automatic monitoring of rocks and structures, especially in remote locations.

2 WORKING PRINCIPLES

This section discusses the working principles of the EMI technique and AE technique in brief.

2.1 The EMI Technique

The underlying principle of EMI method is based on the electro-mechanical interaction between the mechanical impedance of the host structure and the electrical impedance of the piezoelectric sensor which is bonded to the structure. A schematic configuration is shown in Figure 1. The figure shows a square PZT patch that is bonded to the host structure. Here, the data acquisition system excites the PZT patch by sending excitation signals of frequency (ω) and simultaneously measures the corresponding electrical impedance ($Z_E(\omega)$) as the response of the patch. The actuation signals are given as a range of frequency and step interval of frequencies. The electrical impedance signature is acquired in the same frequency range within which the excitation signal is given.

The actuation and sensing behavior of a piezoelectric element can be understood from the following two equations [2]

$$S_j = s_{ji}^E T_i + d_{jm} E_m \quad (1)$$

$$D_m = d_{mj} T_j + \epsilon_{km}^E E_k \quad (2)$$

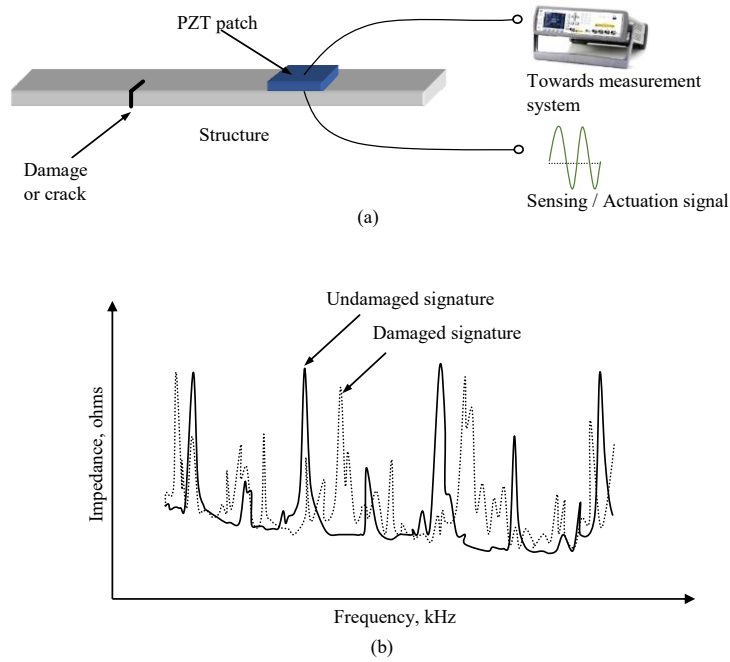

Figure 1: Acquiring EMI signatures of a host structure using PZT patches (a) PZT patch bonded on host structure (b) Impedance signature of the damaged and undamaged structure

The equations (1) and (2) shows the converse and direct piezoelectric effects, where, $[D_m](3 \times 1)$ (C/m²) is the electric displacement vector, $[S_j](6 \times 1)$ is the second order strain tensor, $[E](3 \times 1)$ (V/m) is the applied external electric field vector and $[T](6 \times 1)$ (N/m²) is the stress tensor. Accordingly, $[\epsilon_{km}^E](F/m)$ is dielectric permittivity tensor under constant stress, $[d_{jm}](C/N)$ and $[d_{mj}](m/V)$ is the piezoelectric strain coefficient tensors for direct and converse piezoelectric effects, respectively, and $[s_{ji}^E](m^2/N)$ is the elastic compliance tensor under constant electric field.

In the EMI method, a PZT patch is bonded to the surface of the host structure to be monitored using a high strength epoxy adhesive, as shown in the Figure 1. Electrical terminals are attached to the PZT patch and are then connected to the impedance analyser. The PZT patch can be assumed as a thin axial bar which is vibrating with the host structure. Hence, the mechanical impedance of the structure is the resistance offered to the harmonic vibrations by the PZT patch. Mechanical impedance is a measure for a structure's resistance to movement when subjected to a harmonic force or vibration. It relates the applied force with the velocity of the structure due to the application of the force. The mechanical impedance of a point on a structure is the proportion of the force applied at a point to the subsequent velocity. Mechanical impedance is the opposite of mechanical admittance or mobility. The mechanical impedance is a function of the applied force frequency and can change incredibly over a frequency range. At resonant frequencies, the mechanical impedance is lower. It means less force is expected to cause a

structure to move at a given velocity [3, 4]. Equation (3) shows the relation between the electrical impedance of the PZT patch and the mechanical impedance of the host structure.

$$\bar{Y} = 2\omega j \frac{w_s l_s}{h_E} \left[(\bar{\epsilon}_{33}^T - d_{31}^2 \bar{Y}^E) + \left(\frac{Z_a}{Z + Z_a} \right) d_{31}^2 \bar{Y}^E \left(\frac{\tan \kappa l_s}{\kappa l_s} \right) \right] \quad (3)$$

Here, Z_a is the mechanical impedance of the PZT patch, Z is the mechanical impedance of the host structure. Width length and thickness of the patch is denoted by w , l and h respectively. $\bar{Y}^E = Y^E(1 + \eta j)$ is the complex Young's modulus of elasticity of the PZT patch, d_{31} is the piezoelectric strain coefficient, $\bar{\epsilon}_{33}^T = \epsilon_{33}^T(1 - \delta j)$ is the complex electric permittivity in direction-3 (z) of the piezo material at constant stress and $j = \sqrt{-1}$, η and δ are the mechanical loss factor and the dielectric loss factor of the PZT material, respectively, κ is the wave number, which is dependent on the angular frequency of excitation ω .

So, any variation in the mechanical impedance of the host structure due to any damage or change in the environment reflects a change in the electrical impedance of the PZT patch. Hence, we can visualize any incipient damage in the host structure which is not visible to the naked eyes. In EMI technique the frequency range of excitation is generally in kilohertz (kHz). As the frequencies are very large in comparison to the natural frequency of the structure (which is in the range of 1-100 Hz only), the stress wave generated due to actuation of PZT transducers, are of very small wavelength. Hence, only local structural modes are excited near the PZT patch instead of the global modes. The very high frequency range gives us two advantages. First, small wavelengths can detect incipient damages and second, the sensing zone becomes localized. Hence, we can monitor small crucial areas very well.

2.2 The AE Technique

The same PZT patches can be utilized to acquire AE signals from rocks in a very cost-effective manner. The AE technique is demonstrated for monitoring acoustic events happening within the rock specimens under uniaxial compressive loading. The conventional AE technique has been improved with the advancement in sensor technologies and computing capacities. The present study aims to record acoustic emissions from Kota sandstone rock specimens under unconfined compressive loads. PZT based patches were used as the AE transducers and commercially available sound card of a personal computer (PC) was used for data logging of the AE signals. The proposed technique is found to be very easy and very much cost effective in capturing low frequency AE signals within the targeted range as given by Hardy, 1972 [5] (Figure 2). The recorded data was processed and different AE parameters like the cumulative AE count, the relative energy of the event and the event rate were determined. The results are compared with the conventional stress-strain plots of specimens under uniaxial compressive load.

Figure 2: Frequency ranges for various AE and other related studies [5]

The conventional AE equipment are capable of recording AE signals in MHz range which is essential for delicate laboratory studies like monitoring of micro crack propagation. However, for field monitoring the AE system should be economical as more number of sensors are required to cover larger area, must be easy to install and rugged for long duration monitoring.

In the present study the PZT patches were bonded directly on the specimens using epoxy adhesive whereas, in the conventional AE technique, the piezo transducers are bonded using a couplant like natural wax and silicon grease. The use of couplant increases the signal losses by damping the signals. Moreover, no signal conditioner or amplifier were used herein to condition the signals, thus rendering the whole data acquisition process simple and cost effective. A schematic diagram of the acquisition process is shown in Figure 3.

Figure 3: Schematic diagram of AE recording system used in the present study

The frequency range of 16-32 kHz comprises the maximum concentration of AE activities [6]. The present study considers a range of 20-20000 Hz, which falls in the range of AE lab and field studies on geological materials as illustrated in Figure 2. With the latest advancement in data acquisition techniques, AE events in the range of 1-2.5 MHz range, which is more suitable for metals than rocks, can also be recorded. However, the amplitude of such a high frequency signal is very small and occurs in the range of surrounding noise. Liu et al. (2014) tested four different types of rocks *i.e.* granulite, limestone, granite and siltstone, and plotted the energy spectrum coefficient of the AE signals with different frequency ranges, on a wavelet scale [7]. They observed that the energy of the events decreased in a parabolic manner with linear increase in the event frequency. The amplitude of the signal falling under the frequency band of 1.0-2.5 MHz was in the range of 0.02 mV and of those falling under 0-200 kHz were of the order of 2-10 mV, which is nearly 100 times higher than the megahertz amplitudes.

Generally, the data logging is done through multiple channels at moderate to high sampling rate creating a huge volume of data. Multiple sensors are used for the source localization of the AE event. Brantut, et. al. (2014) used multiple sensors for monitoring sandstone specimen under triaxial loading with a constant strain rate of 10^{-5} s^{-1} and under constant stress condition [8]. In order to analyze such a huge volume of data, high speed processing computing with adequate data storage facility is required. The data can be recorded in the raw form, *i.e.* in time vs amplitude form, and can be processed later to compute various parameters like the event rate and the event energy. If the computing capacity of the data logger is fast enough, the AE parameters can be determined simultaneously while recording the AE events. The AE waveform is recorded through an inbuilt analog to digital (A/D) convertor.

The AE application uses the direct piezoelectric effect (sensor application) to acquire the low frequency waves generated due to AE activities (Equation 1). The sensing region for AE activities of a piezo based sensor depends upon the geometry and material of the host structure (rock in the present study) and the nature of the structural discontinuities like pores and fissures. These discontinuities are the main causes of attenuation in the propagation of a stress wave signal [9].

3 EXPERIMENTATION DETAILS AND RESULTS

This section discusses the experimentation details used in condition monitoring of rocks under static and dynamic loading conditions using EMI technique and setup used for acquiring AE signals from rocks using a very cost-effective technique. Cylindrical Kota sandstone specimens of diameter 54 mm and length 108 mm were used in all the studies. The experimental setup used for conducting tests in static and dynamic loading conditions is shown in Figure 4. The conductance signatures were recorded after every loading stage also mentioned here as Load Ratio (LR). A typical variation in the conductance signatures with different load ratios can be seen in Figure 5. The conductance signatures in the range 300-600 kHz are very much capable of capturing the occurrence of damage in both dry and saturated conditions [10]. It is to be noted that this range is specific for the size of PZT used in the study. For larger patches the range is lesser. The change in the position of the peaks in the conductance signatures are the first indicators regarding the development of any damage in the rock. The PZT patches have

Figure 4: Experimental setup showing compression testing machine and LCR meter for acquiring EMI signatures.

Figure 5: (a) Conductance signatures of rock specimens under different Load Ratio (LR) (b) Non-linear curve fitting for the variation in RMSD with LR

worked properly until the loading reached eighty percent of the peak load value in the dry rock testing and up to hundred percent of peak load in saturated testing conditions. This could be verified based on the consistency of slope in the susceptance signatures. The RMSD index has shown good capability in the quantification of the changes in the conductance signatures and hence damage quantification.

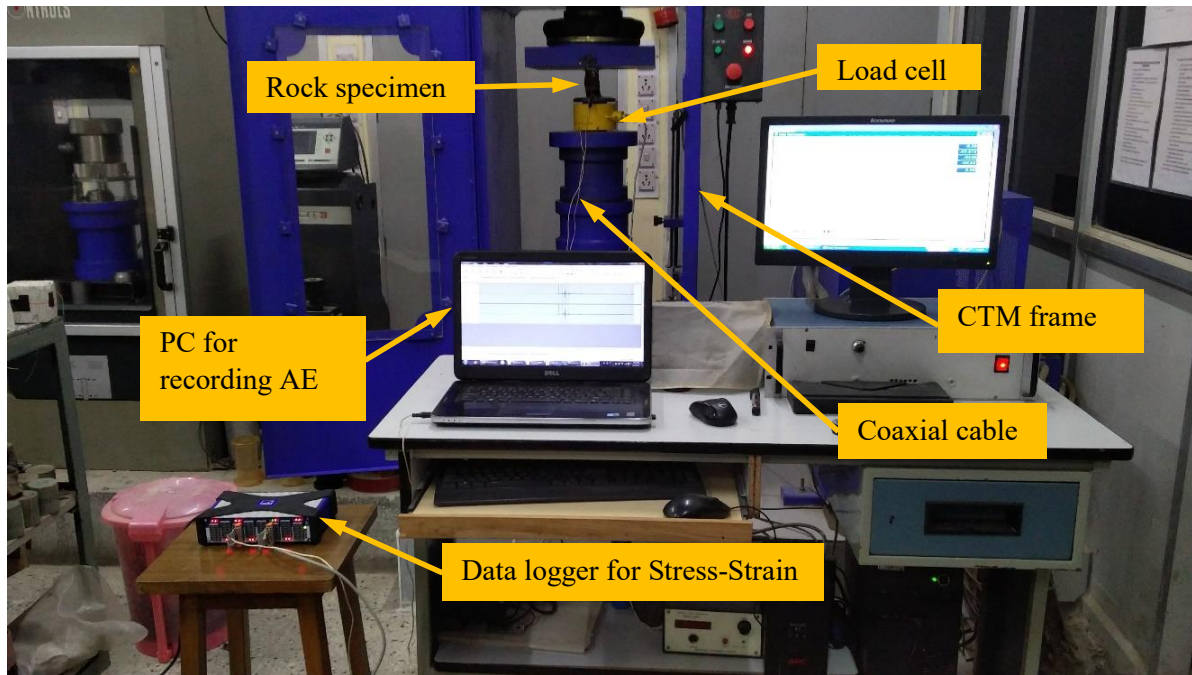

Figure 6: The complete experimental setup for recording acoustic emissions (AE)

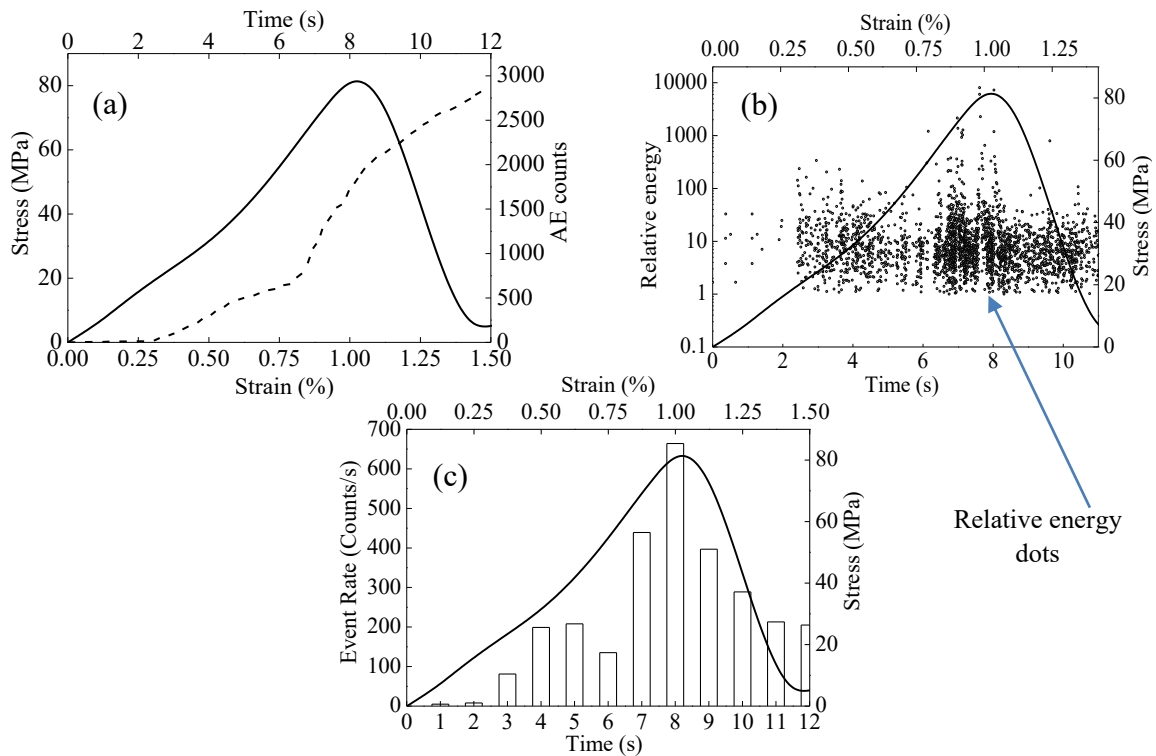

Figure 7: A typical (a) cumulative AE count plot (b) relative energy plot (c) event rate plot

Figure 6 shows the complete experimental setup for acquiring AE signals from the rock specimen under compression. The recorded events were further processed in MATLAB for calculating cumulative event count, relative event energy and event rate. A typical example of recorded parameters is shown in Figure 7. All the parameters are plotted against stress-strain plot of the specimen for better understanding. Based on the test results, it has been found that the PZT patches can record good low frequency AE emissions in rocks. For traditional AE systems, the cost of the complete AE equipment *i.e.* the transducers, data acquisition system, amplifiers, data cables, signal conditioners is around USD 40000-60000. Whereas, the present study needed only PZT patches and a PC with a sound card for data acquisition costing less than USD 1000 including the cost of PC. The cost of traditional AE transducers varies between USD 300-600, whereas the cost of PZT patch is USD 5-15. Further, the cost of the present AE system is subjected to the complexity and nature of the monitoring process. The small patches can be easily instrumented on smaller diameter specimens as less as 38mm, hence are suitable for laboratory demonstration of AE method. Using strong epoxy for bonding the patches provides a dual advantage of less signal attenuation and stable fixity in rough field conditions.

4 CONCLUSIONS

- The EMI technique can be conveniently used as damage monitoring technique in rocks under dry and saturated/ moist underground conditions. Any incipient damage can be detected easily in the initial stage and hence can be taken care of before it advances to a severe condition. The EMI technique can be alongside the conventional monitoring equipment like load cells and extensometers in the initial stage of development for the monitoring of underground structures. There is a huge scope of further research in finding the optimum size of the piezoelectric sensors for extracting more sensitive signatures. There is also a scope of developing a remote monitoring system which can monitor the underground structures remotely in a convenient manner. A standard procedure for using this technique can be developed and then can possibly be followed during construction of the underground structures.
- The PZT patches were found to be good in taking AE signals from rocks under unconfined compressive load. The proposed system aims to drastically reduce overall cost of the whole AE system.
- As sensors were bonded to the rock specimen directly, the emissions have been recorded with a good signal to noise ratio. Once bonded and sealed with epoxy, they are durable and can withstand the rough handling while testing. Hence, they can be used in the site conditions which are generally not suitable for conventional AE sensors.
- The attenuation of the AE signal was negligible as there is absence of air/ couplant in between the host structure and the sensor. The data was recorded straight forward from a PC sound card making the data logging further easier and economical in comparison to the commercially available AE systems.
- As the bonding conditions of every sensor may vary, the acquired data from one specimen testing varies in absolute terms. However, the technique can be further improvised with a higher quality control in bonding the terminals to the PZT patches at manufacturing level.

Key words: Friction Pendulum Bearing, Component Testing, Structural Health Monitoring, On-demand Monitoring, Seismic Isolation, Lidar, Laser scanning.

Abstract. Seismic isolation is a common technique used for the protection of structures and equipment from earthquakes. There are several types of devices providing seismic isolation. One of the most popular and commonly used is a friction pendulum bearing (FPB). The main idea behind a FPB is based on sliding movable spherical surfaces in respect to fixed spherical surfaces. A slider in between the surfaces makes this possible. Since there is some friction associated with the slider's performance, the restoring force is not enough to bring the slider to its zero position and as such, there is a possibility of a residual displacement after a seismic event. Monitoring these displacements is essential to ensure that the isolation can still accommodate a displacement demand of a future earthquake. A technique of on-demand monitoring of this displacement is developed in this paper. A short range LiDAR is used and the feasibility of the approach is validated by tracking geometric shapes with precisely known displacements. Due to recent explosive developments of LiDAR and laser scanning technologies driven by demand for collusion detection for autonomous car and robotic industries, the cost of these devices is decreasing dramatically. The device utilized in this approach is competitively priced and allows mass installation on all FPBs used in any particular project without a significant cost increase. In addition, the residual displacements can be measured simultaneously on all devices that allow instantaneous assessment of all FRB after an earthquake. The benefits of this approach are validated in the tests conducted on a full-scale FPB with a full stroke of ± 81.3 cm. The accuracy of the technique developed herein is compared against more accurate conventional instruments and a terrestrial laser scanner.

1 INTRODUCTION

The concept of Smart City is defined as an urban area that utilizes various types of electronic Internet of Things (IoT) sensors to collect data and use these data to manage assets and resources efficiently [1]. The data can be collected from citizens, devices, and assets that is processed and analysed to monitor and manage traffic and transportation systems, power plants, water supply networks, waste management, crime detection, information systems, schools, libraries, hospitals, and other community services. The objective of this paper is to introduce a novel system for monitoring seismic isolators. The seismic isolation is a common technique for

seismic protection of buildings and structures of high importance: hospitals, emergency service buildings, bridges and others. Periodic assessment of the seismic isolators is beneficial for structural integrity of the building and structures, especially right after a major seismic event. This paper presents a discussion of a device enabling this monitoring in near real-time or on-demand configuration. In anticipation of a mass application, it is based on usage of inexpensive 2D LIDAR [2]. A special procedure is developed to access the location of the slider in plane, which was verified by a 3D laser scanner [3]. The data manipulation of all collected point clouds was conducted in a Matlab environment [4].

2 EXPERIMENTAL SETUP FOR COMPONENT TESTING

There are several types of seismic isolation. One of the most commonly used is the Friction Pendulum Bearing (FPB). In the most basic case, the FPB consists of a spherical surface on which a slider slips. Since the radius of the spherical surface is predefined by the design requirement of the isolator, it controls the resonant frequency of the isolator, which is based on a pendulum theory (see [5], for example).

There are several implementations of this basic idea, and the FPB studied in this paper was a representative of the so-called triple FPBs [6]. It consists of two dishes with polished conceived spherical surfaces and a slider pack between them as presented in Figure 1a. In addition, the slider pack consists of two conceived spherical surfaces with a rigid slider inside. This type of isolation provides several advantages. A few advantages are listed here. First, triple FPB is more compact than FPB with a single sliding surface designed for the same seismic displacement demand. Second, due to the presence of several surfaces there is a possibility of having several resonant frequencies of the isolator depending on which surface is involved in the sliding action. Third, due to the presence of several contact surfaces, the overall damping depends on the friction of the slider's liner, which can be selected in the most beneficial way to meet the design requirements of the isolator. The full-scale isolators used in this study are shown in Figure 1b.

a) Schematic drawing

b) Photo of FPBs used in the study

Figure 1: Triple FPB

Since the main mechanism of the FPB is based on friction, there is a possibility of residual

displacement after an earthquake event. The measurement of this displacement in respect to the remaining travel clearance on the sliding surface is important to ensure that the slider's displacement remains within the seismic displacement demand. The monitoring of the precise location of the slider pack is also important for the validation of the theoretical modelling of the FPB's performance (see [7], for example).

A special experimental setup was developed at the University of California, Berkeley to conduct component testing on seismic isolators [8]. A full-scale triple FPB was studied in this setup by imposing incrementally increasing cyclic horizontal displacements while keeping the vertical load constant. The setup was intended for the performance evaluation of FPBs under relatively low vertical load and feasibility study of their application as a seismic isolation of high-voltage equipment. The setup is presented in Figure 2a. To mimic a real-life installation, where the top and bottom dishes remain parallel to each other, a special linear bearing system was introduced to keep the top dish horizontal while allowing its movement up and down as shown in Figure 2b. The bottom dish was attached to a shaking table platform capable of delivering ± 813 mm displacement.

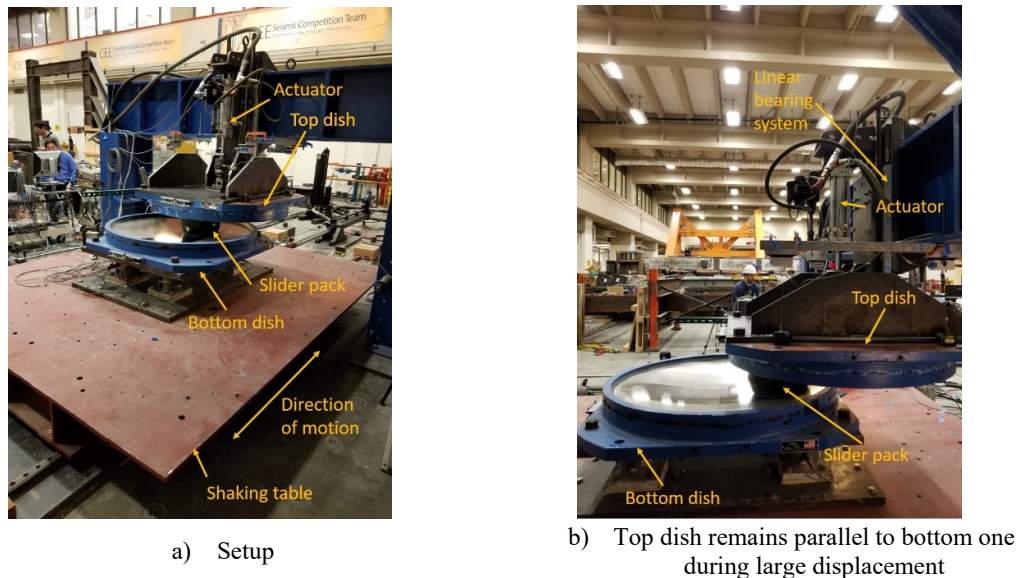

Figure 2: Experimental setup for component tests of full-scale FPBs

In order to study the feasibility of using a 2D scanner for these measurements and their accuracy, the following study was conducted.

3 FEASIBILITY STUDY WITH 2D SCANNER

Prior to the laser scanner measurements on the actual FPB, the 2D LiDAR scanner's performance and accuracy was evaluated in a simple experimental setup inside of a small test room. Objects of different geometry were placed on a linear bearing system as presented in Figure 3. Different cases of geometric shapes were considered: prismatic shapes, globes and cylinders. To study texture and color effects on the results of the laser scanning measurements

the objects were made from different materials: wood, concrete, and spray-painted glass. Some of the examples of the objects used in the study are presented in Figure 3.

Some of the objects remained stationary and were not moved in respect to the 2D scanner. Another object, the so-called movable object, was installed on the carriage of the linear bearing system and was displaced in respect to the stationary object (reference object). The displacements were imposed in an incremental way. The accuracy of the displacements was controlled by high-precision gage blocks [9] as presented in Figure 4. The 2D scanner was used to collect point clouds of all objects at each displacement. The laser scans were conducted from about 0.6 m away from the setup and the laser scanner was not moved during the experiments.

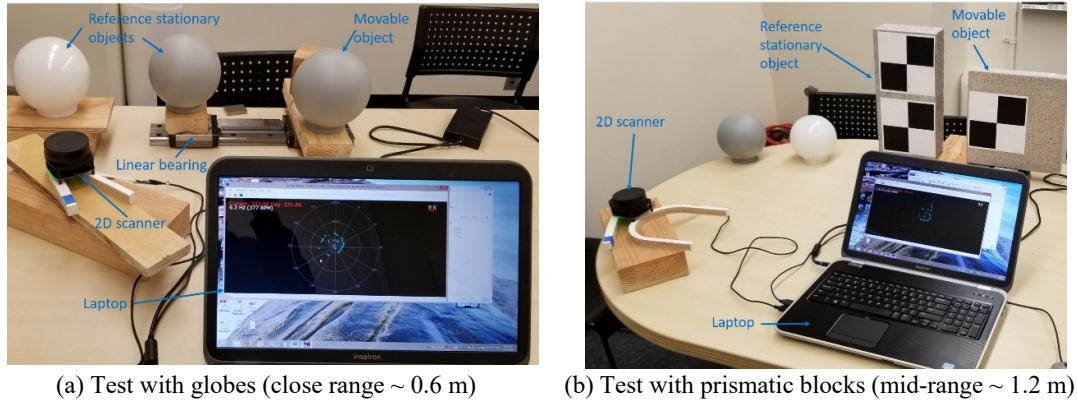

Figure 3: Experimental setup for feasibility study

Figure 4: Examples of how the incremental displacement was imposed

Due to the size limitations of the paper, only discussion related to the globes is presented herein. These results were selected for one additional reason, which is as follows. The horizontal sections of the vertically oriented cylinders and globes will result in circles. Since the slider pack of the FPB consists of many cylinders, the approach with globes can be utilized in tracking the position of the slider pack.

A typical point cloud collected in one of the steps of incrementally applied displacements is presented in Figure 5a. It shows the cross section of the test room and objects used in the study. The scanner's location coincides with the origin of the local coordinate system of the scanner. In the case of the globes, each cross section will be a portion of a circle with only the front side collected by the scanner. The rear side will be in a shadow zone and as such, is not visible to

the scanner. The number of the collected points will depend on the proximity of the scanner to the globe and the density of the laser scans. Point clouds for all positions of the movable globe are presented in Figure 5b.

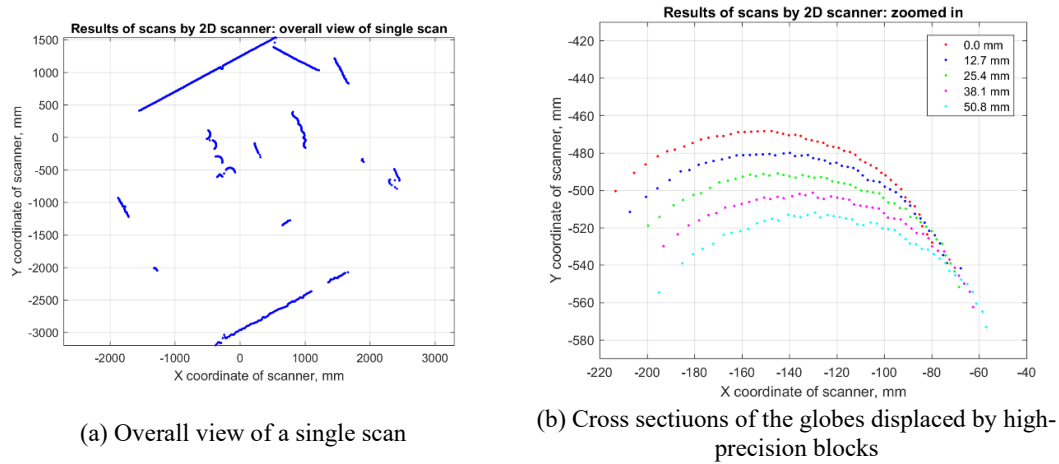

Figure 5: Typical laser scan data

The point clouds of the globe at different displacements were best fitted to circles as presented in Figure 6a. The estimations of the cross sections radii are presented in Figure 6b. The plot also shows the nominal radius of the globe at its center. As can be observed from the plot, there is about 3.5 mm difference between the estimates and the nominal radius. This result has a simple explanation. The radius of the cross section will depend on the elevation of the horizontal section plate and will be close to the nominal radius only at the elevation coinciding with the elevation of the globe's center. All other sections will yield lower estimates. Although originally there was an attempt to scan at the elevation of the globe's center, it was difficult to achieve, resulting in this relatively large difference between the radii.

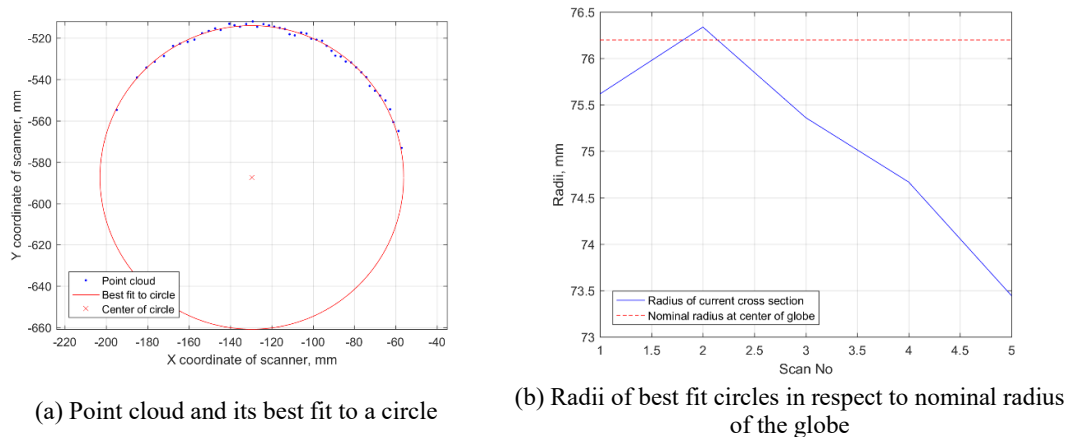

Figure 6: Best fitting of point clouds

An estimate of the circle's centers produced better results, as was expected from the beginning. A comparison between the measured displacement and the estimated location of the

circle's center in respect to its original estimate is presented in Figure 7a. Figure 7b shows an error between the actual displacement and the estimates from the laser scans. As can be observed from the plot, the error does not exceed 2.1 mm, which is considered acceptable for the application of this approach to tracking the slider pack's location inside of FPB.

(a) Measured (red) vs. estimated from point clouds (blue) (b) Error between measured and estimated from point clouds

Figure 7: Comparison results for displacements

4 EVALUATION STUDY ON FULL-SCALE FPB

The final evaluation of the approach discussed herein was completed with the utilization of a 3D laser scanner [3]. The point cloud reduction was conducted by using Trimble RealWorks [10] and Cyclone [11]. The 3D scanner and 2D scanner were installed in close proximity to the FPB as presented in Figure 8a. Figure 8b shows the point cloud collected by the 3D scanner.

(a) Setup's photo (b) Point cloud collected by 3D scanner
Figure 8: Experimental setup for final evaluation by comparing 3D scanner and 2D scanner results

As presented in Figure 8, the load to FPB was applied via lead blocks. The shaking table platform was incrementally displaced along a single axis. The displacement was incremented 14 times and the displacement of the shaking table was measured by a position transducer. Displacements of the slider pack were monitored by both the 2D and 3D scanners. Due to size limitations of the paper, only some typical results are presented herein.

The 2D scanner was installed slightly out of plum to make sure that the scanner will capture the rib of the bottom dish and the slider pack. The point cloud of the bottom dish's rib was also collected by the 3D laser scanner. The tests were conducted in a quasi-static setting. The scanners were installed outside of the shaking table and they were stationary during the tests.

Figure 9 presents the results for the best fitting of the point clouds to circles. The point cloud with its best fit for the bottom dish is presented in Figure 9a and the point cloud with its best fit for the slider pack is presented in Figure 9b.

Figure 9: Typical best fits of corresponding point clouds to circles

Figure 10a presents the small variability of a few millimeters in the estimation of the dish's radius and Figure 10b shows the displacement of the bottom dish's center in respect to the top dish. Both results were obtained by utilizing point cloud data of the 2D scanner.

Figure 10: Results of 2D scan data for bottom dish of FPB

Figure 10 shows the comparison of the results from the 3D and 2D scanners. The displacement of the bottom dish is presented in Figure 10a. The displacement is based on the same approach of best fitting the point clouds to circles. In the case of the point cloud collected by the 3D laser scanner, only horizontal slices of the point clouds were considered. The error between the displacements estimated from point clouds of the 3D and 2D scanners are presented in Figure 10b. The latter shows that the error between the two scanners is relatively small and

does not exceed 4 mm. This accuracy is very close to the accuracy measured in the feasibility test conducted on the globes (see Section 3). Hence, the accuracy of the inexpensive 2D scanner is very close to that of the 3D scanner of surveying grade accuracy. The results obtained from the point clouds of the 2D scanner can adequately describe the displacements of the bottom dish.

Figure 11: 3D scanner versus 2D scanner comparison

The point cloud of the slider pack captured by the 3D scanner was quite noisy because of its high sensitivity to the black color as presented in Figure 12a. It was noticed earlier [12] when surveyor grade scanners from different manufacturers were compared against each other. On the other hand, the point cloud of the slider pack collected by the 2D scanner had very small variations as shown in Figure 9b. A final comparison showing the slider and bottom dish displacements is presented in Figure 12b. Both displacements were estimated from the point clouds collected by an expensive 2D scanner, which is shown to have about the same accuracy as the 3D laser scanner. The plot presented in Figure 12b shows that the slider's displacement is about two times less than that of the bottom dish. This is related to the fact that the sliding occurs on both spherical surfaces of the top and bottom dishes, which is one of the main features of the triple FPB.

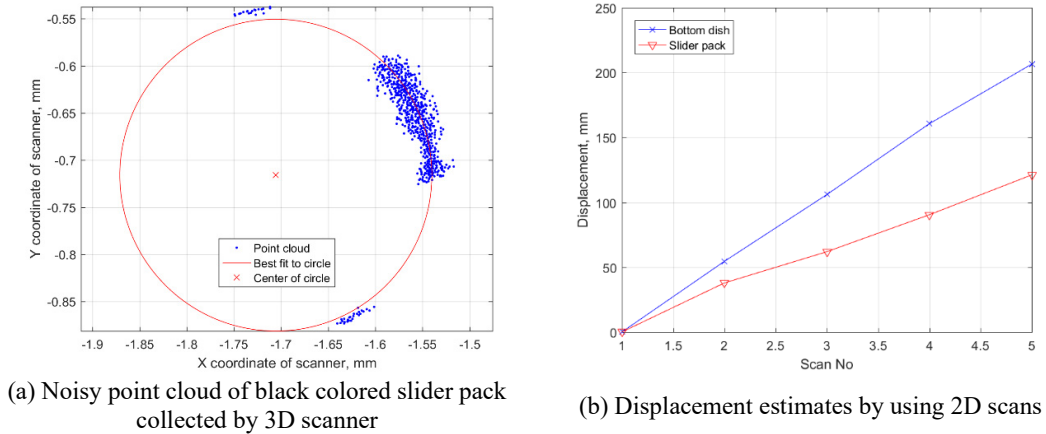

Figure 12: Noisy data of 3D scanner and displacement estimates by using 2D scans

As discussed above, the 2D scanner offers the following advantages. First, it provides an adequate accuracy of the slider pack's position tracking when compared to a 3D laser scanner with a surveyor grade accuracy. Second, it is much more compact and lightweight, which makes it possible for use in permanent installations on a FPB. Third, the price range of the 2D scanner is significantly lower than that of the 3D scanner. The price of a 2D scanner is about 0.2% of the 3D scanner's price. Fourth, low sensitivity of the 2D scanner to the color of the object was observed. Based on all these results, the 2D scanner can be used as one of the sensors in the Smart City's network.

5 CONCLUSIONS

- A smaller sensitivity to the slider's black color was observed for 2D scanner when point clouds from 2D and 3D scanners were compared.
- The approach discussed herein delivers adequate accuracy for monitoring relative dish and slider pack displacements inside of the FPB. Although the advantages of the approach are shown in a static setting, it can be easily extended to a dynamic setting. The sampling rate of the 2D scanner is 10 Hz, which is sufficient for tracking low frequency systems. For example, the FPB used in the study had a frequency close to 0.5 Hz. The approach can be extended to objects of other shapes, which is ongoing.
- Since the approach is based on the utilization of an inexpensive 2D laser scanner with a relatively high sampling rate, it is intended for mass installation to serve as a one of the near-real time sensors in the Smart City network. The approach discussed herein is going to be utilized in a standalone device comprised of a 2D scanner and Arduino [13] or similar boards, which is ongoing.

6 ACKNOWLEDGEMENTS

The work associated with the development of component testing setup for full-scale FPBs was sponsored by the Electric Power Research Institute (EPRI) whose support is greatly appreciated. Special thanks are due to Earthquake Protection Systems for donation of the full-scale FPBs used in the project. The author would like to acknowledge the hard work of the technical staff of Structures Laboratory of Civil and Environmental Engineering (CEE) Department, UC Berkeley: Mr. Matthew Cataleta, Mr. Llyr Griffith, and Mr. Phillip Wong. The 2D laser scanner was provided by 3D Structures along with some additional funding needed for collection of the point clouds, which is greatly appreciated. Technical help by Mr. Martin McDonough (CEE, UC Berkeley) on preparing technical drawings and active participation in testing is greatly appreciated. Special thanks are due to Mr. Bahtiyor Takhirov of Westminster International University in Tashkent (Uzbekistan) for his help on the development of the stand-alone device utilizing the approach discussed in this paper. Special thanks are due to Ms. Holly Halligan of CEE, UC Berkeley for her help with editing the paper.

Key words: Michell truss problem, Micro-truss method, Topology optimization, Optimum structures

Abstract. The damage and catastrophe to social infrastructures by natural disasters, such as earthquakes, floods, landslides and tsunamis in the world, are serious problems in disaster prevention for the inhabitants of a stricken area. So, we propose the optimum layout designs how to rebuild damaged infrastructure and how to build a new type of rescue system which can be implemented quickly when trying to save lives after an emergency. A design domain on the beam model is optimally formed using micro-trusses for the analysis of a macro-structure. This has the benefit of achieving a more realistic lightweight structure form for repetitive analyses. We presented the modified stiffness matrix method to obtain a solution for the topological optimum structures. The optimisation strategy is based on a fully-stressed design that uses the stiffness of the micro-truss members as design variables. From this structural analysis on the optimum structures using micro-truss model, the smart and deployable bridge Mobilebridge, as the emergency bridge at the time of disaster, is designed.

1 Introduction

Research on the optimum design of a structure has been conventionally performed to optimize the dimensions to determine the ideal sectional area, sectional dimension, member length, etc. of the structural members for given design conditions. Recently, geometry optimization and phase optimization problems for obtaining the ideal shape of a member or structure have been actively investigated. For example, of the available approaches, a homogenization method and a ground structure approach have been proposed. The objective of the homogenization approach is to maximize the stiffness and form design of the structure and to optimally arrange the materials [1]-[3]. The aim of the ground structure

Figure 1: Approximation of Michell's truss using the structure of a finite number of members [9]

method is to minimize compliance (maximize stiffness) by restricting the volume of the structure [4]. However, since these methods are combinatorial optimization problems that involve the determination of which constituent elements of the structure should be combined or removed, there are often no viable solutions.

In addition, there is also active research on the application of emergent methods that can simultaneously produce a large number of viable solutions that exist in a combinatorial optimization problem such as Genetic Algorithms (GA) [5], [6] and Cellular Automata (CA). These studies make it possible to easily generate various phase structures using the simple law or numerical method (local rule) that describe local information. Shape optimization has been extensively studied using such a complicated system. However, these studies have been limited to the basic truss structure optimization problem with a small number of elements, and it is difficult to obtain a stable convergence solution in a large-scale structural model, in addition to the requirement of significant computational complexity.

Further, the evolutionary structural optimization (ESO) method was proposed in the early 1990s to solve a variety of size, shape, and topology optimization problems [7]. The ESO method gradually removes unnecessary or inefficient member from a structure to achieve an optimal design. In addition, the bi-directional evolutionary structural optimization (BESO) method is known as an extension of the ESO method. This method gradually adds necessary or efficient members to the structure at the same time that the inefficient ones are removed to achieve an optimal design [8]. However, these methods sometimes lead to a mesh-dependent solution and a non-convergent solution.

Michell's structure is an example of an optimal design in which the structure transfers the vertical load onto two pinned supports. A schematic representation is shown in **Figure 1** [9]. In 2015, A.V. Pichugin, et al. suggested a new half-plane Michell structure that transmits a uniformly distributed load of infinite horizontal extent to a series of equally spaced pinned supports, and also changed the specified ratio for limiting compressive to tensile stress formed from an arch with vertical hangers attached to a cable-stayed bridge [10]. However, formal proof of optimality of the structure has not yet been demonstrated.

On the other hand, in recent years, the damage and destruction to social infrastructure by natural disasters, such as earthquakes, floods, landslides and tsunamis in the world, are serious problems in disaster prevention for the inhabitants of a stricken area. So, we have to consider how to rebuild damaged infrastructure and how to build a new type of rescue system which can be implemented quickly when trying to save lives after an emergency.

From these backgrounds, we propose the optimum layout designs how to rebuild damaged infrastructure and how to build a new type of rescue system which can be implemented quickly when trying to save lives after an emergency. A design domain on the beam model is optimally formed using micro-trusses

Figure 2: Discretisation of a Continuum

for the analysis of a macro-structure. This has the benefit of achieving a more realistic computational cost for repetitive analyses. We used the modified stiffness matrix method to obtain a solution for the topological optimum structures. The optimisation strategy is based on a fully-stressed design that uses the stiffness of the micro-truss members as design variables. From this structural analysis on the optimum structures using micro-truss model, the smart and deployable bridge “Mobile bridge”, as the emergency bridge at the time of disaster, is designed.

2 OPTIMISATION STRATEGY

2.1 Optimum structure using micro-truss method [11], [12]

We represent the design domain Ω of a continuum by micro-trusses, (1). The discretisation is diagrammatically represented in **Figure 2**, where an example of a continuum **Figure 2(a)** is discretised as **Figure 2(b)**. It is proposed that the behaviour of the domain Ω can be adequately modelled by micro-trusses for large number of unit cells, m , where each micro-truss member represents a pin-jointed linear extensional spring.

$$\Omega = \lim_{d\Omega \rightarrow 0} \sum_{m \in \mathbb{Z}}^{(1/d\Omega) \in \mathbb{Z}} d\Omega^{(m)} \approx \sum_{\substack{m \gg 1 \\ d\Omega \propto 1/m}} d\Omega^{(m)} \propto \sum_{\substack{m \gg 1 \\ x^{(m)} \propto 1/m}} x^{(m)}, \quad m = 1, \dots, M \quad (1)$$

The design variable is the stiffness of the micro-truss members, x and therefore the equilibrium equation can be rewritten as (2).

$$F(u, f, x) = 0 \quad (2)$$

where $x = \{\dots, x^{(m)}, \dots\}^T \in \mathbf{R}^m$.

The goal of optimisation is the fully-stressed design, represented as (3) in a discrete form. The design modification is based on the local stress response, where the stiffness of a member is updated at each load step according to (4).

$$\begin{aligned} \text{Min} \quad & \sum_{m=1}^M \left(\frac{\sigma^{(m)}}{\sigma_{\text{nom}}} - 1 \right)^2 \\ \text{Subject to} \quad & x_{\min} \leq x^{(m)} \leq x_{\max} \end{aligned} \quad (3)$$

where $\sigma = \{\dots, \sigma^{(m)}, \dots\}^T \in \mathbf{R}^m$, σ_{nom} = normal stress and M = total number of micro-cell members. Subscripts, min and max denote the lower and upper bounds, respectively.

$$x_{(v+1)} = \gamma \frac{|\sigma_{(v)}|}{\bar{\sigma}_{(v)}} x_{(v)}, \quad v = 1, 2, \dots \quad (4)$$

where v = iteration number, γ = optimisation rate constant and

$$\bar{\sigma}_{(v)} = \frac{1}{M} \sqrt{\sum_{m=1}^M \left(\sigma_{(v)}^{(m)} \right)^2} \quad (5)$$

After one iteration of design modification, the tangent stiffness matrix is updated and the new equilibrium equation is established for the subsequent load step. The design update is applied at each load step.

2.2 Principle of form formation with the iteration method

While the change of the stiffness is limited to a part of structural system, although it is higher for accuracy of the calculation to carry out structural analysis directly, it is possible for the iteration method to observe “the flow of stress” to get stable solutions for sequential correction of a whole of stiffness. In this paper, the correction of the stiffness matrix is assumed to be a feed-back system of the stress response for each member. This computing process is controlled the amount of stiffness for the finite element satisfied under the equilibrium condition. This method is advantage even though including the large-scale calculation or singular problems.

Now, it is assumed that the equilibrium points $(u, f, x_{(1)})$ are obtained by the method of the loading control and/or displacement control with the configuration of the initial design parameters. The stress in each member is defined as

$$\sigma_{\min} \leq \sigma^{(m)} \leq \sigma_{\max} \quad (6)$$

$$\sigma_{(v)} = W(u_{(v)}) \quad (7)$$

It is the displacement function of each node. Here v is defined as the number of iterations, and $\sigma_{(v)} = \left\{ \dots, \sigma_{(v)}^{(m)}, \dots \right\}^T$ is defined as $u_{(v)} = \left\{ \dots, u_{(v)}^{(m)}, \dots \right\}^T$.

Furthermore, the present design variable (stiffness) $x_{(v)}$ is resolved into $x_{(v+1)}$. A new design variable is also resolved into

$$\begin{aligned} x_{(v+1)} &= F(\gamma, \sigma_{(v)}) \\ &= F(\gamma, W(u_{(v)})) \end{aligned} \quad (8)$$

We ensure that the stiffness matrix is also renewed. F means a function to solve the distribution of stiffness. This result enable us to identify solutions $(u_{(v+1)}, f, x_{(v+1)})$ ¹ from the equilibrium equation.

$$J(u, f, x_{(v+1)}) \tilde{u}_{(v+1)} = \frac{\partial F}{\partial f} \tilde{f} \quad (9)$$

¹Now this solution is defined as displacement vector $u_{(v+1)}$ for weight control.

Figure 3: Analytical beam's model with the clamped supports

We substitute this solution into equation (7) and perform a series of repeated calculation, such that the convergence stress and displacement conditions are satisfied. In other words, the nodal displacement and design variable are expressed as

$$\begin{aligned} u_{(v)} &= F(f, x_{(v)}) \\ x_{(v+1)} &= F(\gamma, W(u_{(v)})) \end{aligned} \quad (10)$$

by repeated calculation of the equilibrium equation. If γ , f and W is included, multi-dimensional and multi-feed back of the repeat calculation is expressed as

$$x_{(v+1)} = F(x_{(v)}) = F(F(\cdots F(x_{(1)}))) = F^v(x_{(1)}) \quad (11)$$

We adopt a limited stress condition and variable based on local rules.

3 NUMERICAL RESULTS

3.1 A beam model with the clamped supports

Let us consider the problem of topology optimizing using by the present method of microtruss concept when designing a beam with both-ends fixed model. We consider the discrete model of the design region with a size of 50×200 and mesh division of 25×100 . As shown in **Figure 3**, all nodes of the both sides of the design domein is fixed, and the load position of the vertically downward load was set on the upper side of the beam centre. **Table 1** shows this analysis condition.

The process that needs to be followed step by step to produce the optimum shape is shown in **Figure 4**. **Figure 4** (a)-(d) show the process status from the first step to final shape and stress used by this present method. In this figure, red area shows the compressive members, and blue area shows the tensile members. You can clearly see the shapes determined when balancing compressive (red colour) and tensile (blue colour) members with symmetry. In **Figure 4** (d), we can recognize the final structural frames based on the flow of stress between the load point and the boundary area on which the high stress distribution located at high and low points as far as from the neutral line. And we can carefully see many diagonal members and the triangular substructure. In particular, there are not the horizontal chords at the horizontal positions 50 and 150. If there are only diagonal members in the form of numerical results, and taking all the horizontal members from the structure, the optimized structure can be regarded as a structure compatible with function optimization as a developed structure of the scissors structure.

Figure 5 is the graph shown change in the ratio of the number of necessary members. From this graph, the ratio of the members constituting the final form to the number of initial form is 30.8%. Therefore, about 70% of the number of the initial members could be removed.

Initial section stiffness	$EA_0 = 1$
Load parameter	$f/EA_0 = 0.001$
Maximum section stiffness	$EA_{\max} = 10.0$
optimisation rate constant	$\gamma = 0.019$

Figure 6: Tests of foldable, movable and deployable bridge “Mobile bridge”

3.2 Mobilebridge of smart bridges

In general, it is known that the upper and lower horizontal members of a truss greatly affect the resistance of the bending moment. In this research, however, the truss was used in a new type of bridge that has only diagonal members and no upper or lower horizontal members as the main frames as shown in **Figure 4(d)**. We considered how to develop and apply a new emergency bridge that can be folded up and ready for deployment by using a truss system. The aim is to use the bridge to restore infrastructure that has been damaged in a disaster. Therefore, we have tried to develop Mobilebridge shown in **Figure 6**. This bridge is based on both the concept of a multi-folding micro-structure and research on structural optimization. However, this structural type of the bridge is based on scissors type contains frame as the units of the pin-rahmen members without truss structure. As the result, it is similar for optimisational shape of this bridge which is available to be deployable. To develop Mobilebridge, we need to develop a way to expand it from a folded state.

For example, we can examine an expandable truss structure in which we replace a beam with a structure that works like a pair of scissors. This is effective from the viewpoint of structural optimization for Michell’s problem. If this scissor structure has enough strength when it is deployed with its own weight, it will not need any horizontal members. However, after it has been expanded it may need to be reinforced to make a completed bridge. In this case, although the horizontal displacement is kept in check owing to both the contact side supports and it keeps its stiffness in a plane, we have to design the bridge so that it has enough stiffness when it moves outside a certain plane without undergoing any large deformation. We believe one effective way to change an unstable structure into a stable structure may be to assemble a three-dimensional truss with a tied cable or tied bar between both of the end supports. This makes it possible to produce an expandable and movable bridge. With the technology used in this bridge system, it is possible to completely and quickly construct a bridge system.

4 CONCLUDING REMARKS

This paper presented a stress based topology optimisation strategy using the large size of micro-truss method. We simplified the continuum using a micro-truss representation in order to reduce the lightweight structure form to a realistic level. The modified stiffness iteration method was implemented for the analysis of multiple bifurcation points. Using the stiffness EA of the micro-truss members as design variables, we modified the stiffness based on the stress ratio. Assuming there is a constant material property, the stiffness EA can be interpreted as the cross-sectional area of micro-truss members, which allows us to understand the optimum solutions. We demonstrated the optimisation strategy through the beam model with the clamped supports. We have obtained the optimum shaped frame with compressive

and tensile area like scissors structure in the beam structure.

From this research, we have proposed the new type of the deployable bridge “Mobilebridge” with scissors structure. This new device is one of the rescue tools for the recovery of a bridge after a disaster. This device is the first bridge type with a scissors structure. In general, some control members are required as in the form of structure optimization in order to statically stabilize the scissors structure. Therefore, we should assemble a three-dimensional truss with a tied cable or tied bar between both of the end supports. This makes it possible to rebuild bridges as fast as possible in the field of engineering.

Abstract. This paper aims at developing a fully automated crack monitoring system for concrete structures, based on embedded piezoelectric transducers. The essential elements of the monitoring system are the embedded transducers, the interrogation unit, the post-processing method, and the determination of a threshold for automated alarm triggering. The paper starts with the description of the sensors and interrogation unit, followed by a presentation of the test setup which consists in a short concrete beam with a pair of embedded piezoelectric transducers subjected to a three-point bending test to induce progressive damage. Continuous monitoring is performed throughout the test and the methodology to compute a damage indicator and compensate for the acoustoelastic effect is described. The last section deals with the determination of the threshold for alarm triggering based on statistical analysis of the damage indicator. Two approaches are compared, the first one which relies on the assumption of normality of the damage indicator, and the second more general one based on extreme value statistics.

1 INTRODUCTION

Concrete is the most widely-used construction material in the world; it is a complex material whose mechanical properties evolve continuously from the time of casting until the end of its lifetime. Over time, when the structure is in-service, the mechanical properties of concrete can deteriorate due to several mechanisms, such as the loss of prestress in prestressed concrete or chemical attacks such as alkali-silica reactions or delayed ettringite formation. In order to ensure the safety of the infrastructure, it is important to be able to assess its state of health. Destructive compressive tests can be performed on sampled cores extracted from the structure. For obvious reasons however, non-destructive techniques are preferable. Among these, the ultrasonic pulse velocity method (UPV) is currently one of the most widely used techniques. This is an established technique described in different national norms including the European

standard *EN 12504-4* [1] and the ASTM norm *C 597 – 02* [2], and used in many commercial systems. The technique consists in exciting the emitter by a short pulse signal and measuring the time of propagation of the wave from the emitter to the receiver. Knowing the distance between the transducers, the velocity of the fastest wave (the compressive wave, also called the *P*-wave) can be measured. The *P*-wave velocity is related to the mechanical properties (Young's modulus and Poisson's ratio) of the concrete and can therefore be used to assess the uniformity and relative quality of concrete [3]; it can also indicate the presence of voids and cracks [4] and can be used to evaluate the setting time in fresh concrete [5].

Over the last ten years, several researchers have studied the possibility of embedding the ultrasonic probes directly inside the concrete [6]. The first and obvious advantage of the technique is the potential automation of ultrasonic monitoring. Additional advantages are an enhanced coupling (without coupling agents) with the concrete for stronger wave generation over longer paths, the protection of the transducers from environmental and accidental attacks, the possibility to perform measurements in the presence of formworks, and an added flexibility of transducer arrangements which allows for direct wave propagation paths. A major requirement with such transducers is however, their low-cost, as they will be lost in the structure.

At ULB-BATir, there has been development of tailored embedded transducers to measure the *P*-wave velocity at early-age [7] and monitor cracking in several laboratory tests [8, 9, 10] (pull-out, three-point bending and compressive tests). In particular, based on the measured received wave, there has been developed a damage indicator able to track the appearance of micro-cracking in concrete. The aim of the present paper is to go one step beyond the definition of the damage indicator by proposing robust techniques to set appropriate thresholds for automated damage detection.

2 SPECIMENS AND MONITORING SYSTEM

Experiments we performed on two short non-reinforced concrete beams in which a pair of transducers had been embedded with a spacing of 14.3 cm. The beams are made of ordinary concrete. The geometry and the components of the beams are given in Table 1.

The embedded transducers have been developed at ULB-BATir and are made of a thin Lead Zirconate Titanate (PZT) patch which is a piezoelectric material [11] and surrounded by several coating materials (Fig. 1).

Fig. 1: Embedded piezoelectric transducers designed and manufactured at ULB-BATir.

The ultrasonic monitoring system is described in Fig. 2a; it is composed of a data acquisition board NI

PXI-6115 (10 MHz sampling rate) and a variable-gain preamplifier SmartPre (+18 – 60 dB, band-pass 1 kHz – 1 MHz) designed by SMARTMOTE which are controlled by an in-house program based on the LabView programming environment. The system is able to perform up to 150 ultrasonic measurements per second while the signal which is generated is a short pulse of 5 μ s corresponding to a frequency band up to 200 kHz (–6 dB at 120 kHz). For the present experiments, the ultrasonic measurement rate has been set to 25 Meas./s. The duration of each measurement is 3 ms which allows for a complete attenuation of the ultrasonic wave before the next measurement.

The excitation signal is a low-voltage short pulse (10 V, 5 μ s). Due to the very high measurement rate in this test and the occurrence of damage, some recorded signals are polluted with acoustic emission events which have to be filtered out. Acoustic events are waves generated by the sudden release of energy due to cracking events [12, 13]. In the present study, it was decided to remove these signals from the data, with the procedure described in [10]. This is not problematic as there are enough non-polluted signals due to the very high measurement rate. The measurements which are presented in section 3 correspond to an average of the last 10 sane signals (i.e. without acoustic emission events).

(a) Fast (≤ 150 ultrasonic measurement per second) and low-voltage (≤ 10 V) data acquisition system. (b) Embedded transducers in a prismatic mold.

3 DAMAGE MONITORING

A three-point bending test is performed on one of the two non-reinforced concrete beams after 28 days. An overview of the test setup is shown on Fig. 3. The loading machine is a 200 kN hydraulic jack bending testing machine. The force and the displacement have been recorded on a computer using a National Instruments DAQ system (NI PXI-4461). The vertical displacement at the center of the beam is measured by an inductive displacement transducer (± 5 mm LVDT, HBM W5TK) wired to the DAQ through a specific signal conditioner. The ultrasonic monitoring system is described in Fig. 2a. During the bending test, short low-voltage pulses are sent at regular interval (5 μ s, 10 V, 25 Signals/s).

3.1 Loading Procedure

Since the beam is not reinforced, the maximum load which can be applied is reached at the initiation of the crack. The loading machine is controlled in displacement thanks to an inductive linear displacement transducer (LVDT) as shown in Fig. 3. In order to make sure that the crack is initiating at the center of the beam, a notch of 1 cm of depth is sawed (Fig. 4). The loading procedure and the force-displacement curve are displayed in Fig. 4 where different pictures allow tracking the crack opening. The beam is

unloaded right after the crack visually appears. The different pictures are numbered (from **1** to **3**) in order to relate them to a) the force-displacement and force-time curves in Fig. 4, and b) the evolution of the damage index in Fig. 6. The crack visually appears when the maximum load is already exceeded (see **2** in Fig. 4). It is important to note that the sudden load decreases which can be observed in the loading phase are due to technical features of the loading machine.

3.2 Damage indicator

For real-time monitoring, it is important to be able to distinguish between the effects of damage and operational conditions. As the wave velocity varies due to the appearance of damage as well as changing operational conditions, it is not a robust indicator of damage. The previously-used damage indicator, the early wave damage index, has also been shown to be sensitive to operational conditions [9]. In this paper, the time stretching with DWI [10] is used in order to filter out operational conditions before computing

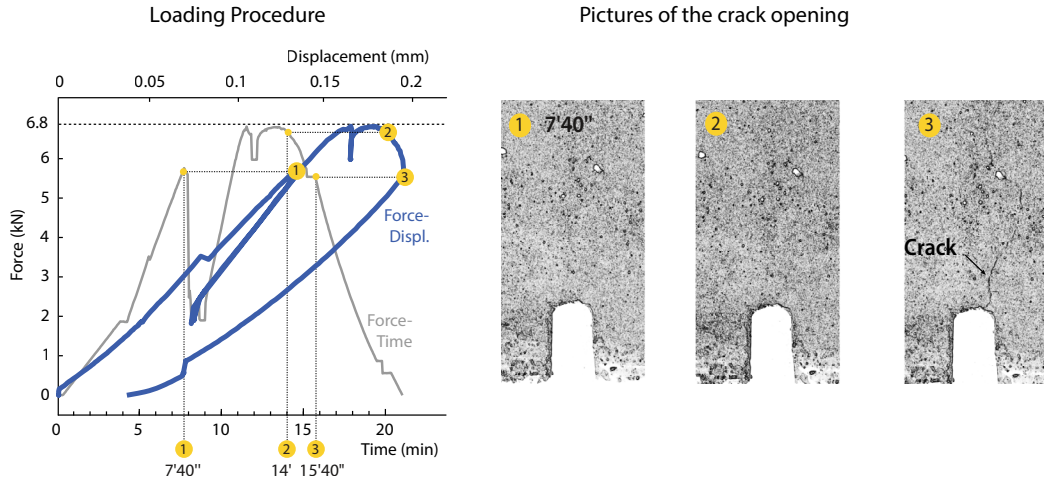

Fig. 4: Loading procedure and force-displacement curve related to the visual appearance of the crack. The three-point bending test is controlled in displacement using a LVDT.

the damage index.

The damage index DI is expressed as

$$DI_j = \sqrt{\frac{\int_{t_1}^{t_2} \left(S_j(t(1 - \epsilon_{max})) - S_0(t) \right)^2 dt}{\int_{t_1}^{t_2} S_0^2(t) dt}} \quad (1)$$

where $S_j(t)$ corresponds to the amplitude of the damaged signal, $S_0(t)$ is the amplitude of the healthy signal, t_1 is the time of arrival of S_0 , and $t_2 - t_1$ corresponds to the duration of the first half-period. This is represented in Fig. 5, where an example of a healthy signal and one with cracking are presented. ϵ_{max} corresponds to the value of time stretching which maximizes the correlation coefficient CC defined by,

$$CC(\epsilon) = \frac{\int_{t_0}^{t_f} S(t) S_0(t(1 + \epsilon)) dt}{\sqrt{\int_{t_0}^{t_f} S^2(t) dt \int_{t_0}^{t_f} S_0^2(t(1 + \epsilon)) dt}} \quad (2)$$

Fig. 6 shows that if no time stretching is applied to the measured signals, the DI is affected by these small velocity changes (see the small increase of the DI around point 1 which can be attributed to the acoustoelastic effect as explained in [10]). Applying time stretching allows removal of the small velocity changes due to operational perturbations, at the cost of a slightly lower sensitivity to the damage. The damage indicators presented in Fig. 6 are obtained after averaging ten ultrasonic signals. This allows to reduce the noise and therefore potentially to increase the sensitivity to damage. In the next section, the methodology to set a robust threshold to distinguish between the healthy and damaged state in an unsupervised manner is discussed. The case where no average is performed on the signals before computing the damage index is also discussed. If no averages are performed, the threshold will most likely be higher and the sensitivity to damage should decrease, but more data is available for the statistical analysis.

Fig. 5: Example of a healthy and a damaged signal and definition of the quantities used for the computation of the damage index (with and without time stretching).

Fig. 6: Evolution of the damage indicator as a function of the time (DWD: direct wave decorrelation, CWD: coda wave decorrelation).

4 Extreme value threshold calculated with differential evolution

The first stage in the analysis is to define an alarm threshold regarding the damage index. Traditionally, the warning levels can be defined by $\bar{n} + a\sigma$, where \bar{n} and σ are respectively the mean and standard deviation of all the values of the novelty index (damage indicator as defined in equation (1)) over the training data. In statistical terms, the parameter a controls the percentage of false-positives. For example, if the distribution is purely Gaussian, then a value of 1.96 will give estimates within warning levels of 95% probability. In this paper, a is set equal to 2.58 giving a 99% confidence limit. In Figures 7, 8, 9 and 10 one can see if the normal/healthy condition of the data as defined before is following a normal distribution. For this reason plots in Figures 7, 8, 9 and 10 show a histogram of values of healthy data and fit a normal density function. Note that as expected, the standard deviation of the data with 10 av-

erages is lower than with no average. It can be seen that the distribution is close to normal but weakly right-skewed with a longer right tail (positive-skew distribution).

Fig. 7: Histogram with a normal distribution fit of the damage indicator without time stretching (no average).

Fig. 8: Histogram with a normal distribution fit of the damage indicator with time stretching (no average).

Fig. 9: Histogram with a normal distribution fit of the damage indicator without time stretching (10 averages).

Fig. 10: Histogram with a normal distribution fit of the damage indicator with time stretching (10 averages).

For this reason, extreme value statistics (EVS)[14] was used in order to establish more robust thresholds. The assumption of a Gaussian distribution (chi-square regarding the distances), although very common and very attractive, may not be very appropriate in cases where the problem is concerned with tails of a distribution. In those cases extreme value statistics may be more suitable [15, 16]. In order to study the tails of an arbitrary parent distribution, the maximum of the samples should be used for the right tail and the minimum for the left. According to Fisher and Tippet extreme value theorem (EVT) [17], the induced distribution on the maxima of the samples can only take one of three forms: Gumbel, Weibull, or Frechet [15, 16].

The EVT in statistics is a good analog of the well known central limit theorem (CLT). The core idea of the CLT is that the average of many independently and identically distributed (iid) random variables converges at the end to a normal distribution provided that each random variable has a finite mean and variance. In the exact same sense the EVT is dealing with the central tendency that the maximum of a sample of iid random variables can only converge in distribution to one of three possible distributions as mentioned before. The distribution used here is the Gumbel and it can be seen in equation (3) for the maxima, and (4) for the minima,

$$H(x) = e^{-e^{-\frac{x-\lambda}{\delta}}} \quad (3)$$

$$L(x) = 1 - e^{-e^{-\frac{x-\lambda}{\delta}}} \quad (4)$$

where λ and δ are model parameters to be estimated from the data. It has to be noted that the central point in this study is that in such situations one would fit models to parts of the parent distribution's tails, as they should follow one of the three possible distributions, and identify thus a parametric model. Once the parametric model is obtained, a threshold can be calculated based on the fitted distribution. The chosen approach for the modelling here was differential evolution (DE) [18].

DE belongs to the family of evolution-based algorithms where an initial random population of solutions is propagated through a repeated cycle of mutation and crossover operations until an optimal (or near optimal, according to desired criteria) solution is obtained. The process is explained in more details in [19] and [20]. Naturally, an evolution process needs the calculation of a cost function, which in the particular problem here is to fit a parametric model to a given cumulative distribution function (CDF). A

well known normalised mean squared error, was applied here.

Here, all three distributions were tried, with the Gumbel providing the best results. The parameters of the DE were crossover ratio 0.5, scaling factor in the mutation vectors 0.9 and a population size of 30. A fixed number of maximum generations was set at 100, as it has been noted that the rate of change of MSE was stabilising before actually reaching this number [15, 16]. Figure 11 shows an example of a Gumbel distribution curve-fit after the DE was left to run and fit to the healthy condition data set from the parent distribution.

Figures 12, and 13 show the alarm thresholds when the EVS was used. The level of confidence used was 99 % meaning that 1 % of outliers was expected to be indicated. Results are shown when the evolution of the damage indicator includes two variants, with and without time stretching, in order to compensate for the acoustoelastic effect. The size of the portion of the data from the training test (assumed healthy state) which was used for fitting a Gumbel distribution was set at 10%. Readers should be aware [15, 16] that there can be a difference in the curve-fits with the size of the portion of the data which is used for fitting (something that is expected). In addition in [15, 16] was observed that variability on the curve-fit and the NMSE values can occur when the process is repeated with different random samples. This can be dealt by using a validation set in order to increase the consistency of the selection of the EV parameters. Here the first 60% of the baseline data was used to do the curve-fit.

Fig. 11: An example of a Gumbel distribution curve-fit after the Differential Evolution algorithm was left to run, fitting on 10% of data.

It is clear from the figures that time stretching is successful in removing the acoustoelastic effect from the features which is responsible for a high number of false alarms around sample 1000 (10000 without average). When 10 averages are used, this effect can however not be fully removed resulting in a few false alarms before the actual damage occurs. The use of no average results in a higher variance in the data, and therefore this effect is masked and there is no false alarm before the actual damage, but the damage is detected slightly later (around sample 1600 compared to 1500 when averaging is used). This shows that there is a compromise between the noise reduction and the sensitivity to operational condition, as well as to damage.

The approach for the calculation of robust thresholds in the damage index made use of EVS and showed a significant similarity with the assumption of a normal condition threshold. This was expected as the damage index is weakly skewed. However, the approach that was followed here using EVS is

more accurate as there are some heavy tails.

The results shown in this section were presented for thresholds under an assumption of Gaussian statistics and using EVS distributions. It is shown that the EVSs provide the appropriate thresholds for a given confidence level as it nicely fits a Gumbel distribution (see Figure 11).

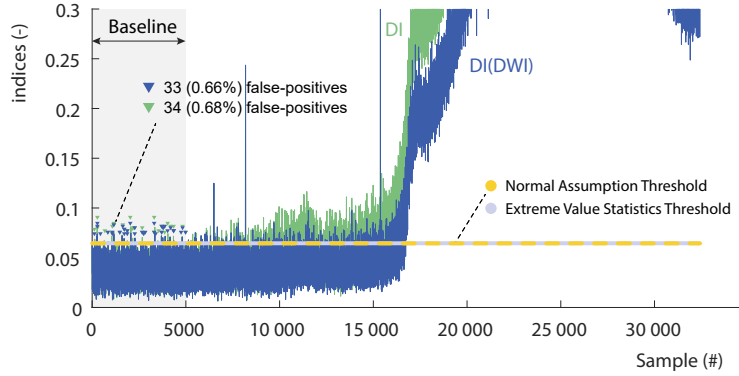

Fig. 12: Alarm threshold of the damage indicator with and without time stretching (no average).

Fig. 13: Alarm threshold of the damage indicator without time stretching (no average).

5 Conclusion

Based on previously obtained results of a crack monitoring system with ultrasonic sensors embedded in a small concrete beam, we have presented a methodology to set a threshold for automated damage detection. The monitoring systems consists in an a pair of transducers embedded in the beam. One of the transducers is used as emitter and the other as receiver. The measured signals are used to build a univariate damage indicator. Due to the very high interrogation rate of the system, the data obtained contains a large number of samples both in the healthy state and during the cracking of the specimen. This allows to perform a sound statistical analysis of the indicator in order to set a meaningful threshold for early damage detection.

Two approaches have been used to determine the value of the threshold: (i) simple threshold based

on the normality assumption and (ii) threshold based on extreme value statistics. The data consists in raw data which is sensitive to the acoustoelastic effect, and data compensated using time stretching in order to remove as much as possible this effect. Due to the fact that the baseline data is shown to follow a distribution very close to normal, extreme value statistics gives very similar results than the ones based on the variance of the baseline data.

Two sets of data are also compared, the first one in which ten averages of the measured signals are used to compute the damage indicator, and the second one where no average is performed on the measured signals. The results show that when averaging is performed, the standard deviation on the baseline is lower, so that damage can be detected earlier, but at the same time, as the acoustoelastic effect is not removed completely, there are a few false positives associated to it. On the other hand, without averaging, the damage is detected slightly later, but the acoustoelastic effect does not cause false alarms as it is mainly covered by the higher noise on the data.

The interesting result of this study is that, at least for the present test, the statistical distribution of the univariate damage indicator is Gaussian, so that extreme value statistics is not essential to set a proper threshold. Further studies will focus on theoretical developments to investigate if this result can be generalized to any type of test using this specific damage indicator.

Abstract. The reliability requirements of wind turbines have increased significantly in recent years in the search for a lower impact on the cost of energy. In addition, the trend towards larger wind turbines installed in remote locations has significantly increased the cost of repair or replacement of the component. In the wind industry, therefore, condition monitoring is crucial for maximum availability [1]. This contribution makes a review of supervised machine learning classification techniques for wind turbine condition monitoring using only SCADA data already available. That is, without installing extra sensors or costly purpose-built data sensing equipment. Although there has been extensive research into the use of machine learning techniques for wind turbine monitoring, the more recent trend in this type of literature is to focus on a specific WT sub-assembly: the bearings and planetary gearbox [2], the generator and power converter [3], the blades [4], etc. Oil debris systems can detect pitting failures but cannot detect cracking faults. Vibration based systems can detect both pitting and cracking, but most cannot determine the health of components in the planetary section. This work approaches condition monitoring of various wind turbine components (torque actuator, pitch actuator, pitch sensor, and generator speed sensor) with a unique strategy. In particular, for this purpose, a review of supervised machine learning classification techniques is performed and analyzed.

SMART 2019 Conference.

1 INTRODUCTION

Wind energy is a renewable energy, this means that as long as the sun continues to shine we will have wind to generate electricity. Wind energy is also clean and green. At the moment developed countries generate most of their energy from fossil fuels like coal, natural gas and oil. However burning fossil fuels creates green house gases that are through to contribute to the global climate change. In order to make wind energy profitable, the global wind industry has been witnessing an increase in average turbine size over the years. In this regard, offshore wind farms can increase energy production, as bigger wind turbines (WT) can be installed and they take advantage of higher and more uniform wind speeds.

The operation and maintenance of wind turbines is difficult and costly, especially for offshore wind turbines. Thus, condition monitoring is essential to reduce the energy cost. The faults must be anticipated before the break down takes place, and it is crucial to know what type of fault is, and where is it taking place.

Reference [5] reports a wide variety of faults in wind turbines. However, the latest research trend is to target only one specific parts of the wind turbine. For example, reference [6] target condition monitoring approaches of WTs with focus on gearbox, generator, blade, braking system, and rotor. The latest tendency in this type of literature review is to focus on a specific WT sub-assembly: the bearings and planetary gearbox [7], [8]. Reference [9] focuses on the generator and power converter, reference [10] targets the blades, etc. These type of localized strategies require almost always to install extra (an costly) sensors. However, there is already a huge amount of data from the existing sensors in the wind turbine (SCADA-Supervisory Control and Data Acquisition) that could be used for condition monitoring. The reason it is not actually used is that SCADA data is typically recorded at 10-minute intervals to reduce transmitted data bandwidth and storage. This low-frequency resolution negatively affects the diagnosis capabilities, and may hide short-lived events. On the other hand, high-resolution (but feasible) SCADA data should allow the dynamic turbine behavior to be identified with higher fidelity and thus improve detection efficiency. Following what is stated in [1], in this work a research framework is proposed that takes SCADA data with an additional high but feasible (1 s) frequency from the sensors. That is, the only requirement is to increase the frequency rate in the SCADA data from the already available sensors. Thus, this work approaches condition monitoring of various wind turbine components (torque actuator, pitch actuator, pitch sensor, and generator speed sensor) with a unique strategy and using only SCADA data.

Machine learning has been essential in the condition monitoring research arena. For example, application of machine learning method in bridge health monitoring[11], health monitoring of aeroplane structural component based on K-means clustering [12], etc . However, machine learning for condition monitoring of WT is still an incipient research area. In this work different machine learning strategies are used to monitor the condition of a 5 MW wind turbine using only SCADA data and taking into account faults in various WT components (torque actuator, pitch actuator, pitch sensor, and generator speed sensor).

This work is organized as follows. In Section 2, we describe the fault detection and classification methodologies. We discussed and analyzed the results in Section 3. In Section 4, some conclusions about the current challenges and future work are given.

2 FAULT DETECTION AND CLASSIFICATION METHODOLOGIES

2.1 Model overview

The simulated model stated in [13] is utilized in this work. It integrates a 5 MW wind turbine modelled using the FAST software (National Renewable Energy Laboratory, Golden, Colorado, USA), see [14]. The model proposes to simulate the sensors in the block diagram environment Simulink by adding signals from band-limited white noise blocks that are parameterized by noise power to the actual variables provided by the FAST software, see Table 1.

The fault scenarios, that comprehend sensors and actuators, are displayed in Table 2. The interested reader can find a comprehensive description of these faults and their importance in [15].

2.2 Data collection

A total of 260 simulations were conducted in this work: 100 with a healthy WT, and 20 simulations for each studied fault. The simulations have a duration of 400 seconds. Observe that the wind sequence is not used as a known measurement. It is also noteworthy that the data used by the fault detection strategy has a sampling period of 1 second. As noted in the introduction, following what is stated in [1], in this work a research framework is proposed that takes SCADA data with an additional high but feasible (1

Table 1: Available sensors (measured data).

Number	Sensor Type	Symbol	Unit	Noise Power
S1	Generated electrical power	$P_{e,m}$	W	10
S2	Rotor speed	$\omega_{r,m}$	rad/s	104
S3	Generator speed	$\omega_{g,m}$	rad/s	$2 \cdot 10^4$
S4	Generator torque	$\tau_{c,m}$	Nm	0.9
S5	Pitch angle of first blade	$\beta_{1,m}$	deg	$1.5 \cdot 10^3$
S6	Pitch angle of second blade	$\beta_{2,m}$	deg	$1.5 \cdot 10^3$
S7	Pitch angle of third blade	$\beta_{3,m}$	deg	$1 \cdot 10^3$
S8	Tower top fore-aft acceleration	$a_{fa,m}$	m/s^2	$5 \cdot 10^4$
S9	ower top side-to-side acceleration	$a_{ss,m}$	m/s^2	$5 \cdot 10^4$

Table 2: Fault scenarios.

Number	Fault	Type
F1	Pitch actuator (High air content in oil)	Change in system dynamics
F2	Pitch actuator (Pump wear)	Change in system dynamics
F3	Pitch actuator (Hydraulic leakage)	Change in system dynamics
F4	Generator speed sensor	Gain factor (1.2)
F5	Pitch sensor	Stuck value ($\beta_{3,m} = 5$ deg)
F6	Pitch sensor	Stuck value ($\beta_{3,m} = 10$ deg)
F7	Pitch sensor	Gain factor (1.2)
F8	Torque actuator	Offset value (2000 Nm)

second) frequency from the sensors.

2.3 Data reshape

Our goal is to minimize the detection time (T_d) and at the same time to obtain a high accuracy. T_d specifically means the time from when the fault occurs till it is detected. It is proposed to organize the available data from the simulations in samples of only three time steps (this will lead to a detection time of approximately three seconds). In reference [13] the faults detection requirements are given in terms of the sampling time. Fault 8, related to the torque actuator, requires to achieve $T_d < 3s$. This is the fault that requires the fastest detection time. The other faults have a slower dynamic. Fault 1 requires to be diagnosed in less than $8s$ and Faults 4 to 7 require a T_d less than 10 seconds. We will organize our data in 3 time steps. As mentioned before, we used only 400 seconds duration of 260 simulations, from 9 available sensors. Since we will organize the data in 3 time steps, and 400 is not divisible by 3, we will use only 399 seconds. Recall that initially the data was stored as below:

$$\begin{pmatrix} x_{1,1}^{(k)} & x_{1,2}^{(k)} & \dots & x_{1,399}^{(k)} \\ x_{2,1}^{(k)} & x_{2,2}^{(k)} & \dots & x_{2,399}^{(k)} \\ \dots & \dots & \dots & \dots \\ x_{260,1}^{(k)} & x_{260,2}^{(k)} & \dots & x_{260,399}^{(k)} \end{pmatrix} \in M_{260 \times 399}^{(k)}(\mathbb{R}) \quad (1)$$

where k is linked to different sensors $k = 1, 2, 3 \dots 9$, so there is one matrix associated to each sensor. There are 260 simulations, therefore the matrix has 260 rows. In order to minimize the detection time, instead of using this matrix, we reshape the data in a matrix with only 3 columns ($J = 3$):

$$\begin{pmatrix} x_{1,1}^{(k)} & x_{1,2}^{(k)} & x_{1,J}^{(k)} \\ x_{1,J+1}^{(k)} & x_{1,J+2}^{(k)} & x_{1,2J}^{(k)} \\ \vdots & \vdots & \vdots \\ x_{1,400-J+1}^{(k)} & x_{1,400-J+2}^{(k)} & x_{1,399}^{(k)} \\ x_{2,1}^{(k)} & x_{2,2}^{(k)} & x_{2,J}^{(k)} \\ x_{2,J+1}^{(k)} & x_{2,J+2}^{(k)} & x_{2,2J}^{(k)} \\ \vdots & \vdots & \vdots \\ x_{2,400-J+1}^{(k)} & x_{2,400-J+2}^{(k)} & x_{2,399}^{(k)} \\ \vdots & \vdots & \vdots \\ x_{260,1}^{(k)} & x_{260,2}^{(k)} & x_{260,J}^{(k)} \\ x_{260,J+1}^{(k)} & x_{260,J+2}^{(k)} & x_{260,2J}^{(k)} \\ \vdots & \vdots & \vdots \\ x_{260,400-J+1}^{(k)} & x_{260,400-J+2}^{(k)} & x_{260,399}^{(k)} \end{pmatrix} \in \mathcal{M}_{260 \cdot \frac{399}{3} \times 3}^{(k)}(\mathbb{R}), \quad (2)$$

As each sample has 3 seconds, the number of total samples is $I = 260 \cdot \frac{399}{3} = 34580$. Finally, the

matrices coming from all sensors ($k = 1, 2, \dots, 9$) are concatenated to obtain the data matrix X as follows:

$$X = \left(\mathcal{M}^{(1)} | \mathcal{M}^{(2)} | \dots | \mathcal{M}^{(9)} \right)$$

2.4 Preprocess

As the data comes from different sensors and has different magnitudes, it is columnwise normalized. Then, principal component analysis is used to reduce the dimensionality of the data. In this work, the number of principal components is selected based on keeping 99.98% of the variance. In particular, from a total of 27 components, 99.98% of the variance is accomplished by the first 16 components.

2.5 Supervised classifiers

In this work, two well known classifiers have been studied: k -nearest neighbour and support vector machines. It is not the purpose of this work to review these techniques, however the interested reader can find a comprehensive description of these methods in [17] and [18]. In this work, the parameters of both classifiers have been optimized using the 5-fold cross-validation technique. Cross-validation is a resampling procedure used to evaluate machine learning models on a limited data sample. The procedure has a single parameter called k that refers to the number of groups that a given data is to be split into. The choice of k is usually 5 or 10, but there is no formal rule. As k gets larger, the difference in size between the training set and the resampling subsets gets smaller. As this difference decreases, the bias of the technique becomes smaller [19]. In this paper we used 5-fold cross-validation.

3 RESULTS, ANALYSIS, AND DISCUSSION

3.1 k -NN

In order to choose the number of neighbours in k -NN, we test the overall accuracy for different numbers of neighbours. As shown in the Fig. 1, we get the highest accuracy when the number of neighbours is 1. Finally, the results for $k = 1$ and $k = 5$ are shown. Confusion matrices show us a comprehensive decomposition of the error between the true classes and predicted classes, see Figures 2 and 3 (an empty blank square means 0 %). In these matrices, each row represents the instances in a true class while each column represents the instances in a predicted class (by the classifier). In particular, the first row (and first column) is labeled as 0 and corresponds to the healthy case. The next labels (for rows and columns) correspond to each fault (from Fault 1 to Fault 8). From the confusion matrices, the following issues can be highlighted.

When the number of neighbours is $k = 1$ (Fig. 2), the overall accuracy is 95.7 %. In this case, the healthy class has a true positive rate (TPR, the percentage of correctly classified instances) higher than 99% and a false negative rate (FNR, the percentage of incorrectly classified instances) smaller than 1%. Fault 1 (related to the pitch actuator fault with high dynamics) has a TPR of 91% and an FNR of 9%. This FNR percentage was mainly obtained from 2% missing faults, 1% misclassified as Fault 3, 5, 6, 7 or 8, and 6% confusion with Fault 2, which is also a fault located in the pitch actuator. Fault 2, related to pitch actuator (pump wear), has a TPR of 89% and an FNR of 11% . It was misclassified as healthy 4% of the time, 2% of the time it was confused with Fault 1, and 5% of the time it was confused as Fault 3, 5, 6, 7 or 8. Fault 6 (related to the pitch sensor) was the most difficult to be classified, it had a TPR of 88%, 4% was misclassified as Fault 5 (related also to pitch sensor), 3% missing fault, and 5% misclassified as Fault 1,2,3,4,7 or 8. We can see from the confusion matrix that all the Faults, except Fault 2 and Fault 6, have a TPR higher than 91%.

Figure 1: Number of neighbours with respect to overall accuracy.

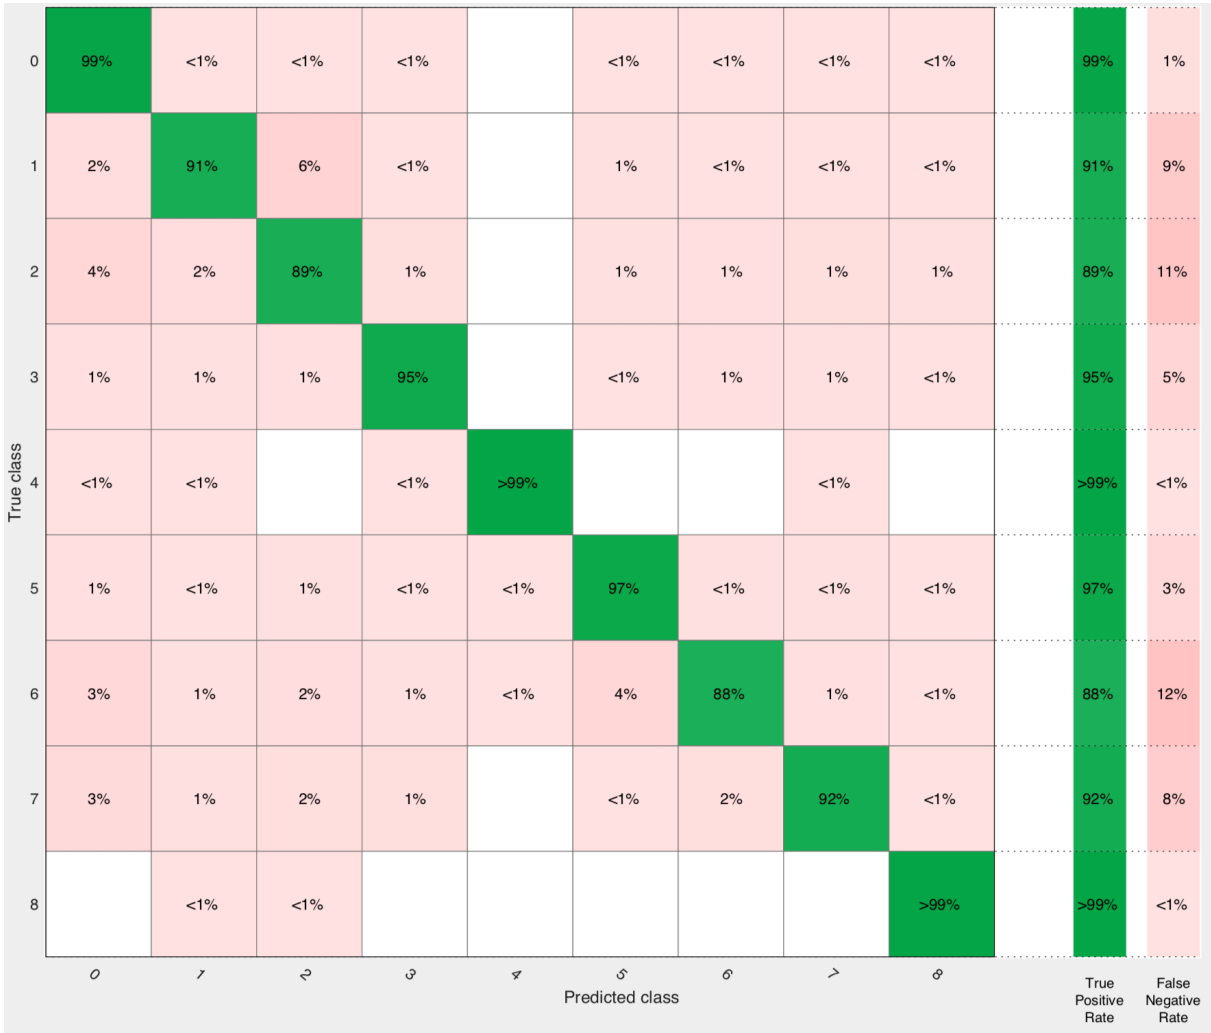

Figure 2: Confusion matrix when the number of neighbours is selected 1

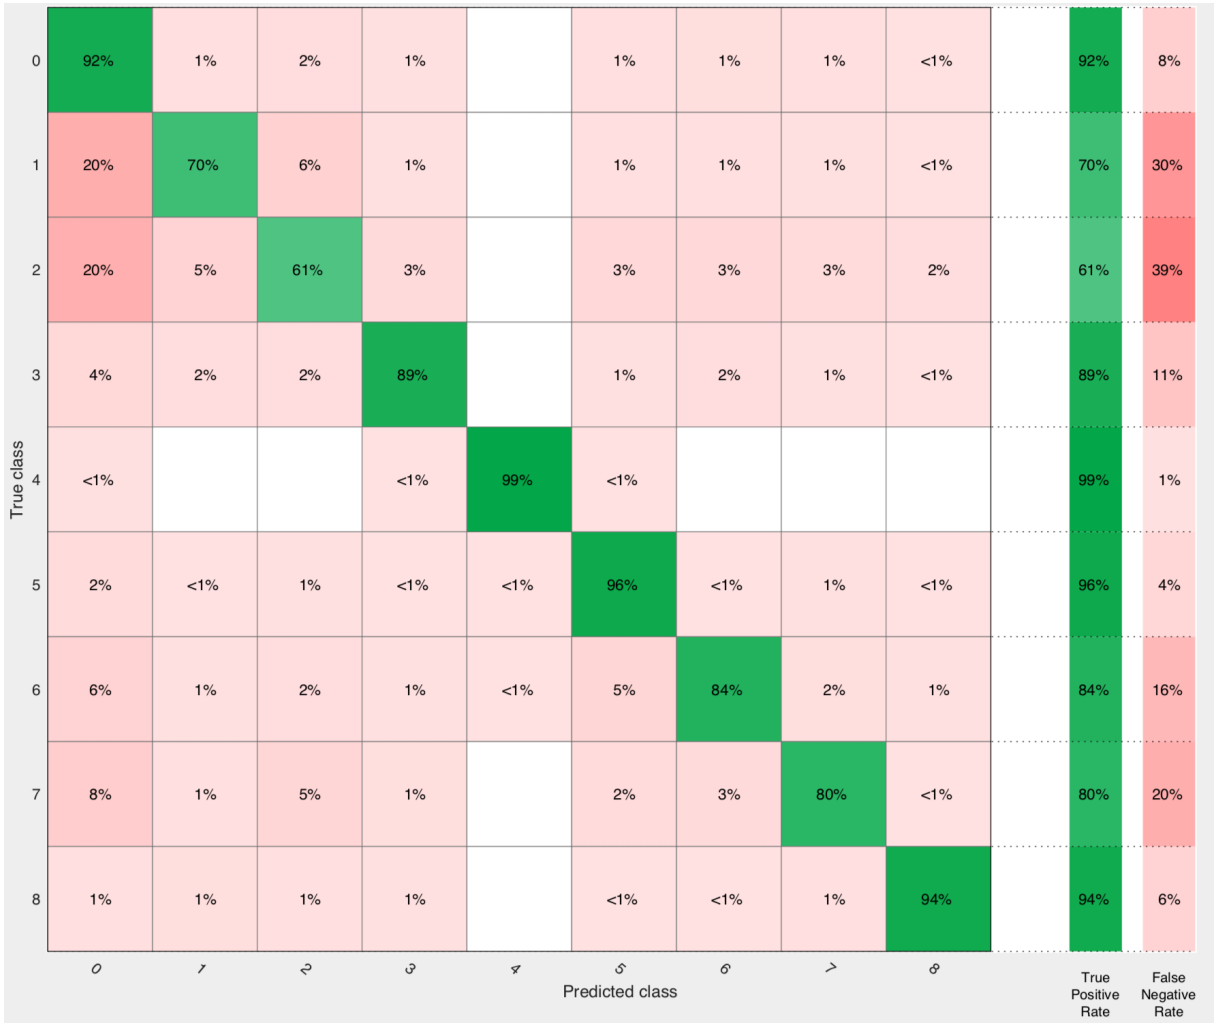

Figure 3: Confusion matrix when the number of neighbours is selected 5

When the number of neighbours is $k = 5$ (Fig. 3), the overall accuracy is 87.2 %. Fault 4 (related to the generator speed sensor) as in the previous case has a TPR of 99%. All the other classes decrease their TPR. The most affected classes are Fault 1 and Fault 2, in particular, Fault 1 decreases its TPR to 70% and Fault 2 to 61%.

3.2 SVM

The 5-fold cross-validation technique is used to select the following parameters: box constraint and kernel scale of the Gaussian kernel, see [20]. The results are presented in Fig. . The highest accuracy is 95% and it is achieved when the kernel scale is equal to 1/4 and the box constraint is 75 or 100.

Figure 4: Box constraint value and kernel scale with respect to overall accuracy

Fig. 5 shows the confusion matrix when the box constraint is equal to 75 and the kernels scale is 1/4. In this case Fault 1 (the most difficult to classify) has a TPR of 77%, 17% of the times is misclassified as no fault and 6% is misclassified as Fault 2. Fault 6 has a TPR of 89% and an FNR of 11%. The FNR is mainly obtained from 4% missing fault, 2% misclassified as Fault 2, 3% as Fault 5 and remaining percentage 2% is a misclassification to Fault 1,3,4 or 7. The rest of the faults has a TPR above 90%. Note that Fault 8 has a TPR of 100%.

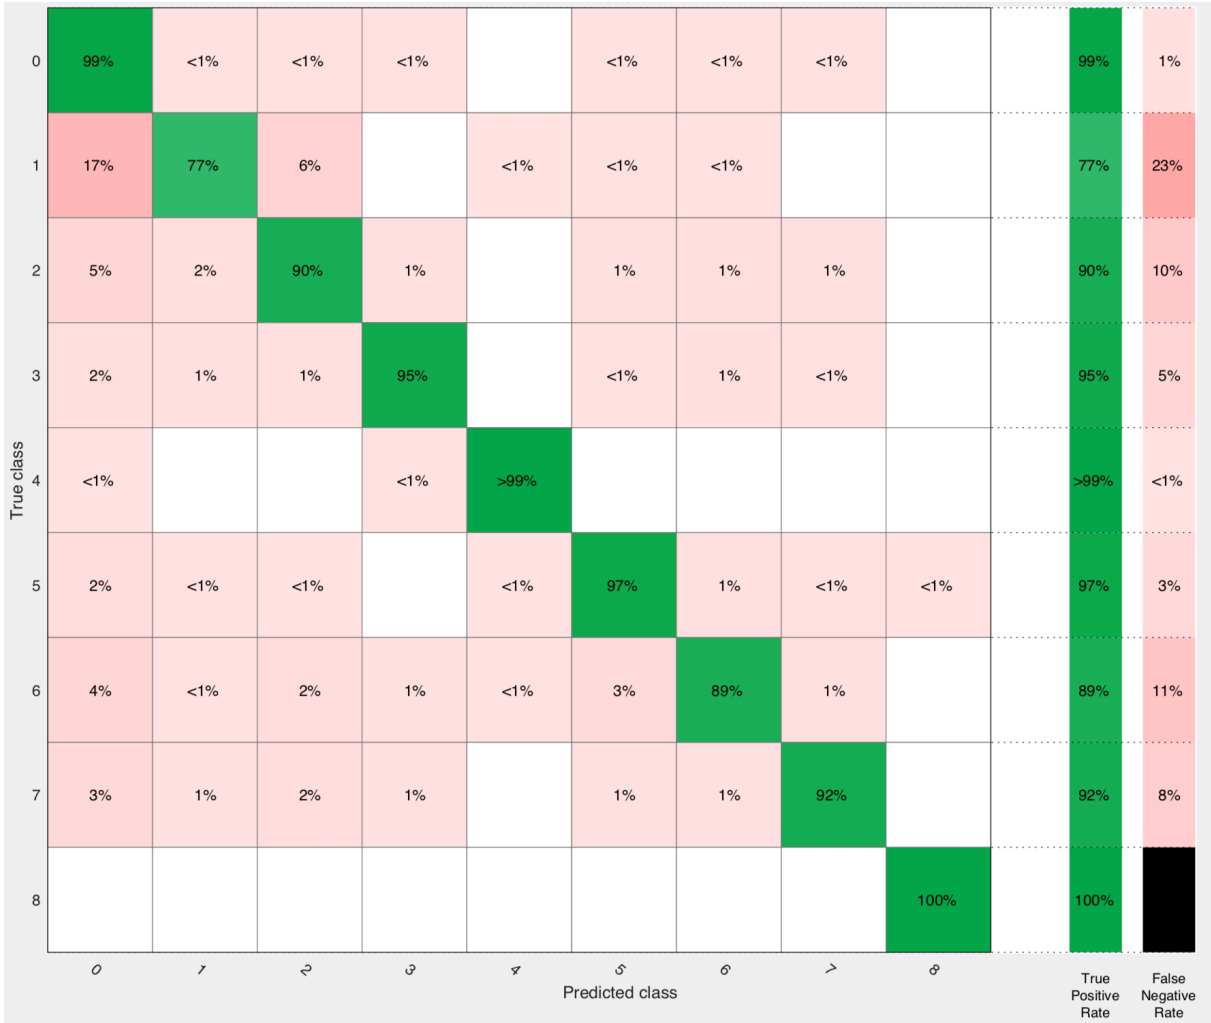

Figure 5: Confusion matrix, SVM with box constraint value 75 and kernel scale 1/4.

4 CONCLUSIONS

In this paper, it was presented a strategy to monitor the condition of a wind turbine. Eight different faults were studied and the model was able to detect and classify the type of the fault. That is, without installing extra sensors or costly purpose-built data sensing equipment. Supervised machine learning classification techniques were essential for wind turbine condition monitoring using only SCADA data already available. Two different classifiers were used, KNN and SVM. It was achieved an overall accuracy of 95.7% when KNN was used and 95% with SVM.

As a future work, we will try to optimise the model, and also include other faults.

Key words: Damage Detection, Inverse Problem, Modal Curvatures, Modal Frequencies

Abstract. The problem of identifying small damages in beam-like structures is studied by defining a suitable inverse problem with different modal quantities including frequencies, mode shapes and modal curvatures. With the aim of making a critical analysis of the different approach followed in the literature, we study a prototype problem of a free-free beam with single and multiple damages. The attention is mainly devoted to modal curvatures. It is shown that by making use of a perturbative solution of the equation of motion of a damaged beam, it is possible to obtain a closed form relationship between the modal curvature differences due to damage and the damage distribution itself. This information is added to the contributions of other modal quantities, frequencies and mode shapes, to improve the inverse problem of damage identification and to eliminate possible redundant solutions. On the other side, the variations of the curvature due to damage is concentrated at damage location and this circumstance can lead to difficulties in its detection. The results of the proposed approach are validated by using the results of an experimental campaign carried out by the authors.

1 INTRODUCTION

Vibration-based damage identification techniques have recently been the subject of much research, with particular emphasis on natural frequencies [1, 2]. As a global structural property, they are easily and reliably measured and their variation with damage is clearly monotonic. Unfortunately, due to them being a global characteristic, frequencies offer a modest sensitivity to local damage, mainly when the damage intensity is limited [3]. As such, variations of temperature or humidity could cause changes in frequencies sometimes as large as those induced by damage.

With the increasing availability of more affordable experimental techniques, other modal quantities – modal shapes and modal curvatures – have been the focus of an increasing attention by researchers, with the aim of detecting low intensity damages [4, 5].

In particular, modal curvatures are known to considerably change in the neighbourhood of the damage [6, 7]. However, their evaluation is not simple mainly for two reasons: (i) their variations due to distributed damage could spread over the entire structure [8]; (ii) in the presence of sharp damages, the evaluation of the modal curvature requires sensors placed in close proximity of the damage. For this

reason, this work starts with a critical review of the different approaches for damage identification, with a special focus on those using modal curvatures.

Making use of a perturbative solution of the equation of motion of a damaged beam, it is possible to obtain a closed form relationship between the modal curvature differences due to damage and the damage distribution itself [9]. Such a result suggests that a proper filtering of the modal curvature variations must be carried out for using them in damage localization or in damage assessment techniques when used with other modal quantities, such as frequencies and mode shapes as shown in [10].

The validation of the procedure that makes use of the modal quantities measured by an experimental setup, able to record frequencies, modal shapes and modal curvatures, is performed by means of numerical investigation with pseudo-experimental data and of an experimental laboratory campaign. The experiments deal with a free-free beam. Several damage cases are considered with different intensities. The contribution of using the modal curvature differences in the identification of damage position and intensity is evidenced.

2 MODAL CURVATURES

2.1 Filtering technique

In this section, we briefly review the main results in [8, 9] which concern the localization of damage through modal curvature. The transverse motion of a cracked beam is studied by exploiting the perturbative solution of the dynamic Euler-Bernoulli equation. The procedure is fully described in [8] and very shortly recalled here.

The dimensionless equation governing the i -th transverse mode of a damaged beam is:

$$\frac{d^4\phi_i(x)}{dx^4} - \varepsilon \frac{d^2}{dx^2} \left[\eta(x) \frac{d^2\phi_i(x)}{dx^2} \right] - \omega_i^2 \phi_i^*(x) = 0 \quad (1)$$

where $x = s/L \in [0, 1]$ is the dimensionless abscissa, ε is damage intensity, $\phi(x)$ is the transverse displacement and $\eta(x)$ is a smooth function representing the damage shape, such that $\|\eta(x)\| = 1$. The eigenfunctions ϕ_i and eigenvalues ω_i^2 can be expanded as a power series in terms of ε , i.e.,

$$\phi_i(x) = \tilde{\phi}_i(x) - \varepsilon \bar{\phi}_i(x) + O(\varepsilon^2), \quad \omega_i^2 = \tilde{\omega}_i^2 - \varepsilon \bar{\omega}_i^2 + O(\varepsilon^2) \quad (2)$$

where $\tilde{\phi}_i$ and $\tilde{\omega}_i^2$ are respectively the i th eigenfunction and eigenvalue of the undamaged beam, and $\bar{\phi}_i$ and $\bar{\omega}_i^2$ are their first order variations. By taking into account only the contributions up to the first order in ε , the following system of ordinary differential equations is obtained

$$\text{0-th order:} \quad \frac{d^4\tilde{\phi}_i(x)}{dx^4} - \tilde{\omega}_i^2 \tilde{\phi}_i(x) = 0 \quad (3)$$

$$\text{1-st order:} \quad \frac{d^4\bar{\phi}_i(x)}{dx^4} - \tilde{\omega}_i^2 \bar{\phi}_i(x) = \bar{\omega}_i^2 \tilde{\phi}_i(x) - \frac{d^2\eta_i(x)}{dx^2} \quad (4)$$

where the function $\eta_i(x)$ is the *modal damage shape* weighted through the i th modal curvature, i.e. $\eta_i(x) := \eta(x) d^2\tilde{\phi}_i/dx^2$. Eq.(3) is simply the governing equation of the undamaged system.

The damage shape function $\eta(x)$ can be expressed in terms of the modal quantities of the undamaged system and of the difference between the modal curvature of the damaged and undamaged beams, $\Delta\psi_k$, as in [8], i.e.,

$$\eta_k = -\Delta\psi_k + \frac{\Delta\omega_k^2}{\tilde{\omega}_k^2} \frac{\tilde{\psi}_k}{\|\tilde{\psi}_k\|} + \sum_{l \neq k} \frac{\tilde{\omega}_k^2}{\tilde{\omega}_l^2} \int_0^1 \tilde{\psi}_l^T(x) \Delta\psi_k(x) dx \frac{\tilde{\psi}_l}{\|\tilde{\psi}_l\|^2}, \quad (5)$$

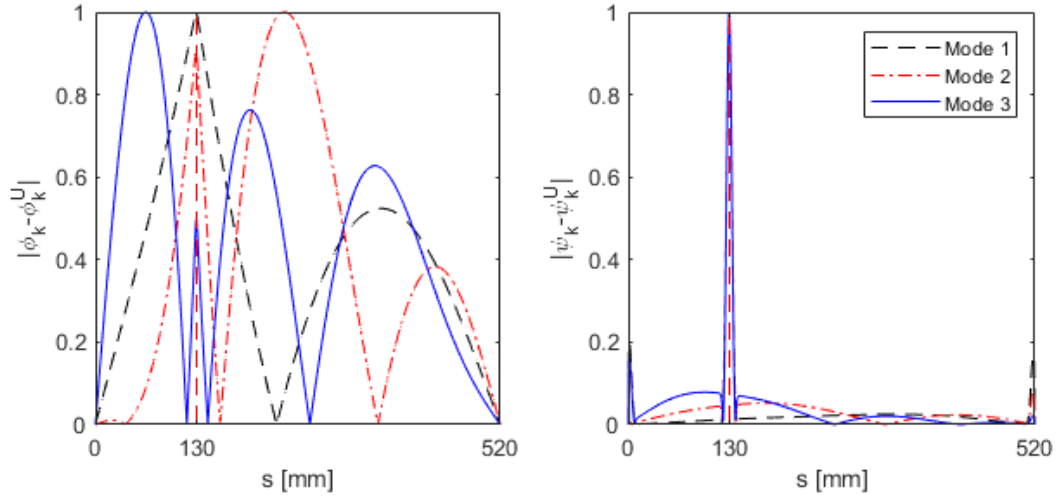

Figure 1: Modal displacement difference (left) between the damaged and undamaged system for the damage case D1 for the first three modes (right). Corresponding modal curvature differences. The dashed red line shows the actual position of the damage.

where $\Delta\omega_k^2 = \tilde{\omega}_k^2 - \omega_k^2$ is the modal frequency variation, between the k -th modal frequency of the undamaged and damaged systems. For the sake of brevity, we have indicated the k -th modal curvature, i.e., the second derivative of the k -th mode shape, as $\psi_k(x) := \phi_k''(x)$.

Equation (5) highlights that the function η_k , i.e., the product of the damage shape with the k -th modal curvature, is, as a matter of fact, the *observable quantity* of the inverse problem based on modal curvatures rather than the modal curvatures themselves. As such, if the damage occurs in a region where the k -th modal curvature vanishes, the damage shape can not be reconstructed from the k -th modal curvature. In addition, Eq. (5) shows that the damage shape can be evaluated only after the k -th modal curvature difference is filtered as that equation suggests; interestingly, all quantities that appear on the right hand side of the equation are indeed easy to measure: $\Delta\psi_k$ is the difference between the k -th modal curvatures of the damaged and undamaged beam, $\Delta\omega_k^2$ is the difference of the corresponding modal frequencies, $\tilde{\psi}_l$ is the l -th undamaged modal curvature divided by its norm $\|\tilde{\psi}_l\|$.

2.2 Numerical evaluation of modal shapes and modal curvatures

In the case of sharp damages, modal curvatures are known to be localized quantities even if not properly filtered. In this respect Fig. 1a shows the first four mode displacement differences obtained by a numerical model of the free-free beam experimentally tested by the authors, whose mechanical and geometric characteristics are shown in Fig. 2 for damage cases D1 (Fig. 3). For the sake of comparison, Fig. 1b shows the corresponding modal curvature differences. It is seen from the figure that multiple peaks appear in the difference when considering modal displacements whereas a more localised information can be extracted from the modal curvature difference. In the case of mode shapes, these peaks are located in a region close to but not correspondent with the actual damage position (represented by a dashed red line). As already pointed out, such a circumstance makes the solely use of eigenmode difference in the damage localization problematic and potentially leading to false indications. However, their use in the objective function together with the eigenfrequencies variation can lead to a more accurate evaluation of the damage parameters with respect to the use of frequencies only.

Figure 2: Geometry of the undamaged free-free (FF) beam and steel material properties.

2.3 Experimental evaluation of modal curvatures

Much care must be devoted when extracting modal curvatures from experimental data. When strain gauges are used to measure the structural response, the frequency response function measured at the abscissa s_i for a point force applied at the abscissa s_j is

$$H_{ij}(\omega) = \frac{G_{ij}(\omega)}{G_{jj}(\omega)} \quad (6)$$

where $G_{ij}(\omega)$ is the cross-power spectral density between input and output, and $G_{jj}(\omega)$ is the auto-power spectral density of the input. In particular, when strains are measured, Eq. (6) can be written as:

$$H_{ij}(\omega) = \sum_{k=1}^{\infty} \frac{\psi_k(x_i)\phi_k(x_j)/\rho L \omega^2 \|\phi_k\|^2}{1 - (\omega_k^2 + i\eta_r \omega_k^2)/\omega^2}. \quad (7)$$

The experiments were carried out at the laboratory of the Department of Structural and Geotechnical Engineering, Sapienza University of Rome, on a steel beam whose geometric and mechanical characteristics are reported in Fig. 2. The beam was dynamically excited by a point force generated by an electrodynamic shaker, that was driven by a white noise input signal up to a frequency of 2500/3000 Hz. To measure the proper frequency response function, the input force was recorded with a load cell installed at the base of the shaker stinger, which was realized with a thin steel bar with circular cross section. The response was measured using seven strain gauges equally spaced along the beam axis, in the damaged and undamaged cases.

The investigated damage cases are reported in Figure 3. Case D1 includes a notch localized below the strain gauge #1 with a residual height of the damaged cross-section equal to $h^D = 3h/4$, case D2 has the same localization, but a residual height equal to $h^D = h/2$, case D3 the same damage as D2, plus a second notch of residual height $h^D = 3h/4$ located between strain gauges #5 and #6.

A reduction of natural frequencies with increasing damage is observed. This is shown by the shift of the peaks in Figure 4, which compares the modulus of the frequency response function in terms of strains in the undamaged and damaged (D2) cases. The frequency response function $H_{1P}(f)$ is measured in channel #1 for the forcing function applied at point P. The values of the first four natural frequencies are reported in Table 1 for the undamaged (U), and the three cases of damage under investigation (D1, D2, D3, Figure 3).

Figure 5 shows the modal curvatures for the first four identified modes, in the undamaged and damaged states. Figure 6, which reports the variation of modal curvatures between the undamaged and damaged states, normalized so that the maximum equals one, shows that the local increase in curvature

where damage is located is very clear when damage is placed just below strain gauge #2 (all cases). On the contrary, when damage is located between strain gauges #5 and #6 (D3), the presence of damage is less evident from the increase in curvature.

3 DAMAGE IDENTIFICATION

The analysis in previous paragraphs has shown that, in case of sharp damages, modal curvature can directly give information on the location of damage. However, the assessment of the damage intensity requires the definition of an inverse problem based on the comparison between the undamaged and damaged state responses. To do that, a finite element model of the beam in Fig. 2 is implemented in Ansys with $n=520$ elements (BEAM 189). The damage is schematically represented as a concentrated

Figure 6: Curvature differences for the three damage states of the FF beam. Mode 1 - dashed grey line; Mode 2 - dashed black line; Mode 3 - grey thick line; Mode 4 - thin grey line.

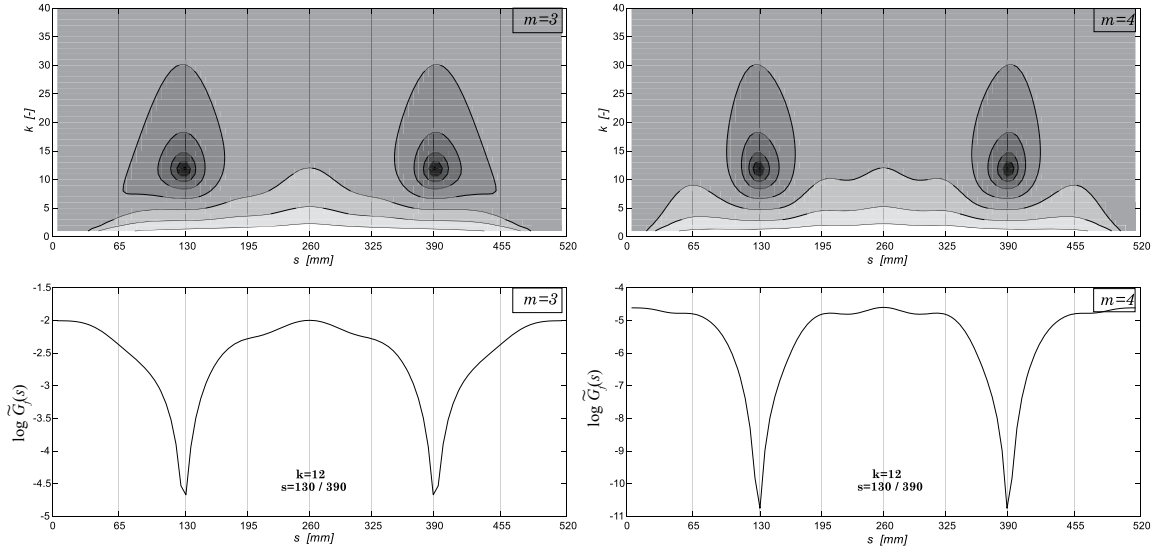

Figure 7: Top line: contour plot of the objective function $G_f(k, s)$ calculated with three (left) and four (right) frequencies in the case of damage D2. Bottom line: function $\tilde{G}_f(k, s)$

spring at position s with dimensionless stiffness $k = \frac{2L}{h^U} \frac{1-\beta}{\beta}$ with $\beta = (EI^U - EI^D)/EI^U$, and EI^U and EI^D respectively the flexural rigidities of the undamaged and damaged cross sections [11]. An optimal estimate of the parameters k and s is obtained by minimizing an objective function which is built as the sum of differences between selected response quantities. As a first step, we consider an objective function which depends only on the first m frequency differences, i.e.,

$$G_f(k, s) = \sum_{i=1}^m \left(\frac{\Delta\omega_i(k, s)}{\omega_i^U} - \frac{\Delta\omega_{ei}}{\omega_{ei}^U} \right)^2 \quad (8)$$

which is the sum of the squares of the differences between the numerical $\Delta\omega_i(k, s)$ and experimental $\Delta\omega_{ei}$ frequency variations between the undamaged and the damaged states, normalized with respect to the frequencies of the undamaged beam, ω_i^U and ω_{ei}^U . Since the $\Delta\omega_i(k, s)$ are not observable in closed-form, they are evaluated at discrete values of k and s , which enables to calculate the function (8) on a grid.

The $G_f(k, s)$ is shown in Fig. 7 (top) by using three ($m=3$) and four ($m=4$) frequencies for the damage case D2; as expected, the function is symmetric with respect to the mid span, since the use of frequencies only cannot distinguish between symmetric locations of damage. The curves on the bottom line are the function $\tilde{G}_f(s)$, which, for each possible damage position, is the minimum of $G_f(k, s)$ with respect to k . The insets in the figure report the values of the parameters s and k at the position of the minimum, to be compared with the real position of the damage $s = 0.130$ and damage parameter $k = 10$. These results show that already with three frequencies a good estimate of the damage position can be achieved despite having a 20% error on the damage intensity.

In order to verify the possible improvement of the identification using modal curvature differences, the following enhanced objective function is considered

$$G_{fc}(k, s) = G_f(k, s) + \alpha G_c(k, s) \quad (9)$$

Figure 8: Top line: contour plot of the objective function $G_{fc}(k, s)$ calculated with four frequencies and the first mode curvature difference in the case of damage D2. Bottom line: plot of the function $\tilde{G}_{fc}(s)$.

where α is a positive scaling constant, assumed equal to 0.3 in the present case, and G_c is the function based on the modal curvature differences

$$G_c(k, s) = \sum_{i=1}^n \left(\frac{\Delta\psi_i(k, s)}{\|\psi_i^U\|} - \frac{\Delta\psi_{ei}}{\|\psi_{ei}^U\|} \right)^2 \quad (10)$$

with $\Delta\psi_{ei}$ the experimental modal curvatures and $\Delta\psi_i$ the corresponding numerical value, normalized with respect to the norm of the undamaged modal curvature. Since a robust localization of damage was already obtained with the first modal curvature difference (see Fig. 6), only the first modal curvature is included in the objective function ($n = 1$). The results in Fig. 8 show that the minimum of the enhanced G_{fc} is much sharper and the correct values of the parameter are obtained, confirming the important role played by modal curvatures.

4 CONCLUSIONS

The great part of damage identification techniques used in the literature are based on the differences of the modal frequencies of the damaged and undamaged system. In this work, to enhance the solution of the inverse problem and to have a better estimate of damage parameters, we have examined the use of both frequencies and modal curvatures. The latter have always been considered strictly related to the damage region but some drawbacks have been highlighted:

- modal curvature differences are influenced by the damage distribution in a more significant way than modal shape differences;
- if the damage is extended compared to the characteristic dimensions of the structure, the use of modal curvatures in a damage identification technique requires them to be properly filtered;
- for sharp damages, modal curvature differences are also very sharp and this could make their experimental evaluation difficult.

With reference to an experimental campaign carried out on a free-free beam, we have shown the feasibility of using modal curvature variations, experimentally measured through strain gauges, together with modal frequency variations. For a certain damage scenario, we have compared the results of the identification obtained with an objective function weighing only the modal frequency differences and an enhanced function with both frequency and curvature variations. In the latter case, a more accurate estimate of the damage parameter was achieved and, in addition, the symmetric solution, which can not be distinguished by using only the frequency difference, was eliminated.

Key words: Optimal sensor placement, Structural parameter identification, Topology optimization.

Abstract. Recent progress in sensing technology and measurement techniques allows a growing number of critical infrastructures to be equipped with Structural Health Monitoring (SHM) systems. Sensors in such SHM systems should be placed in a proper way to facilitate extracting valuable information from the structure under investigation. In the case of relatively simple spatial truss structures, sensors can be located with the aid of classical methods such as *Effective Independence (EI) method proposed by Kammer*. However, in the case of large structures, which are intended to be equipped with hundreds if not thousands of sensors, other sensor placement methods may be needed.

The goal of this study is to extend a topology optimization based approach for sensor placement (*proposed originally by Mariani and co-workers*) to the case of real bridge structures represented by finite element models with a few thousand degrees of freedom. Structural topology optimization aims to find the optimum material distribution in order to minimize the mass of the structure while maintaining mechanical properties (load capacity, displacements, etc.). A similar concept can be used to determine the optimal placement of sensors in a structure to identify its dynamic characteristics. The sensor positions are determined in such a way that estimation error of modal coordinates is minimized. The effectiveness of the proposed methodology is demonstrated on an *example of a detailed FE model of a tied-arch bridge*.

1 INTRODUCTION

One of the earliest works on optimal sensor placement (OSP) over a multi-degree of freedom (MDOF) flexible structure was presented by Shah and Udwadia [1]. They proposed time domain sensitivity analysis and its application to sensor placement intended to minimize the error of structural parameter estimation. The second important work in that field was the paper by Kammer [2] introducing the frequently used method called Effective Independence (EFI). The analysis was conducted in modal domain and the concept of Fisher information has been introduced. The EFI method tends to maximize the amount of information in the

measurement signals and it was shown that such a problem is closely related to maximization of the determinant of the Fisher matrix. Next, Cobb and Liebst [3] introduced modal sensitivities into the process of sensor placement optimization. Additionally, they proposed co-linearity metrics for comparing different sensor network configurations. These metrics were used to distribute a sensor network for damage identification in a spatial truss structure. Another interesting concept for optimal sensor placement has been proposed by Papadimitiou [4]. He utilized Bayesian statistical framework for sensor placement over large structures with many DOFs. In particular, information entropy (IE) has been suggested to be efficient in sensor placement for identification of uncertain structural parameters.

All the above mentioned methods treated the problem of sensor placement as a discrete optimization problem, i.e. assumed that candidate locations for a set of sensors, most frequently in form of accelerometers, are discrete variables. An alternative approach has been proposed by Mariani et al. [5]. They formulated sensor placement as continuous optimization and employed numerical methods used in structural topology optimization, where discrete variables are replaced with continuous ones ranging from zero to unity.

A comparison of four different approaches for optimal sensor placement, including: mode shape difference, effective independence, information entropy and modal energy method, has been published by Zhou et al. [6]. A new method for sensor placement based on Virtual Distortion Method has been proposed by the team of Professor Holnicki (Blachowski et al. [7]). In this method, a ranking of sensors has been created and its effectiveness in the selection of optimal sensor locations has been demonstrated on an example of a six-bay planar truss structure. Finally, Blachowski [8] proposed a method for optimal sensor placement and damage identification under sparsity constraints. He applied this method to two engineering examples: one related to a spatial truss girder and the second one to an upper-deck arch bridge.

The purpose of this study is to extend the topology optimization based approach for sensor placement to the case of real bridge structures represented by finite element models with a few thousand degrees of freedom.

2 SENSOR PLACEMENT AS A DISCRETE OPTIMIZATION PROBLEM

Before solving the optimal sensor placement problem, appropriate metrics have to be defined. One of the most frequently used is the determinant of the Fisher information matrix. The basic information about this metric and formulation of the sensor placement as a discrete optimization problem will be briefly recalled in the following two sections.

2.1 Estimation error and metrics for optimal sensor placement

We start the derivation of the topology optimization method for sensor placement with equations representing the response vector of the structure

$$\mathbf{y}(t) = \Phi \boldsymbol{\eta}(t) \quad (1)$$

where $\mathbf{y} \in \mathbb{R}^{n_d}$, $\Phi \in \mathbb{R}^{n_d \times n_m}$ and $\boldsymbol{\eta} \in \mathbb{R}^{n_m}$. Indices n_d and n_m denote the number of DOFs and the number of modes, respectively.

Equation (1) describes structural response in the absence of measurement noise. In reality, however, signals from sensors are always corrupted by noise and the corresponding equations take the following form

$$\mathbf{y}_s(t) = \mathbf{\Phi}_s \boldsymbol{\eta}(t) + \mathbf{w}(t) \quad (2)$$

where $\mathbf{y}_s \in \mathbb{R}^{n_s}$, $\mathbf{\Phi}_s \in \mathbb{R}^{n_s \times n_m}$ and $\mathbf{w} \in \mathbb{R}^{n_s}$. Matrix $\mathbf{\Phi}_s$ denotes measured components of the modal matrix $\mathbf{\Phi}$, vector \mathbf{w} represents measurement errors and index n_s is the number of sensors.

Assuming that the number of sensors is equal to or greater than number of modal coordinates to be identified, i.e. $n_s \geq n_m$, we can determine the least square estimate of modal coordinates using equation (2), namely

$$\tilde{\boldsymbol{\eta}}(t) = (\mathbf{\Phi}_s^T \mathbf{\Phi}_s)^{-1} \mathbf{\Phi}_s^T \mathbf{y}_s(t) = \mathbf{\Phi}_s^+ \mathbf{y}_s(t) \quad (3)$$

where matrix $\mathbf{\Phi}_s^T \mathbf{\Phi}_s$ is called the Fisher information matrix (FIM) and constitutes an essential part of eqn.(3). Using equation (3), an estimate of the structural response can be determined as follows

$$\tilde{\mathbf{y}}(t) = \mathbf{\Phi} \tilde{\boldsymbol{\eta}}(t) = \mathbf{\Phi} \mathbf{\Phi}_s^+ \mathbf{y}_s(t) \quad (4)$$

The difference between the structural response obtained from equation (1) and its estimate from equation (4) gives the estimation error

$$\mathbf{e}(t) = \tilde{\mathbf{y}}(t) - \mathbf{y}(t) = \mathbf{\Phi} \mathbf{\Phi}_s^+ \mathbf{y}_s(t) - \mathbf{\Phi} \mathbf{\Phi}_s^+ [\mathbf{y}_s(t) - \mathbf{w}(t)] = \mathbf{\Phi} \mathbf{\Phi}_s^+ \mathbf{w}(t) \quad (5)$$

and the covariance matrix of the estimation error takes the following form

$$E\{\mathbf{e}(t)\mathbf{e}(t)^T\} = \mathbf{\Phi} \mathbf{\Phi}_s^+ E\{\mathbf{w}(t)\mathbf{w}(t)^T\} (\mathbf{\Phi} \mathbf{\Phi}_s^+)^T \quad (6)$$

Assuming that the components of the measurement noise have zero mean $E\{\mathbf{w}(t)\} = \mathbf{0}$ and uncorrelated covariance matrix $E\{\mathbf{w}(t)\mathbf{w}(t)^T\} = \sigma_w^2 \mathbf{I}$, the above covariance matrix takes the following form

$$E\{\mathbf{e}(t)\mathbf{e}(t)^T\} = \sigma_w^2 \mathbf{\Phi} \mathbf{\Phi}_s^+ (\mathbf{\Phi}_s^+)^T \mathbf{\Phi}^T \quad (7)$$

where σ_w^2 represents the noise variance specific to a selected type of sensors.

From the formula (7) it can be easily observed that by selection of proper measurement locations we can influence the overall estimation error. To compare two different sensor configurations, certain metrics should be defined first. Two such metrics are frequently used in the literature. The first one is based on a trace of the covariance matrix (7)

$$\sigma_{e,avg}^2 = \frac{1}{n_s} \text{trace}(E\{\mathbf{e}(t)\mathbf{e}(t)^T\}) \quad (8)$$

Formula (8) gives information about average estimation error.

The second metric is related to the maximal element on the diagonal of the covariance matrix

$$\sigma_{e,\max}^2 = \max\{\text{diag}(E\{\mathbf{e}(t)\mathbf{e}(t)^T\})\} \quad (9)$$

and corresponds to the component of the response vector with the largest estimation error for a given sensor configuration. The above metrics (eqns. 8 and 9) can be incorporated into the optimization process for finding the best achievable sensor locations.

2.2 Combinatorial methods for optimal sensor placement

The number of ways in which n_s sensor positions can be chosen from among n_d candidate locations is given by the well-known formula

$$\binom{n_d}{n_s} = \frac{n_d!}{n_s!(n_d - n_s)!} \quad (10)$$

This formula shows that in the case of real engineering structures with many degrees of freedom, complete enumeration of possibilities for finding the optimal location of sensors is impractical if not impossible. For that reason a number of approximate methods have been proposed, among which the Effective Independence and Information Entropy methods are the most prominent ones. Both methods are operating in an iterative manner sequentially removing or adding sensors at subsequent iterations. Such an approach related to discrete optimization methods may not be efficient in the case of structures with a large number of degrees of freedom. Therefore, in the next section of this paper, an alternative approach for finding optimal positions of sensors is proposed which assumes that design variables are continuous.

3 THE PROPOSED TOPOLOGY OPTIMIZATION BASED SENSOR PLACEMENT

For the purpose of continuous optimization we introduce the function of sensor density $\rho(\mathbf{x})$, which takes values between 0 and 1. Then, instead of removing individual rows from the full modal matrix we will multiply it by the value of the sensor density function at a given location \mathbf{x}

$$\Phi_s = \text{diag}(\rho(\mathbf{x}))\Phi \quad (11)$$

Using the above relation we can replace the combinatorial problem related to sensor placement with its continuous version. Additionally, depending on the requirements, two continuous formulations are possible.

In the first one the goal is to optimize estimation error under a constraint on the volume (or equivalently - a number) of sensors:

$$\begin{aligned} \text{Minimize } J_1 &= \|E\{\mathbf{e}(t)\mathbf{e}(t)^T\}\| \\ \text{subject to } \int_V \rho(\mathbf{x})dV &\leq \bar{V} \end{aligned} \quad (12)$$

The second formulation aims at minimizing the number of sensors, while limiting the resulting estimation error

$$\begin{aligned} &\text{Minimize} && \mathcal{J}_2 = \int_V \rho(\mathbf{x}) dV \\ &\text{subject to} && \|E\{\mathbf{e}(t)\mathbf{e}(t)^T\}\| \leq \bar{\varepsilon} \end{aligned} \quad (13)$$

4 ILLUSTRATIVE EXAMPLE

4.1 The structure under investigation

The effectiveness of the proposed methodology for optimal sensor placement has been demonstrated on an example of a real tied-arch bridge located in Poland (figure 1). The bridge's main span is 76,6-meter long and consists of an arch box girder supporting the bridge deck using 13 vertical members (hangers). The arch and hangers are made of steel with the following material properties: $E = 210$ GPa, $\nu = 0.2$, $\rho = 7850$ kg/m³. The bridge deck is made of concrete and is additionally supporting a railway track.

Figure 1: General view of the investigated arch bridge

A numerical model of the bridge was created with the aid of commercial finite element software Abaqus 3DEXPERIENCE R2016x. The model consists of three types of finite elements including brick, shell and beam elements. The total number of finite elements is 68195 and the number of nodes is 76792. The task is to find a distribution of sensors for optimal estimation of the first five modal coordinates of the structure shown in figure 2.

4.2 Optimal sensor distribution

The optimization problem was stated as follows:

$$\begin{aligned} &\text{Maximize} && \det\left((\text{diag}(\rho_i)\Phi)^T(\text{diag}(\rho_i)\Phi)\right) \\ &\text{subject to} && \sum_{e=1}^{n_e} \rho_i \leq n_s, \end{aligned} \quad (14)$$

where ρ_i is the value of the sensor density function at the i -th node's location. The sensor

density function takes values within the range (0,1). The remaining symbols have the following meanings: n_s is the number of sensors, n_e is the number of finite elements. In our approach it is assumed that the sensor density function can be represented as a linear combination of coefficients x_j and y_j together with some prescribed basis functions $\bar{\rho}_{ij}$:

$$\rho_i = \sum_{j=1}^{n_c} x_j \bar{\rho}_{ij}^{(x)} + \sum_{j=1}^{n_c} y_j \bar{\rho}_{ij}^{(y)} \quad (15)$$

where n_c is the number of candidate locations; in this example $n_c = 26$. The design variables for the horizontal and vertical direction are $\mathbf{x} = \{x_1, x_2, \dots, x_{n_c}\}$ and $\mathbf{y} = \{y_1, y_2, \dots, y_{n_c}\}$, respectively.

Each function's value is equal to 1 at nodes connecting vertical hangers with the arch girder and deck of the bridge. The basis function approaches zero at nodes located farther than a certain distance away from the connection.

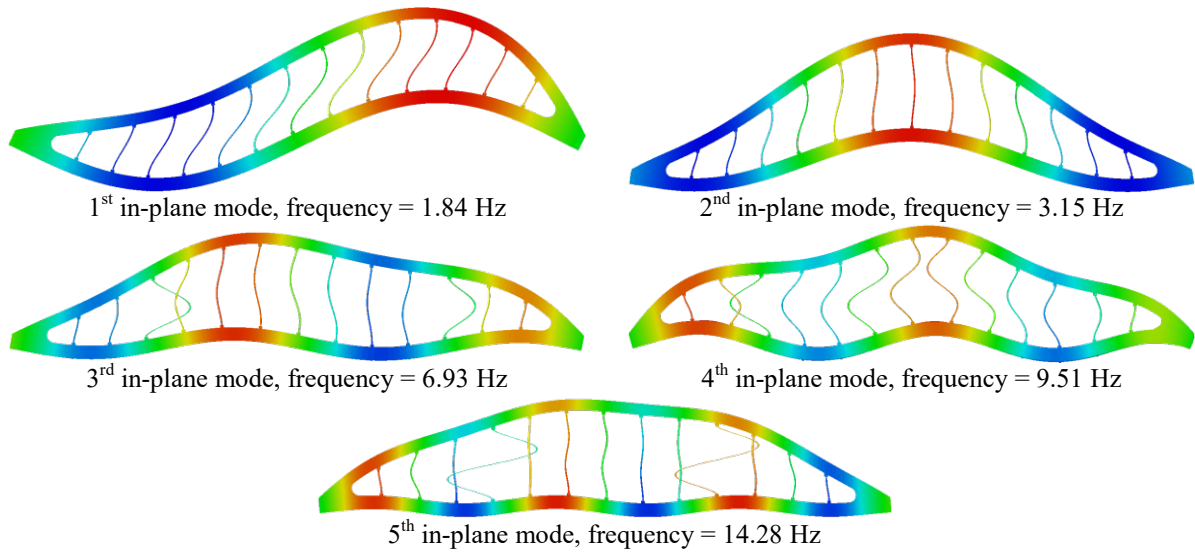

Figure 2: Mode shapes of the investigated arch bridge

The sensor arrangement dedicated to optimal identification of the five modal coordinates described above is presented in figure 3 (red circles in this figure indicate candidate locations).

Figure 3: Optimal sensor arrangement for the investigated arch bridge

5 CONCLUSIONS

- In the present study the problem of sensor placement over a large structure with thousands of DOFs has been formulated as continuous optimization similarly to the methods for finding optimal structural topology.
- A real-scale arch bridge had been selected as a numerical example for which the problem of sensor placement for five vibration modes was considered.

Key words: bridge collapse-test; energy capacity; loading capacity; PC girder bridge; vibration monitoring

Abstract. Vibration-based structural health monitoring (SHM) has been successfully applied to damage detection for a specific type of bridges. However, it is still a challenging task to assess structural integrity or structural performance by means of SHM. This study is intended to examine changes in load resistance capacity and modal parameters of an actual PC girder bridge through a bridge collapse-test. In the static loading test, the PC girder bridge was put under several loading and unloading levels until failure. Besides, forced vibration tests from both impact hammer test and moving-vehicle test were carried out along the static loading test in order to assess the changes in the dynamic properties of the PC girder bridge with different health conditions. An energy performance which is a function of energy dissipation and potential energy of the PC bridge is adopted as a feature relevant to structural performance. Observations demonstrated that changes in the frequency of the second bending mode was more strongly correlated with the changes of load resistance capacity than the first bending mode.

1 INTRODUCTION

Prestressed concrete (PC) girder bridges have been constructed since 1970s in Japan, and various damages due to deterioration such as a corrosion of PC tendon have been reported. Many methods have been proposed to evaluate soundness of bridges, and visual inspection is one of the most popular approaches to assess integrity of the PC bridge. In the PC bridge, the compressive stress introduced by the PC tendon cancels the tensile stress generated by applying load, and the crack occurs when the tensile stress reaches crack strength. Occurrence of cracks on the concrete girders is associated with higher possibility of excessive stresses and less margin of strength in the PC bridge.

In addition, damages caused by different phenomena have different effects on load resisting capacity of the PC bridge, and it is desirable to evaluate soundness of the PC bridge not only from external appearance but also from physical index.

Vibration-based structural health monitoring (SHM) thus has been developed as an approach providing physical index on soundness of bridges. Natural frequencies from deteriorated concrete girders have shown to be a sensitive feature for the strength reduction when evaluating the residual strength in bridges with 50 years of service life [1]. At the same time, it rises the likelihood of using natural frequencies as a symptom to be monitored in order to estimate the structural reliability [2]. Literatures also show that the modal damping ratio can be a damage sensitive feature for reinforced and prestressed concrete structures. Moreover, researches indicate that a trend of getting higher value of modal damping ratios with the age of the bridges could be a sign of possible deterioration, which is a strong reason to investigate the relationship between damping parameter and degree of damage [3]. However more evidences are required to validate residual strength models of deteriorating bridges [4] and to prove the link between structural resistance and information for SHM [5].

Inconsistencies between experiment and theoretical models occur due to different reasons that should be clarified [6]. Damage in structures is interpreted as a decay of its mechanical properties, or a decrease in stiffness. However, the tendency of natural frequencies to the development of damage shows an abnormal increase/decrease from one configuration to another, even experimentally [7].

The natural frequency of the first vertical mode showed to rapid decaying tendency, but little change in the damping was observed in the failure process of a PC bridge [1]. It was noticed that the small changes in modal parameters, regardless the large presence of cracks in concrete structures, might be due to the cracks closing by effective prestressing when the structure is unloaded. The decrease of prestressing force should increase the natural frequencies in a concrete element theoretically because a reduction in the axial compressive load would stiffen the element. However, an opposite trend was observed in a PC bridge under test [8] where the frequencies had a small decrement after the decrease of prestress force. Moreover, researches also show that no substantial change was detected in the modal parameters after cutting the prestressing tendons at specific locations of a concrete bridge [9].

This study is intended to examine changes in load resistance capacity and modal parameters of an actual PC girder bridge through a bridge collapse-test. In the static loading test, several loading and unloading levels until failure were considered. Forced vibration tests were carried out along with the static loading test in order to estimate the relationships between modal parameters and structural performance.

2 STATIC LOADING TEST AND VIBRATION TESTS

2.1 Target bridge

Figure 1 shows the target bridge with a static loading device. The bridge is a five-span simply-supported PC girder bridge with four main girders. The length of each span is 34.3 m and width of 7.2 m. 12 pairs of PC steel strand (12 ϕ 7) were utilized as a PC tendon for each girder. The bridge is about 170 m away from the coastline and had been operated over 50 years since its construction. Therefore, chloride attack to the main girder was significant, and cracks of the main girder caused by corrosion of the internal steel rebar and spalling of the concrete

were observed by visual inspection. Figure 2 shows the damage location map of the bridge obtained from the periodic inspection before the experiment. Damage was distributed throughout the span, and exposure of the reinforcing bar due to concrete peeling was observed at three locations. In considering the inspection result, high possibility of reduced load carrying capacity was expected.

2.2 Static loading test

The static loading test was carried out by using two 3000kN center hole type hydraulic jacks installed on the loading beam with a loading block. Figure 3 shows the loading device installed on the PC bridge. The load was given statically and monotonously.

As a reaction device for the static loading, two tendons having a loading capacity of 2500kN for each are anchored to the underground sandstone layer. The applying load was monitored by the load cell and the jack stroke was also monitored during loading. The loading point was set at the span center of the G1 girder shown in Figure 2.

Sensor deploying map is shown in Figure 4. The vertical displacement of each observation

Figure 1 Target bridge.

Figure 3 Loading device.

Figure 2 Damage location map.

point was measured by laser displacement meters (LDS-7H, Murakami Giken) and the tape measure type displacement meter (DP-500E, Tokyo Sokki) installed under the girder.

The loading test was conducted over three days, and repeated five stages of loading tests (Loading-1 to Loading-5) until collapse of the upper surface of the loaded PC girder which is assumed as the final state. Loading-1 shows a loading up to 600kN where bending cracks occur to the main girder. Loading-2 shows a loading up to 1200kN which is the yield load of tensile rebars. In Loading-3, as with Loading-2, loading of 1200kN was applied again but the loading was kept for about 2 hours. Loading-4 is loading up to 2400kN which is the failure load predicted in a preliminary structural analysis. Loading-5 was planned to load up to collapse of the upper flange of the loaded PC girder that is the final state, but before the final state, the loading test was terminated under the load of about 3200kN as the jack stroke reaches its admissible length of 50cm prior to the whole collapse of a superstructure. The loading progress is shown in Figure 5 in which “Stage n ” indicates the time of vibration test.

2.3 Vibration test

In order to estimate the vibration characteristics of each state, forced vibration tests were conducted at each unloading state as shown in Figure 5. Stage 1 is the initial state before the

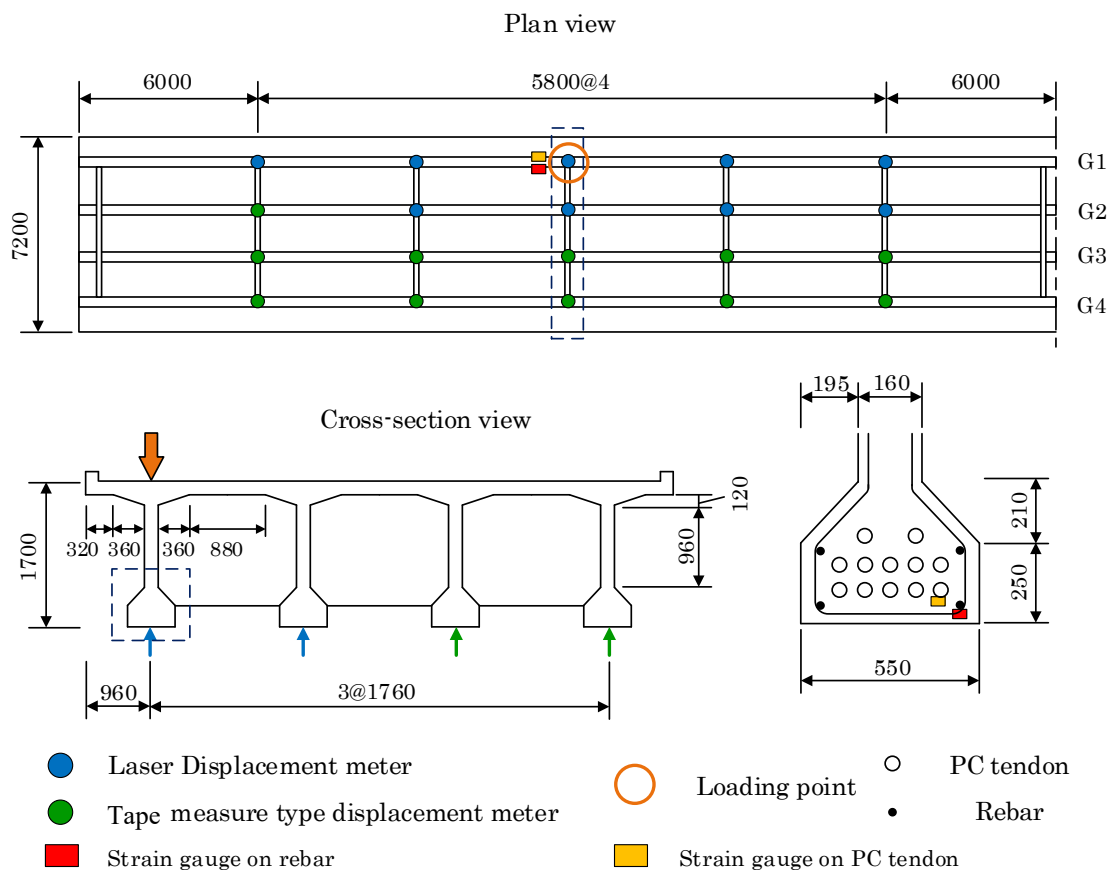

Figure 4 Observation span and location of sensors.

static load test. Stage 2 is the unloaded state after the Loading-1 (600kN) test, and Stage 3 is the unloaded state after the Loading-2 (1200kN) test. Stage 4 is the unloaded state after the Loading-3 test which was the state of being loaded by 1200kN for two hours. Stage 5 indicates the state which was left overnight after the Stage 4. Stage 6 shows the unloaded state of Loading-4 (2400kN). Stage 7 shows the state when it is left overnight after Stage 6. Finally, Stage 8 shows the unloaded state of Loading-5 (3200kN).

Two kinds of vibration tests were carried out. One is the moving-vehicle test which is practical as traffic loads are used as excitation sources without traffic regulation for the experiment. Traffic-induced vibrations of the bridge at each stage are measured by strain gauge type accelerometers (ARS-10A, Tokyo Sokki). The location of accelerometers is shown in Figure 6. As a test vehicle, a heavy vehicle is desirable as it is expected to provide greater excitation force. However, a smaller vehicle, van type vehicle (HIACE, Toyota Motor Corporation), was used because of the restriction of the vehicle passageway due to the static loading device on the bridge. The speed was approximately 30km/h. Three runs for Stage 1, and five runs for other stages were carried out.

Another vibration test is the impact hammer test whose identification accuracy is higher than

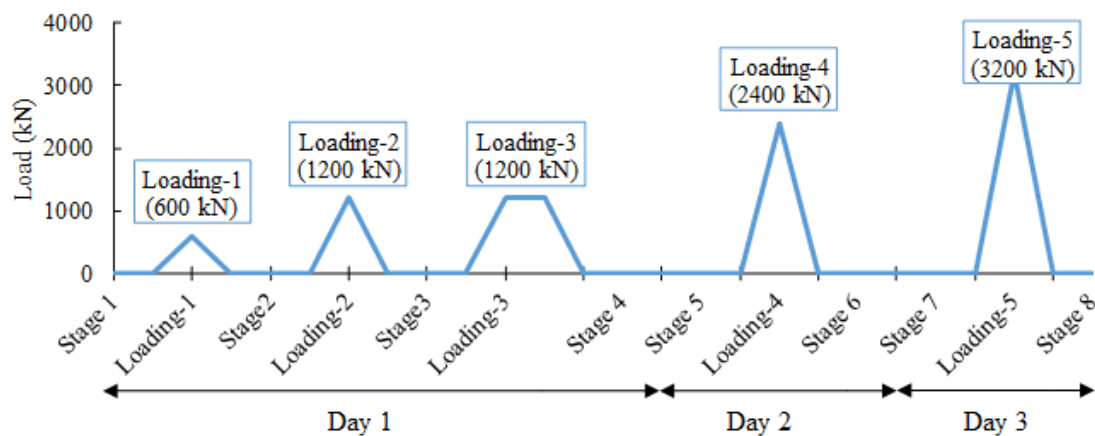

Figure 5 Loading process of the experiment.

Figure 6 Location of impact points and accelerometers.

that from moving-vehicle test. The equipment used for this test consists of an impact hammer Brüel & Kjær type 8210 – Modal sledge hammer 12 pounds head with a maximum compressive force of 44.4 kN and a sensitivity of 0.225 mV/N. The same accelerometers as moving-vehicle test were used during the impact hammer test. In each stage, the bridge was hit 10 times in each impact point by using two different types of impact tip (medium and tough tips), and the total hitting times was 40 per each stage. The hitting points are also shown in Figure 6.

3 STRUCTURAL PERFORMANCE OF PC BRIDGE

3.1 Load-displacement relation

The load-displacement curve observed at the span center of the G1 girder is shown in Figure 7 in which no clear residual displacement was observed until Loading-3. It indicates the bridge behavior was elastic until Loading-3. After Stage 5, the bridge was loaded up to 2500kN, which is the maximum design load (Loading-4), and unloaded. The maximum design load resulted in the residual displacement of around 16mm. Moreover, when the bridge is reloaded, the load-displacement curve traces the unloading point (point A in Figure 7), which showed enough restoration performance. The gradient of reloading was almost the same as that of the Loading-1 to Loading-4 until the tensile stress is generated at the lower edge of the concrete (point B in Figure 7). This proved that the prestressed force remains in order to keep the entire section effective. Therefore, when the load level is low it can be said that the vibration characteristics are hardly changed as the initial stiffness was about the same as those of Stage 1 to 5. Relationships between structural performance and vibration characteristics are discussed in Section 4.

3.2 Load-strain relation

Load-strain curves of rebar and PC tendon observed near the span center of the G1 girder are shown in Figures 8 and 9 respectively. Figure 8 shows that the load 1100kN in the load-strain curve under Loading-2 (see point C in Figure 8) is close to the yield load calculated by the preliminary analysis, and the behavior also seems to be the yield of the bar. However, the residual displacement after unloading hardly occurred, so this is not an actual yielding. This is because the adhesion force decreases due to the crack development. The same behavior can also be observed in the load-strain curve of PC tendon as shown in Figure 9. From Figure 9, it can be inferred that PC tendon yields at Loading-4 since residual strain occurs. After that, when the strain exceeds 4000 μ at Loading-5, it is considered that the rupture of PC tendon occurs.

3.3 Energy-based bending performance

As performance feature (Z) is introduced to normalize bending performance of PC bridges utilizing the potential energy and energy dissipation in each load step of the experiment. Equation (1) shows the performance feature at n loading stage with function of the energy dissipation (ΔW) and the potential energy (W). The energy dissipation (ΔW) is the enclosed area in the load- displacement graph when the concrete structure is tested in a specific loading-unloading step as shown in Figure 10(a). On the other hand, the potential energy (W), or work applied, is the area below the curve in the same graph, but this time without considering the unloading process as shown in Figure 10(b). Once the dissipated and potential energy are

calculated in a specific stage, the performance Z can be defined as:

$$Z_n = \left(1 - \frac{\Delta W_n}{W_n}\right) \cdot 100 \quad (\%) \quad (1)$$

where, “ n ” represents the loading stage.

Figure 7 Load vs. displacement curve.

Figure 8 Load vs. strain curve of rebar.

Figure 9 Load vs. strain curve of PC tendon.

Figure 11 Energy performance w.r.t. stages.

Figure 10 Energy dissipation and potential energy.

When the concrete structure behaves elastically and no damage has occurred, the energy dissipation would be zero and the performance would remain 100%. On the contrary, if damage is introduced or the beam reaches its plastic range, the energy dissipation should be different from zero and the performance feature shows lower value than 100%.

Figure 11 shows the change in the performance with respect to each stage. It can be seen from Figure 11 that the performance Z has been drastically decreased when the static load is larger than the yielding load.

4 MODAL PARAMETERS FROM VIBRAITON TESTS

4.1 Natural frequency and damping ratio

Modal parameters of the PC bridge such as natural frequency and damping ratio are identified from the vibration data as representative vibration characteristics. Stochastic subspace identification (SSI) [10] is adopted as a system identification method for the acceleration response obtained from moving-vehicle test. For vibration data from the impact hammer test, modal parameters are estimated using the frequency response function.

Changes in identified frequencies for the 1st and 2nd bending modes corresponding to structural integrity are plotted in Figure 12 which shows that the frequency for the 2nd bending mode obtained from impact hammer test resulted in stronger relationship with structural integrity. The precision of the natural frequency identified from moving-vehicle test was poor due to the weak excitation.

Figure 13 shows changes in damping ratio corresponding to the 1st and 2nd bending modes. Existing researches [11,12] suggests that decrease of the prestressed force causes increase of damping ratios. Similar phenomena on increase of damping ratio for the 2nd bending mode due to decrease of the prestressed force was observed: the rupture of the PC tendon was confirmed in Stage 8, and the damping ratio for the 2nd bending mode increased as shown in Figure 13. However, change in damping ratio for the 2nd bending mode was unclear comparing to that change in the frequency for the 2nd bending mode.

In summary, the frequency for the 2nd bending mode showed stronger relationship with structural integrity of the PC bridge. This result is similar to the PC girder damage experiment in laboratory [13].

4.2 Energy performance and natural frequency

The relationship between changes in energy performance and changes in natural frequency is shown in Figure 14. The natural frequency obtained from impact hammer test is examined as quality of the data from the impact hammer test was better than that from the moving-vehicle test. The dotted line shows a linear regression between frequency and energy performance from Stage 1 to Stage 7. Stage 8 was not considered to the regression since Stage 8 is close to the ultimate condition which rarely occurs in real bridge monitoring. From the linear regression curve, a strong correlation was observed between the 2nd bending modal frequency and the energy performance.

Figure 14 Energy performance vs. Frequency.

5 CONCLUSIONS

This study investigates the relationship between bridge performance and modal frequencies. In regard to natural frequency, the 2nd bending mode showed stronger correlation with energy

performance than the 1st bending mode. For the damping ratio, the 2nd bending mode showed an increase from Stage 7 to Stage 8 due to the rupture of PC tendon. However, modal damping ratio for the 1st bending mode barely changed from Stage 7 to Stage 8. Observations demonstrated the usefulness of the 2nd bending mode in vibration-based bridge health monitoring of the PC bridge. However, it is still a challenge to estimate the structural performance of the PC bridge from changes in the natural frequency of 2nd bending mode. As a next step for this research, comprehensive investigations on structural performance of the PC bridge will be carried out even utilizing strains measured at concrete and rebar. Moreover, effectiveness of the correlation between the bridge performance and vibration characteristics will be investigated by numerical analysis.

ACKNOWLEDGEMENTS

This study is partially sponsored by a Japanese Society for the Promotion of Science (JSPS) Grant-in-Aid for Scientific Research (B) under project No.19H02225, which is greatly appreciated.

Abstract. This paper investigates numerically the potential of ground floor linear tuned inerter damper (TID) to mitigate floor acceleration causing occupants' discomfort in wind-excited multi-storey buildings due to vortex shedding (VS) effects while generating electric energy. To this aim, TID stiffness and damping properties were optimally designed to minimize root mean square (RMS) floor acceleration at the top occupied floor for wide range of fixed inertance values, while an electromagnetic motor (EM), modelled as an ideal damper, was added to endorse energy harvesting capabilities to the TID. Numerical data pertaining to a 15-storey steel moment resisting frame structure with square floor plan, deficient to occupants' comfort (OC) code-prescribed criteria under moderate wind action, are furnished. Wind excitation is by a spatially-correlated across-wind force field accounting for VS effects. It is found that optimally designed ground floor TID can readily meet OC criteria without any structural modification (stiffening) which for the case-study building would require 67% increase of steel weight. It is further shown that increasing EM damping coefficient increases energy harvesting potential at the expense of increased floor accelerations. However, increasing TID inertance enhances *simultaneously* floor acceleration and energy harvesting performance. Hence, it is concluded that it is possible to increase energy generation in ground floor TID-equipped wind-excited multi-storey buildings without necessarily relaxing performance requirements in terms of floor accelerations through judicious changes to EM damping coefficient and/or inertance.

1 INTRODUCTION

Design and construction of slender high-rise buildings in congested modern city centers have been gaining popularity in recent decades mostly due to ever-increasing cost of land associated with urbanization. Satisfying the structural integrity criteria under gravitational and wind design loads at the ultimate limit state is relatively straightforward in such structures using high strength materials and stiff lightweight structural components [1]. However, it is found that slender buildings with rectangular floor plan are prone to excessive oscillations in the across-wind direction (i.e., within the normal plane to the wind direction) due to vortex shedding (VS) effects generated around their corner edges [2]. These oscillations may generate floor

accelerations trespassing occupants' comfort thresholds under moderate wind action (i.e., at the serviceability limit state) [3-4] leading to loss of functionality and to downtime. Increasing the lateral stiffness of VS prone buildings cannot efficiently address serviceability performance associated with floor accelerations [5]. Therefore, dynamic vibration absorbers, with most representative the tuned mass damper (TMD), are widely used in practice for vibration mitigation in wind-excited slender buildings to meet floor accelerations thresholds prescribed by building codes and guidelines [6]. In its simplest form, the classical linear passive TMD comprises an oscillating mass attached towards the building top via linear stiffeners and viscous dampers. Stiffness and damping properties of the TMD are optimally designed/tuned to the dominant building mode shape for fixed attached mass. This provision facilitates the transfer of kinetic energy from the wind-excited building to the TMD secondary mass and, eventually, its dissipation through the dampers. Recently, the potential of TMDs to harvest energy from wind-induced oscillations in slender buildings has been explored by employing electromagnetic motors (EMs) coupled with energy harvesting/storage circuitry to replace viscous dampers in connecting the TMD mass to the host structure [7-8]. In this manner, part of the kinetic energy of the host structure is transformed into usable electric energy instead of being "lost" at the dampers in the form of heat. Moreover, Giaralis and Petrini [9-10] demonstrated that by coupling the TMD with an inerter device in the so-called tuned mass-damper-inerter (TMDI) configuration reduces significantly floor acceleration in tall/slender buildings subject to VS effects for the same attached mass. This improved vibration control efficiency of the TMDI is attributed partly to the mass-amplification effect and partly to higher-modes-damping effect endowed to the TMD by the inerter: a device developing acceleration proportional force by a coefficient termed inertance [11]. Further, Petrini et al. [12] added an EM to the TMDI and showcased significant gains in the available energy for harvesting by varying the inertance and/or the damping property of the TMDI.

Notably, all the above dynamic vibration absorbers are installed towards the top floor of buildings occupying high premium space. To address this issue, herein, the potential of a tuned inerter damper (TID), that is a TMDI with no mass property, [13] installed at the ground floor of wind-excited buildings is explored to mitigate floor accelerations at the upper floors. This consideration is inspired by several studies [13,14,15] demonstrating the high efficiency of ground floor TIDs to control earthquake-induced vibrations in multi-storey buildings. In this work, a ground floor TID is considered for the first time to control wind-induced vibrations. Furthermore, the TID is coupled with an EM to gauge its potential for harvesting energy from wind-induced oscillations. To this aim, a planar dynamical model of a 15-storey benchmark building with square floor plan deficient to floor acceleration thresholds due to VS effects is considered. Attention is focused on quantifying savings in the total weight of the structure achieved by adding a ground floor TID optimally designed for top floor acceleration reduction as opposed to increase the lateral floor stiffness. Additionally, energy harvesting potential is quantified as inertance and EM damping are let to vary.

2 BENCHMARK STRUCTURE AND WIND MODELLING

2.1 Benchmark structure description and reduced order modelling

The benchmark building considered in this paper is a doubly symmetric, 15-storey, 3-bay steel moment resisting frame (MRF) structure with 16.5m-by-16.5m footprint. It totals 49.8m

of height: ground floor is 5.0m high, while the rest of the floors are 3.2m high. The structure comprises four parallel planar MRFs along each principal axis with all beam-to-column joints taken as rigid as shown in Figure 1(a). Columns have hollow square sections with varying outer dimensions and thickness along the building height ranging between 0.48m and 0.32m, and 0.024m to 0.016m respectively. Beams are of various welded wide flange sections with section height and flange width varying between 0.5m and 0.3m, and 0.3m and 0.18m, respectively. Horizontal perfectly rigid diaphragm constraints are imposed at the height of each floor in developing a detailed finite element (FE) linear model of the structure. By deactivating the out-of-plane DOFs, the first three natural frequencies of the building and corresponding modal mass participating ratios in parentheses are 0.548Hz (0.7118), 1.391Hz (0.1675), and 2.342Hz (0.0593). The building is designed to all serviceability and ultimate limit state requirements for static design load combinations including gravitational loads and mean wind component forces acting in the along-wind direction. The required steel tonnage (MRFs self-weight) is 471tons.

To expedite computational work in later sections, a low-order planar dynamic model with 15 degrees of freedom (DOFs) corresponding to the lateral in-plane translations of the rigid slabs is derived from the detailed FE model of the benchmark building using the modal-based procedure detailed in [9]. The 15-DOF model is defined in terms of a diagonal mass matrix, and full damping matrix and stiffness matrices. Building mass including nominal gravitational loads is lumped at each floor as shown in Figure 1(b), while modal damping ratios for the j -th mode are taken as: $\xi_j=1\%$, for $j= 1,2,3$; $\xi_j= 2\%$ for $j= 4,5,6$; $\xi_j= 4\%$ for $j= 7,8,9$; $\xi_j=8\%$ for $j= 10,11,12$; and $\xi_j=16\%$ for $j= 13,14,15$. The first three mode shapes obtained by the detailed FE model and the 15-DOF system match very well as shown in Figure 1(c).

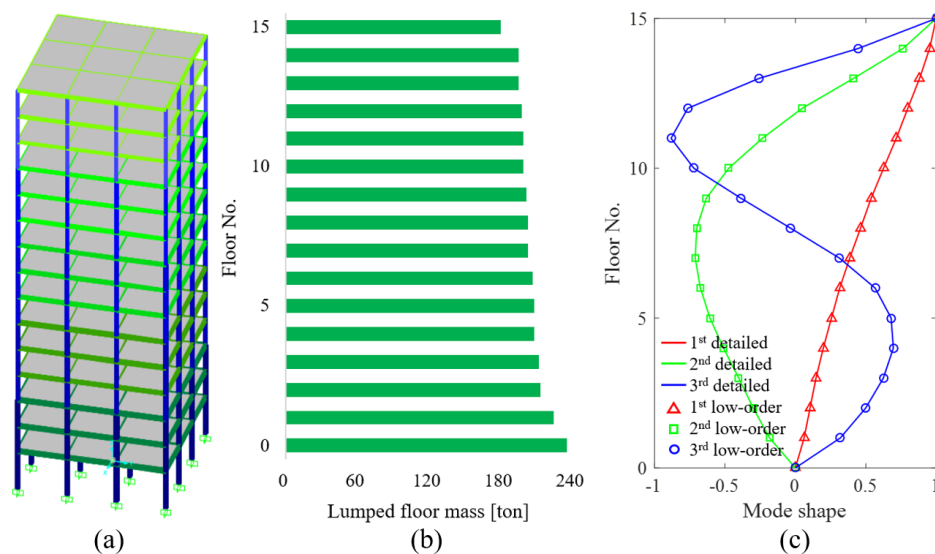

Figure 1: Benchmark building structure: (a) Detailed FE model, (b) lumped floor mass distribution along building height, (c) First three mode shapes obtained by the detailed FE and by the low-order models.

2.2 Across-wind loading model

The input wind action to the 15-storey (15-DOF) low-order model is herein represented by the stochastic across-wind force model developed in [2] for buildings with rectangular footprint.

This wind forcing model is based on experimental data from a comprehensive wind tunnel testing campaign and accounts for both the turbulence and the VS components of the wind force in the across-wind direction, the latter being critical for occupants' comfort. It is defined by a zero-mean stationary Gaussian spatially correlated random field represented in frequency domain by a full power spectral density (PSD) matrix. For the 15-DOF dynamic model, a $\mathbf{S}_{\text{FF}}^{15} \in \mathbb{R}^{15 \times 15}$ wind force PSD matrix is determined upon spatial discretization of the wind random field at each building floor. Throughout this work, the logarithmic mean wind velocity profile of Eurocode 1 [3] is assumed for rough/urban terrain and for a (moderate) basic wind speed of 20m/s (i.e., 10mins mean wind velocity at 10m height above open flat terrain) plotted in Figure 2(a). For this wind profile, wind force PSDs at three different floor slab heights are plotted in Figure 2(b) following [2]. It is seen that the dominant VS frequency increases with floor height. The same happens for the wind force amplitude except from the last floor whose tributary height is only 1.6m. That is, half of the tributary height of typical floors.

Figure 2: Assumed wind excitation model: (a) mean wind velocity profile, (b) power spectral density functions (PSDs) of across-wind forces acting at different floor levels of the benchmark structure.

2.3 Optimal re-design of benchmark structure for occupants' comfort

Whilst the case-study building in Figure 1 satisfies all requirements for *static* design load combinations, it is found to be deficient for the occupants' comfort serviceability limit state for the wind action defined in Figure 2 according to the ISO Standard 6897 [3] criteria. Figure 3(a) reports the root mean square (RMS) accelerations developing at each floor of the structure (initial structure) along its height together with the ISO 6897 occupants' comfort threshold: it is seen that RMS acceleration is over the threshold at the top two floors.

To this end, the structure is herein re-designed to satisfy the ISO6897 occupants' comfort criteria. This is achieved by using the optimal design method in [16] for MRFs with fixed layout which is based on the optimality criteria (OC) formulation in [17]. The method seeks to minimize the total structural weight while satisfying design constraints including RMS floor acceleration being below the ISO6897 threshold at all floors below the top one (roof) which is not occupied. Figure 3(b) shows the MRF self-weight variation (steel tonnage of lateral load resisting system) throughout the iterations of the optimization starting with the initial deficient design with total weight of 471tons and fundamental frequency 0.548 Hz. The iterative optimization process converges at 786tons of MRF self-weight with fundamental frequency increased to 0.920Hz after 20 design cycles. Consideration of further cycles does not improve much the self-weight. Figure 3(a) plots RMS floor accelerations of the final optimally designed

structure along with the corresponding ISO6897 threshold. The latter has increased since the re-designed structure is stiffer. It is confirmed that in the re-designed structure code-prescribed threshold for RMS floor acceleration is satisfied in all occupied floors, while floor accelerations reduce noticeably compared to the initial structure. However, this is achieved at the expense of using an additional 315tons of steel (i.e., 67% increase of steel tonnage). In following sections, an optimally designed ground floor TID is considered to meet occupants' comfort requirements without without any stiffening of the MRF load-resisting system of the initial structure.

Figure 3: (a) root mean square floor accelerations of initial and optimally re-designed structures with occupants' comfort thresholds (b) Variation of total weight of structure throughout the optimal re-design process.

3 TID-EQUIPPED STRUCTURE AND FREQUENCY-DOMAIN ACROSS-WIND RESPONSE ANALYSIS

The tuned inerter damper (TID) is a linear passive dynamic vibration absorber introduced in [13] for suppressing the lateral motion of seismically excited multi-storey buildings. Herein, a TID installed at the ground floor of the ISO6897 deficient structure in Figure 1 is considered to mitigate wind-induced accelerations in the across-wind direction. TID modelling and its incorporation to the adopted structure is graphically shown in Figure 4(a) depicting the low-order 15-DOF model discussed in section 2.1 as a planar 15-storey frame-like building with lumped floor masses m_k , $k=1,2,\dots,15$, and lateral floor displacements x_k . The TID consists of a visco-elastic link, modelled as a linear spring with k_{TID} stiffness in parallel with a dashpot with damping coefficient c_{TID} , which connects one terminal of an inerter device, highlighted in red in Figure 4(a), with the first building slab. The second inerter terminal is fixed to the ground. The inerter device is idealized by a mechanical element resisting relative acceleration at its two ends through the inertance coefficient b [11]. In this regard, the inerter element force reads as

$$F_b = b\ddot{x}_{TID} \quad (1)$$

where x_{TID} is the lateral TID displacement shown in Figure 4(a) and a dot over a symbol signifies differentiation with respect to time. Therefore, the (control) inerter force depends on the inertance which may be interpreted as a “weightless mass” [11].

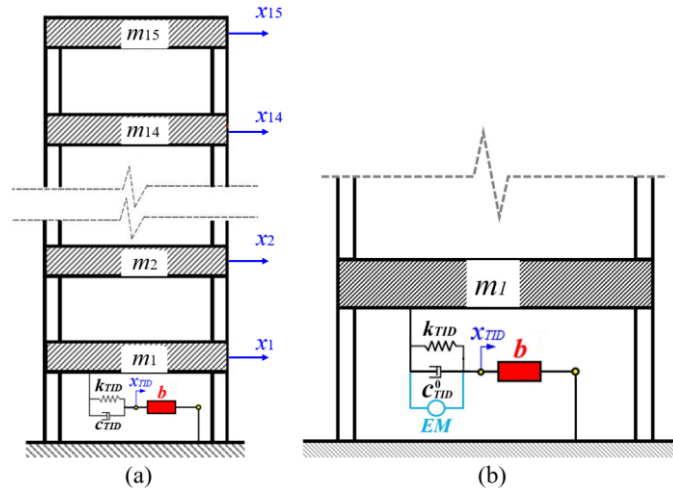

Figure 4: (a) Ground floor TID-equipped lumped-mass planar frame model of the wind-excited case-study building in the across-wind direction, and (b) Considered energy harvesting enabled TID with EM.

In this regard, it is important to note that inertance is readily scalable. Indeed, supplemental damping devices for seismic protection of building structures incorporating inerters with several hundred thousand tons of inertance have been prototyped and experimentally verified in recent years [18]. To shed further light on this issue, consider a commonly used inerter device embodiment employing a rack-and-pinion mechanism to transform the translational motion into rotational motion of a flywheel (i.e., a solid spinning disk) through a gearbox [11]. It can be readily shown that the inertance of such device is given as [19]

$$b = m_f \frac{\gamma_f^2}{\gamma_{pr}^2} \left(\prod_{q=1}^n \frac{r_q^2}{pr_q^2} \right), \quad (2)$$

where m_f and γ_f are the mass and radius of the gyration of the flywheel, respectively, γ_{pr} is the radius of gyration of the flywheel pinion, $r_q/(pr_q)$ is the gearing ratio of the q -th stage/gear of the gearbox with n stages. Clearly, the inertance can be scaled by orders of magnitude through changing the gearing ratios and/or the number of gears. Along these lines, Brzeski et al. [20] demonstrated experimentally the feasibility of inerter devices with continuously varying transmission gearbox, rather than stepped gearing changes, leading to inerters that may achieve any desired inertance value within the gearbox effective range of transmission.

Mathematically, the mass, \mathbf{M} , damping, \mathbf{C} , and stiffness, \mathbf{K} , matrices of the TID-equipped lumped-mass 15-DOF model in Figure 4(a) are given as

$$\mathbf{M} = \begin{bmatrix} b & 0 & 0 & \cdots & 0 & 0 \\ & m_1 & 0 & \cdots & 0 & 0 \\ & & m_2 & \cdots & 0 & 0 \\ & & & \ddots & \vdots & \vdots \\ & & & & m_{14} & 0 \\ & & & & & m_{15} \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} c_{\text{TID}} & -c_{\text{TID}} & \cdots & \cdots & 0 & 0 \\ & c_{1,1}+c_{\text{TID}} & c_{1,2} & \cdots & c_{1,14} & c_{1,15} \\ & & c_{2,2} & \cdots & c_{2,14} & c_{2,15} \\ & & & \ddots & \vdots & \vdots \\ & & & & c_{14,14} & c_{14,15} \\ & & & & & c_{15,15} \end{bmatrix}, \quad (3)$$

$$\text{and } \mathbf{K} = \begin{bmatrix} k_{\text{TID}} & -k_{\text{TID}} & \cdots & \cdots & 0 & 0 \\ & k_{1,1}+k_{\text{TID}} & k_{1,2} & \cdots & k_{1,14} & k_{1,15} \\ & & k_{2,2} & \cdots & k_{2,14} & k_{2,15} \\ & & & \ddots & \vdots & \vdots \\ & & & & k_{14,14} & k_{14,15} \\ & & & & & k_{15,15} \end{bmatrix}$$

respectively, where $c_{k,p}$ and $k_{k,p}$ with $k=1,\dots,15$ and $p=1,\dots,15$ are the damping and stiffness coefficients of the low-order 15DOF system representing the benchmark building. Response displacement, velocity, and acceleration PSD matrices of the TID-equipped structure subject to the wind force PSD matrix defined in section 2.2 can be obtained as

$$\mathbf{S}_{\text{xx}}(\omega) = \mathbf{B}(\omega)^* \mathbf{S}_{\text{FF}}(\omega) \mathbf{B}(\omega), \quad \mathbf{S}_{\dot{\text{x}}\dot{\text{x}}}(\omega) = \omega^2 \mathbf{S}_{\text{xx}}(\omega), \quad \text{and} \quad \mathbf{S}_{\ddot{\text{x}}\ddot{\text{x}}}(\omega) = \omega^4 \mathbf{S}_{\text{xx}}(\omega) \quad (4)$$

respectively. In Eq. (4), \mathbf{S}_{FF} is the wind force PSD matrix $\mathbf{S}_{\text{FF}}^{15}$ augmented by an upper zero row and a left-most zero column corresponding to the x_{TID} displacement DOF as the TID is internally housed and not subjected to any wind load. Further, the “*” superscript denotes complex matrix conjugation, and the transfer matrix \mathbf{B} is given as

$$\mathbf{B}(\omega) = [\mathbf{K} - \omega^2 \mathbf{M} + i\omega \mathbf{C}]^{-1} \quad (5)$$

where, $i = \sqrt{-1}$, and the “-1” superscript denotes matrix inversion. The RMS response velocity, and acceleration of the k -th DOF for the TID-equipped structure are obtained as

$$\text{RMS}\{\dot{x}_k\} = \sigma_{\dot{x}_k} = \sqrt{\int_0^{\omega_{\max}} S_{\dot{x}_k \dot{x}_k}(\omega) d\omega} \quad \text{and} \quad \text{RMS}\{\ddot{x}_k\} = \sigma_{\ddot{x}_k} = \sqrt{\int_0^{\omega_{\max}} S_{\ddot{x}_k \ddot{x}_k}(\omega) d\omega} \quad (6)$$

respectively. That is, by integrating the response auto-spectra in the main diagonal of the response velocity and acceleration PSD matrices in Eq. (4) to a cut-off frequency, ω_{\max} , above which the energy of the underlying processes is negligible. Further, the relative RMS velocity between two different DOFs k and j is obtained as

$$\text{RMS}\{\dot{x}_k - \dot{x}_q\} = \sigma_{\dot{x}_{kq}} = \sqrt{\sigma_{\dot{x}_k}^2 + \sigma_{\dot{x}_q}^2 - 2 \int_0^{\omega_{\max}} S_{\dot{x}_k \dot{x}_q}(\omega) d\omega} \quad (7)$$

where the integrand is the response velocity cross-spectra between k and q DOFs.

4 OPTIMAL TID DESIGN FOR VIBRATION CONTROL

In this section, the properties of the ground floor TID in Figure 4(a) are optimally designed to mitigate floor accelerations in multi-storey buildings subject to VS effects associated with

occupants' comfort. To this aim, an optimal design problem is formulated aiming to minimize the RMS floor acceleration of the highest occupied floor taken as the objective function (OF). This is because RMS acceleration increases monotonically with building height in the across-wind direction of typical multi-storey buildings prone to VS effects (see e.g. Figure 3(a)). The problem design variables (DV) are the non-dimensional TID parameters defined as

$$\beta = \frac{b}{M_{tot}}, \quad \nu_{TID} = \frac{\sqrt{k_{TID}/b}}{\omega_1}, \quad \text{and} \quad \xi_{TID} = \frac{c_{TID}}{2\sqrt{k_{TID}b}}, \quad (6)$$

namely, inertance ratio, frequency ratio, and damping ratio, respectively. In the last equation, M_{tot} is the total mass of the building (including design dead and live loads), while ω_1 is the first natural frequency of the uncontrolled (no TID-equipped) structure. The optimization problem is solved numerically using the pattern search algorithm [21] to determine optimal primary DVs frequency ratio, ν_{TID} , and damping ratio, ξ_{TID} , which minimize the OF for fixed building structure, wind excitation, and inertance ratio β treated as secondary DV.

To exemplification of the above TID optimal design problem, Figure 5 furnishes results from application to the 15-storey structure discussed in section 2.1 under the wind force PSD matrix in section 2.2 to minimize $\text{RMS}\{\ddot{x}_{14}\}$ computed by Eq.(6). In doing so, practically meaningful range of values for the primary DVs are searched: ν_{TID} is bounded in the $[0.9, 1.1]$ range based on real-life TMD installations in high-rise buildings tuned to the first natural frequency ω_1 , while ξ_{TID} is bounded in the $[0.0, 0.2]$ range to ensure realistic viscous damping coefficients. Strong convex behavior of the OF on the primary DVs, ν_{TID} - ξ_{TID} , plane is noted with a single global optimal design point readily identified for inertance ratios β ranging within $[0,1]$ interval. For illustration, $\text{RMS}\{\ddot{x}_{14}\}$ surface of the TID-equipped structure normalized by $\text{RMS}\{\ddot{x}_{14}\}$ of the uncontrolled structure is plotted in Figure 5(a) on the ν_{TID} - ξ_{TID} plane for $\beta=0.2$. Further, optimal DV values are plotted in Figure 5(b) as functions of β .

5 PERFORMANCE ASSESSMENT OF OPTIMAL TID-EQUIPPED BENCHMARK STRUCTURE

5.1 Vibration suppression efficiency of ground-floor TID

In this section, the potential of ground-floor TID to satisfy occupants' comfort criteria with no further structural modification in wind-excited multi-storey buildings sensitive to VS effects

is numerically assessed. Attention is focused on demonstrating that ground floor TID can support lightweight slender building designs compliant to occupants' comfort serviceability criteria leading to reduced steel usage. To this aim, optimally designed TIDs obtained as detailed in the previous section are considered for the 15-storey structure of Figure 1 which was found to be deficient to the ISO6897 occupants' comfort criteria, as seen in Figure 3(a), for the moderate across-wind excitation in Figure 2.

Figure 6: Normalized RMS floor acceleration at penultimate floor and available RMS energy for harvesting for TID-equipped structure in Figure 1 subject to wind forcing of Figure 2.

Figure 6 plots RMS acceleration at the penultimate (last occupied) floor of the optimal TID-controlled structure, $\text{RMS}\{\ddot{x}_{14}\}$, normalized by the corresponding value of the uncontrolled structure, as a function of inertance ratio. In this graph, the limiting case of $\beta = 0$ corresponds to the uncontrolled structure. It is seen that floor acceleration reduces monotonically with the inertance though performance improvement saturates as inertance ratio increases. Notably the inertance values examined in Figure 6 are realistic: even the case of $\beta = 100\%$, which reduces floor acceleration by 44.8% compared to the uncontrolled structure, is achievable. Indeed, this inertance ratio corresponds to inertance $b = M_{\text{tot}} = 3285 \text{ tons}$ which is below the inertance achieved by the hydraulic inerter device discussed in [18]. However, a reduction of 14.2% in 14th floor RMS acceleration is required for the considered benchmark structure to meet ISO6879 occupants' comfort criteria. This is achieved by equipping the initial structure with an optimally tuned TID with $\beta = 6\%$ (or $b = 197 \text{ tons}$), as indicated in Figure 6, without altering in any other way the MRF lateral load-bearing system. Recalling that meeting ISO6879 criteria through structural modification would require 315 tons of additional steel to stiffen the initial MRF if no TID is installed, as discussed in section 2.3, one concludes that optimal ground-floor TID is quite efficient in meeting occupants' comfort criteria in wind excited buildings leading to lightweight designs and material savings.

5.2 Energy harvesting potential for TID with varying inertance and damping coefficient

Having established the benefits of the TID for suppressing floor accelerations in wind-excited tall buildings, the attention is now turned to explore its potential for harvesting energy from wind-borne building oscillations. To this aim, a standard linear translational EM coupled with an energy harvesting (EH) circuit is added in parallel to the visco-elastic TID element as

shown in Figure 4(b). The considered EM consists of a moving magnet travelling within a coil while the EH circuit is equipped with a rectifier to ensure unidirectional electric current flow irrespective of the magnet direction of motion [22]. The resistance of the EM is equal to R_C while EM inductance is negligible for the motion frequencies in the application at hand [22]. Moreover, the EH circuit is assumed to be purely resistive with resistance R_L : a simplification deemed sufficient for the comparative quantification of the available energy for harvesting as TID properties are let to vary (see also [8]). Under the above assumptions, the electromechanical damping coefficient of the EM coupled with the EH circuit is given as [22]

$$c_{EM} = \frac{J^2}{(R_C + R_L)} \quad (8)$$

where J is the magnetic field in the EM with constant flux density, and the resisting damping force contributed by the EM element to the structure in Figure 4 reads as

$$F_{EM} = c_{EM} (\dot{x}_1 - \dot{x}_{TID}) \quad (9)$$

Then, structural analysis to wind excitation remains the same as in section 3 by setting

$$c_{TID} = c_{TID}^0 + c_{EM} \quad (10)$$

where c_{TID}^0 is the TID viscous damping coefficient, as shown in Figure 4(b) and the RMS value of the available energy for harvesting, EHpot, is quantified as

$$\text{RMS}\{\text{EHpot}\} = c_{EM} (\text{RMS}\{\dot{x}_1 - \dot{x}_{TID}\})^2 \quad (11)$$

making use of Eq.(7).

Figure 6 plots the RMS of EHpot for optimal TID-controlled case-study building against the inertance ratio normalized by the value attained for $\beta=1$. In obtaining this data, it is assumed that the EM contributes to half of the (optimal) TID damping, that is, $c_{TID}^0 = c_{EM}$ in Eq.(10), following optimal EH criteria [22]. It is seen that EHpot increases monotonically with inertance and, therefore, increasing inertance is beneficial for both vibration suppression and for energy harvesting in ground floor TID optimally designed for vibration suppression.

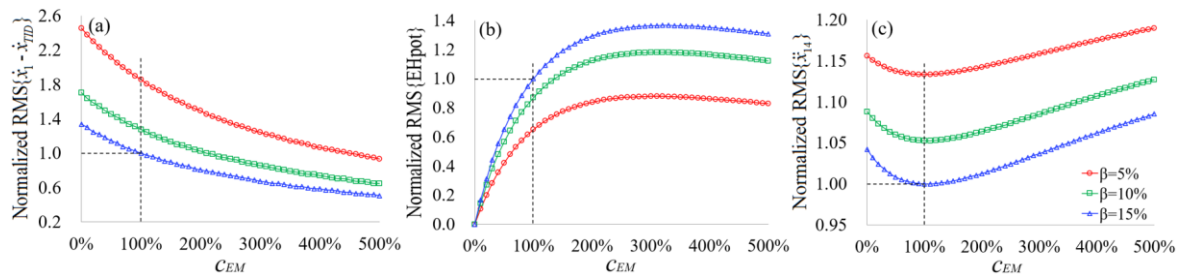

Figure 7: Normalized EH potential and performances of the EH-TID for $v_b = 20\text{m/s}$, $\beta=0.05, 0.10$, and 0.15 , and for (a) RMS relative velocity, (b) RMS EH potential, and (c) RMS acceleration at the last occupiable floor.

Moreover, Figure 7 quantifies RMS EHpot and penultimate RMS floor acceleration for non-optimal TID-equipped structure as c_{EM} in Eq.(9) is let to vary for fixed k_{TID} and c_{TID}^0 , and for three different β values. Values of k_{TID} and c_{TID}^0 are optimal for TID with $\beta=15\%$ and all plotted quantities are normalized to the attained values for this optimal TID design including the value

of c_{EM} . This investigation is motivated by the fact that both the c_{EM} in Eq.(9) and the inertance b in Eq.(2) can vary in a passive-adaptive mode by changes to the EH circuit and to the inerter gearing, respectively. It is seen in Figure 7(b) that c_{EM} increases with c_{EM} until it reaches a plateau due to reduction of $\text{RMS}\{\dot{x}_1 - \dot{x}_2\}^2$ with c_{EM} in Figure 7(a). At the same time, as expected, RMS floor acceleration in Figure 7(c) increases as c_{EM} deviates from its optimal value. Nevertheless, for a fixed, possibly non-optimal, c_{EM} , *simultaneously* enhanced vibration suppression performance and increased EH_{pot} is achieved by increasing inertance. These observations suggest that it is possible to increase energy generation in ground floor TID-equipped wind-excited multi-storey buildings without necessarily relaxing performance requirements in terms of floor accelerations through judicious changes to EM damping coefficient and/or inertance.

6 CONCLUDING REMARKS

The efficacy of a ground floor TID to achieve occupants' comfort performance and to harvest kinetic energy in wind-excited multi-storey buildings susceptible to VS effects has been numerically established. To this aim, a 15-storey steel structure, deficient to occupants' comfort code-prescribed criteria for moderate wind action, has been equipped with optimal TID stiffness and damping properties minimizing floor acceleration in the across-wind direction, being critical for occupants' comfort, for fixed inertance. Further, the TID was coupled with a standard EM modelled as a damper and allowing for energy harvesting. Major conclusions in view of the herein furnished numerical results are: (1) Optimally tuned TID for floor acceleration minimization is a potent retrofitting measure to meet occupants' comfort criteria without structural modifications leading to considerable increase of steel usage (up to 67% increase for the considered structure), (2) Increasing TID inertance is beneficial for both suppressing floor accelerations and for increasing available energy for harvesting in both optimal and non-optimal TID for floor acceleration mitigation, and (3) Increasing the EM damping coefficient increases the available energy for harvesting at the expense of increased floor accelerations. Overall, it is concluded that ground floor TID is a promising dynamic vibration absorber configuration for occupants' comfort criteria which govern the design of slender multi-storey buildings with square floor plan under wind excitation while allows for generating energy from wind-induced building oscillations. Still, further numerical and experimental work is warranted to examine ground-floor TID efficiency for different wind excitation intensity in a performance-based design context and to compare it to alternative widely used solutions such as top-floor TMDs.

Abstract. This study is intended to discuss feasibility of a long-term scour monitoring for an in-service railway bridge by means of a remote microtremor monitoring. In the context of the structural health monitoring, vibration-based approach might be a promising technique for the scour monitoring of railway bridges, as it is well known that changes in the vibration characteristics of the railway bridge pier under scour is obvious. Japanese railway companies make decisions on occurrence of scour investigating changes in a target frequency. Therefore, the impact test on the railway bridge pier to identify changes in frequencies has been adopted as a promising scour detection method in Japan. However, the impact test is a laborious and time-consuming method, and is inapplicable for the real time monitoring to make a proper decision on the train operation control during heavy rains. This study investigates feasibility of vibration-based scour monitoring as an alternative method for the impact test. A railway bridge with high potential of scour was monitored utilizing a smart sensing unit which includes functions of vibration measurement, data processing and remote control. Observations showed that target frequency was slightly decreased under increase of water surface during flood. However, the decreased frequency recovered once water surface level decreased after flood. Scour assessment following a Japanese guideline showed an extremely low probability of scour.

1 INTRODUCTION

Scouring is the erosion of the riverbed caused by fluctuation in the flow of river, turbulence, etc. The number of bridges with scoured piers is increasing due to the deterioration, heavy rain, and the reduction of sediment supply volume [1]. If scouring occurs around the foundation ground, the substructure may settle, incline, or fall, and thus, train operation should be suspended during flood.

Many Japanese railway companies have adopted an impact test on the railway bridge pier as a promising scour detection method focusing on changes in frequencies. However, the impact test is a laborious and time-consuming method, and is inapplicable for the real time monitoring during heavy rains to make a proper decision on the train operation. Therefore, a remote monitoring system and a decision rule to detect scouring are desired.

This study aims to propose a way to monitor scour of piers of railway bridges efficiently and quantitatively without approaching the target bridge especially during flood. A bridge under operation is monitored as a case study. To estimate the natural frequency of the target bridge, accelerometers are installed on the top of the bridge pier and the connected girders for the impact test, and two sensors on the pier top were left for scour monitoring in terms of long-term ambient vibration monitoring. In modal identification of the bridge, this study utilizes time domain method called stochastic subspace identification (SSI) [2,3,4] that is effective for forced vibrations of bridges. Bayesian operational modal analysis (BAYOMA) [5,6,7] is also adopted for the modal identification from microtremor measurement during flood.

2 METHODOLOGY

2.1 Mode Identification by Stochastic Subspace Identification (SSI)

The dynamical system representing the pier vibration is modeled as the following state space model.

$$\mathbf{x}(k+1) = \mathbf{A}\mathbf{x}(k) + \mathbf{w}(k) \quad (1)$$

$$\mathbf{y}(k) = \mathbf{C}\mathbf{x}(k) + \mathbf{v}(k) \quad (2)$$

Therein, $\mathbf{x}(k)$ and $\mathbf{y}(k)$ denote the state of structure and measurement at each time step k , respectively. Also, $\mathbf{w}(k)$ and $\mathbf{v}(k)$ respectively denote the process noise and measurement noise vectors which are assumed to be stationary white noise. System matrix \mathbf{A} comprising modal information is estimated using least-squares method for the minimal prediction error of the state $\mathbf{x}(k)$ given by the forward Kalman filter. The poles of the dynamical system provide modal properties of the dynamical system.

The algorithm for the SSI is described briefly as follows. First, we obtain the projection matrix \mathbf{O}_i , as estimated from Eq. (3).

$$\mathbf{O}_i = \mathbf{Y}_f \mathbf{Y}_p^T (\mathbf{Y}_p \mathbf{Y}_p^T)^\dagger \mathbf{Y}_p \quad (3)$$

Therein $(\cdot)^\dagger$ denotes the Moore-Penrose pseudo-inverse matrix. \mathbf{Y}_f and \mathbf{Y}_p represent the block Hankel matrices of the future and past outputs as shown in Eq. (4) and Eq. (5).

$$\mathbf{Y}_p = \begin{bmatrix} \mathbf{y}(0) & \mathbf{y}(1) & \dots & \mathbf{y}(j-1) \\ \dots & \dots & \dots & \dots \\ \mathbf{y}(i-2) & \mathbf{y}(i-1) & \dots & \mathbf{y}(i+j-3) \\ \mathbf{y}(i-1) & \mathbf{y}(i) & \dots & \mathbf{y}(i+j-2) \end{bmatrix} \quad (4)$$

$$\mathbf{Y}_f = \begin{bmatrix} \mathbf{y}(i) & \mathbf{y}(i+1) & \dots & \mathbf{y}(i+j-1) \\ \dots & \dots & \dots & \dots \\ \mathbf{y}(2i-2) & \mathbf{y}(2i-1) & \dots & \mathbf{y}(2i+j-3) \\ \mathbf{y}(2i-1) & \mathbf{y}(2i) & \dots & \mathbf{y}(2i+j-2) \end{bmatrix} \quad (5)$$

The singular value decomposition (SVD) is then applied to factorize \mathbf{O}_i as follows.

$$\mathbf{O}_i = \mathbf{U}\mathbf{S}\mathbf{V}^T \simeq (\mathbf{U}_1\mathbf{U}_2) \begin{pmatrix} \mathbf{S}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{pmatrix} (\mathbf{V}_1\mathbf{V}_2)^T = \mathbf{U}_1\mathbf{S}_1\mathbf{V}_1^T \quad (6)$$

where, \mathbf{U} and \mathbf{V} are unitary matrices with appropriate size; \mathbf{S} is a diagonal matrix with non-negative elements. The diagonal elements of \mathbf{S} are known as singular values of \mathbf{O}_i . Singular values in \mathbf{S} are listed in descending order. Therefore, the components in $\mathbf{U}_1\mathbf{S}_1\mathbf{V}_1^T$ include most of the information defining the elements in \mathbf{O}_i . Components in $\mathbf{U}_2\mathbf{S}_2\mathbf{V}_2^T$ are regarded as trivial components. The optimal state sequence predicted by the Kalman filter in a least squares sense is obtained as shown below.

$$\mathbf{X}_i = \mathbf{S}_1^{1/2}\mathbf{V}_1^T \quad (7)$$

where $\mathbf{X}_i = [\mathbf{x}(i) \quad \mathbf{x}(i+1) \quad \dots \quad \mathbf{x}(i+j-1)]$.

The system matrices are obtainable from \mathbf{X}_i . The number of poles corresponds to the number of singular values in Eq. (6). In other words, we can extract the modal response of the bridge from the measured acceleration data by the SVD.

2.2 System Identification based on Bayesian Approach

Assume that the acceleration was collected under ambient condition. Let $\{\hat{\mathbf{x}}_j \in R^n: j = 1, \dots, N\}$ denote the measured acceleration data at n degrees of freedom (DOFs) of a structure, abbreviated as $\{\hat{\mathbf{x}}_j\}$, where N is the number of samples collected in the time domain. The j th acceleration response can be modelled as follows:

$$\hat{\mathbf{x}}_j = \check{\mathbf{x}}_j + \mathbf{e}_j \quad (8)$$

where $\check{\mathbf{x}}_j \in R^n$ denotes the model acceleration response; $\mathbf{e}_j \in R^n$ denotes the prediction error between the measured and theoretical responses, mainly consisting of the electronic noise of the data acquisition system, environmental noise and modelling error.

The FFT of $\{\hat{\mathbf{x}}_j\}$ is defined as follows:

$$\hat{F}_k = \sqrt{\frac{2\Delta t}{N}} \sum_{j=1}^N \hat{\mathbf{x}}_j \exp \left[-2\pi i \frac{(j-1)(k-1)}{N} \right] \quad (k = 1, 2, \dots, N) \quad (9)$$

where the FFT corresponds to the frequency $f_k = (k-1)/N\Delta t$ for $k = 2, 3, \dots, N_q$, with $N_q = \text{int}[N/2] + 1$, being the frequency index at the Nyquist frequency, and $\text{int}[\cdot]$ is the integer part; Δt denotes the sampling interval; $i^2 = -1$.

For well-separated or closely spaced modes, they should be included in a series of specified frequency bands. Let D_i denote the FFT data in the i th selected frequency band containing the

possible modes. According to Bayes' Theorem, the posterior PDF of $\boldsymbol{\theta}_i$ for given data, where $\boldsymbol{\theta}_i$ denotes the modal parameters in the i th selected frequency band, can be expressed as:

$$p(\boldsymbol{\theta}_i|D_i) = \frac{p(\boldsymbol{\theta}_i)p(D_i|\boldsymbol{\theta}_i)}{p(D_i)} \quad (10)$$

where $p(D_i|\boldsymbol{\theta}_i)$ is the likelihood function; $p(D_i)$ is a constant; $p(\boldsymbol{\theta}_i)$ is the prior PDF.

The likelihood function $p(D_i|\boldsymbol{\theta}_i)$ can be obtained as follows. Define a vector $\hat{\mathbf{Z}}_{ik} = [\text{Re}\hat{F}_{ik}; \text{Im}\hat{F}_{ik}] \in R^{2n}$ consisting of the real and imaginary parts of the FFT data in the i th selected frequency band at frequency f_k ; Let $D_i = \{\hat{\mathbf{Z}}_{ik}\}$ which includes all the FFT data in the i th selected frequency band. For large N and small Δt , the vector $\hat{\mathbf{Z}}_{ik}$ is shown to be independent at different frequencies and follow a Gaussian distribution with zero means and covariance matrix \mathbf{C}_{ik} . Therefore, the likelihood function $p(D_i|\boldsymbol{\theta}_i)$ in the i th frequency band can be constructed by a Gaussian distribution, i.e.,

$$p(D_i|\boldsymbol{\theta}_i) = \prod_k \frac{1}{(2\pi)^n \det(\mathbf{C}_{ik})^{0.5}} \exp\left[-\frac{1}{2} \hat{\mathbf{Z}}_{ik}^T \mathbf{C}_{ik}^{-1} \hat{\mathbf{Z}}_{ik}\right] \quad (11)$$

in which, $\det(\cdot)$ denotes the determinant; \mathbf{C}_{ik} , the covariance matrix of $\hat{\mathbf{Z}}_{ik}$, is given by

$$\mathbf{C}_{ik} = \frac{1}{2} \begin{bmatrix} \boldsymbol{\Phi}_i & \\ & \boldsymbol{\Phi}_i^T \end{bmatrix} \begin{bmatrix} \text{Re}\mathbf{H}_{ik} & -\text{Im}\mathbf{H}_{ik} \\ \text{Im}\mathbf{H}_{ik} & \text{Re}\mathbf{H}_{ik} \end{bmatrix} \begin{bmatrix} \boldsymbol{\Phi}_i^T \\ \boldsymbol{\Phi}_i \end{bmatrix} + \frac{S_{e_i}}{2} \mathbf{I}_{2n} \quad (12)$$

where $\boldsymbol{\Phi}_i = [\boldsymbol{\Phi}_{i1}, \boldsymbol{\Phi}_{i2}, \dots, \boldsymbol{\Phi}_{im_i}] \in R^{nm_i}$ denotes the mode shape matrix in a selected frequency band; \mathbf{I}_{2n} is an $2n \times 2n$ identify matrix; $S_{e_i} \in R$ is the PSD of prediction error in the i th frequency band; \mathbf{H}_{ik} is a transfer function, whose element can be expressed as:

$$\mathbf{H}_{ik}(u, v) = S_{uv}[(1 - \beta_{iuk}^2) + \mathbf{i}(2\zeta_{iu}\beta_{iuk})]^{-1}[(1 - \beta_{ivk}^2) - \mathbf{i}(2\zeta_{iv}\beta_{ivk})]^{-1} \quad (13)$$

where $\beta_{iuk} = f_{iu}/f_k$; S_{uv} denotes the cross spectral density between the u th and v th modal excitation. Define $\boldsymbol{\theta}_i = \{f_{iu}, \zeta_{iu}, S_{iu}, \boldsymbol{\Phi}_{iu}; u = 1, \dots, m_i, S_{e_i}\}$, where $f_{iu} \in R$ is the u th natural frequency in the i th frequency band; $\zeta_{iu} \in R$ is the u th damping ratio in the i th frequency band; $S_{iu} \in R$ is the u th power spectral density (PSD) of modal force in the i th frequency band; $\boldsymbol{\Phi}_{iu} \in R^n$ is the u th mode shape of the measured DOFs in the i th frequency band; m_i is the number of modes included in the i th frequency band. It is more convenient to write the likelihood function in term of the 'log-likelihood function', i.e.,

$$L(\boldsymbol{\theta}_i) = -\ln p(D_i|\boldsymbol{\theta}_i) \quad (14)$$

$$p(D_i|\boldsymbol{\theta}_i) = \exp[-L(\boldsymbol{\theta}_i)] \quad (15)$$

Note that the log-likelihood function can be well approximated by a second-order Taylor expansion, and so it can be expressed as

$$L(\boldsymbol{\theta}_i) \sim L(\hat{\boldsymbol{\theta}}_i) + \frac{1}{2}(\boldsymbol{\theta}_i - \hat{\boldsymbol{\theta}}_i)^T \hat{\mathbf{H}}_L(\boldsymbol{\theta}_i - \hat{\boldsymbol{\theta}}_i) \quad (16)$$

where $\hat{\mathbf{H}}_L$ denotes the Hessian matrix of $L(\boldsymbol{\theta}_i)$ when the MPV $\hat{\boldsymbol{\theta}}_i$ is evaluated. Substituting (16) into (15), the likelihood function can be given by:

$$p(D_i|\boldsymbol{\theta}_i) \sim \exp\left[-\frac{1}{2}(\boldsymbol{\theta}_i - \hat{\boldsymbol{\theta}}_i)^T \hat{\mathbf{C}}_{\hat{\boldsymbol{\theta}}_i}^{-1}(\boldsymbol{\theta}_i - \hat{\boldsymbol{\theta}}_i)\right] \quad (17)$$

with

$$\hat{\mathbf{C}}_{\theta_i} = \hat{\mathbf{H}}_L^{-1} \quad (18)$$

denotes the covariance matrix of the modal parameters.

The likelihood function in an individual frequency band can be determined according to equation (11). In the damage detection, usually all the possible identifiable modes will be used and the data in all the related frequency bands will be included. Assuming the data in n_b frequency bands are available, the likelihood function considering all these frequency bands can be given by:

$$p(\{D_i\}|\{\theta_i\}) = \prod_{i=1}^{n_b} p(D_i|\theta_i) = \prod_{i=1}^{n_b} \prod_{k=k_{i1}}^{k_{i2}} \frac{1}{(2\pi)^n \det(\mathbf{C}_{ik})^{0.5}} \exp\left[-\frac{1}{2} \hat{\mathbf{z}}_{ik}^T \mathbf{C}_{ik}^{-1} \hat{\mathbf{z}}_{ik}\right] \quad (19)$$

where $\{D_i: i = 1, \dots, n_b\}$ is a collection of the data in all the frequency bands, abbreviated as $\{D_i\}$; $\{\theta_i: i = 1, \dots, n_b\}$ denotes a collection of the modal parameters in all the selected frequency bands, abbreviated as $\{\theta_i\}$; k_{i1} and k_{i2} denotes the start and end frequency indexes in the i th selected frequency band, respectively.

The prior PDF of θ_i can be constructed as follows. The identified modal parameters can be modelled as

$$\hat{\theta}_i = \theta_i + \epsilon_i \quad (20)$$

where θ_i is the theoretical modal parameters and ϵ_i is the prediction error of modal parameters between identified value and theoretical value. Assuming ϵ_i follows a Gaussian distribution, then the prior PDF of θ_i can be given by

$$p(\theta_i) = \frac{1}{(2\pi)^n \det(\mathbf{C}_{\theta_i})^{0.5}} \exp\left[-\frac{1}{2} (\theta_i - \hat{\theta}_i)^T \mathbf{C}_{\theta_i}^{-1} (\theta_i - \hat{\theta}_i)\right] \quad (21)$$

where \mathbf{C}_{θ_i} denotes the covariance matrix of the modal parameters θ_i in the i th frequency band. Since the modal parameters in different frequency bands can be taken to be independent, the prior PDF considering all these frequency bands can be given by:

$$p(\{\theta_i\}) = \prod_{i=1}^{n_b} p(\theta_i) = \prod_{i=1}^{n_b} \frac{1}{(2\pi)^n \det(\mathbf{C}_{\theta_i})^{0.5}} \exp\left[-\frac{1}{2} (\theta_i - \hat{\theta}_i)^T \mathbf{C}_{\theta_i}^{-1} (\theta_i - \hat{\theta}_i)\right] \quad (22)$$

3 TARGET BRIDGE AND MONITORING INFORMATION

The target bridge is a single railway track steel plate girder bridge. The height of target pier is 11m and width is 2.5m. As there is high potential risk of scouring on the target pier, a long-term scour monitoring has been carried out. The photo of the target bridge pier is shown in Figure 1. The elevation and plan views of the target bridge are shown in Figure 2. Eight triaxial sensors were installed on the top of the pier and connecting girders for the impact test as shown in Figure 2 a). All sensors except two sensors installed upstream and downstream of the pier top were removed after the impact test. Two sensors left on the pier top (see Figure 2b) are for the long-term ambient vibration monitoring. The sampling frequency of the measurement was 200Hz. A laser water level meter is installed on the target bridge.

Figure 1: Photo of target bridge pier.

Figure 2: Elevation view and plan view of the acceleration sensor installation position: a) for the impact test, and b) for the long-term ambient vibration monitoring.

4 MODE IDENTIFICATION OF TARGET BRIDGE

Modal characteristics of the bridge pier were identified from the vibration data excited during the impact test. Stability criteria are used to decide stable vibration modes [11]. Figure 3 shows the stabilization diagram (SD) in which the horizontal and vertical axes respectively stand for the frequency and model order. The black dots indicate modal frequencies associated with each model orders. The red circles indicate stably estimated modes that satisfy predefined deviation tolerances of the modal properties, i.e. the natural frequencies, damping ratio, and mode shapes. This study adopted the frequency deviation tolerance of 0.25 Hz, the damping deviation tolerance of 0.1 %, and the lower bound of Modal Assurance Criteria (MAC) of 0.95.

The vertical blue broken lines show dominant modes that appear stably throughout a wide range of model order and satisfy the deviation tolerances. The dominant frequency was identified at 9.2Hz. Figure 4 shows the mode shape of the dominant mode. As shown in Figure 4, this mode shape is relevant to the transversal rocking mode of the pier.

5 SYSTEM IDENTIFICATION DURING FLOOD

On September 30 in 2018, typhoon no.24 was approached and daily precipitation was 114mm, and ambient vibrations monitored on September 30 and October 1 were investigated to identify dominant frequency of the target pier during the flood.

Figure 3: Stabilization Diagram (SD).

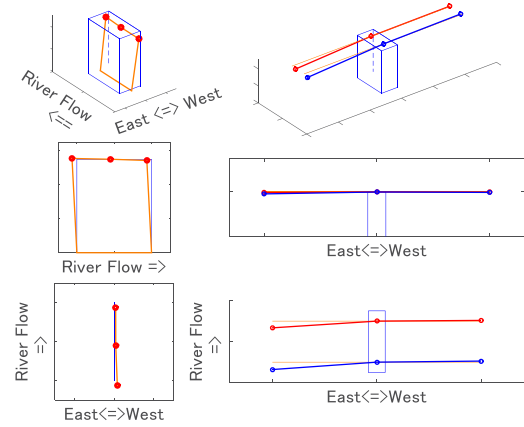

Figure 4: Identified mode shape (9Hz).

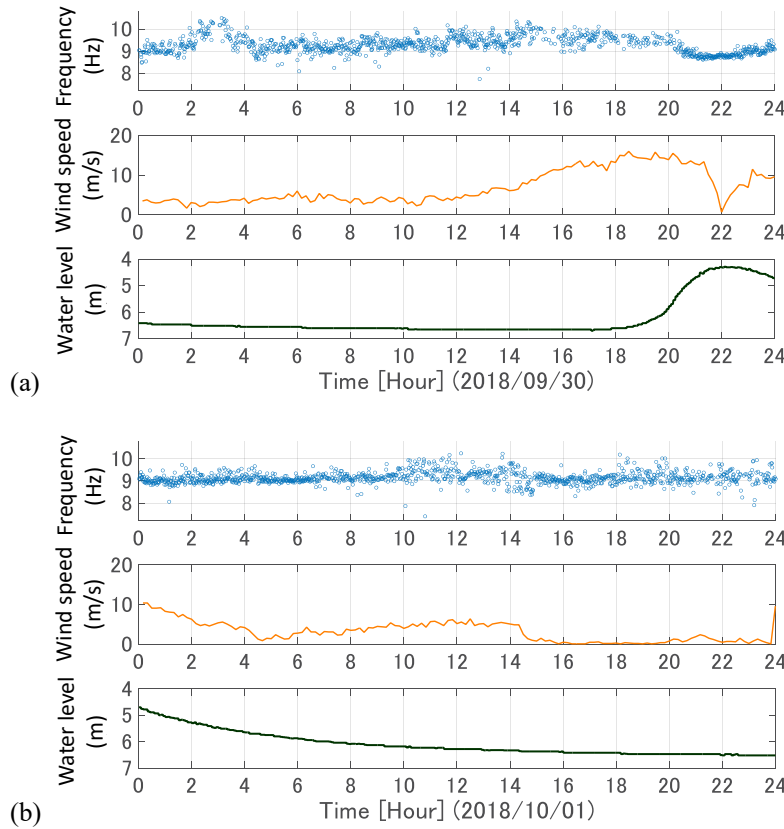

Figure 5: Monitoring data: (a) 30th September 2018; and (b) 1st October 2018.

Plots of the identified frequency per every minute are shown in Figure 5 with observed wind speed and water level. It should be noted that “water level” represents the distance between water surface and lower flange of the bridge girder: i.e. as the water surface goes up, the “water level” gets smaller. In Figure 5, the horizontal axis indicates time, and the vertical axis indicates frequency (Hz), wind speed (m/s), and water level (m) from the top respectively. From 0:00 to

20:00 on September 30 before flood, identified frequencies varied widely between 8.5 Hz and 10 Hz. However, during flood from 20:00 on September 30 to 6:00 on October 1, variation in frequency was quite small. One reason for scattering of identified frequency is the quality of acceleration. Before flood only microtremor measurement whose amplitude was around 0.1 gal was examined. On the other hands during the flood the bridge pier was vibrated by water flows and the maximum amplitude was around 1 gal.

Histograms of identified frequency for different water level are shown in Figure 6. Assuming all distributions follow normal distributions, the mean and variance values are estimated as also seen in Figure 6. The frequency decreases as the water surface level rises (water level decreases), the variance of the identified frequency also decreases. The influence of the additional mass due to flood might be a reason for the decrease of the frequency during flood [12]. The results show that the natural frequency of the bridge pier is identified with high accuracy during the flood condition.

Figure 7 shows that the histogram of identified frequencies during flood: i.e. the water level between 4m and 5m. The blue solid line is the approximate curve of the distribution of the identified frequency. Occurrence of scour during flood is examined following the guideline of Japanese government [13]. The guideline is shown in the Table 1. The soundness index x is calculated by Eq. (23) [13].

$$x = (\text{monitored frequency}) / (\text{frequency of healthy condition}) \quad (23)$$

Table 1: Soundness assessment [13]

Soundness Index x	Category	Assessment
$x \leq 0.70$	A1	Abnormal condition: repair or reinforcement are needed
$0.70 < x \leq 0.85$	A2	Need to check progress of deterioration: <i>e.g.</i> decrease of frequency, etc.
$0.85 < x \leq 1.00$	B	Low possibility of abnormal condition
$1.00 < x$	S	Healthy

Figure 6: Identified frequency distribution: (a) water level more than 6m (before flood); (b) water level between 5m and 6m; and (c) water level between 4m and 5m (during flood).

Figure 7: Histogram of identified frequency from ambient vibration (during flood).

Figure 8: Distribution of natural frequency before and after the flood.

In the guideline, occurrence of scour is decided if it is observed that 85% or less than the natural frequency in the health condition. Therefore, the frequency of 85% of the natural frequency in the health condition is adopted as a threshold of occurrence of scouring. The vertical red solid line in Figure 7 shows 85% of the natural frequency in the healthy condition. It is noted that the mean frequency observed before flood was assumed as healthy condition in scour assessment. The probability of exceeding the threshold was lower than 0.001%, which indicates extremely low possibility of scour occurrence during this flood.

Figure 8 shows the distributions of the identified frequencies before and after the flood. Considering mean values of the identified frequencies 9.23Hz and 9.19Hz for healthy condition and flood condition respectively, the soundness index takes $x = 0.996$ according to Eq. (23), and categorized as B (Low possibility of abnormal condition) according to Table 1. Observations showed low possibility of scouring due to flood.

6 CONCLUSIONS

This study investigates a way of scour detection by means of ambient vibration monitoring of the bridge pier during flood. The natural frequency of the bridge pier was identified with

high accuracy from the ambient vibration during the flood condition. The probability of exceeding the threshold for the scour was lower than 0.001%. Moreover, the soundness index was 0.996 which is categorized as B indicating low possibility of abnormal condition. Observations, thus, demonstrated extremely low possibility of scour occurrence during this flood. This study also demonstrated that it is possible to evaluate scour by using the ambient vibration data during the flood.

ACKNOWLEDGEMENTS

This study is partially sponsored by a Japanese Society for the Promotion of Science (JSPS) Grant-in-Aid for Scientific Research (B) under project No.19H02225, which is greatly appreciated.

Abstract. This contribution presents an experimental analysis of the control system configuration for a semi-active frame structure. The structure is equipped with a system that implements a Prestress Accumulation Release strategy for mitigation of vibration. A proper distribution of the sensors for monitoring the actual state of the structure is the key factor that determines the overall effectiveness of the applied strategy. The results and findings presented here reveal a set of basic rules dedicated to solving this crucial issue.

1 INTRODUCTION

Prestress Accumulation Release (PAR) is a recently developed control strategy for mitigation of structural vibrations [1,2], which belongs to the class of semi-active control approaches [3]. It utilizes an extremely effective approach, based on the concept of controllable structural constraints, which assumes that it is possible to introduce short lasting modifications of the local effective stiffness of vibrating structures. In practice, the method requires dedicated, semi-actively controllable fuses to be implemented in the structure, which allows local mechanical properties to be modified in a controllable way [4].

The investigations published until now revealed, both numerically and experimentally, a superior effectiveness of the PAR-based vibration control approach, which stems from an optimization procedure and a basic mechanical analysis of the control problem [2]. The experimental verification of the previous results was focused on testing of the control law and on implementing the control algorithm [5], and it prepared the ground for developing a methodology for the optimal distribution of the semi-active fuses within the structure [6].

The idea of the localised control algorithm assumes that internal energy level is monitored locally in a structure and dissipated accordingly [7]. Therefore, it is preferable that the semi-active joints are collocated with the sensors. This is an essential advantage of the concept in comparison to the control systems with the global response monitoring approach. It can be achieved due to the fact that the span of the sensor placement is limited to the direct neighbourhood of the semi-active elements and therefore such a compact installation may be characterised with low complexity and be less expensive. Nonetheless, the exact localisation of

the sensor needs to be determined precisely. The experimental survey presented in this contribution aims at determination of sensors placement of such a type that a system observability is sufficient for the performance of the controller.

2 EXPERIMENTAL INVESTIGATION METHODOLOGY

The examined structure is a frame in a cantilever configuration as depicted schematically in Figure 1. The general dimensions of the frame are 1200 mm length and 300 mm width. The cross-section of the structural members is a square tube 30 mm in height and 15 mm in width. The thickness of the wall is 2 mm. An internal part of the frame is the semi-active member consisting of two joints with an interconnecting element positioned in between. The semi-active member is located between the branches of the structure in a distance of 600 mm from the support, which is half of the total length of the frame. The utilized sensors are strain gauges in a half bridge connection type and configured for measurements of the in-plane bending in the frame members. The coordination system adopted for this investigation is depicted in Figure 1.

Figure 1: Scheme of the experimental frame and location of sensors #1 – #6

The frame under examination has the eigenfrequencies determined in a spectral testing. The parameters of the structure are given in Table 1.

Table 1: Eigenfrequencies of the in-plane modes

Mode No.	1	2	3
Eigenfrequencies	13.6	38.8	125.3

The testing procedure for this investigation is following. Firstly, six potential sensing locations are determined and evenly distributed on the structure. There are two locations per each of the frame branches, as depicted in Figure 1. Due to symmetry of this particular structure,

the locations are chosen in the neighbourhood of only one of the semi-active joints. Secondly, in order to reveal the sensor locations with satisfactory system observability of the structural eigenfrequencies, spectral tests of the frame in a passive mode (not activated semi-active joints) are carried out. Thirdly, the influence of the sensor location on the overall algorithm effectiveness is assessed by means of quality tests.

The locations of the sensors are evaluated on the basis of the following three criteria:

1. the highest possible level of system observability of the modal vibrational forms exhibited on the structure,
2. the lowest possible level of disturbances created by the semi-active member,
3. a satisfactory level of the overall control procedure quality.

The quality of the vibrational response of the system is tested in a SISO (Single Input Single Output) setup. The FRF accelerance functions are calculated and the resulting amplitudes are compared. The input is a swept sinusoidal force signal in a defined driving location and the output is a vibration level in a defined reference location. The two locations on the structure are determined as constant for the test:

1. Driving Point, which is the point through which vibrational excitation is introduced to the structure by means of a modal shaker (Figure 1).
2. Reference Point, which is the point of acceleration measurement and which is dedicated for assessment of control algorithm quality (Figure 1).

3 RESULTS

The results of the experiments are presented in three groups. The first group introduces the spectral characteristics of the Driving Point and Reference Point. The second group of results presents the spectral responses of the sensors in a passive state of the structure (not activated semi-active joints). The third group reflects how the operation of the activated joints influences

3.1 Spectral characteristics of Driving Point and Reference Point

The quality reference case for the study are accelerance functions (Figure 2) obtained as an effect of an FRF calculation in a passive system. Measurement of acceleration and force is conducted along direction OX (as defined in Figure 1).

The Driving Point response, depicted in colour red in Figure 2, indicates three clear resonances, which suggests that the exciter is connected in a right location to excite the first three in-plane modal forms. The in-plane modal forms are the only properly excited ones in this particular configuration of the experimental setup. It is due to the fact that the signals have been measured in accordance to the chosen excitation direction and measurement direction (OX). The other line on the graph (colour green) depicts the frequency response of the Reference Point, which is positioned on the free tip of the tested frame (Figure 1). The presented FRF graph proves that the Reference Point reflects the mechanical response of the structure in all of the considered in-plane modal forms and can be utilized as a control quality indicator and for assessment purposes.

Figure 2: Accelerance functions of the tested system

3.2 Spectral responses of the sensors

Sensor placement is tested on the example of six locations of the strain gauges. The location scheme of the sensors is presented in Figure 1 and denoted as #1 – #6. The sensors are distributed in defined distances from the semi-active node. The graphs in Figures 3–5 present the FRFs of the signals acquired with the particular sensors. The objective of this study is to determine the responsiveness of the particular locations and reflecting it on the FRF graphs. High amplitudes of resonances, exhibited on the particular graphs, indicate that a particular sensor generates a signal, which is characterised by a sufficient SNR (signal to noise ratio) for the control purposes. The criterion for assessing the particular sensor locations is based on the spectral modes observability in the system determined on the basis of the FRF functions. A sufficient location is characterised by a defined level of the FRF amplitude and the threshold is established on level 1 $\mu\text{E}/\text{N}$.

Figure 3 presents the data acquired for locations #1 and #2. These location are characterised by a high observability of the in-plane modes of the structure and therefore satisfy the demands of the system design. Figure 4 depicts the FRFs that characterise the responses in locations #3 and #4, which indicate that both sensor #3 and sensor #4 exhibit lacks in system observability of modes 3rd and 1st respectively. Figure 5 presents that the sensor localised in position #5 allows for observations of all three vibrational modes, which predestines it for adopting in the control system design.

In summary, two locations #2 and #5 seem to exhibit the most favourable features from the point of view of the signal quality. One of them is positioned on the semi-active member of the structure and the other one is positioned on the structural element. Further analysis of the locations is provided in the next section.

3.3 Effectiveness of the control procedure

The following section discusses the third group of the results, in which the influence of the activated joints on the structure is studied. The tests are configured in order to carry out an experiment with each of the six tested sensor locations. The experiments are sweep tests of the frame in the control mode. Each experiment is conducted with a specific sensor. The algorithm applied for the test is described in [1] and it follows a rule, in which the joints reduce their torque transmission periodically for a 3 millisecond periods. The time instants for the transmission reduction are determined as the instants of the maximal value of the local internal energy of the structure. The results of the system operation in the controlled mode are presented in Figures 6–8. All of the sensors provide a signal that is functional in the tested control system. The results related to the specific sensors are summarised in Table 2.

Table 2: Accelerance amplitudes under the control procedure

Control case	1 st mode shape			2 nd mode shape		
	Absolute amplitude	Relative amplitude	Gain	Absolute amplitude	Relative amplitude	Gain
	[g/N]	[%]	dB	[g/N]	[%]	dB
Passive	0.187	–	–	0.533	–	–
Controlled with sensor #1	0.026	13.9	-17.1	0.321	60.2	-4.4
Controlled with sensor #2	0.056	29.9	-10.5	0.298	55.9	-5.0
Controlled with sensor #3	0.03	16.0	-15.9	0.304	57.0	-4.9
Controlled with sensor #4	0.044	23.5	-12.6	0.339	63.6	-3.9
Controlled with sensor #5	0.034	18.2	-14.8	0.282	52.9	-5.5
Controlled with sensor #6	0.075	40.1	-7.9	0.243	45.6	-6.8

4 DISCUSSION

Effects of the control system on vibrational response of the structure are noticeable for each of the sensor locations as suggested in the results in Table 2. In most of the cases, the reduction of the accelerance amplitudes is correlated with the quality of the signals generated by the sensors. Sensor locations #1 and #2 both exhibit high system observability of the vibrational modes and in the both cases the amplitude of accelerance is reduced by 17.1 dB and 10.5 dB respectively (Table 2). Contrary to what was expected of the test, the control quality (Figure 6) does not reflect that the sensor location #2 is characterised by a significantly higher system observability level in reference to the sensor location #1 (Figure 3). A possible reason can be that the acquired results are influenced by the stochastic character of the phenomenon. A good correlation between the signal quality and the control results can be observed for the sensor locations #3 and #4. The signal generated in location #4 has low quality for mode no1 and it is reflected in the results of control effects. However, even though the signal acquired seem to be relatively poor in quality, the vibration accelerance amplitude is reduced by 12.6 dB, which indicates a satisfactory level of the control effectiveness. Evidently, lower effectiveness of the control and therefore good correlation with the signal quality can be observed in the case of sensor location #6. The signal quality in location #6 is low for both 1st and 2nd vibration modes of the structure (Figure 5). In contrast, the sensor location #5 exhibits high quality of the signal (Figure 5). This is reflected in the effectiveness of the control procedure. The structure controlled with a system based on sensor location #5 is over 2 times more effective in comparison to location #6. Another important factor is the fact that the semi-active joints

introduce self-vibration during operation. This can disturb the sensor readings in the direct neighbourhood of them. In the analysed case the most endangered sensor location is #5. However, the control effectiveness results disprove this thesis.

5 CONCLUSIONS

The presented results provide a contribution over a specific case, in which a frame is excited in the described, unique, in-plane configuration. That gives a specific results related to the particular configuration of the sensor placement. However, the objective of this work is to derive knowledge about general rules of the sensor placement in the localised control approach. The following clues can be drawn from the conducted research:

1. The basic conclusion coming from the study is that a control system based on the PAR algorithm is sensitive to local distribution of the sensors which makes the study crucial from the point of view of the system preliminary configuration.
2. An improper determination of a sensor location can decrease the effectiveness of the control procedure even by 200%.
3. The system governed by the PAR algorithm exhibits a significant effectiveness of the vibration control (Gain: 13–17 dB).
4. Even suboptimal distribution of the sensors results in an effective vibration reduction, which suggests that the system is robust to slight incorrectness in the final sensors positioning.
5. Vibration induced by the joints by themselves do not interfere with the control input signal and the procedure can be performed successfully.
6. A satisfactory level of correlation is observed between the system observability in the particular locations and the control effectiveness. The method of observability assessment in the sensor locations can be considered as a potential solution in the case of practical implementations.

Key words: Continuously Variable Transmission, Mechanical Speed Variator, Inerter, Tuned Mass Damper

Abstract. In this paper we investigate mechanical speed variator for novel tuned mass damper (TMD) application equipped with inerter. In such application inerter consist continuously variable transmission (CVT). Hence the motion of the transmission is oscillatory and we test it for the actual working conditions. We derive the mathematical model of the mechanical speed variator. We analyse the actual transmission ratio, internal motion resistances and identify the inertia of mechanical speed variator components and validate further. We apply actual working conditions and compare the experimental and numerical exciting torques of the CVT. We obtain good agreement between them, hence the proposed model is robust and gives reliable results. Finally, we apply model of the mechanical speed variator into our TMD and propose possible application.

1 INTRODUCTION

The idea of tuned mass dampers (TMD) has more then one hundred years. It is a device designed to reduce undesired oscillations of a structures by addition of a additional body to the system instead of changing its support properties. The first solution was proposed by Frahm in 1909 [1]. The simple device consisted of a mass and a spring. Its natural frequency was tuned to natural frequency of the damped body. Despite impressive performance in resonance and its close neighborhood it was poorly efficient outside the narrow range. The improvement was made by Den Hartog [2] by adding dash-pot between the TMD and damped structure which causes significant increase of TMD efficiency range. Alternative idea concerns interchange the linear spring of TMD by the nonlinear one (with the linear and nonlinear parts of stiffness) [3, 4] or with purely nonlinear characteristic [5, 6, 7]. Further studies led to applications with multiple TMD instead of one [8, 9, 10, 11] able to work with more complex system with multiple natural frequencies. Recently, a novel concept of varying the tuned mass damper natural frequency has been applied using TMD with variable inertia [12, 13].

One of crucial part in solution presented in [13] is continuously variable transmission (CVT). Authors in [14] use belt driven CVT for inertia change. Nowadays CVT is well know transmission design, firstly presented by Leonardo da Vinci. Mechanical designers can select from many realizations of it, following the best type for the chosen application. Currently the most popular types are variable-diameter pulley (VDP), toroidal and speed variators. The first, belt driven transmission consists two pulleys divided into

two sheaves each and a V-belt. Depending on application a steel reinforced rubber V-belt or a chain can be used. Another type is toroidal CVT transmitting power between discs through system of rollers. Transmissions that type can be be partial or full toroidal. Similarly to the belt driven CVTs, efficiency requirements determine the design. The last group are mechanical speed variators. They are designed to provide a variable speed drive. Its main advantage is mechanical and continuously change of the transmission ratio. Such devices are mainly used for production purpose and design to work in specific direction of motion.

According to the main research of our group concerns tuned mass dampers (TMDs) we decided to examine variator as a potential part of a inerter and TMD [13, 14]. We modify CVT produced by Motovario in order reduce internal motion resistance what is a critical factor in case of TMD performance [15, 16]. Considering that type of the CVT as a part of TMD makes difference in operating conditions. Instead of typical one directional motion such application demands bidirectional rotations.

To examine properties of modified variator we create its mathematical model and perform several experimental tests. We study the actual transmission ratio, internal motion resistances and identify the inertia of mechanical speed variator components and validate further. We conduct test with actual working conditions and compare the experimental and numerical exciting torques of the CVT. Obtained good agreement between them, we prove proposed model robustness. We simulate actual working conditions of the mechanical speed variator as a part of complete TMD system. We present results for our laboratory rig showing limitations due to internal motion resistance. Finally, we modify parameters of the damped construction and TMD showing good system performance and proving mechanical speed variator application.

2 INVESTIGATED DEVICE

2.1 Description and model of the modified variator

In this section we introduce the model of the modified CVT produced by Motovario. Our version of this CVT is modified for our specific propose and its properties vary from original one. The schematic model is shown in Fig. 1. The divide is symmetric, hence we draw its half and we neglect all parts that are not involved in the kinematic chain. In panel (a) we show a schematic cross-section of the device with numbering of all parts. Then, in panel (b) we show the front view with geometrical dimensions and we mark all characteristic points. The last panel (c) includes the back view of plate (No. 3). Now let us describe the operation of the device. The output shaft (No. 1f) has velocity ω_1 and it rotates with all parts attached to it (Nos 1a-e). Parts Nos 1a and 1b are internal fixed and mobile tracks respectively. The planet (No. 2) is placed and between them. The necessary pressure to transfer the motion between tracks and planet without slips is ensured by four Belleville springs (No. 1c) which are tensioned in respect to the shaft (No. 1a) via stop ring belleville springs (No. 1d) and Seeger ring (No. 1e). The performed modification concerns reduction amount of Belleville washers by one. The planet (No. 2) is in contact with inertial tracks in point *B* and with external fixed and mobile tracks (Nos. 4a,b) in point *C*. It can rotate in planet bush and slide radially according to paths in the input shaft part No. 3b. One of the external tracks is fixed to the body of CVT (No. 4b) and do not perform any motion. The second external track control gear ratio by its linear movement caused by tension in spring - part No. 4c. Point *C* is a instantaneous center of zero velocity ($V_C = 0.0$ [m/s]). The planet performs the plane motion in respect to external tracks.

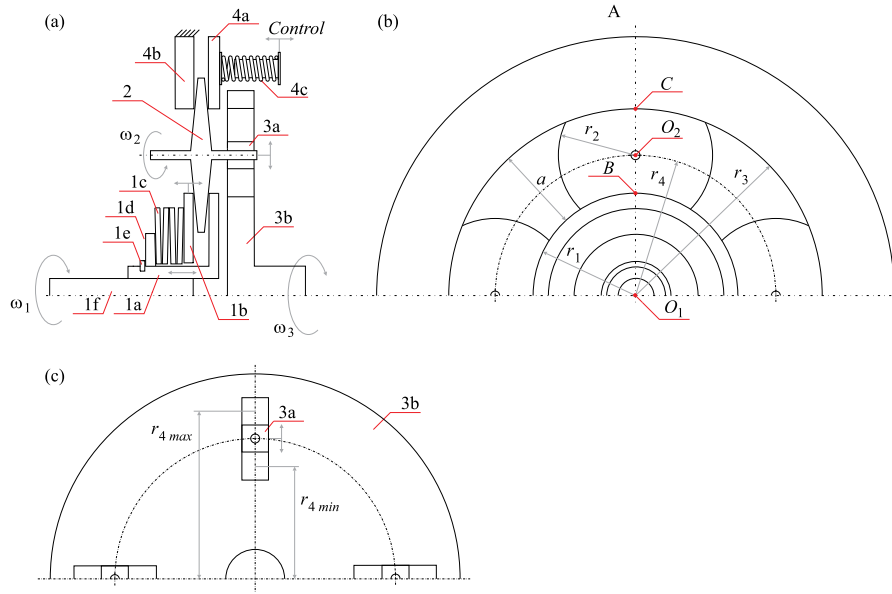

Figure 1: Schematic model of the modified variator.

Now, let us introduce the kinematic relation between all parts of the CVT. The output angular velocity in respect to point O_1 is ω_1 , so $V_B = \omega_1 r_1$. The same velocity can be calculated in respect to point C : $V_B = \omega_2 a$, where $a = (r_3 - r_1)$. This let us calculated the angular velocity of planet: $\omega_2 = \frac{\omega_1 r_1}{a}$. The distance between points C and O_2 is the difference $(r_3 - r_4)$, so the velocity of planet in its center (O_2) is $V_{O_2} = \omega_2 (r_3 - r_4)$. The same velocity has plate (No. 3) $V_{O_2} = \omega_3 r_4$ so the relation between output and input angular velocities are given as follow:

$$\omega_1 = \omega_3 \frac{ar_4}{r_1(r_3 - r_4)} = \omega_3 i, \quad (1)$$

where i is gear ratio. The values of parameters are as follow: $r_1 = 0.0359$, $r_3 = 0.0630$ and r_4 is controlling parameter.

The next step is the dynamical model of the CVT. We assume that the motion is without slips, so the device has one DoF. We divide the moving parts into three groups: input shaft and all connected parts (Nos 1a-f) with total moment of inertia I_1 , planet with moment of inertia I_2 and output shaft with moment of inertia I_3 . The total kinetic energy is as follow:

$$T = \frac{1}{2} I_1 \omega_1^2 + 4 \left(\frac{1}{2} I_2 \omega_2^2 + \frac{1}{2} M_p V_{O_2}^2 \right) + \frac{1}{2} I_3 \omega_3^2 \quad (2)$$

where M_p is mass of planet (there are four planets in the CVT). We use kinematic relations for ω_1 , ω_2 and V_{O_2} to find the equivalent moment of inertia I_{eq} of the system:

$$I_{eq} = I_1 i^2 + 4 \left(I_2 \left(\frac{r_4}{r_3 - r_4} \right)^2 + M_p r_4^2 \right) + I_3. \quad (3)$$

Hence, the equation of motion is as follow:

$$I_{eq} \ddot{\phi}_1 + f(\dot{\phi}) = M_{ext} \quad (4)$$

where $f(\dot{\phi})$ is the internal resistance function which is dependent on the current ratio of the CVT. M_{ext} is external torque applied to the input shaft.

2.2 Laboratory rig

We examine mechanical speed variator in order to find the gear ratio characteristics and value of the inertial motion resistances. While, the first parameter is important from control point of view the second affects overall system performance. Tests are carried out on small laboratory rig designed and build for this particular task. We use structure of the variator (see Fig. 1) and additional parts creating system presented in Fig. 2.

Figure 2: Isometric views of the test rig for the modified CVT (a) project (b) practical realization. Parts presented in the figure: 1 - Supporting profiles, 2 - Angle brackets, 3 - Servo plate, 4 - Servo motor, 5 - Two claw clutches, 6 - Torque sensor, 7 - Sleeve, 8- Motovario supporting plate, 9 - Motovario, 10 - Flywheel.

Therefore, the additional parts are placed on the supporting aluminum profiles (parts Nos. 1) which is a base for an angle brackets (parts Nos. 2) and for a servo plate (part No. 3). Servo motor (part No. 4) is screwed to the servo plate and it drives the CVT with two claw clutches (parts Nos. 5) and torque sensor (part No. 6) mounted between them. The connection between the second clutch and the variator (part No. 9) is realized by the sleeve (part No. 7). Variator is mounted on supporting profiles through supporting plate (part No. 8). At the output shaft of the variator the flywheel (part No. 10) is mounted. The servo motor is driven by a driver controlled from the PLC.

3 TEST OF CVTs CRUCIAL PARAMETERS

3.1 Gear ratio in dependence on rotations of the control knob

Gear ratio for modified variator vary from $1.55[-]$ to $3.15[-]$ achievable with 10 rotations of the control knob. In this case the results are shown in Fig.3 where we can see the nonlinear dependence on angular position of the control knob. Such characteristic exists due to construction of the CVT. Nevertheless there is no hysteresis effect proving transmission robustness and ease in control. According to measured variator parameters we obtain numerical correlation between the control knob rotations and position of r_4 . One can see good correctional between numerical model and the experimental results.

Figure 3: Gear ratio in dependence on rotations of the control knob for the modified variator.

3.2 Internal motion resistance

In next step, we examine the inertial motion's resistance. We choose five specific points equally distributed on the gear ratio characteristic plot. The test rig is equipped with the torque sensor which allows to create the torque versus angular velocity plots. Plots are created with respect to the input velocities of CVTs. In measurements we assume that the input velocity vary in range from -350 [rpm] to 350 [rpm], hence we run the servomotor with constant velocity in counterclockwise and clockwise direction respectively. The internal resistance of the modified variator varies in $\langle 0.8, 2.0 \rangle$ [Nm] range (see Fig. 4). The highest values are observed for low speed of the output shaft and values of internal resistance significantly decrease with increase of the CVT's velocity. The reason of this phenomenon is the oil distribution over the cooperating tracks and planets. The lubrication is achieved by motion of the planets which distribute the oil over all moving elements. In case of the low rotational speed the oil drips into the sump being integral part of the transmission body. According to that the oil cannot be properly distributed to the higher parts of transmission which cause the increase of the internal resistance. Another aspect of observed phenomenon is that the increase of the gear ratio causes the increase of the velocity of the planets and better oil distribution which results in reduce of the resistance. Hence, the general conclusion is that the higher velocity causes better distribution of the oil and decreases the internal resistance.

We also prepare mathematical model of the internal motion resistance. It is formulated as follows:

$$\begin{aligned} & \frac{1}{2} \left(-\frac{2}{\pi} \arctan(10^5 \phi) + 1 \right) (p1 \arctan(p2\phi) + p3) + \\ & \frac{1}{2} \left(\frac{2}{\pi} \arctan(10^5 \phi) + 1 \right) (p4 \arctan(p5\phi) + p6) = f(\phi). \end{aligned} \quad (5)$$

It is based on \arctan function, consists shape parameters, namely from $p1$ to $p6$ and depends from the shaft rotational velocity. It allows different characteristic for negative and positive shaft velocities.

Hence parameters from $p1$ to $p3$ represents negative values of the shaft rotational velocity. Contrary parameters from $p4$ to $p6$ represents positive direction of the shaft rotations. In result we are able to precisely replicate experimental results from laboratory rig. We identify friction parameters according to the model. Tests are carried out for three transmission ratios $i = 1.55 [-]$, $i = 2 [-]$ and $i = 3.15 [-]$. In result, blue curve in Figure 4 is generated. Basing on experimental data we fit internal motion resistance model parameters. In result we obtain a curve fitted to the direction of the shaft velocity. The modeled internal motion resistance model is marked red in Figure 4. For all cases we receive sufficient agreement between the model and the experiment.

Figure 4: Internal motion resistance as a function of input shaft velocity. Blue curve correspond to experimental data, whereas friction model is marked blue. Three subplots represents gear ratios: (a) $i = 1.55 [-]$, (b) $i = 2 [-]$ and (c) $i = 3.15 [-]$.

3.3 Oscillatory trapezoidal test

The trapezoidal velocity path is controlled with the PLC and the programmed trajectory is presented in Fig. 5. The plot is exemplary, but the values of its parameters given in text correspond to values used in measurements. The motion starts with a small jump to the initial velocity equals $s_0 = 0.3 [\text{rad/s}]$ followed by acceleration to a target speed $s_t = 31.42 [\text{rad/s}]$ in $t_a = 300 [\text{ms}]$. The system performs six rotations (the controlled target value) of the input shaft with constant velocity and decelerates in $t_d = 300 [\text{ms}]$ to the final velocity s_0 . Next stage is a stop followed by change of the rotation direction which takes $t_s = 1 [\text{ms}]$ and is restricted by the motor driver. Then, the same sequence is repeated for the opposite direction of motion.

Figure 5: The exemplary trapezoidal velocity path.

We subject to this test transmission for selected transmission ratios. The results obtained for transmission ratio equals to $i = 1.55 [-]$ are presented in Fig. 6. Figure poses three subplots corresponding to the angular positions and the angular velocities of the input and output transmission's shafts marked with blue and red lines respectively. Last subplot presents the torque needed to be applied to achieve the desired velocity path. The diagrams starts during acceleration to the constant negative value of the rotational velocity. Hence it starts with decreasing value of driving torque which levels at constant value equals transmission internal motion resistance. After motion with constant velocity system beginning deceleration stage with reduction of driving torque. Amount of internal motion resistance makes deceleration process too quick and in order to follow velocity path drive controller reacts by adding additional negative torque. After the stop system starts to accelerate to the target speed in clockwise direction which is possible by increase of positive torque. Than, torque stabilizes at target level. We observe minor fluctuations of the velocity during the motion with constant velocity caused by the unbalance of the output shaft. The six rotations are followed by deceleration which leads to the system stop followed by acceleration with negative torque. Presented sequence is repeated in a same way in the second period. We perform same test for transmission ratio equals to $i = 2 [-]$ and $i = 3.15 [-]$. We validate mathematical model, comparing experimental torque-time traces with numerical results. For all transmission ratios we obtain good agreement. Moreover we divide the equivalent moment of inertia into input and output shaft moment of inertia. We use obtained results to study possible application of mechanical speed variator for the TMD.

Figure 6: Three subplots represents positions (a), velocities (b) and torque (c) for input (blue) and output (red) transmission shafts in oscillatory motion test. Test is performed with ratio equals to $i = 1.55$ [–] and obtained by trapezoidal forcing.

4 Application of analyzed CVT to TMD

In this section we present application of the studied CVT to TMD with inerter that enables changes of inertance. Inerter is a two terminal device in which force is proportional to the relative acceleration between its ends [17]. Typically, inerter is attached to oscillating bodies. It is a mechanical device where the linear motion is changed into rotational via mechanical gear, hence the energy of vibration is accumulated in the rotating flywheel [18, 19]. In our realization between gear and flywheel we placed CVT, hence we are able to change inertia of inerter. We introduce such device in 2015 [13]. The changes of inertia is realized via change of the gear ratio of the CVT which cause increase or decrease of inertia of the CVT. If we divide the inertia by pitch radius we obtain inertance (I_n [kg]) which is added to total mass of TMD, hence the equivalent mass of TMD is as follow: $(m + I_n)$. Thanks to variable inertance we are able to vary equivalent mass of TMD, thus we are able to change its natural frequency and tune it to current frequency of excitation. In our previous papers we present such TMD with CVT designed in our lab. In this paper we analyze out of shelf CVT with modifications. The main difference in compare to our CVT is larger internal motion resistance, which is crucial to proper operation of TMD (the lower internal motion resistance causes better damping properties). CVT investigated in this paper has approximately two times larger internal motion resistance. In this section we show how it affect damping properties.

4.1 Mathematical model of TMD

In this subsection we present the mathematical model of TMD with inerter attached to damped body presented in Fig. 7. Such system has two DoF and its motion is described by two generalized coordinates: the position of the main oscillator by coordinate x , while the displacement of the TMD by coordinate y . The main oscillator is characterized with the following parameters: M is its mass, K is the stiffness

of the single spring that connects the main mass to the ground, $C = \xi_1 2\sqrt{7KM}$ is the viscous damping coefficient of dash-pot that links mass M and the support and ξ_1 is its damping ratio. The system is forced kinematically via a spring of stiffness K with the displacement $a(t) = A \cos(\omega_e t)$.

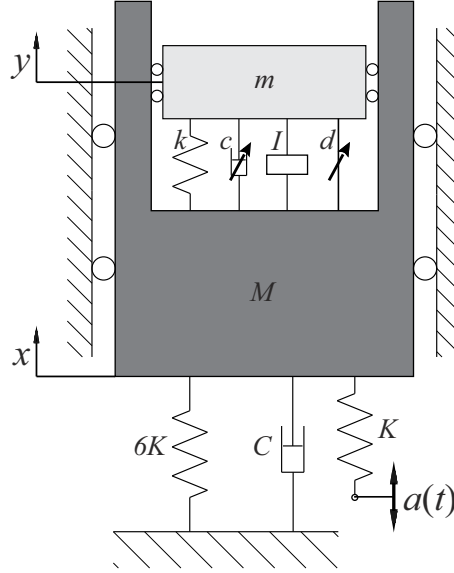

Figure 7: Physical model of the system.

To characterize TMD we use the following parameters values: the moving mass is given by m , the stiffness of the spring that connects it to the main oscillator is described with parameter k . The viscous damper that connect mass m with M is an active device and its damping coefficient $c = \xi_2 2\sqrt{km}$ can be changed according to controlling function. In this study we use two options, i.e., small ($\xi_2 = 0.0222$) and large damping ($\xi_2 = 0.2$). The dry friction force function $f(\dot{\phi})$ corresponds to internal motion resistance of the CVT and for simplicity we use values for $i = 3.15$ [–] (the lowest internal resistance). Inertance $I(i)$ is calculated based on formula ???. Inertia of CVT with flywheel is calculated based on Eq. (3) for ranges of ratio described in subsection 3.1. When we divide inertia by pitch radius $r_p = 0.42$ [m] we obtain the inertance in range $I(i) \in (3.01, 17.2)$ [kg]. Values of other parameters correspond to real existing rig described in our previous papers (see [14, 16]) and are as follow: $M = 102.66$ [kg], $K = 8181.0$ [N/m], $\xi_1 = 0.0041$, $m = 11.26$ [kg], $k = 10448$ [N/m], $A = 0.0148$ [m] and $\omega_e \in (10, 30)$ [rad/s]. To show how proposed device is working for larger total mass of main system and TMD we introduce the scaling factor α . Thus, the dynamics of the system presented in Fig. 7 is governed by the following equations of motion:

$$\alpha M \ddot{x} + \alpha 7Kx + C\dot{x} + \alpha I(i)(\ddot{x} - \ddot{y}) + \alpha k(x - y) + c(\dot{x} - \dot{y}) + f(\dot{\phi}) = \alpha Ka(t), \quad (6)$$

$$\alpha m \ddot{y} - \alpha I(i)(\ddot{x} - \ddot{y}) - \alpha k(x - y) - c(\dot{x} - \dot{y}) - f(\dot{\phi}) = 0. \quad (7)$$

As it easy to see we do not scale internal motion resistance of the CVT because it does not change with change of inetance. Damping coefficients (C and c) are described as factors (ξ_1 and ξ_2) of critical damping, hence they also scale with varying α .

Figure 8: FRCs for different masses of main system.

In Fig. 8 we present the FRCs (frequency response curves) of main body for different configuration of the TMD. In Fig. 8 we present the response of the main system for $\alpha = 1$ without TMD (black line) and with TMD for $\alpha = 1$ (red line) and $\alpha = 3$ (blue line). The inertance for cases with TMD is equal to $I = \alpha \times 10.56 [kg]$. The amplitude for case without TMD reaches $0.255 [m]$ (we cut this plot above $0.05 [m]$ for better visibility). One can see that system with TMD for $\alpha = 1$ reduces amplitude of the main system but the internal motion resistance of the transmission limitates amplitude reduction. TMD with controlled CVT for such configuration is not beneficial in comparison to a classical optimized TMD. Contrary system with TMD for $\alpha = 3$ reduces influence of the internal motion resistance. Hence one can see significant decrease of the amplitude of the main system.

5 CONCLUSIONS

In this paper we show the comprehensive experimental investigations of the CVT. We modify variator produced by Motovario in order to validate it application for the novel TMD [13, 14] which can be tuned to the current frequency of external excitation to efficiently mitigate vibrations. We perform several tests of the CVT to assess its performance and validate its simplified mathematical model. We examine gear ratio in dependence on rotations of the control knob, internal motion resistance and inertias of transmission shafts. We also create mathematical model of the transmission. Identified parameters allow us to validate the prepared model with satisfactory results. Furthermore we implement modeled variator into our model of the TMD. We restricted considered case to constant inertance in order to trace application for the modified TMD. In case of application to the TMD and inerters the internal motion resistance is critical factor. Hence we prove that internal motion resistance in the modified variator is too large for application in our laboratory rig. Nevertheless we show that it is possible to scale the system by three times and obtain proper working conditions. We prove that variator type transmission can be used for damping oscillations of a large constructions with TMDs.

Key words: Modal control, Semi-active control, Lockable joints, Energy harvesting.

Abstract. This contribution proposes a semi-active control approach for a directed energy transfer between structural vibrational modes. The motivation is the intended localization of the vibration energy in a selected mode for the purpose of energy harvesting and mitigation of structural vibrations. The proposed control strategy aims at the instantaneous maximization of the energy transfer to the target mode. It is based on an untypical approach of dynamic structural reconfiguration and implemented using a semi-actively controllable node: a lockable joint. Such a joint, depending on the control signal, can act as a hinge or as a typical frame node. Effectively, it provides thus an on/off ability to control the transfer of bending moments between the adjacent structural elements. The effectiveness of the approach is demonstrated in a numerical example of a plane frame structure.

1 INTRODUCTION

Attenuation of vibrations is a well-known problem [1] with a range of possible optimal control formulations [2]. The topic of vibration reduction by accumulation of the related energy, which is known as energy harvesting, is relatively less explored [3]. Usually, the structural excitation cannot be directly controlled nor easily predicted; it may have a broad frequency spectrum or take the form of rare impulsive shocks that result in free vibrations. The uncertain characteristics of the excitation can affect the efficiency of the energy harvesting process, because the energy-harvesters are usually designed for a single vibration frequency. This problem has motivated the development of a semi-active control strategy that allows the vibration energy to be transferred between selected vibrational modes, so that the energy-harvesters can be efficiently excited.

Controlled energy transfer between vibrational modes can be also used for the related purpose of attenuating the vibrations. Transferring the energy to a mode with a large amplitude at the position of the energy dissipator can speed up the process of vibration reduction. Besides, such an approach can be used to transfer the energy of vibrations to such modes that do not interfere with the intended operation of the structure. The method proposed in this contribution is formulated in a relatively general way, which makes it potentially applicable and implementable with a wide range of semi-active damping devices [4][5][6][7].

This contribution deals with a semi-active control strategy for a directed transfer of the mechanical energy between structural vibration modes. The considered structure is equipped with lockable joints, which enable or disable the transmission of bending moments between the neighbouring structural members in a controlled manner. Such devices have been successfully developed for attenuation of vibrations by stimulating energy transfer to higher-order modes that provide quick material damping [8]. The approach relies on semi-active control, which has several advantages compared to active control, including no need to generate large external control forces. Consequently, as no high-performance power source is required, the strategy is relatively easy to be applied, including large structures [9] and decentralized control [10].

The proposed semi-active control strategy aims to maximize the instantaneous mechanical energy transfer to the target vibrational mode. In the case of free vibrations, the energy of the target mode will increase only at the expense of other modes, which justifies the notion of energy transfer. A mathematical description of the mode mixing and energy transfer between vibrational modes, as well as a respective measurement technique, are proposed. The model is based on coupling the modal equations by coefficients that depend on the control signals, mode shapes and the placement of the lockable joints.

As a demonstrative example, a three-bar frame structure is used. Two different kinds of finite element models of such a structure are analysed: a crude one (with one finite element per beam only) and a refined one (with four elements per beam). The first model is very simple and clearly introduces and illustrates the semi-active control strategy. The second model allows the participation of the higher modes and their influence on the modal energy transfer to be studied. It is shown that the proposed methodology can be used for controlling the modal energy transfer, but a part of the vibration energy is lost due to the inevitable natural material damping of higher modes.

2 SYSTEM DYNAMICS AND CONTROLLABILITY

2.1 Dynamics of a structure with lockable joints

The proposed lockable joint acts as a pin connection, which can be temporarily dynamically locked to transmit the bending moment between the suitable rotational degrees of freedom (DOFs). This concept is illustrated in the Figure 1.

Figure 1: Model of the structural lockable joint in the locked state

In the locked state of the connection, an internal moment f_k of a suitable magnitude acts at the attachment points in order to maintain constant the angle between the joined structural elements.

Assuming small displacements, the structure is described by the linear equation of motion:

$$\mathbf{M}\ddot{\mathbf{q}}(t) + \mathbf{C}_0\dot{\mathbf{q}}(t) + \mathbf{K}\mathbf{q}(t) = \mathbf{L}\mathbf{f}(t) + \mathbf{w}(t) \quad (1)$$

where $\mathbf{q}(t)$ is the vector of the configuration coordinates, \mathbf{M} is the mass matrix, \mathbf{C} is the material damping matrix, \mathbf{K} is the stiffness matrix, $\mathbf{f}(t) = [f_1 \ \cdots \ f_{N_k}]^T$ is the vector of the generalised internal forces at the joined DOFs, \mathbf{L} is the matrix that selects the DOFs for the individual lockable joints, and $\mathbf{w}(t)$ denotes the vector of the external excitation forces. The matrix \mathbf{L} can be expressed in the following form:

$$\mathbf{L} = [\mathbf{L}_1 \ \cdots \ \mathbf{L}_k \ \cdots \ \mathbf{L}_{N_k}] \quad (2)$$

$$\mathbf{L}_k = [0 \ \cdots \ 1 \ \cdots \ 0 \ \cdots \ -1 \ \cdots \ 0]^T$$

where nonzero are only these elements of \mathbf{L}_k that are related to DOFs involved in the k -th lockable joint.

To describe the energy transfer between vibrational modes, modal analysis is performed. The eigenvalue problem for all joints in the unlocked state takes the well-known form

$$(\mathbf{K} - \omega_m^2 \mathbf{M})\boldsymbol{\phi}_m = \mathbf{0} \quad (3)$$

where ω_m is the m -th natural frequency and $\boldsymbol{\phi}_m$ is the corresponding eigenvector. The eigenvectors are collected in the modal matrix $\boldsymbol{\Phi}$ and constitute the basis for the modal coordinates η_m . In the matrix notation

$$\mathbf{q}(t) = \boldsymbol{\Phi}\boldsymbol{\eta}(t), \quad (4)$$

where $\boldsymbol{\eta}(t) = [\eta_1 \ \cdots \ \eta_m \ \cdots \ \eta_{N_m}]^T$ is the vector of the modal coordinates. Additionally, the eigenvectors are normalized with respect to the mass matrix. After substitution of (4) into (1) and a left-side multiplication by $\boldsymbol{\Phi}^T$, the following form of the equation of motion is obtained:

$$\underbrace{\boldsymbol{\Phi}^T \mathbf{M} \boldsymbol{\Phi}}_{\mathbf{I}} \ddot{\boldsymbol{\eta}}(t) + \underbrace{\boldsymbol{\Phi}^T \mathbf{C}_0 \boldsymbol{\Phi}}_{\boldsymbol{\Gamma}_0} \dot{\boldsymbol{\eta}}(t) + \underbrace{\boldsymbol{\Phi}^T \mathbf{K} \boldsymbol{\Phi}}_{\boldsymbol{\Omega}^2} \boldsymbol{\eta}(t) = \underbrace{\boldsymbol{\Phi}^T \mathbf{L}}_{\mathbf{L}_\Phi} \mathbf{f}(t) + \boldsymbol{\Phi}^T \mathbf{w}(t), \quad (5)$$

where \mathbf{I} is the identity matrix, $\boldsymbol{\Gamma}_0$ is the diagonal damping matrix, $\boldsymbol{\Omega}^2$ denotes the diagonal matrix of the squared natural frequencies. Finally, the equation can be expressed as follows:

$$\ddot{\boldsymbol{\eta}}(t) + \boldsymbol{\Gamma}_0 \dot{\boldsymbol{\eta}}(t) + \boldsymbol{\Omega}^2 \boldsymbol{\eta}(t) = \mathbf{L}_\Phi \mathbf{f}(t) + \boldsymbol{\Phi}^T \mathbf{w}(t) \quad (6)$$

2.2 Controllability of modes

A controllability measure is introduced in order to quantify how easily a mode can be controlled. The form of equation (6) allows the controllability measure of vibrational modes to be calculated before employing any joint model or proposing any control law. The controllability measure G_m of the m -th mode is defined as the ℓ_2 norm of the vector contained in the m -th row of the matrix \mathbf{L}_Φ :

$$G_m = \sqrt{\sum_{k=1}^{N_k} l_{\phi m k}^2} = \sqrt{\sum_{k=1}^{N_k} (\boldsymbol{\Phi}_m^T \mathbf{L}_k)^2} \quad (7)$$

The measure G_m is very simple and it provides information about the expected level of modal accelerations for mode m .

2.3 Mechanical model of the lockable joint

Lockable joints are usually friction-based. For the purpose of vibration attenuation, advanced friction models such as the LuGre model are used [7][11]. It is required for proper calculation of the dissipated energy. However, in this contribution, the lockable joints are not intended to dissipate energy, but rather to transfer the energy between the selected modes. The model of the joint considered here can be thus significantly simplified.

The locked state of the joint is modelled by a viscous damper of relative rotations with a large constant. In transient analysis, such a model simulates a rigid connection. The moment f_k in the k -th joint takes thus the form:

$$f_k = u_k c_{MAX} \dot{\phi}_k = -u_k c_{MAX} \mathbf{L}_k^T \dot{\mathbf{q}} \quad (8)$$

where $u_k \in \{0,1\}$ is the control signal that locks or unlocks the k -th lockable joint, c_{MAX} is a large viscous damping coefficient, and $\dot{\phi}_k$ is the relative angular velocity between the DOFs involved in the k -th lockable joint. Taking into account equation (4) and (8), formula (6) takes the following bilinear form:

$$\ddot{\boldsymbol{\eta}} + \boldsymbol{\Gamma}_0 \dot{\boldsymbol{\eta}} + \boldsymbol{\Omega}^2 \boldsymbol{\eta} = - \sum_{k=1}^{N_k} u_k \boldsymbol{\Gamma}_k \dot{\boldsymbol{\eta}} + \boldsymbol{\Phi}^T \mathbf{w} \quad (9)$$

$$\boldsymbol{\Gamma}_k = c_{MAX} \boldsymbol{\Phi}^T \mathbf{L}_k \mathbf{L}_k^T \boldsymbol{\Phi}$$

The terms under the sum in equation (9) couple the modal equations. The equation of motion of the m -th mode reads as follows:

$$\ddot{\eta}_m + 2\mu_m \omega_m \dot{\eta}_m + \omega_m^2 \eta = - \sum_{k,m=1}^{N_k, N_m} u_k \gamma_{mn}^{(k)} \dot{\eta}_n + \sum_{i=1}^{N_i} \phi_{mi} w_i \quad (10)$$

where $\gamma_{mn}^{(k)}$ denotes the m,n -th element of the matrix $\boldsymbol{\Gamma}_k$, and ϕ_{mi} is the i -th element of the m -th eigenvector. Coupling of modal equations by lockable joints allows the mechanical energy to be transferred between selected vibrational modes.

2.4 Energy transfer between the vibration modes

In this section, the physical basics on the modal energy transfer are presented. The total energy of the system V is equal to the sum of the kinetic and strain energies:

$$V = \frac{1}{2} (\dot{\mathbf{q}}^T \mathbf{M} \dot{\mathbf{q}} + \mathbf{q}^T \mathbf{K} \mathbf{q}). \quad (11)$$

Substituting equation (4) into equation (11) the total energy is represented by:

$$V = \frac{1}{2} \left(\dot{\boldsymbol{\eta}}^T \underbrace{\boldsymbol{\Phi}^T \mathbf{M} \boldsymbol{\Phi}}_{\mathbf{I}} \dot{\boldsymbol{\eta}} + \boldsymbol{\eta}^T \underbrace{\boldsymbol{\Phi}^T \mathbf{K} \boldsymbol{\Phi}}_{\boldsymbol{\Omega}^2} \boldsymbol{\eta} \right). \quad (12)$$

The matrices \mathbf{I} and $\boldsymbol{\Omega}^2$ are diagonal, therefore the total energy V is equal to the sum of the energies of each mode:

$$V = \sum_{m=1}^{N_n} V_m = \frac{1}{2} \sum_{m=1}^{N_n} (\dot{\eta}_m^2 + \omega_m^2 \eta_m^2). \quad (13)$$

From (13) it follows that if modal equations are coupled, then any modal energy can increase only at the expense of the other ones. Applying m -th modal energy differentiation its increase represented in watts is obtained:

$$\dot{V}_m = \dot{\eta}_m (\ddot{\eta}_m + \omega_m^2 \eta_m). \quad (14)$$

Respecting equation (10), the terms in brackets in (14) can be replaced by

$$\sum_{i=1}^{N_n} \phi_{mi} w_i - 2\mu_m \omega_m \dot{\eta}_m - \sum_{k,n=1}^{N_k, N_n} u_k \gamma_{mn}^{(k)} \dot{\eta}_n. \quad (15)$$

From (15) it follows that the increase of any m -th mode energy is equal to work performed by external forces reduced by dissipated energy in material damping and modified by term derived from coupling of the modal equations. The last term in (15), caused by modal equations coupling, is equal to the sum of energy transfers from all modes through each joint and is denoted by $\dot{\hat{V}}_m$. It is described in the formula below.

$$\dot{\hat{V}}_m = \sum_{k,n=1}^{N_k, N_n} \dot{\hat{V}}_{mn}^{(k)} = -\dot{\eta}_m \sum_{k,n=1}^{N_k, N_n} u_k \gamma_{mn}^{(k)} \dot{\eta}_n \quad (16)$$

Equation (16) refers to any mode m when vibrational modes are coupled.

Let us denote by p an index of mode selected to maximization. Then, function $\dot{\hat{V}}_p$ described analogously to formula (16) becomes the objective function which is to be maximized at each time instance. It is studied in detail in the following section.

3 INVERSE LYAPUNOV BASED METHOD FOR SEMI-ACTIVE CONTROL

The semi-active control strategy is called “*inverse Lyapunov based method*” since some ingredients of the total energy are to be maximized while traditionally only minimization is pursued. Joint can take two states in the assumed model: locked and unlocked. It follows that the control has the bang-bang form. In the last section, it has been shown that for the free vibration, the energy of a selected mode can increase only at the expense of the others. The controller is of the semi-active type, and thus the energy transfer imposed by maximization of the target mode p cannot destabilize the system [10].

3.1 Instantaneous optimal semi-active control law

The instantaneous optimality has been pursued by maximization p -th modal energy increase at each time instant, namely:

$$\mathbf{u}^* = \arg \max_{\mathbf{u} \in U} \dot{\hat{V}}_p, \quad (17)$$

In (17), p – is the index of maximized mode $\mathbf{u} = [u_k \ \cdots \ u_{N_k}]^T$, $U = \{0,1\}^{N_k}$ – is the set of admissible controls. The substitution of equation (16) into equation (17) yields:

$$\mathbf{u}^* = \arg \min_{\mathbf{u} \in U} \dot{\eta}_m \sum_{k,n=1}^{N_k, N_n} u_k \gamma_{mn}^{(k)} \dot{\eta}_n. \quad (18)$$

Formula (18) can be written in the following matrix form:

$$\mathbf{u} = \arg \min_{\mathbf{u} \in U} \dot{\eta}_p \sum_{k=1}^{N_k} u_k \mathbf{\Gamma}_{k,p\text{-th row}} \dot{\mathbf{\eta}}. \quad (19)$$

From equation (19) it follows that it is profitable to lock the k -th joint when energy transfer through this join is positive. Otherwise, it is supposed to be unlocked:

$$u_k = \begin{cases} 0, & \text{when: } \dot{\eta}_p \mathbf{\Gamma}_{k,p\text{-th row}} \dot{\mathbf{\eta}} > 0 \\ 1, & \text{when: } \dot{\eta}_p \mathbf{\Gamma}_{k,p\text{-th row}} \dot{\mathbf{\eta}} < 0 \end{cases}. \quad (20)$$

The control law as in (20) requires that the modal velocities must be measured globally but each lockable joint can be controlled independently on each other. It is valuable property for large-scale structures, since each joint can have an individual controller.

In general, the matrices $\mathbf{\Gamma}_k$ are coupling all modes. It follows that any joint locked in a suitable instant can excite a broad range of vibrational modes including higher ones. Participation of higher modes can cause high frequency lockable joins switching. Furthermore, in real situation, the actuators in lockable joints may have some time delays, and thus, the control of the higher modes may not be feasible. This problem can be solved by applying the measurement with so called modal filtering, which is required to measure modal velocities. The higher vibration modes can be rejected during this process.

3.2 Measurements – sensor placement and modal filtering

In this section, the method for measurement employing the modal filtering is presented. The modal filtering is used to extract modal velocities from the measured motion of the structure. This technique has been initially proposed by Meirovitch [12] to reduce the effect of observation spillover in actively controlled systems. Mode shapes of the controlled structure need to be known a priori. When a limited number of sensors is used in measurement, the so called spatial aliasing arises of the measured modes with the higher modes [13]. In order to avoid it, in the first step, the sensor placement optimisation should be performed. In the second step, the matrix extracting modes participation from sensor data is designed.

Step I – sensor placement. In this contribution, sensor placement optimization is to select the sensor locations from a candidate set (nodes of the FE mesh) for which the determinant of

the Fisher information matrix achieves the maximum value. This method has been verified in many works, e.g., in modal identification [14] and structural damage identification [15]. Maximization of the norm of the Fisher information matrix minimizes the norm of the covariance matrix of the error between the real values of measured modal coordinates and the estimated ones when gaussian, uncorrelated noise affects the measurement. This property also allows avoiding influence of the higher modes on the accuracy of the measurement. The sensor placement satisfies the following equation:

$$I_S^* = \arg \max_{I_S \subset I_{\text{DOF}}} \det(\hat{\Phi}^T \hat{\Phi}), \quad (21)$$

where $I_S = \{i_1, i_2, \dots, i_S\}$ is the searched set of locations (indices of the FE model DOFs), which is a subset of all possible locations I_{DOF} , S is the number of sensors, $\hat{\Phi} = \hat{\Phi}(i_1, i_2, \dots, i_S)$ is the matrix that contains i_1, i_2, \dots, i_S rows of the modal matrix and the columns related to the measured modes. Matrix $\hat{\Phi}$ for the optimal placement of sensors is denoted by $\hat{\Phi}_{\text{opt}}$.

Step II – weighted matrix design. The weighted matrix \mathbf{F}_ϕ is computed taking into account the orthogonality criteria. The rows of \mathbf{F}_ϕ should be vectors as close to vectors of matrix $\hat{\Phi}_{\text{opt}}$ as possible and they simultaneously should be orthogonal to the eigenvectors of the unmeasured modes (known from the mathematical model). Some compromise is required to satisfy these criteria. The computation is performed in two steps:

1. Solving least-squares problem for each row of the matrix \mathbf{F}_ϕ :

$$\bar{\mathbf{F}}_\phi = \arg \min \left\| \tilde{\Phi}_{\text{opt}}^T \tilde{\mathbf{F}}_\phi^T - \tilde{\mathbf{I}} \right\|_F, \quad (22)$$

where $\tilde{\Phi}_{\text{opt}}$ arises from the matrix $\hat{\Phi}_{\text{opt}}$ by attaching additional columns related to the unmeasured modes, $\tilde{\mathbf{I}}$ is the identity matrix with attached rows of zeros to obtain a proper size, and $\|\cdot\|_F$ is Frobenius norm.

2. Rows of $\bar{\mathbf{F}}_\phi$ are scaled by coefficients to obtain the matrix \mathbf{F}_ϕ that fulfils the condition that each element on the diagonal of $\mathbf{F}_\phi \hat{\Phi}_{\text{opt}}$ is equal to one.

The measured modal velocities $\dot{\mathbf{q}}_M = [\dot{q}_{M1} \ \dots \ \dot{q}_{MN_F}]^T$ are given by:

$$\dot{\mathbf{q}}_M = \mathbf{F}_\phi \underbrace{\tilde{\Phi}_{\text{opt}}}_{\dot{\mathbf{q}}_M} \dot{\mathbf{q}} \quad (23)$$

Here $\dot{\mathbf{q}} = [\dot{q}_{i_1^*} \ \dots \ \dot{q}_{i_S^*}]^T$ is the vector of data collected from sensors, $\{i_1^*, i_2^*, \dots, i_S^*\} = I_S^*$. The control law taking into account the measurement process is as follows:

$$u_k = \begin{cases} 0, & \text{when: } \dot{q}_{Mp} \mathbf{\Gamma}_{k,p\text{-th row}}^M \dot{\mathbf{q}}_M > 0 \\ 1, & \text{when: } \dot{q}_{Mp} \mathbf{\Gamma}_{k,p\text{-th row}}^M \dot{\mathbf{q}}_M < 0 \end{cases} \quad (24)$$

In (24), $\mathbf{\Gamma}_{k,p\text{-th row}}^M$ is of the size $1 \times N_F$.

4 NUMERICAL EXAMPLES

The proposed inverse Lyapunov method for semi-active control has been examined on a three-bar structure. The beams of this structure are connected by means of two lockable joints as demonstrated in Figure 2.

Figure 2: The considered structure with lockable joints

Table 1: Physical parameters of the controlled structure

Young modulus (steel)	E [Pa]	$210 \cdot 10^9$
Material density (steel)	ρ [$kg\ m^{-3}$]	7860
Cross section area (square)	A [m^2]	10^{-4}
Moment of inertia	I [m^4]	$8,33 \cdot 10^{-10}$

The vertical beams are clamped in the ground. For the beam model, we assume small deflections and employ the Euler–Bernoulli beam equation. The assumed parameters of the structure are summarized in table 1.

We consider two FE models of structure. The first one is to justify the semi-active modal control and the second one is to demonstrate the influence of the higher vibration modes on measurement. Each of the presented simulation has been performed by using the Newmark integration method.

4.1 Illustrative 5-DOF FE model

In this example, the model consists of only one FE element per beam to clearly show the basic properties of the presented semi-active control method. The employed finite elements have cubic shape functions. In such a case, the entire model has only five DOFs: 1 horizontal displacement of the top beam and 4 rotational DOFs of beam ends in the lockable joints. There are also 5 vibrational modes which have natural frequencies listed in Table 2 and the shapes shown in Figure 3.

Table 2: Natural frequencies of the considered structure

No.	Natural frequency ω_m [Hz]	Time period T_m [s]
1	1.198	0.835
2	6.504	0.154
3	12.168	0.083
4	13.678	0.073
5	29.804	0.034

Figure 3: Mode shapes for the 5-DOF model

The controllability measure G_m for each mode is shown in the form of a bar plot in Figure 4.

Figure 4: Controllability measure for the modes of the 5-DOF model

The initial condition is defined by the potential (strain) energy: $0.5 J$ in the second mode and $0.5 J$ in the third mode. The case of a free vibration is considered. The fourth vibrational mode is the target mode, with its energy to be maximized. The time histories of the control signals u_k , the modal energies V_m and the modal coordinates η_m are shown in Figure 5.

The first (left) joint is locked immediately at the beginning of the simulation. It results in excitation of all 5 vibrational modes, but after a short time the most pronounced is the target (fourth) mode. Notice that the modal energies change only when at least one joint is locked.

The stepwise changes of the total energy V and the modal energies V_m are the results of a small number of FE elements per beam. A beam with only one relatively massive FE element cannot immediately bend in the way which should follow from the action of the joints; the beam ends rotate thus during joint lock, which results in a slight local energy dissipation. This problem disappears in the model with a finer mesh of FE elements.

4.2 Refined 23-DOF FE model

Next example concerned three-bar structure discretized with 4 elements per beam resulting in 23 DOFs. Damping of 1.5% of critical value for each mode was assumed. First 3 modal velocities were measured with aid of 7 sensors. Measurement signals were subjected to the process of modal filtering. Optimization of sensors placement and filter design was performed according to the procedure described in subsection 3.2.

Numerical simulation of energy transfer has been performed for the structure with initial strain energy of the 2nd mode equal to $1 J$. The structure was released from the initial state performing free vibration. The goal of the control was maximization of energy in the first vibration mode. Time histories of control signals u_k , modal energies V_m and corresponding modal coordinates η_m are shown in Figure 6.

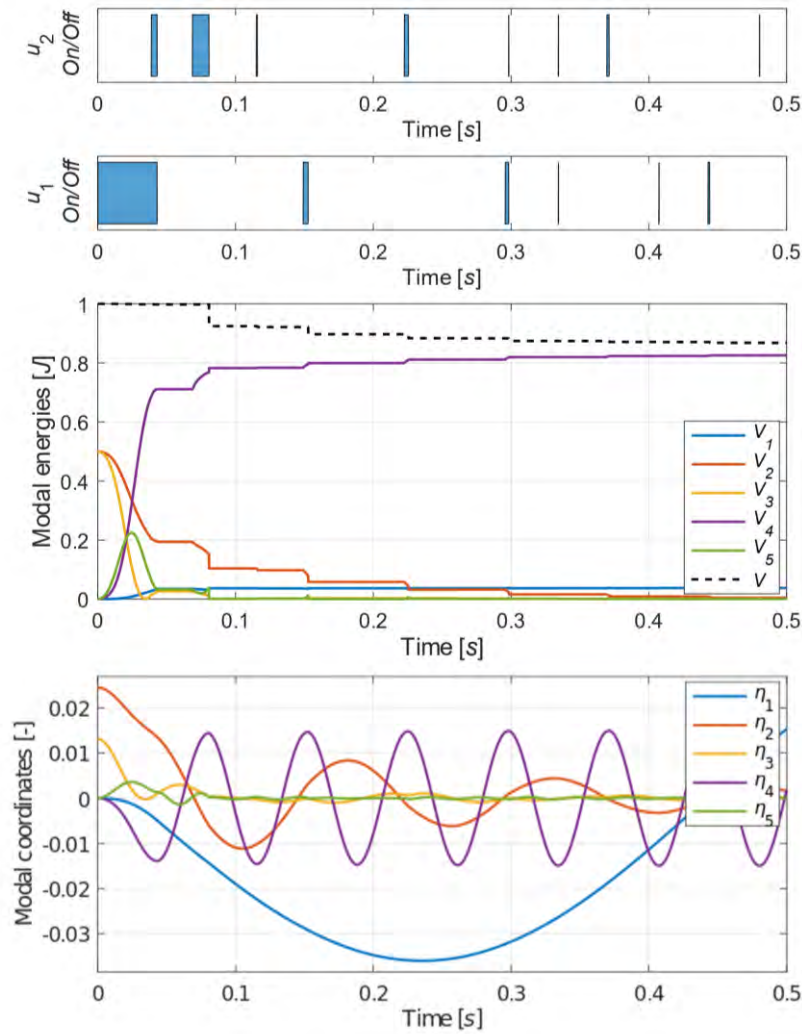

Figure 5: Time histories of the control signals (blue colour means ON), modal energies, modal coordinates

It was assumed that data coming from sensors is not filtered in time domain, so even with modal filtering the influence of higher modes is visible. It resulted in high frequency of oscillation of the control signal. This problem can be avoided by applying e.g. low pass filter or predictor within the control algorithm, which can check averaged energy transfer in finite time horizon and based on this information make decision about locking or unlocking of joint under consideration.

Numerical results in Figure 6 show that presented semi-active modal control is efficient even when limited set of modes is measured – only three modes in this case. It is valuable property for many realistic structures.

Dissipation rate of the total energy V changes during control process, because different modes – with different damping – are excited by lockable joints. This phenomenon is undesirable in the case of energy-harvesters. When targeted mode (the first one) has dominant participation energy dissipation is slower.

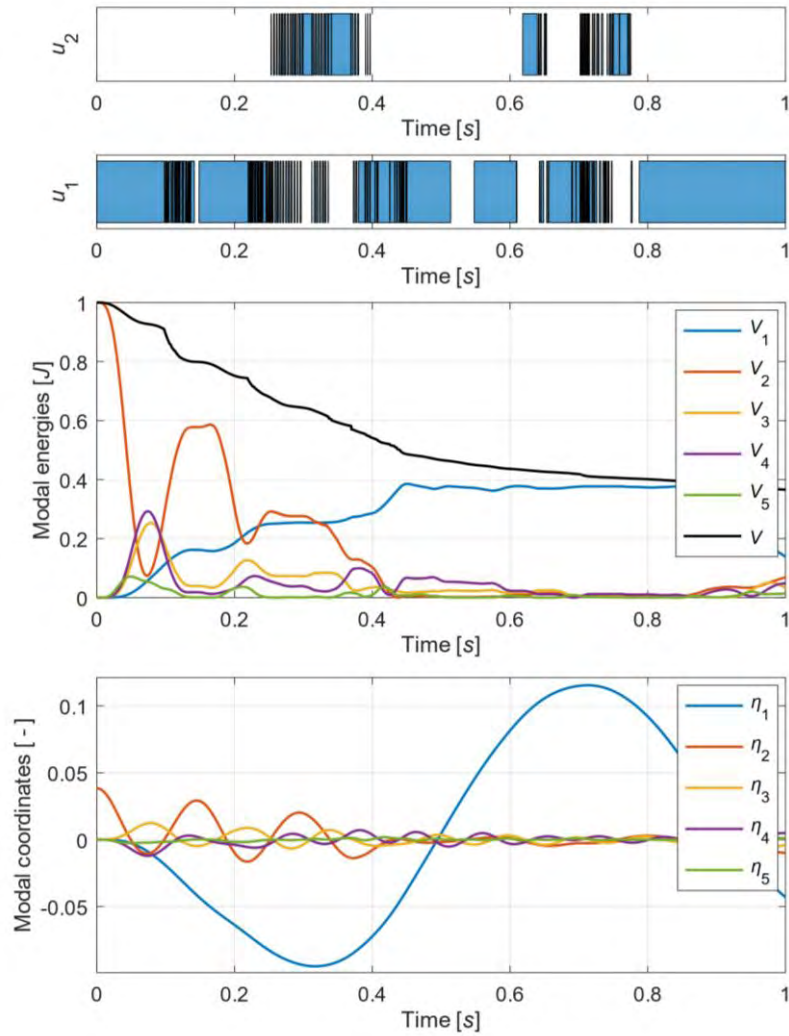

Figure 6: Time histories of the: control signals (blue colour means ON), first five modal energies, first five modal coordinates

5 CONCLUSIONS

This contribution proposes a semi-active control approach for energy transfer between vibrational modes of a frame-like structure. The control method is based on an instantaneous maximization of the momentary energy transfer to the target mode and the other modes. It is implemented by means of a specific actuator that takes the form of a lockable joint, which allows a controllable imposition and configuration of structural constraints. Effectively, such a joint allows the bending moment to be transferred between the adjacent structural elements to be controlled according to the control signal. The work is ongoing mainly to (1) include a more physical models of actuators and to avoid the chattering effect, (2) perform experimental verification, and (3) include energy harvesting devices (dissipators).

Abstract. Semi-active control systems are investigated for more than 40 years [1, 2], and despite the great progress in this research area, they are still considered to be a complex topic in both theoretical and technical terms. However, their advantages ensure that these control systems remain an extremely attractive subject of scientific and technological development.

In this contribution, we present a semi-active strategy for mitigation of vibration, which utilizes an energy management approach called Prestress-Accumulation Release [3] and is based on controllable activation and removal of selected structural constraints. Here, it is implemented by means of controllable structural nodes of a specific design that allow the transmission of moments between adjacent structural elements to be controlled in an on/off manner. The developed control strategy turned out to be very effective in damping of free structural vibrations of planar frame structures [4]. Extension of the research to other types of vibrations has shown that the proposed control algorithm is versatile and stays efficient in a range of applications and different configurations of the investigated structures. This work is focused on mitigation of vibrations excited by a randomly generated force load.

Decentralization, understood here as controlling the employed actuators based on locally measured structural response [5], results in a decisive reduction of the complexity of the data acquisition and control systems, which is crucial for actual implementations in real structures, and which facilitates an ad hoc reconfiguration and expansion of the control system if necessary. It also provides the possibility of considering selected structural elements as separate energy dissipative devices, which in our approach act effectively as vibration dampers. This feature, provided by the decentralization, enables to take the advantage of two complementary, interrelated mechanisms of material damping: global dissipation of vibration energy by the PAR and local dissipation in single involved elements.

Numerical and experimental analyses indicate a high degree of effectiveness in alleviation of the amplitude of vibrations induced by a random transient force excitation. The proposed control strategy can be thus utilized not only in the case of momentary impulsive loads that result in predominantly free vibrations [4], but also in the case of transient random force excitation. It significantly extends the range of possible modes of operation of a structure equipped with the proposed damping system.

1 INTRODUCTION

The wide range of possible applications and ways of implementation makes semi-active vibration control systems a very attractive subject of engineering and scientific considerations. Such an approach

to control is recently becoming more and more popular, as evidenced by the ever-growing number of publications on the subject. Applications have been studied in a large number of engineering fields, such as suspension bridges [6], vehicle seat suspension [7], seismic response reduction [9], wind turbines under wind, wave and earthquake loads [10], rotating machinery drivetrains [11], landing gears [12], and many others. The technologies used are also diverse, i.e., MR fluids [8], tuned mass dampers [10], MEMS [13], special valves controlling the fluid flow between two absorber chambers [14], etc.

Semi-active vibration damping systems bridge the gap between passive and active damping systems. They make use of active force generation, but only to the extent necessary to enable the structure to adapt itself in a way that would lead to the mitigation of vibration energy. Such a design philosophy causes semi-active vibration damping systems to be generally very reliable. High reliability is a property that brings semi-active systems close to passive systems. The efficiency of a well-designed semi-active vibration damping system can be comparable to the active one, but the main advantage of the semi-active control systems, over the active ones, is their very low demand for the energy. However, these advantages are usually achieved at the cost of a much higher level of the technical and theoretical complexity.

Semi-active control systems typically employ a technique of reconfiguration of the controlled system to achieve the desired dynamic behavior. This could be, for example, a temporary “freezing” of a certain deformation in a selected part of the system in order to resist the inertial forces. Another approach may be to temporarily reconfigure the system to change its mechanical characteristics, such as effective stiffness [3] or, as often related to a change in stiffness, the number of the degrees of freedom.

One of the simplest ways to achieve such a goal is to utilize piezoelectric stacks in bolted joint connections [15]. It allows the normal pressure between the joint interfaces to be controlled so that control of the rotational motion of the structural members can be achieved. The approach pursued here is similar, but the energy dissipation mechanism is focused on global and local dissipation in beams rather than exclusively on local friction-based dissipation in controllable joints. The presented work is focused on vibration mitigation of 2D frame structures with the use of some especially designed semi-active nodes which can switch their state of operation from frame-like to truss-like on demand in a matter of milliseconds. When used in pairs, as joints connecting selected beams to the rest of the structure, they allow the developed control algorithm to be utilized in order to mitigate structural vibrations.

The effectiveness of the proposed algorithm in mitigation of vibrations turned out to be very high for free structural vibrations [4]. This contribution briefly presents the performance of the control algorithm in the case of randomly excited vibrations. Its effectiveness is confirmed both numerically and experimentally.

2 NUMERICAL MODEL OF THE SEMI-ACTIVE NODE

The mathematical model of the semi-active node used to simulate its behavior has been selected based on the criterion of the ease of implementation in numerical calculations. The cost of its simplicity is that its applications are limited to dynamic simulations only.

Numerical model of the considered structure consists of beam finite elements with three degrees of freedom (DOFs) in each node. Typically, the appropriate local DOFs in the coinciding nodes are aggregated to the same global DOF, but in order to create a semi-active node, a different procedure of aggregation is pursued: The translational DOFs are aggregated in the same way as in the typical finite element model; however, the rotational DOFs have to be uncoupled. It is achieved by employing additional rotational DOFs in the nodes that are turned into semi-active ones. In this way, the selected nodes have four global DOFs: two translational and two rotational. The two rotational DOFs are then coupled to each other with a rotational damper with a controllable, high damping coefficient, which

prevents their relative movement in transient, dynamic simulations. The described technique leads to the following equation of motion:

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \left(\mathbf{C} + \sum_{i=1}^N \gamma_i(t) \mathbf{C}_i \right) \dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = \mathbf{f}(t) \quad (1)$$

where \mathbf{M} is the mass matrix of the structure, \mathbf{C} is the damping matrix and \mathbf{K} is the stiffness matrix. All of them include the additional rotational DOFs. The vector of external forces applied to the structure is denoted by \mathbf{f} and γ_i is the control function which is responsible for coupling and uncoupling the rotational DOFs in the i th semi-active node. When γ_i is set to 0, the node is in its truss-like state in which it does not transfer any moments. When γ_i is set to a value large enough, then the semi-active node is in its frame-like state with the maximum moment transfer capability. The matrices \mathbf{C}_i model the rotational relative dampers which in the 2D case are of the following form:

$$\mathbf{L}_i^T \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \mathbf{L}_i \quad (2)$$

where \mathbf{L}_i are the global–local transformation matrices.

Such an approach does not introduce any non-linearity into the numerical model, which greatly facilitates the theoretical investigations, control and the simulation of the dynamic behavior of the structure.

3 CONTROL ALGORITHM

The control algorithm is designed to mitigate various types of vibrations, such as free vibrations and vibrations excited by a harmonic or a random force. The structures, for which it is best suited, are frames with slender elements, such as the one presented in Figure 1.

Figure 1: Exemplary frame structure equipped with semi-active nodes

The semi-active nodes are used pairwise, on two ends of selected beams. The control algorithm uses the (strain-based) measurements of the potential energy accumulated in the beams. It indicates the point in time, when the state of operation of the semi-active nodes shall be switched from their default frame-like state to the truss-like state, in which the relative in-plane rotation of the beams joined in the node is temporarily allowed. The switching takes place when the strain energy achieves its local maximum. The energy is measured only locally in selected parts of the controlled structure, for example in the single beam between the nodes.

Such a control strategy is completely local, but it affects the entire structure. Instantaneous local reconfiguration of the structure results in the excitation of the high-frequency vibration modes, which are usually very efficiently damped by means of the standard mechanisms of material damping. The same logic of transferring the energy from low-frequency to high-frequency vibration modes, however at the global level and based on global measurements, was introduced in [16], where it was named the Prestress–Accumulation Release (PAR) strategy.

Knowing the general characteristics of the globally optimal open-loop control, derived with the Pontryagin's minimum principle, which is of the bang-bang type, a heuristic control algorithm has been proposed in [4] for mitigation of vibrations. It can be briefly described in the three simple steps:

1. Semi-active nodes are in their default frame-like state as long as the local strain energy (for example of the involved beam) raises due to the growing deflections of the structure.
2. When the local maximum of the measured energy is achieved, the nodes switch to the truss-like state, in which they do not transfer any moments (only normal and shear forces are transferred).
3. When certain conditions are met, nodes are switched back to their default frame-like state of operation.

The period of time for which the semi-active node stays in truss-like state can be determined on the basis of different conditions. For example, it can be:

1. an arbitrarily set percentage decrease of the strain energy or simply
2. a predetermined period of time.

The first condition seems the most intuitive indicator of the coupling moment of the rotational DOFs in a semi-active node. The condition refers directly to the current state of the controlled object and it can be easily calculated in numerical simulations. However, in the case of a real structure, the condition becomes problematic: the strain energy can be only approximated in terms of the signal obtained from strain gauges, and the high frequency of the induced local vibrations would require a very fast control system. In such a case, the second condition can be used, and it was shown that the control algorithm remains effective over a wide range of time in which the nodes remain open [4]. It can be also utilized as an additional safety condition, in order to avoid long-term weakening of the structure in case of a failure of the data acquisition system. Maintaining the high efficiency of vibration mitigation over a wide range of time period, when the semi-active nodes stay in the truss-like state, in conjunction with the second condition, is very significant for experimental research. Due to some delays in data acquisition and processing, as well as the inertia of piezoelectric stacks and semi-active node casings, the control algorithm is characterized by a certain time shift. Thanks to the aforementioned feature, it is possible to achieve good damping performance even with these control delays.

4 NUMERICAL SIMULATION

Numerical analyses were conducted for the structure presented in Figure 1. It is a slender planar frame, made of steel beams with a cross-section of 5x5 [mm] each, equipped with two semi-active nodes, which make the middle vertical beam a dissipative device. The DOFs of the left-hand side nodes of the frame are fixed, while the exciting force, which is applied at point Q, is a realization of the white noise process with an appropriate amplitude.

The comparison of the results obtained when the control algorithm is activated (controlled, semi-active case) and when it is turned off (passive case) is presented in Figure 2. The graph presents the comparison of the vertical tip displacements in time of the investigated structure (point P in Figure 1). It is clearly visible that the vibration mitigation algorithm is effective even when the exciting force is random. In this case, the mean amplitude of the absolute value of the tip displacement is reduced by almost 25%. The displacement amplitude is reduced, when compared to the passive case, almost in the entire time range of simulation.

Figure 2: Time courses of the vertical tip displacements of the investigated structure

The results obtained in numerical simulations are very promising. Together with the previously investigated cases of free and harmonic vibrations, they confirm the effectiveness of the proposed control algorithm in a wide variety of structural load conditions.

5 EXPERIMENTAL RESULTS

The effectiveness of the control approach was also studied experimentally. The investigated lab frame structure is presented in Figure 3. The geometry is not exactly the same as in the numerical simulations, but the overall topology resembles the numerical case very closely.

Figure 3: Geometry of the experimental stand

Similarly as in the computer simulation, a random force load is applied in the midpoint of the lower horizontal beam to the left of the semi-active node.

Figure 4: In-plane accelerations of the tip: experimental results

The data presented in Figure 4 are the time courses of the in-plane frame tip accelerations. Even a superficial observation indicates that the obtained result is very good. Application of the control algorithm significantly reduces the tip accelerations in the entire time range. The presented comparison of the dynamic response of the examined real structure is even better than in the numerical analyses.

6 CONCLUSIONS

This work investigates the problem of semi-active mitigation of vibration by local structural reconfiguration. The scope of applicability of a previously proposed control algorithm has been extended to new cases beyond free vibrations. The effectiveness of the proposed algorithm for random force excitation has been confirmed numerically and, more importantly, experimentally.

The results obtained show that the created control algorithm is versatile and at the same time it remains effective in all investigated cases of vibration mitigation. Experimental analyses are promising and allow to believe in successful implementation of such vibration damping systems in real engineering structures.

Abstract. This paper describes the layout of an innovative adaptive tuned mass damper based on shape memory alloys able to change more than one eigenfrequency at the same time with a given level of independency. Therefore, the adaptive TMD is multi-modal, in the sense that it is able to damp more than one mode of the primary system, and it can also recover the possible changes of the different eigenfrequencies considered for the primary system.

The paper explains how to model such a new device, provides details about how the multi-mode working principle is achieved and, finally, shows the experimental tests which prove the reliability of this type of device.

1 INTRODUCTION

The use of Shape Memory Alloys (SMA) to damp vibrations is a promising approach. Indeed, different SMA-based devices have been proposed in the literature in the last years (e.g. [1–4]) with the aim of attenuating vibrations and different real applications have been shown to be solvable by using SMAs (e.g. [5,6]). Moreover, many research works demonstrated the possibility to develop SMA-based adaptive Tuned Mass Dampers (TMD) able to change their dynamic features thanks to the special and advantageous characteristics of SMAs. This makes possible for the adaptive TMDs to change their dynamics and thus to stay tuned on the primary systems to be damped in case they change their dynamics as well (e.g. due to thermal shifts).

Different layouts of SMA-based adaptive TMDs have been proposed in the literature. The two main configurations proposed were cantilever beams [7–10] and strings with a central mass [11,12]. This work focuses on this latter configuration, whose working principle is described in the next section, because of its advantages:

- it allows changes of its first eigenfrequency (which is the one tuned on the eigenmode of the primary system to be damped) of more than 100% of its initial value;
- it requires low power consumption for the adaptation process;
- it easily allows to couple devices for adapting also the damping (e.g. using eddy-current devices);
- it does not require any special feature for the SMA used.

All the adaptive TMDs relying on the mentioned principles are mono-modal, meaning that they are able to adapt just a single eigenfrequency at time, and thus to damp a single eigenmode of the primary system. The aim of this paper is to show that the layout of adaptive TMD presented in [11,12] can be also used to develop a multi-mode adaptive TMD able to adapt more than one eigenfrequency at the same time with a given level of independency. This would allow to follow the changes of more than one eigenmode of the primary system at the same time.

The structure of this paper is as follows: Section 2 recalls the basics of SMAs and their use in the adaptive TMD presented in [11,12]. Then, Section 3 discusses the layout of the new multi-mode adaptive TMD, together with an introduction about how to model it. Section 4 shows the adaptation capabilities of the new device and Section 5 presents some experimental tests demonstrating the effectiveness and the reliability of the new device.

2 BASICS OF SMA AND THEIR USE IN AN ADAPTIVE TMD

SMA materials can be in three different phases: twinned martensite (TM), detwinned martensite (DM) and austenite (AU) [13]. Once the SMA is stressed over a given stress value at environmental temperature and the transformation from TM to DM is completed, it is then possible to change the shape of the SMA between the strained and unstrained shapes by changing the temperature (temperature-induced transformation) or changing the stress at high temperature (pseudoelasticity) [12,13].

The basic idea behind the work presented in [11,12] is the use of SMA wires with a central mass and elastic elements connecting the SMA wires to the primary system. These springs, together with the mass and the SMA wires, constitute the adaptive TMD (see Figure 1a). When the eigenfrequency of the TMD must be increased, it is possible to heat the SMA wires passing from DM to AU. Hence, the SMA wires undergo to a length decrease, thus causing an increase of the axial load (thanks to the elastic elements) in the wires and, therefore, the eigenfrequency increases. The heating is obtained increasing the current made flow into the SMA wires. Conversely, a decrease of this current allows to pass from AU to DM and, thus, to have a decrease of the eigenfrequency value. More details about this working principle are available in [12].

Relying on this layout, this paper will present how it is possible to extend this working principle in order to make the TMD able to change more than one of its eigenfrequencies with a given level of independency (multi-modal adaptive TMD). This is accomplished in the next sections.

Figure 1: Original adaptive TMD based on SMAs (a) and the new multi-modal adaptive TMD (b). PS means primary system (i.e. the system to be damped).

3 THE MULTI-MODAL ADAPTIVE TMD

If other masses are added to the layout of Figure 1a, a device like that in Figure 1b is obtained. The first modes of this new device (i.e. those with a significant vertical deflection in correspondence of the masses) are those considered here.

If the current flowing in each SMA wire is set independently from that flowing in the other SMA wires, a double effect can be exploited in order to change the eigenfrequencies of the adaptive TMD:

- the axial load into the wires is changed, exactly as previously;
- the geometry of the device is changed. As an example, suppose to start from a configuration where all the wires have the same length (see Figure 1b). Then, the first wire (that on the left side) is heated more than the others. This causes a decrease of its length higher than for the other wires, causing a loss of symmetry of the whole device. Therefore, a change of the device geometry is obtained.

The mentioned double effect is expected to allow for changing two (or more, according to the number of masses used in the device) eigenfrequencies of the adaptive TMD with a given level of independency.

The new multi-modal adaptive TMD can be modelled in order to analyse its behavior and quantify its capability of changing at least two eigenfrequencies with a given level of independency. Such a model must link the input to the TMD (i.e. the currents flowing in the different SMA wires, which are set by a user/controller) and the desired output (i.e. eigenfrequencies and mode shapes of the TMD). This model is, actually, composed by three different models: a thermal model, a model of the material and a dynamic model. They are briefly discussed in the next subsections. More details about the models can be found in [14].

3.1 Thermal model

This model links the current flowing in a wire to its temperature. Such a model, which is written for each of the SMA wires, is based on a power balance which equals that produced by the Joule's effect and that dissipated towards the surrounding environment by means of convection.

3.2 Model of the material

This model takes as input the wire temperatures provided by the thermal model and gives in output the axial stress into the wires and the length of the wires. This is accomplished by

exploiting the one-dimensional (1D) material model [13], in its modified version able to account for partial transformations [12]. The knowledge of the axial stress in the SMA wires allows to estimate also the axial load acting on the whole device. More details about this model can be found in [14].

3.3 Dynamic model

Once the length of the wires and the axial load are known, it is possible to write the equations of motion of the strings (i.e. the SMA wires) with the hypotheses that the masses are concentrated [15] and that the vibration amplitude is small enough to neglect geometrical non-linearity. The solution of the system dynamics leads to the knowledge of the system eigenfrequencies and the related mode shapes. Also in this case, more details on this model are available in [14].

4 SIMULATIONS

This section investigates the performances of the new multi-mode adaptive TMD. At first, an analysis is carried out in order to show how it is possible to change the initial values (i.e. at environmental temperature and with no current flowing in the SMA wires) of the eigenfrequencies of the TMD (see Section 4.1). Then, in Section 4.2, the adaptation capability is investigated, evidencing that it is possible to tune two (or more) different eigenfrequencies of the TMD with a given level of independency by supplying the different wires independently.

4.1 The tuning of the initial eigenfrequency values

It is well known that there are different parameters for tuning the initial values of the TMD eigenfrequencies: an increase of the mass values and of the length of the whole TMD cause a decrease of the eigenfrequency values. The same effect can be also achieved by decreasing the initial axial load in the TMD. The initial axial load can be tuned by changing the elastic constant of the elastic elements connecting the TMD to the primary system (see Figure 1b) [12].

Another factor able to change the initial values of the device eigenfrequencies is the geometry of the device: the eigenfrequencies change by changing the positions of the masses in the TMD (e.g. passing from a symmetric configuration to a non-symmetric one or vice versa).

If the initial percentage change of the eigenfrequencies (named Δ_i , where i indicates the i -th eigenfrequency), caused by a change of the positions of the masses along the TMD, is calculated by using the model described in Section 3, the plot of the percentage changes of two different eigenfrequencies can be obtained. As an example, Figure 2a, Figure 2b and Figure 2c show such a plot for a TMD with two masses in case of equal masses (each dot of the plots is related to given positions of the two masses). These plots reveal that their shapes do not change once the ratio between the masses is kept constant and either the length of the TMD or the mass values are changed. A change of the plot can be obtained by changing the mass ratio [14].

Figure 2 shows that it is possible to have a large number of possible combinations between two different eigenfrequency values tuning the different parameters. Therefore, it is possible to tune the initial values of the eigenfrequencies in order to have tuning between the TMD and the primary system. More details about this analysis can be found in [14].

Figure 2: Relationship between Δ_1 and Δ_2 for a TMD with two masses and three wires: length of 20 cm and masses of 100 g (a), length of 40 cm and masses of 100 g (b) and length of 20 cm and masses of 200 g (c). Axial stress into the wires equal to 50 MPa.

4.2 Adaptation capability

This section investigates whether it is possible to have a given level of independency for changing the first eigenfrequencies of the TMD when each of the wires is heated/cooled independently. Simulations, relying on the model of Section 3, were carried out to investigate how different combinations of the temperatures of the wires (e.g. in the case of the mentioned adaptive TMD with two masses, thus having three wires) can change the eigenfrequency values. The percentage change of each eigenfrequency due to temperature changes of the wires are here indicated as Θ_i . Plots like those of Figure 3 are then obtained. The span, which is evident in the middle of the plot, shows that it is possible to have a given level of independency in tuning the first eigenfrequencies of the adaptive TMD. This allows to recover different changes of the corresponding eigenfrequencies of the primary system.

The span evidenced in Figure 3, which is related to the mentioned level of independency, can be changed by changing the SMA material (particularly, changing the value of the current maximum transformation strain [13]), the initial geometrical configuration of the masses (i.e. position of the masses along the whole TMD), the number of the masses and their relative values. A detailed analysis of these effects is available in [14], where it is also shown that the achievable level of independency is enough for real applications.

Figure 3: Relationship between Θ_1 and Θ_2 for a TMD with two masses of 100 g, a length of 20 cm and an initial configuration at environmental temperature with the first wire length equal to the 25% of the total TMD length, the central wire with a length equal to the 30% of the total length and the last wire with a length equal to the 45%.

5 EXPERIMENTAL TESTS

A test-set-up was built in order to experimentally validate the possibility of having a given level of independency in tuning two different eigenfrequencies by heating/cooling the different SMA wires of the device independently. A TMD made of three wires and two masses was thus built. The total length of the device was about 35 cm and the two masses had a value of 18 g and 25 g (see Figure 4). The elastic elements were built through cantilever beams. The whole device was excited by means of an electro-dynamic shaker providing a random disturbance. The currents flowing into the wires (and, therefore, the temperatures of the wires) were changed test by test, estimating each time the first two TMD eigenfrequencies (ω_1 and ω_2) by measuring the vibration of the masses with an accelerometer and a laser velocimeter. The experimental results were superimposed to the plot built by using simulations, where many numerical results were reported. The experimental results were in the same area of the plot covered by the numerical results, proving the reliability of the model developed. Furthermore, different experimental points of the plot show the same value for the first eigenfrequency for different values of the second one (e.g. at about 18.75 Hz on the horizontal axis, see Figure 5) and vice versa (e.g. at about 30.8 Hz on the vertical axis, see Figure 5). These results prove that it is actually possible to have a given level of independency in the tuning of at least two different

eigenfrequencies and this makes possible to design and build multi-modal adaptive TMDs based on SMAs.

Figure 4: Experimental set-up.

6 CONCLUSIONS

The paper has dealt with the use of SMA wires to build adaptive TMDs able to change with a given level of independency more than one eigenfrequency at the same time thanks to the special features of SMA materials. This allows to build a multi-modal adaptive TMD able to follow the changes of different eigenfrequencies of the primary system in order to avoid mistuning and a worsening of the attenuation performance provided by the TMD.

The layout of this new TMD is based on the use of different masses and SMA wires to build the TMD. Each wire is heated/cooled independently from the others and this allows to obtain the mentioned level of independency.

The effectiveness of the proposed approach is demonstrated experimentally by means of a TMD made from two masses and three SMA wires.

Key words: Inerter, non-linear damper, tuned mass damper

Abstract. In this paper we study the dynamics of two degree freedom system, which is consisted of main body and tuned mass damper with inerter (TMDI) and dash-pot with nonlinear damping characteristic. We study influence of non-linear dash-pot on efficiency of proposed device. The non-linear characteristic of the dash-pot is dependent on control parameters which let us change freely its characteristics. To compare response of main system with TMDI with linear and non-linear damper.

1 INTRODUCTION

In this paper, we focus on mitigation of vibrations using a tuned mass damper (TMD). The TMD was patented by Frahm in 1909 [1]. His device is a linear oscillator that consists of a mass and a linear spring with the same natural frequency as the damped system. When both frequencies match, one can avoid the resonance of the main system, but the decrease in the amplitude is observed only around the resonant frequency. There are a lot of modifications of the TMD which lead to the increase in the range of effectiveness. The most fundamental one was the addition of a dash-pot to the TMD [2]. Such TMD can be efficient in much wider range of excitation's frequencies than the Frahm's device. Nowadays, the passive TMDs are used in many systems to mitigate the oscillations, e.g., they prevent damage of buildings due to seismic excitation [3, 4], suppress vibration of tall buildings subjected to wind [5, 6], achieve the best properties of cutting processes [7, 8], decrease vibration of floors or balconies [9, 10], reach stable rotations of rotors [11, 12, 13], stabilize drilling strings [Viguie2009b], etc. Despite the fact that scientists and engineers are working on designing the best passive device, there are also many efforts to improve properties of the TMDs by control (hybrid, semi-active and active systems) [15, 16].

Inerter - introduced in early 2000s by Smith [17] - is a two terminal element which has the property that the force generated at its ends is proportional to the relative acceleration of its terminals. Its constant of proportionality is called inertance and is measured in kilograms. The first studies of this device have been devoted to the possible application as an element of cars' suspensions [17]. It has been shown that oscillations induced by road imperfections and load disturbances can be reduced more effectively using suspensions with inerters. Then, in 2004 Smith and Wang [18] studied several simple passive suspension struts, each containing at most one damper and inerter. The theoretical results are confirmed with experiment showing that suspension layouts with inerter are more effective than classical designs with

dampers and springs only. Wang and Su [19] present how the performance of suspension is influenced by the non-linearities which appear due to inerter's construction including friction, backlash and the elastic effect. They show that the performance benefits are slightly degraded by the inerter non-linearities but still the overall performance of suspension with a nonlinear inerter is better than traditional ones, especially when the stiffness of suspension is large. In 2005 the inerter was profitably used as a part of suspension in Formula 1 racing car under the name of J-damper [20].

In our previous papers we combine TMD with inerter (TMDI) and nonlinear damper and we test its efficiency in comparison to TMDI with linear damper.

2 Non-linear damper

2.1 Model of non-linear damper

Let us introduce the non-linear damper with piecewise quadratic damping characteristic proposed by Y. Starosvetsky i O.V. Gendelman [21]. Such dampers are often considered for hydraulic damping devices [22] that are based on a flow of fluid through orifices in a moving piston. The force in damper is dependent on the square of relative velocity $\dot{X}|X|$ between the terminals of device and is given by following equation:

$$f = \begin{cases} \lambda_1 \dot{X}|\dot{X}|, & \text{if } X < a_{cr} \\ \lambda_2 \dot{X}|\dot{X}|, & \text{if } X > a_{cr} \\ \lambda_2 \geq \lambda_1 \end{cases} \quad (1)$$

where $\lambda_{1,2}$ are damping coefficients and a_{cr} is critical value of deflection $|X|$ for which the damping change its characteristic (rapid increase or decrease of damping coefficient's value). This type of damping characteristics is typical in hydraulic dampers based on the same principle of orifice flow with the addition of semi-active control [23]. It can be realized in the hydraulic dampers containing several on/off orifice valves in a moving piston. State of the valves can change during the work as soon as the piston reaches critical value of deflection a_{cr} that is defined by the designer. When this value is reached, some of the orifices are closed and this results in the increase of damping coefficient. When the piston hits the critical value a_{cr} in the opposite direction, it simply reopens the closed orifices, thus brings the damping coefficient to its original value. The idea behind this type of non-linear damper is simple, but also powerful and with correctly chosen parameters such device can solve the problem of the increase of the amplitude for large deflections.

Figure 1: Free response of one DoF system for different values of damping

2.2 Response of one DoF system with nonlinear damper

To compare the response of classical linear damper with considered nonlinear damper we perform simple test on one DoF system. For simplicity we assume $\lambda = \lambda_1 = \lambda_2$. The equation of motion of test system is as follow:

$$m\ddot{x}_1 + kx + c\dot{x}_1 + k(x_1 - x_2) + c\dot{x}_1 + \lambda(\dot{x}_1)|(\dot{x}_1)| = 0, \quad (2)$$

where $m = 10 [kg]$, $k = 9600 [N/m]$. Damping coefficients c and λ are controlling parameters. The critical damping for this system is as follow: $c_{kr}2\sqrt{km}$ and we use as a reference value for $\lambda_{ref} = c_{kr}$ parameter. The results are presented in Fig. 1. The dashed line corresponds to $c = c_{kr}$ and $\lambda = 0$, while continuous lines of different color to $c = 0 [Ns/m]$ and $\lambda = 0.25\lambda_{ref}$, $\lambda = 0.5\lambda_{ref}$, $\lambda = 1.0\lambda_{ref}$, $\lambda = 1.5\lambda_{ref}$ respectively.

As it is easy to see the response of system with nonlinear damper is closest to system with critical damping for $\lambda = 0.25\lambda_{ref}$. For higher values of λ system reaches equilibrium after significantly longer time.

3 Model of the system

In this section we introduce model of the considered system. It is presented in Fig. 2. It consists of two oscillators that can move in vertical direction. The first oscillator is forced by external harmonic excitation. It is used as a model of the structure which vibrations should be mitigated and will be called base oscillator. The second oscillator is connected to the first one and represents the TMD.

The motion of the system is described by two generalized coordinates: the vertical position of the base oscillator by coordinate x_1 , while the vertical displacement of the TMD by coordinate x_2 . The notation of parameters used to characterize the base oscillator is as follows: M is the mass of the oscillator, k_1 and k_2 are the linear and non-linear parts of the base oscillator spring stiffness and its viscous damping coefficient is given by parameter c . To describe the TMD itself we use the following parameters: m is the mass, k describes spring stiffness, c_T is a viscous damping coefficient and I represents the inertance of the inerter. Parameter m describes the total mass of the elements which can perform movement with respect to the base oscillator and will be called the mass of TMD.

Figure 2: Model of the system

The model of the system is given by:

$$\begin{cases} M\ddot{x}_1 + k_1x_1 + k_2x_1^3 + c\dot{x}_1 + k(x_1 - x_2) + c_T(\dot{x}_1 - \dot{x}_2) + \lambda(\dot{x}_1 - \dot{x}_2)|(\dot{x}_1 - \dot{x}_2)| + \\ + I(\ddot{x}_1 - \ddot{x}_2) = F \sin \omega_0 t \\ m\ddot{x}_2 - k_2(x_1 - x_2) - c_T(\dot{x}_1 - \dot{x}_2) - \lambda(\dot{x}_1 - \dot{x}_2)|(\dot{x}_1 - \dot{x}_2)| - I(\ddot{x}_1 - \ddot{x}_2) = 0. \end{cases} \quad (3)$$

with following parameters: $M = 100 [kg]$, $k_1 = 24000 [N/m]$, $k_2 = 0 [N/m^3]$, $c = 124 [Ns/m]$, $F = 192 [N]$, $m = 10 [kg]$, $k = 9600 [N/m]$, $c_T = 30.98 [Ns/m]$ and I is one of control parameters.

We perform calculations in Auto07p. It is toolbox for continuation of smooth problems, so we had to smooth the damping function by following formula:

$$\lambda = \lambda_2 + (\lambda_2/2 - \lambda_1/2)[\tanh(\gamma(x_1 - x_2 - a_{cr})) - \tanh(\gamma(x_1 - x_2 + a_{cr}))],$$

where $\gamma = 400$.

Then, we rewrite equations to dimensionless form introducing $\tau = \omega_r t$, reference length $l_0 = 1 [m]$ and natural frequency of main body $\omega_r = \sqrt{k_1/M}$:

$$\begin{cases} \ddot{x}'_1 + x'_1 + k_{2D}x'^3_1 + c_D\dot{x}'_1 + k_D(x'_1 - x'_2) + c_{TD}(\dot{x}'_1 - \dot{x}'_2) + \lambda_D(\dot{x}'_1 - \dot{x}'_2)|(\dot{x}'_1 - \dot{x}'_2)| + \\ + I_D(\ddot{x}'_1 - \ddot{x}'_2) = F_D \sin \omega \tau \\ m_D\ddot{x}'_2 - k_{2D}(x'_1 - x'_2) - c_{TD}(\dot{x}'_1 - \dot{x}'_2) - \lambda_D(\dot{x}'_1 - \dot{x}'_2)|(\dot{x}'_1 - \dot{x}'_2)| - I_D(\ddot{x}'_1 - \ddot{x}'_2) = 0. \end{cases} \quad (4)$$

where: $x'_{1,2} = x_{1,2}/l_0$, $\dot{x}'_{1,2} = \dot{x}_{1,2}/l_0\omega_r$, $\ddot{x}'_{1,2} = \ddot{x}_{1,2}/l_0\omega_r^2$, $k_{2D} = k_2l_0^2/M\omega_r^2$, $c_D = c/M\omega_r$, $k_D = kl_0^2/M\omega_r^2$, $c_{TD} = c_T/M\omega_r$, $m_D = m/M$, $F_D = F/Ml_0\omega_r^2$, $\lambda_D = \lambda/M$, $\omega = \omega_0/\omega_r$, $I_D = I/M$. For simplicity primes in dimensionless equations will henceforth be neglected.

4 Results

In this section we present results for obtained for TMD and TMDI with nonlinear and linear dampers.

4.1 Response of TMD with nonlinear damper

Let us study first the influence of nonlinear damper on response of the system mitigated with TMD ($I = 0.0 [kg]$). First we equate values of λ_1 and λ_2 to selected fractions of λ_{ref} . Results are presented in Fig. 3(a). We plot FRC of main body for varying frequency of excitation. Dashed line corresponds to FRC of the system without TMD and continuous lines to FRCs with applied TMD for $\lambda = 0.25\lambda_{ref}$, $\lambda = 0.5\lambda_{ref}$, $\lambda = 1.0\lambda_{ref}$, $\lambda = 1.5\lambda_{ref}$. As we can see for low values of λ we observe similar response as for TMD with linear damper. However, for $\lambda = 1.5\lambda_{ref}$ (large damping) we observe the non-linear trace of FRC (black line). In panel (b) we plotted FRC for optimal values of $\lambda = 0.62\lambda_{ref}$ and $c_{TD} = 0.62$ which corresponds to minimum L_2 norm (optimization procedure is not presented in this paper) for FRC plot. As one can see both FRC are similar, so we can obtain significant reduction of amplitude using both types of dampers.

Next, we fixed damping coefficients $\lambda_1 = 0.05\lambda_{ref}$, $\lambda_2 = 0.6\lambda_{ref}$ and we vary the switching distance a_{cr} . Thus, the damping coefficient is small for small relative amplitude and large for large relative amplitude. In Fig. 4(a) we show response with just nonlinear damping, while in Fig. 4(b) we combine nonlinear damper and linear one ($c_{TD} = 0.02$). In panel (a) we see typical change of response of system damped by TMD with increasing of damping in the system. The interesting observation is in panel (b) where with increase of a_{cr} we see decrease of minimum amplitude in valley while maximum values of amplitude preserve the same.

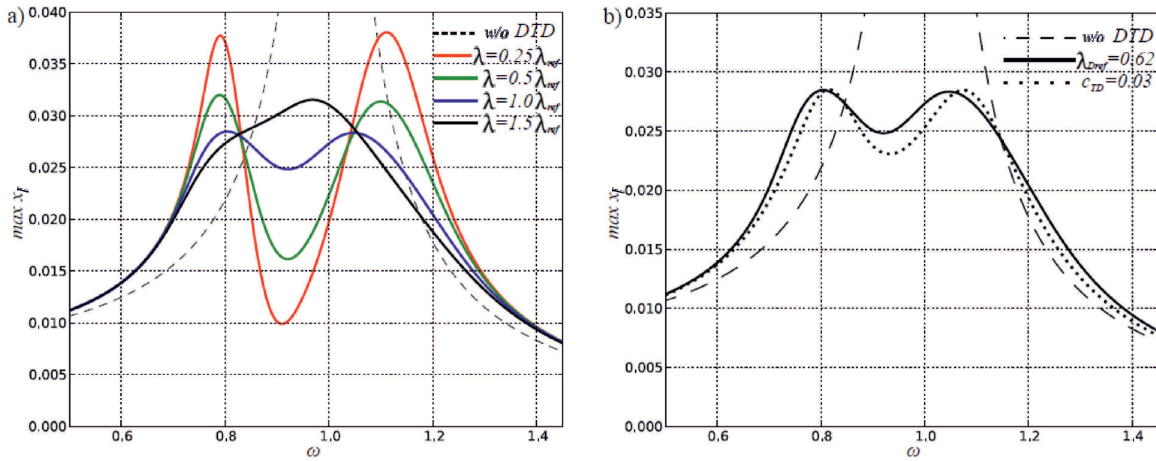

Figure 3: (a) FRC of system for with nonlinear damper and $F_D = 0.008$; $m_D = 0.1$; $c_D = 0.08$; $k_D = 0.08$; $c_{TD} = 0$; $a_{cr} = 0.02$; (b) FRC for system with nonlinear damper $\lambda_1 = \lambda_2 = \lambda_{ref}$ - continuous damper and linear damper $c_{TD} = c_{TDopt}$ - dotted line. Dashed line corresponds to response of the system without TMD.

4.2 Response of TMD inerter

In this subsection we perform calculation for system with TMDI and both types of dampers. We introduce control of inertance to tune natural frequency of TMDI to current frequency of excitation. We change inertance according to formula as follow: $I_D = \frac{k_D}{\omega^2} - m_D$ which changes equivalent mass of the TMDI. For details of this procedure see our previous papers where we preset it in details [24, 25, 26]. Such assumption let us follow response of the main system for varying value of inertance and find minimum amplitude for given equivalent mass of TMDI. In this paper we do not consider control of inertance value, but such theoretical study gives us fast answer about its efficiency. In Fig. 5 we can see four plots and reference dashed line which corresponds to response of the system without TMDI. There are two pairs of lines. In each pair we study TMDI with linear and nonlinear damper. The bottom lines are for low damping coefficients, while top lines for larger values of damping coefficients. As we can see, we obtain the same level of mitigation of vibrations in both cases. Thus, we can use two damper interchangeably.

5 CONCLUSIONS

In this paper we present the properties of TMDI with liner and nonlinear damper. We investigate properties of non-linear damper with piecewise quadratic damping characteristic using one DoF system and compare its free oscillations with response of system with linear viscous damper. Then, we applied TMDI with both types of dampers and we show their FRC plots. Finally, we applied control to inerter which let us change the inertance to tune natural frequency of TMDI to current frequency of excitation. In such configuration obtained FRC have similar amplitude, thus we show that both dampers are comparable. In further studies we will investigate influence of nonlinear damper parameters on response of damped body. We will prepare control algorithm which will change their values based on current state of the system to increase efficiency of TMDI.

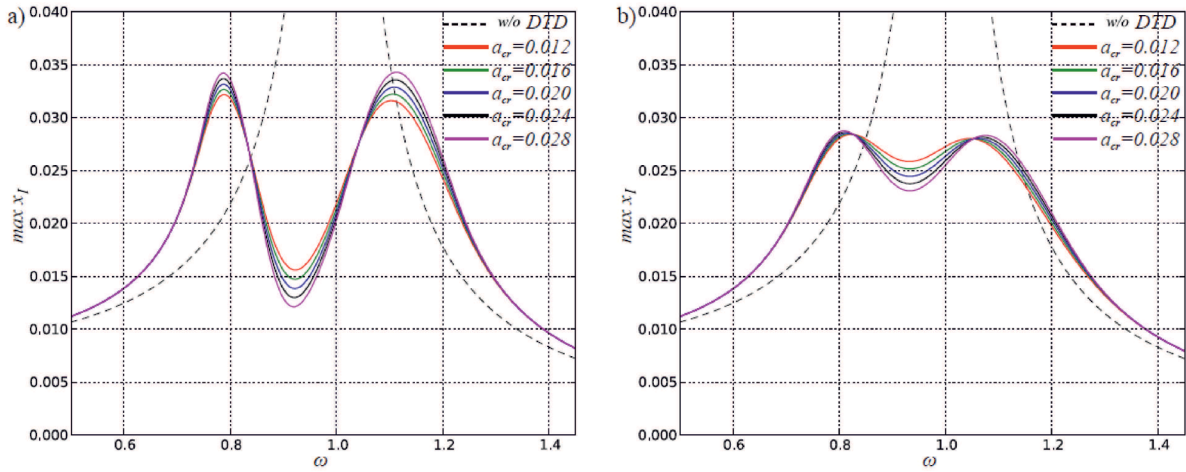

Figure 4: FRC of system for different values of a_{cr} with following parameters of the system: (a) $F_D = 0.008$; $m_D = 0.1$; $c_D = 0.08$; $k_D = 0.08$; $\lambda_1 = 0.05 \lambda_{ref}$, $\lambda_2 = 0.6 \lambda_{ref}$, $c_{TD} = 0$; (b) $F_D = 0.008$; $m_D = 0.1$; $c_D = 0.08$; $k_D = 0.08$; $\lambda_1 = 0.05 \lambda_{ref}$, $\lambda_2 = 0.6 \lambda_{ref}$, $c_{TD} = 0.02$. Dashed line corresponds to response of the system without TMDI.

Keywords: composites, SHM, numerical simulation, Lamb waves, guided waves

Abstract: Composite materials are now commonly used in various industries ranging from building to space science. The damage analysis in composites is an important task to ensure safe use and prevent failures. Structural health monitoring (SHM) approaches are developed to identify the damage in various structures. This research focuses on the guided wave-based SHM. The guided waves propagate throughout the material and get reflected at the damage or after reaching the boundaries. This is the basis for the damage detection method. The group velocity, RMSD, amplitude variation, the time of flight for the healthy, damage cases are analyzed. The frequency range of 50 kHz is used with a periodic cycle of 5 to analyze the wave pattern over the surface of the composite material. Thus, the change in the signals can be extracted through the developed algorithms and the damage location can be indicated. The studies comprised of scanning laser measurements. A composite GFRP plate with an L-stiffener was studied. The damage localization algorithms are employed for simulated damage in the form of stiffener debonding. The study comprised of analyzing the results from the laser Doppler vibrometer (LDV). The analysis of the LDV results and processing it provides further information about the damage location and its influence on the wave propagation.

1 INTRODUCTION:

Fiber reinforced composite materials are more and more popular in the industry. Such composite structures are lightweight, have large strength and are easy to form. However, they are prone to damage like debonding and delamination very often hidden inside the structure. Therefore the structural state of composite structures needs to be assessed. This allows for increasing the safety of composite structures exploitation. Very popular is the elastic wave propagation method. Many research works towards the development of damage assessment methods for composite structures using elastic wave propagation were published. There was the numerical and experimental study of elastic wave propagation in composite laminate conducted by Gresil, et al [1]. Authors investigated the dispersion curves and wave propagation. This is useful knowledge for the development of elastic wave based damage detection methods for composite structures. Very important is the problem of the debonding in the adhesive joints. Such problems were analyzed with the help of energy propagation RMS methods by Rucka, et al [2]. Gaul, et al [3] paper deals about the surface bonded transducers inspecting a large testing area. The paper is related to early warning maintenance of the structures with the help of built-in sensor network arrangements. LDV helps in the detailed analysis of various anisotropic materials. The interaction of Lamb waves with a T-stiffener has been analyzed by Allen, et al

[4]. Visualization of the damage in the bonding area between the composite plates was analyzed by Sohn, et al [5]. The delamination location between the composite plates was analyzed by Duflo, et al [6]. LDV analysis in the contactless observation in the anisotropic plate was presented by Owens, et al [7]. The damage observation depends on the area of the defect [8] and thus Kehlenbach, et al showed that the numerical and experimental results were analyzed together with it. Use of RMS in damage detection was shown by Radzienski, et al [9]. The delamination detection in the composite plate based on the change in Lamb wave response amplitudes was analyzed by Staszewski, et al [10].

This paper uses guided wave propagation with the help of laser Doppler vibrometer (LDV). The research in this paper focuses on processing the data obtained from the LDV using various methods of analysis guided wave propagation in a composite plate with stiffener.

2 EXPERIMENTAL PROCESS

In this paper, the Lamb wave propagation utilized for bond assessment in the composite plate is analyzed. The plate is of dimension 50x50x0.3 cm³ and includes bonded L-stiffener with a length of 50 cm (figure 1). The plate is made of 12 layers of VV 192T 202 IMP503 prepreg. The L-stiffener is bonded by 3M AF3109 2U bonding agent. The stiffener is not bonded in the middle part with the length 15 cm what simulating its debonding. The piezoelectric transducers (PZT) are attached at 3 different locations. One at the bottom and others to the right and left corner of the plate respectively (figure 1). The LDV with laser heads as shown in figure 2 is used for measuring the guided wave (GW) signals on the flat side of the plate.

Figure 1: Composite plate and PZT arrangement

Figure 2: Scanning laser heads

2.1 Setup

The elastic wave excitations are performed in 3 PZT across the plate as shown in figure 3.

1. PZT 3 is placed at the bottom of the plate.
2. PZT 2 is placed at the left end of the plate/flat side.
3. PZT 1 is placed at the right end of the plate/stiffened side.

The signals are registered with the help of only one LDV head (an out-of-plane component of velocity). Fine mesh area of about 61503 scanning point where elastic waves are registered is considered in the research. The very dense mesh allows correct space sampling for the shortest wave propagating in the structure.

Figure 3: PZT positions – view from the top

3 RESULTS

In the research analysis of the time of arrival (ToF) of the elastic wave is performed. The ToF of the elastic waves is identified based on analyzing the time instances between the wave packets. In this case, the first time instant related to the arrival time of the waves is noted. This is performed by using Hilbert transformation which allows creating the envelope of the signal. Higher the TOF value the larger the time taken for the waves to reach the same set of location. The obtained ToF values help to analyze the changes in the group velocities of the propagating wave modes. In figure 4, the time of arrival of the first wave packet is calculated by identifying the highest peak value (marked in the red spot). In a similar way, the time of arrival for other scanning points is calculated and noted down in table 1.

Figure 4: Time of arrival extraction

Figure 5 shows the different snapshots from the animation of the propagation of waves for 50 kHz excitation. At figure 5a the waves get excited from the PZT location to propagate in the plate. Then waves reached the middle stiffener region as shown in figure 5b. At figure 5c the propagating waves reaching the L-stiffener region and starts to separate indicating the region of damage. This is followed by the reflection of the waves after reaching the edges of the composite plate as shown in figure 5d. Table 1 shows the time of the first arrival of waves of various scanning points. It is understood that the time of arrival of the first wave packet is related to fundamental symmetric S0 wave mode which is faster than the fundamental antisymmetric A0 wave mode (also termed as slow waves in general).

3	281
4	296

Table 1: Time of arrival values of the S0 mode for varying scanning point

3.1 1D plot analysis:

In this section, a one-dimensional analysis is performed. The graphs are plotted by selecting points in two configurations as presented in figure 6a for case 1 and figure 6b for case 2 (focusing on the debonding zone). These analysis are carried out to understand the wave propagation from the results of the LDV measurements at different time points. In this study, the excitation with frequency 50 kHz is applied to PZT 3.

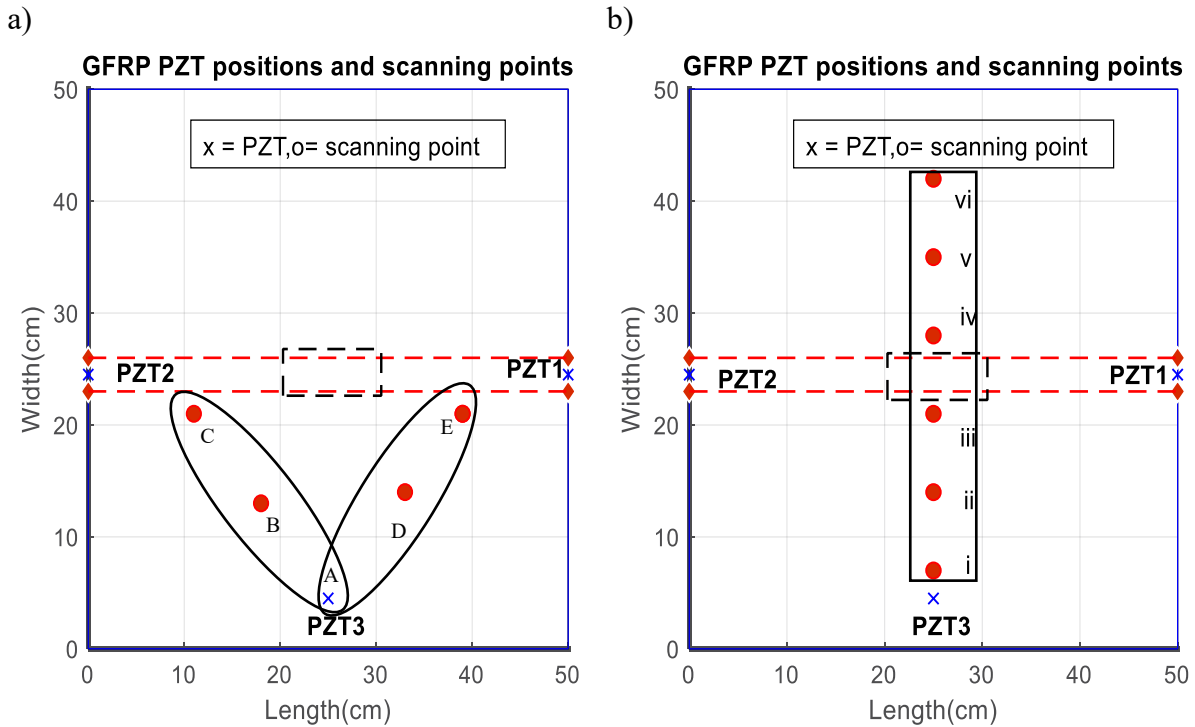

**Figure 6:** Scanning point distribution a) Case 1-angular distribution b) Case 2-linear distribution

Figure 7 indicates the wave propagation for case 2 of points distribution (i-vi) respectively. The case 2 analysis reveals that at the stiffener region which is at the mid-section of the plate occurs larger disruption of the signals indicating the damage region. Figure 7e indicates the wave propagation where it interacts with the stiffener region and passes through it. We have noticed the decrease in the wave amplitude as shown in table 2 is due to structural damping and reflection of the waves after striking the boundary. The case 2 plot informs about the waves and its propagation at various linear paths. We have found the change in the wave pattern happening

in the particular region as shown in figure 7d,e after it passes through the damage stiffener region. Figure 6a case1 is used to understand the propagation of the waves in an angular fashion before the debonding zone. There occurs a change in the amplitude and velocity values before and after the disbond region as shown in table 2 and table 3 respectively.

a) Points	Amplitude difference drop (%)	b) Points	Amplitude difference drop (%)
A-B	83.80	i-ii	54.63
B-C	55.21	ii-iii	38.44
A-D	83.33	iii-iv	75.59
D-E	44.41	iv-v	29.93

Table 2: Amplitude variation a) Case 1-angular distribution b) Case 2-linear distribution

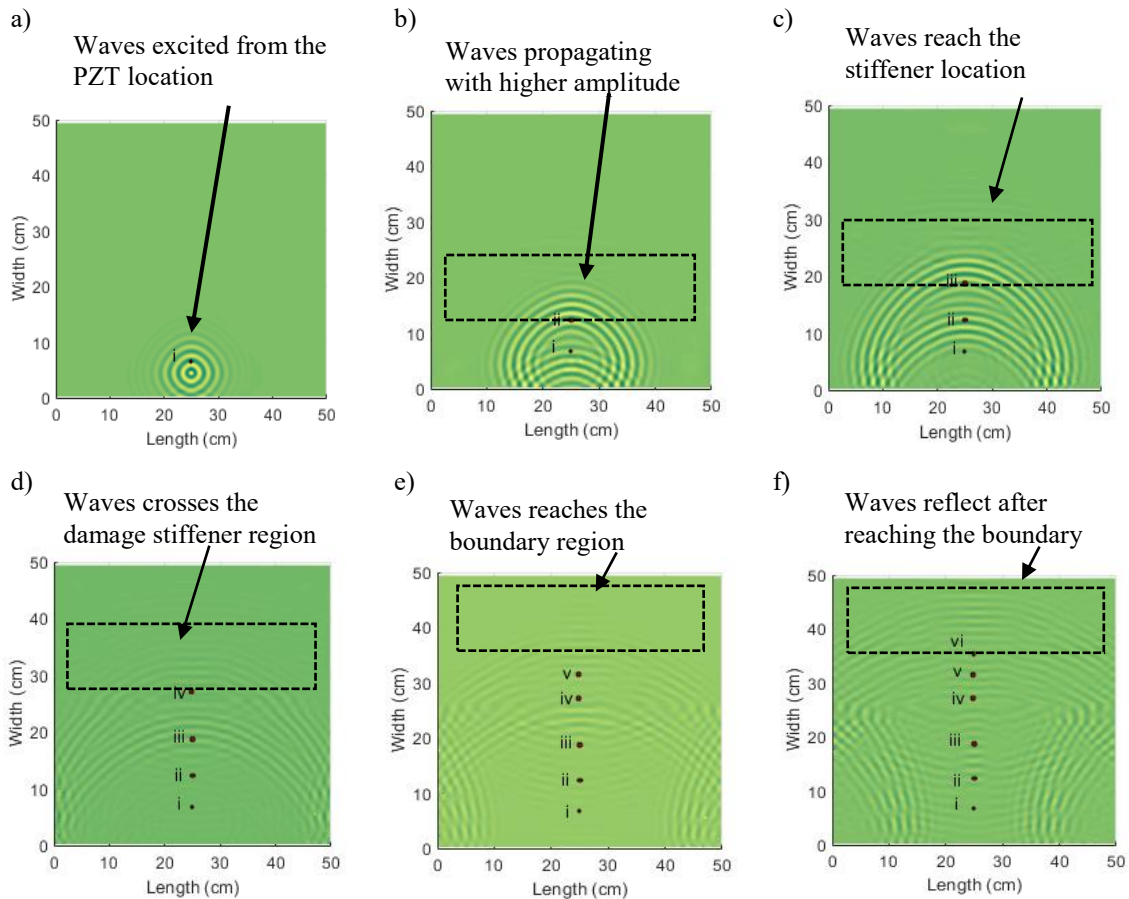

Figure7: Case 2 analyzed at a) 78 μ s, b) 130 μ s, c) 180 μ s, d) 250 μ s, e) 0.29 μ s, and f) 340 μ s

The velocity of the waves is analyzed as shown in table 3. This table shows the result for the case 1 and shows that higher velocity mode S0 mode that propagates from the PZT travels along the line and strikes the debonding region. Thereby an increase in velocity is noted at the path

between points B and C. Also from case 2, the velocity of the waves drops after crossing the debonded stiffener region as shown in points (iii-iv) and then the velocity increases which may be due to higher reflection from the boundary surfaces that results in the overlapping and interfering in the wave movement.

a) Case 1	A-B	B-C	A-D	D-E
Velocity (m/s)	702.459	875	702.459	875

b) Case 2	i-ii	ii-iii	iii-iv	iv-v	v-vi
Velocity (m/s)	1076.26	1328.27	995.73	1790.28	1328.27

Table 3: Velocity distribution a) Case 1-angular distribution b) Case 2-linear distribution

We have also used the root mean square deviation (RMSD) index for signal analysis in this paper [11]. The time signal is limited to 208 μ s to understand the change in the signals before and after the debonded region. Figure 8 is made with the RMSD formulation as shown below in equation (1):

$$RMSD = \sqrt{\sum_{i=1}^N \left(\frac{(a_i - b_i)^2}{(a_i)^2} \right)} \quad (1)$$

where: a - amplitude values for reference scanning point, b - amplitude values for final scanning point, N - no of time samples

Figure 8: RMSD values a) Case 1-angular distribution b) Case 2-linear distribution

From figure 8a, the RMSD results are analyzed for situation waves have not reached the stiffener region yet. It shows symmetrical values of RMSD index values for two paths of wave propagation. By analysing results presented in figure 8b it could be noted that the RMSD index values drop in a linear fashion and between points i, ii it shows higher wave signal difference. The RMSD values for case 2 do not indicate the influence of the stiffener disbond.

4 CONCLUSION

The paper shows the experimental approach for assessing the influence of stiffener debonding on wave propagation in the composite plate. The methodology is based on analysing the amplitude changes in the wave patterns before it reaches the debonding zone (L-stiffener) and the amplitude change after it crosses the debonding region. The process done may be concluded that the approaches used helps to assess the L-stiffener region. The amplitude gets reduces at the stiffener region indicating a decrease in the energy of the propagating waves. The use of LDV helps in measuring the wave measurements and velocity. In most of the cases, the basic symmetric and antisymmetric modes (A0 and S0) are detected. The excitation signals help to map the damage L-stiffener zone well. The 50 kHz maps the damage region well and thus chosen to be studied further.

The final conclusion is that the amplitude graphs from plotting distributed scanning points help to locate the damage region in the composite plate. The identification of the distributed waves at the L-stiffener region gets identified by the excitation frequency 50 kHz which produce shorter wave movements. These waves pass through the other side of the stiffener and reflect back after touching the boundary.

ACKNOWLEDGMENT:

The authors would like to acknowledge the support funding provided by the National Science Center, Poland under SONATA BIS project titled: Study of piezoelectric sensors placement and their interaction with structural elements (2016/22/E/ST8/00068).

Acknowledgment also provided to Task-CI for allowing the use of computational resources.

Key words: Electromechanical Impedance, Composite Materials, Debonding, Temperature Influence.

Abstract. In this paper authors present results of application of electromechanical impedance (EMI) method based on resistance spectra for damage assessment in composite materials. The EMI method is based on measurements of electrical parameters of piezoelectric transducer bonded on the structure. Due to electromechanical coupling structural changes are seen in electrical characteristics of the piezoelectric transducer. Authors investigated influence of bonding transducer on structural parts with different material and geometrical properties on the resistance spectra. Authors investigated also influence of changing temperature and damage (stiffener debonding) existence on resistance spectra. Results showed that temperature compensation is needed for the purpose of damage detection. Authors proposed temperature compensation algorithm based on signal correlation. Research was conducted for model of structure of composite powerboat. Preliminary measurements were also conducted for the powerboat.

1 INTRODUCTION

Fibre reinforced polymer (FRP) composite structures are very popular in many branches of industry like aviation, automotive and maritime. Application of these materials allows a reduction of weight ensuring high strength to weight factor. Beside the advantages there are also disadvantages related to application of such materials. Important one is related to vulnerability of FRP composites to hidden/barely visible delamination caused by impact loading. Such a hidden damage could cause serious failure of the structure resulting in human injury or even

dead. In order to increase safety of exploitation of FRP composite structures non destructive testing (NDT) or structural health monitoring (SHM) techniques are utilised. Such methods like ultrasound testing (UT) [1], thermography [2], elastic waves propagation [2],[3] and electromechanical impedance [4], [5] are utilised.

The research reported in this paper is related to electromechanical impedance. The authors focused attention on damage detection under the temperature influence for complex composite structures utilised in real maritime structures, i.e. a powerboat. Such structures are manufactured using curved composite laminates with varying thickness, sandwich composite with honeycomb or foam filled and bonded stiffeners. Research was mainly focused on the model of composite structure utilised in powerboat construction. Preliminary research was related to real powerboat. The research that results are presented in this paper is related to development of structural health monitoring system based on electromechanical impedance method for assessment of composite powerboat.

2 ELECTROMECHANICAL IMPEDANCE METHOD

The electromechanical impedance (EMI) method is based on measurements of electrical parameters of piezoelectric transducer coupled with the investigated structure. Due to electromechanical coupling of piezoelectric transducer with the structure the mechanical resonant characteristics of structure could be indentified based on electrical characteristics of piezoelectric transducer. This method is suitable for damage detection and transducer self-diagnosis.

In the research presented in this paper measurements for EMI were realised using impedance analyser HIOKI IM3570 and piezoelectric transducers in the form of discs with diameter 10 mm and thickness 0.5 mm. Transducers were manufactured by NOLIAC using NCE51 piezoelectric material and had a wrap-around electrodes. Spectra of real part of impedance (resistance) were registered in this research.

3 EXPERIMENTAL RESEARCH

Experimental research was related to two objects. First object was a model of composite structure of powerboat (Figure 1). Model includes all the structural features related to real composite powerboat: curved sandwich GFRP honeycomb structure with thickness 4 mm (location of transducer PZT1), composite sandwich of GFRP structure filled with the foam with thickness 12 mm (location of PZT2), bonded stiffeners (e.g. CFRP stiffener with thickness 3mm – location of PZT3).

Second object was composite powerboat. In the Figure 2 the rear part of powerboat including structure where the engine is mounted was shown. This structure was equipped with piezoelectric transducer PZT4. Transducer was located near bolted joints connecting engine to the powerboat.

Figure 1: Model of composite structure of powerboat in climate chamber

Figure 2: Demonstrator of composite powerboat

3.1 Influence of structure of EMI characteristics

First step was related to study the influence of bonding of piezoelectric transducer on structures with different material and geometry properties on EMI resistance spectra. All measurements were performed in the room temperature.

In the Figure 3a) resistance spectrum for free (not bonded) piezoelectric transducer was presented. Peak with largest amplitude at frequency 220 kHz is related to radial resonance of transducer which could be estimated using frequency constant of NCE51 piezoelectric material. In the Figure 3b) resistance spectrum for the piezoelectric transducer PZT1 bonded on the curved part of model of composite structure (Figure 1) was presented. Model was installed in the climatic chamber (Figure 1). Influence of bonding on structure is clearly visible. Peak with frequency 220 kHz is much wider and its amplitude was reduced. Frequency of small peak at 500 kHz for free transducer after bonding remains almost the same. Frequency of small peak at 800 kHz for free transducer after bonding increased to about 850 kHz. Additionally after bonding new peak at frequency around 100 kHz could be noticed. In the Figure 4a) magnification of frequency band up to 150 kHz for bonded transducer PZT1 was presented. Peaks related to resonant frequencies of the structure with bonded transducer could be noticed.

In the Figure 3c) resistance spectrum for transducer PZT2 bonded on the thicker part of composite model filled with the foam is presented. There are large peaks about frequencies 250 kHz and 550 kHz and peak at frequency 50 kHz. In the Figure 4b) low frequency region of resistance spectrum was presented. Resonant peaks below frequency 25 kHz have smaller amplitudes than for transducer PZT1.

In the Figure 3d) resistance spectrum for transducer PZT3 bonded on CFRP stiffener (100 mm x 100 mm x 3 mm) bonded to the composite model was presented. Additional peaks in the region about 200 kHz – 350 kHz are visible.

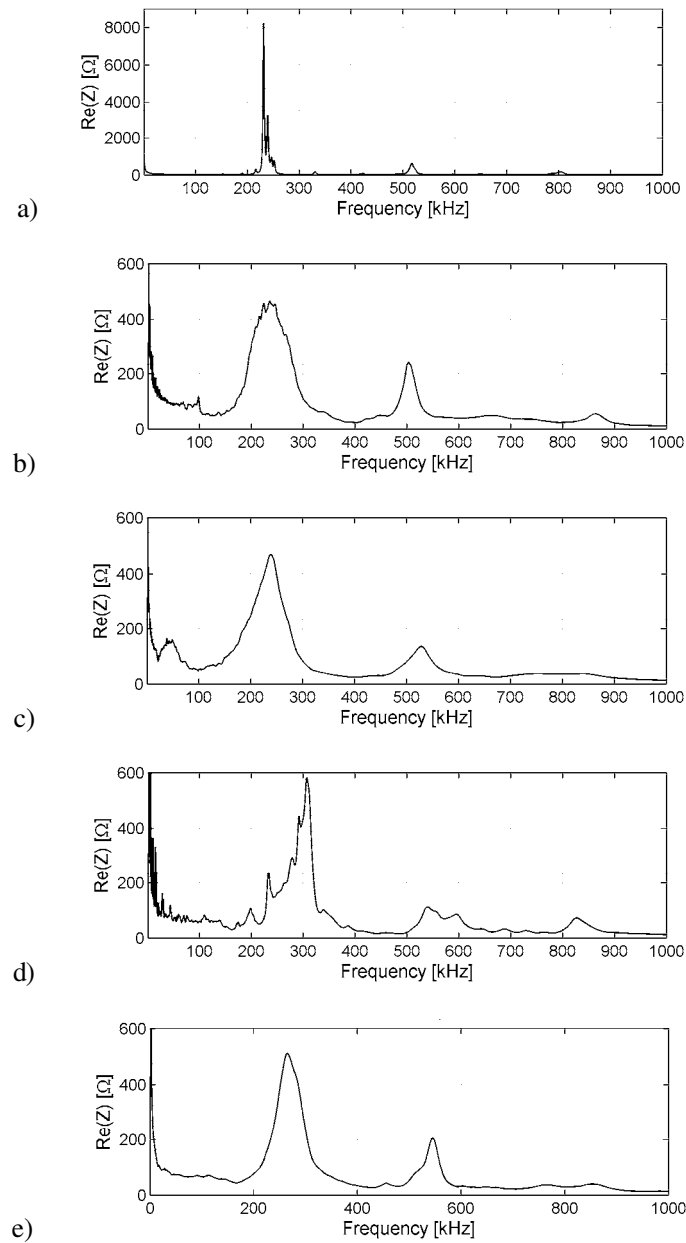

Figure 3: Resistance spectra for piezoelectric transducers: a) free, b) PZT1, c) PZT2, d) PZT3, e) PZT4

Moreover, resonant peaks for frequencies lower than 100 kHz are visible. This could be clearly visible in the Figure 4c). There are clear and strong peaks related to the resonant frequencies of this stiffener.

In the Figure 3e) resistance spectra for transducer PZT4 bonded on the powerboat (Figure 2) was presented. There are two large peaks at frequencies about 250 kHz and 550 kHz. Resonant peaks for frequencies below 150 kHz are clearly visible in Figure 4d). Amplitudes of those peaks are very low. Summarising all presented results, it could be noticed that amplitudes for resonant peaks for frequencies bellow 150 kHz decrease with increase of the thickness of the structure.

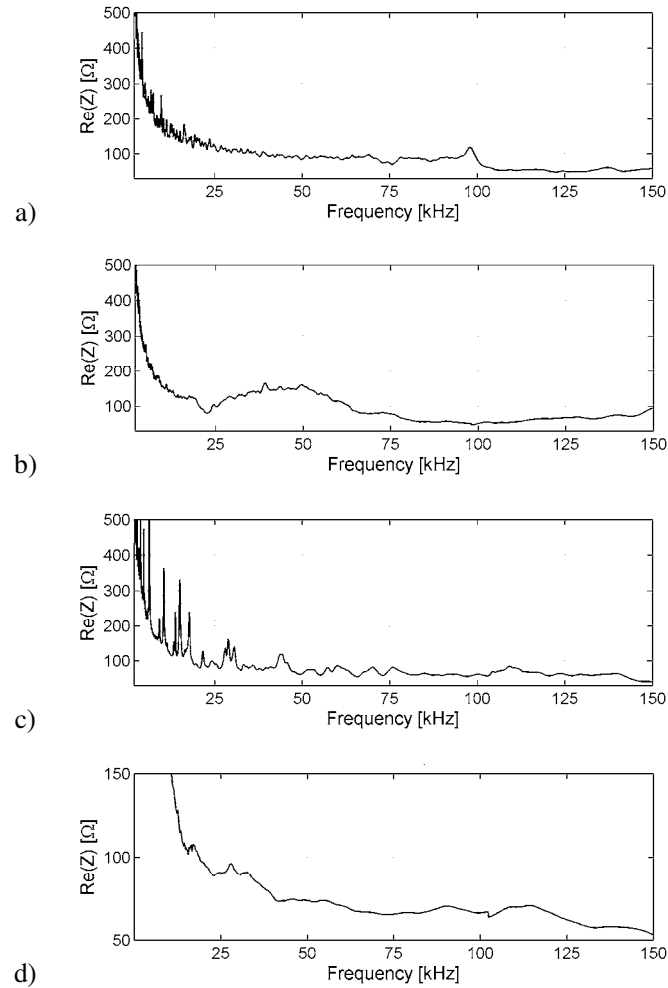

Figure 4: Low frequency region of resistance spectra for piezoelectric transducers:
a) PZT1, b) PZT2, c) PZT3, d) PZT4

3.2 Influence of temperature on EMI characteristics

In next step analysis of influence of changing temperature on resistance spectra for piezoelectric transducer PZT3 bonded on the composite model of structure of powerboat (Figure 1) was investigated. This is very important problem, because changing temperature is source of change of resistance spectra and it can result in false alarms in the SHM systems. Therefore temperature compensation needs to be performed. Measurements for this part of research were performed in climatic chamber under 5 stable temperatures 30, 20, 10, 0 and -10°C .

In the Figure 5 results in the form of resistance spectra for two selected frequency bands were presented. In the Figure 5a) resistance spectra for frequency band 8–17 kHz was presented. As referential resistance spectrum for temperature 30°C is taken. With decreasing temperature resonant peaks shift rightwards. In the Figure 5b) resistance spectrum for frequency range 200–350 kHz was presented. In this case the same effect is observed. Resonant frequencies shift rightwards with decreasing temperature. Such effects were observed in the whole investigated frequency band 1 kHz –1 MHz.

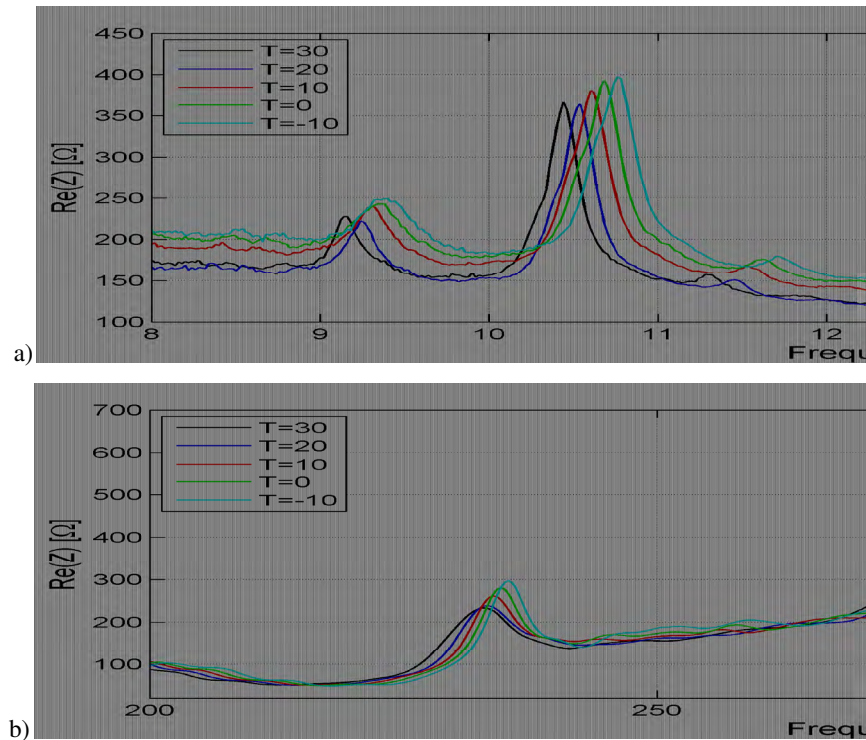

Figure 5: Influence of changing temperature on resistance spectra for frequency band:
a) 8–17 kHz, b) 200–350 kHz

3.3 Influence of debonding on EMI characteristics

Next part of research was related to influence of debonding of CFRP stiffener on resistance spectra. In this case measurements were also taken by transducer PZT3 bonded on the stiffener (Figure 1). Artificial debonding was simulated by 10 mm long cut of bonding layer joining stiffeners with the model (Figure 6).

Figure 6: Artificial debonding of stiffener

Figure 7: Relative frequency shift as a function of relative temperature change for pristine and damaged structure (D)

Investigations started from analysis of temperature influence on frequency shift for pristine (healthy) and damaged structure. Few resonant peaks were selected from the resistance spectra for both cases. Then the frequency shifts for both cases (pristine and damaged) were extracted taking as a reference spectra gathered at temperature 30 °C. Relative frequency shifts for pristine and damaged structure in the function of relative temperature change are plotted in Figure 7. It could be noticed that relative frequency shifts for pristine and damaged structure differ.

For detailed analysis resonant peak from frequency band 3.6-4 kHz (peak with frequency 3.776 kHz for pristine and 3.756 kHz for damaged structure) was considered. Debonding of the stiffeners caused leftward shift for the selected peak. In Figure 8a) comparison of resistance spectrum for pristine structure (R30) and structure with deboned stiffener (D30) both measured at temperature 30 °C were presented. It could be noticed that in the case of debonding resonant peak was shifted leftwards in respect to the one from healthy structure. In the same figure, also the spectrum for the pristine structure taken at temperature 20 °C was presented. In this case rightwards shift of peak in pristine structure for decreasing temperature is observed. Decrease of temperature by 10 °C for pristine structure caused similar value of frequency shift like debonding but direction of the shift is opposite.

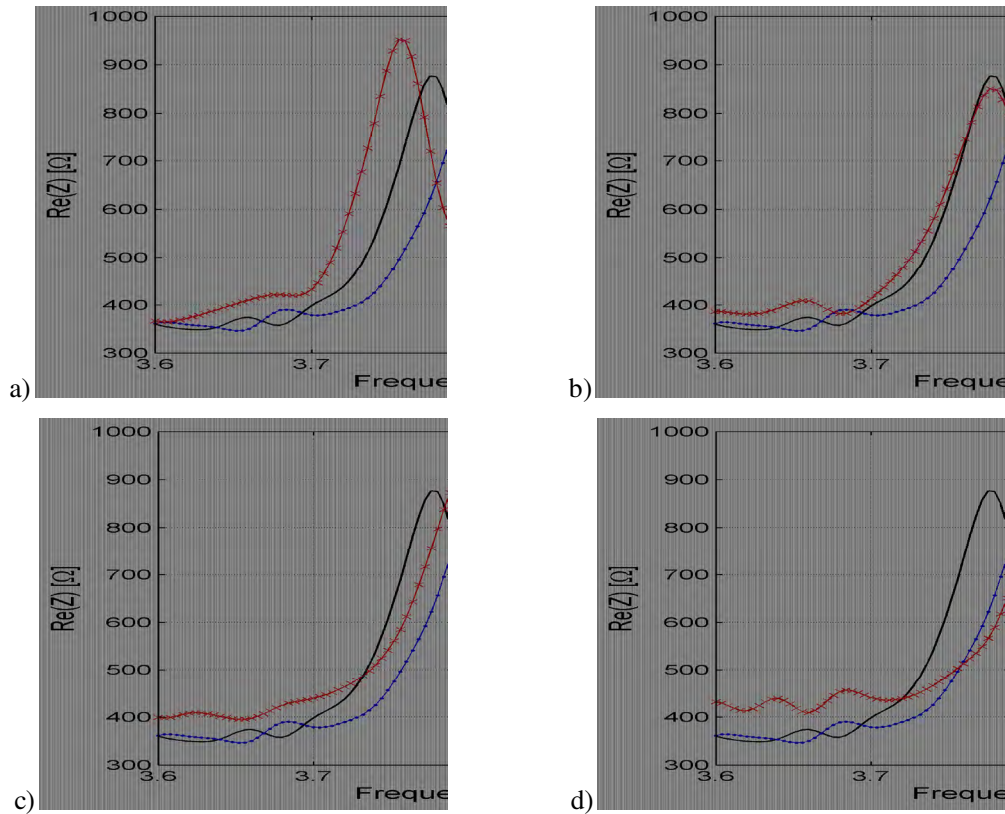

Figure 8: Influence of temperature and debonding on selected resonant peak, deboned stiffener measured at:
a) 30 °C, b) 20 °C, c) 10 °C, d) 0 °C

In the Figure 8b) resistance spectra for pristine structure taken at referential temperature 30 °C (R30) and at temperature 20 °C (R20) are compared with resistance spectrum for deboned structure at temperature 20 °C (D20). It could be noticed that resonant peak for deboned structure measured at decreased temperature 20 °C (D20) has similar frequency to the pristine spectrum taken at referential temperature 30 °C (R30). So a damage indicator based on the shift of resonant peak would not distinguish differences between pristine and damaged structure. Influence of debonding together with decrease of temperature by 10 °C caused that resonant frequencies for pristine and damaged structure are almost the same.

In the Figure 8c) effects of further decrease of temperature for deboned stiffener could be observed. Resistance spectrum for deboned structure at temperature 10 °C (D10) was plotted. Moreover resistance spectra for pristine structure taken at temperatures 30 °C (R30) and 20 °C (R20) were plotted. Resonant peak for deboned structure (D10) was further shifted rightward due to temperature decrease. However, its shift is still lower than for the peak at temperature 20 °C for pristine structure (R20). Further decrease of temperature to 0 °C for deboned structure caused further shift of resonant peak (D0) what is presented in Figure 8d). Resonant peak for deboned structure at temperature 0 °C (D0) is more shifted than resonant peak for pristine structure at temperature 20 °C (R20). This analysis shows that effects of changing temperature need to be compensated for the problem of damage detection.

3.4 Compensation of changing temperature influence

In the purpose of compensation of temperature influence formula (1) is utilised. This allows comparing the correlation of resistance spectra at referential and changed temperature conditions.

$$CCD = 1 - \sum_{i=1}^n \frac{[R(i)_0 - \bar{R}_0] [R(i)_1 - \bar{R}_1]}{\sigma_0 \sigma_1} \quad (1)$$

where: $R(i)_0$ – is the i -th sample of resistance spectrum in signal at referential temperature, $R(i)_1$ – is the i -th sample of temperature influenced resistance spectrum, \bar{R}_0, \bar{R}_1 – mean values of respectively referential and temperature influenced spectra, σ_0, σ_1 – standard deviations for referential and temperature influenced spectra. Temperature influenced resistance spectrum is shifted in such a manner in order to obtained the minimum value of CCD index indicating maximum correlations of the signals. As results frequency shift needed to obtain best match of analyzed signals is registered.

This approach was utilized for resistance spectra including selected resonant peak for pristine structure for temperatures: 20, 10, 0 and -10 °C. In the Figure 9 frequency shift in the function of temperature was plotted for the investigated temperature change.

Figure 9: Frequency shift in the function of temperature for pristine structure

Figure 10: Results of temperature compensation for pristine structure

It could be noticed that this shift is linear for investigated temperature range. In the Figure 10 result of temperature compensation algorithm for selected peak was presented. In this figure spectra for pristine structures taken at temperature 30 °C (R30) and 10 °C (R10) were presented. Frequency shift due to temperature decrease is clearly visible. Moreover, compensated spectrum (RC10->30) which was shifted based on relation presented in Figure 9 was shown. It could be noticed that frequency shift was removed. In the Figure 11a) values of CCD index for comparison of signals for pristine structure at different temperatures were presented. In this case referential resistance spectrum at temperature 30 °C was compared with the spectra taken at temperatures 20, 10, 0 and -10 °C. CCD index values for those cases were marked respectively as R20, R10, R0 and R-10.

In the Figure 11b) results of influence of compensation of temperature change on CCD index were plotted. CCD index values for compensated spectra were marked respectively as RC20->30, RC10->30, RC0->30, RC-10->30. It could be noticed that values of CCD index decreased significantly after the compensation. This indicates the fact that frequency shift caused by temperature change was removed.

Figure 11: The CCD index values for comparison of referential spectrum with temperature influenced spectra for pristine structure: a) before compensation, b) after compensation (see descriptions in the text)

Then such approach was utilised for the spectra for deboned stiffener registered at different temperatures. In this case spectrum for pristine structure taken at temperature 30 °C was compared with spectra registered at different temperatures for damaged structure. Results in the form of values of CCD index were presented in the Figure 12. First value (R20) is related to comparison with the spectra for pristine structure at temperatures 30 and 20 °C. Next results of comparison were presented of spectrum for pristine structure at temperature 30 °C with spectra for damaged structure at temperatures 50, 30, 20, 10, 0 and -10 °C in the form of CCD index values. Measurement at temperature 50 °C for damaged structure was utilised for the purpose of verification temperature compensation algorithm. CCD index for this case is the largest. Analysing further values of CCD index it could be noticed that decrease temperature to 20 °C for pristine structure has larger influence on CCD than debonding for structure at referential temperature 30 °C. Decreasing the temperature of damaged structure to 20 caused that CCD is even smaller than for temperature 30 °C. Then slightly CCD is increased for temperature 10 °C. In the case of temperature 0 °C CCD value for damaged structure is higher than CCD valued for pristine structure at temperature decreased to 20 °C. This is related to frequency shift of signal due to temperature and debonding discussed in for the Figure 8. In the case of damage structure at temperature -10 °C CCD index further increased. This shows that without temperature compensation correct damage assessment is not possible. Therefore procedure of temperature compensation for spectra taken for damaged structure at different temperatures was performed. In this case frequency shifts for compensation were taken from the case of analysis performed for pristine structure. In the case of temperature 50 °C (lack of spectrum for pristine structure) frequency shift was extrapolated based on linear relation presented in Figure 9. Results of temperature compensation were presented in Figure 12. The CCD index values for compensation cases were marked as DC50->30 – DC-10->30. The values of CCD index for compensated spectra for damaged structure at temperatures: 20, 10, 0, -10 and 50 °C are similar like for damaged structure at 30 °C. It could be noticed that CCD for the case DC50->30 related to damaged structure measured at 50 °C and compensated to 30 °C is much larger than for the rest compensated cases.

Figure 12: The CCD index values for comparison of referential spectrum with temperature influenced spectra for damaged structure before and after compensation (see descriptions in the text)

In the Figure 13 results of temperature compensation for spectra measured for damaged structures at temperatures 10 and 50 °C were presented. In the Figure 13a) spectra for damaged structure measured at temperatures 30 °C (D30) and 10 °C (D10) were presented. Moreover spectrum measured at temperature 10 °C and compensated to temperature 30 °C was presented. It could be noticed that spectrum after temperature compensation (DC10->30) does not perfectly match the spectrum measured at temperature 30 °C (D30).

The same approach was performed for the spectrum for damaged structure taken at temperature 50 °C. Results are presented in the Figure 13b). In this figure spectra at temperatures 30 °C (D30) and 50 °C (D50) were presented. Moreover, compensated spectrum from 50 °C to 30 °C (DC50->30) was presented. This compensated spectrum also does not match the spectra measured at temperature 30 °C (D30). This could be caused by fact that for compensation frequency shift was extracted from the case of pristine structure. Damage changed slightly the influence of temperature on frequency shift (see Figure 7). This could also be caused by fact that value of frequency shift for temperature 50 °C was extrapolated due to the lack of value of frequency shift for pristine structure.

Moreover, analyzing results in the Figure 13 it could be noticed that decreasing temperature from 30 to 10 °C caused rightward frequency shift (Figure 13a) while increasing temperature from 30 to 50 °C caused leftward shift (Figure 13b).

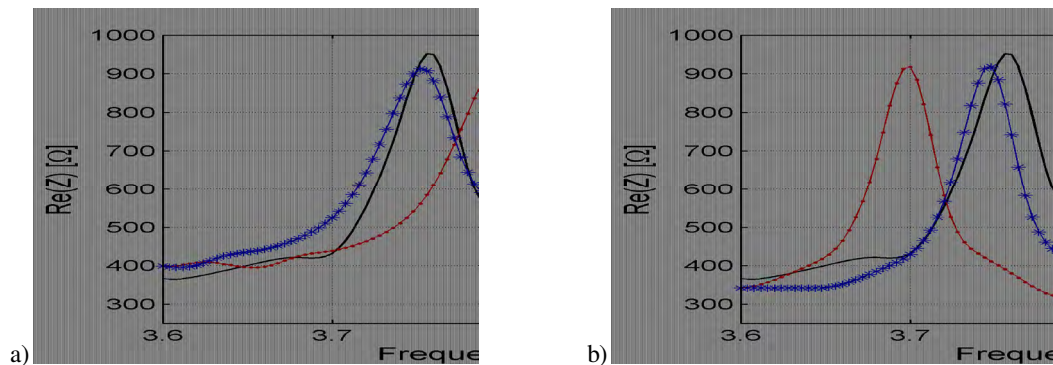

Figure 13: Results of temperature compensation for damaged structure at temperature: a) 10 °C, b) 50 °C

CONCLUSIONS

In this paper influence of bonding of piezoelectric transducer on composite structures with different material and geometrical properties on resistance spectra for EMI method was

discussed. It was noticed that amplitudes of resonant peaks for frequencies below 150 kHz were smaller for the thicker structures.

Detailed analysis of influence of changing temperature on resistance spectra was also investigated. Changing temperature caused leftward shift with decreasing temperatures observed for frequency range 1 kHz – 1 MHz. For selected resonant peak in low frequency range (3.5-4 kHz) linear frequency shift was noticed for the changing temperature. Authors investigated positive and negative temperatures.

Moreover influence of debonding of stiffener on change of resistance spectra was investigated. In this case additional influence of temperature on damaged structure was investigated. It was shown that compensation of changing temperature influence is needed for the purpose of damage detection. Temperature compensation algorithm based on cross-correlation was proposed. Application of this algorithm allowed compensating the influence of temperature.

Further work will be related to similar test for the transducers installed on a powerboat. Measurements will be also carried out on the water in the real operational conditions.

Abstract. Commercial composite aerospace structures are required to be designed and life cycle managed under the damage tolerant principle, while the airworthiness is maintained through the process of scheduled inspection, repair or replacement [1]. In that sense, the scheduled inspection of a structural component is addressed by visual and if needed by non-destructive inspection (NDI) techniques. However, this current practice accounts for more than 27% of the total cost of an aircraft [2], where this cost is mainly due to the high degree of human interaction, and the fact that the structural components which are difficult to access have to be disassembled. To reduce the maintenance cost, Structural Health Monitoring (SHM) has emerged in the inspection strategies, where the health state of the structure is monitored using in-situ sensors [3]. Along with sophisticated data management and multiphysics modeling, the actual state of the structure can be assessed (in sense of reliability), and its remaining useful can be prognosed.

The objective of this study is the development of a damage detection methodology based on principal component analysis, applied to composite coupons that have undergone different impact energies and delaminated area.

2 EXPERIMENTAL SETUP

The test set-up consists of “49” composite coupons of dimensions: $400 \times 400 \times 2$ [mm³]. Six single-lead zirconate titanate (PZT) were surface-mounted on each coupon using an adhesive (cf. Figure 1). The employed PZT emitters/receivers are “10 mm” in diameter and “0.5 mm” in thickness. An SHM hardware/data acquisition were used to carry out the experiments using a pitch-catch setup. A pulse with a duration of 100 μ s was driven the PZT in round-robin mode with sampling frequency acquisition of 5 MHz.

After the baseline signals were recorded on each coupon, impact testing with different energies were carried out in order to obtain different size of delaminated area (cf. Figure 2-3). It is to be noted that impact energies were defined from 8 to 13 J, with different location on the coupons.

3. DAMAGE DETECTION APPROACH

3.1 Blind Source Separation

Let $\underline{\mathbf{y}}(k)$ be a zero mean measurement vector from n_y PZT sensors at time index k :

$$\underline{\mathbf{y}}(k) = [y_1(k) \dots y_{n_y}(k)]^T \quad (1)$$

The measurement matrix $\mathbf{Y} \in \mathbb{R}^{n_y \times N}$ gathering N samples $\underline{\mathbf{y}}(k) (k = 1, \dots, N)$ is defined as follows:

$$\mathbf{Y} = [\underline{\mathbf{y}}(1) \dots \underline{\mathbf{y}}(N)] \quad (2)$$

The linear Blind source separation (BSS) is defined as [4-5]:

$$\underline{\mathbf{y}}(k) = \mathbf{T}\underline{\mathbf{s}}(k) + \underline{\boldsymbol{\epsilon}}(k) \quad (3)$$

where \mathbf{T} is the mixing matrix, $\underline{\mathbf{s}}(k) = [s_1(k) \dots s_{n_y}(k)]^T$ is the sources vector and $\underline{\boldsymbol{\epsilon}}(k) = [\epsilon_1(k) \dots \epsilon_{n_y}(k)]^T$ represents all the uncertainties and perturbation effects (modeling uncertainty and noises). In the present study, we consider the noise-free model (4):

$$\underline{\mathbf{y}}(k) = \mathbf{T}\underline{\mathbf{s}}(k) \quad (4)$$

BSS is an estimation problem, and it is accomplished by finding simultaneously an estimated sources vector $\underline{\hat{\mathbf{s}}}(k)$ and a separation matrix noted \mathbf{W} only from the observed data $\underline{\mathbf{y}}(k)$:

$$\underline{\mathbf{r}}(k) = \underline{\hat{\mathbf{s}}}(k) = \mathbf{W}\underline{\mathbf{y}}(k) \quad (5)$$

where $\underline{\mathbf{r}}(k) = [r_1 \dots r_{n_y}]^T \in \mathbb{R}^{n_y \times 1}$ and $\mathbf{W} \in \mathbb{R}^{n_y \times n_y}$ are respectively the estimated sources vector at instant k and the separation matrix. Equation (5) is called the separation model.

Clearly, without additional assumptions, the BSS problem (equation (5)) is ill-posed. Cardoso [4] has shown that the BSS problem can be resolved using assumptions done on the nature of sources. In this paper, we assume that the sources are temporally identically and independently distributed (*iid*) and Gaussian, which leads to the principal component analysis method.

3.2 Principal component analysis

The separation of sources relies on the basic knowledge of the mutual independence of source components. It is then natural to resolve the BSS problem by minimizing a dependence criterion between these components. In our study, we adopt the mutual information as the separation criterion [5]. From equation (5), the solution is to find the matrix \mathbf{W} , so that the mutual information is zero. In the case where the sources are assumed to follow Gaussian distribution, the mutual information $I(\underline{\mathbf{r}})$ is given by:

$$I(\underline{\mathbf{r}}) = \frac{1}{2} \ln \frac{\prod_{i=1}^{n_y} \sigma_{r_i}^2}{\det(\underline{\Sigma}_{\mathbf{r}})} \quad (6)$$

If the components r_i of the vector $\underline{\mathbf{r}}$ have to be statistically independent, mutual information defined in (6) is equivalent to:

$$I(\underline{\mathbf{r}}) = 0 \quad \Rightarrow \quad \prod_{i=1}^{n_y} \sigma_{r_i}^2 = \det(\underline{\Sigma}_{\mathbf{r}}) \quad (7)$$

Knowing that covariance matrix $\underline{\Sigma}_{\mathbf{r}}$ is symmetric, equality (7) is satisfied if the covariance matrix $\underline{\Sigma}_{\mathbf{r}}$ is diagonal: the sources are uncorrelated and statistically independent. Principal component analysis of a measurement vector $\underline{\mathbf{y}}$ is defined as a pair of matrices $\{\mathbf{P}, \underline{\Lambda}_{\Sigma_{\mathbf{y}}}\}$ such that the covariance matrix $\underline{\Sigma}_{\mathbf{y}}$ is factorized:

$$\underline{\Sigma}_{\mathbf{y}} = \mathbf{P} \underline{\Lambda}_{\Sigma_{\mathbf{y}}} \mathbf{P}^T \quad (8)$$

where $\mathbf{P} = [\underline{\mathbf{p}}_1 \cdots \underline{\mathbf{p}}_{n_y}] \in \mathbb{R}^{n_y \times n_y}$ is the matrix of eigenvectors and $\underline{\Lambda}_{\Sigma_{\mathbf{y}}}$ is the diagonal matrix of eigenvalues. The separation matrix, noted now \mathbf{W}_{PCA} , is given by:

$$\mathbf{W}_{\text{PCA}} = \underline{\Lambda}_{\Sigma_{\mathbf{y}}}^{-\frac{1}{2}} \mathbf{P}^T \quad (9)$$

In order to reduce the number of principal components (PCs), we use the cumulative percent variance (CPV). It is a measure of the percent variance captured by the first n_r PCs:

$$\text{CPV}(n_r) = 100 \frac{\sum_{i=1}^{n_r} \lambda_i}{\sum_{i=1}^{n_y} \lambda_i} \quad (10)$$

3. Damage Index and Results

We seek to detect changes in the structure by monitoring specific features estimated from baseline observation set (referred by the exponent "s") and observation set of an unknown state (referred by the exponent "u"). We note \mathbf{Y}^s , \mathbf{Y}^u , respectively, the measurement matrix of the structure in a healthy and unknown state. To define the feature, we use the separation matrices $\mathbf{W}_{\text{PCA}}^s$ and $\mathbf{W}_{\text{PCA}}^u$. From (9), we have:

$$\mathbf{W}_{\text{PCA}}^s = \underline{\Lambda}_{\Sigma_{\mathbf{y}^s}}^{-\frac{1}{2}} (\mathbf{P}^s)^T \quad (11)$$

$$\mathbf{W}_{\text{PCA}}^u = \underline{\Lambda}_{\Sigma_{\mathbf{y}^u}}^{-\frac{1}{2}} (\mathbf{P}^u)^T \quad (12)$$

Using a fixed CPV, the separating matrix $\mathbf{W}_{\text{PCA}}^s$ and $\mathbf{W}_{\text{PCA}}^u$ can be rewritten as follows [7]:

$$\begin{aligned} \mathbf{W}_{\text{PCA}}^s &= \mathbf{I}_{n_y \times n_y} \mathbf{\Gamma}^s (\mathbf{V}^s)^T = [\mathbf{I}_{n_y \times n_r} \quad \mathbf{I}_{n_y \times (n_y - n_r)}] \begin{bmatrix} \mathbf{\Gamma}_1^s & \mathbf{0} \\ \mathbf{0} & \mathbf{\Gamma}_2^s \end{bmatrix} [\mathbf{V}_1^s \quad \mathbf{V}_2^s]^T \\ &= \mathbf{W}_{\text{PCA1}}^s + \mathbf{W}_{\text{PCA2}}^s \end{aligned} \quad (13)$$

where:

$\mathbf{\Gamma}_1^s = \text{diag}(\sigma_1 \cdots \sigma_{n_r})$, $\mathbf{V}_1^s = [\mathbf{v}_{11}^s \cdots \mathbf{v}_{1n_r}^s] \in \mathbb{R}^{n_y \times n_r}$ and $\mathbf{W}_{\text{PCA1}}^s \in \mathbb{R}^{n_y \times n_y}$ are respectively the matrix of singular values, the matrix of right singular vectors and the separation matrix associated to the principal subspace of the healthy structure.

$\mathbf{\Gamma}_2^s = \text{diag}(\sigma_{n_r+1} \cdots \sigma_{n_y})$, $\mathbf{V}_2^s = [\mathbf{v}_{2(n_r+1)}^s \cdots \mathbf{v}_{2n_y}^s] \in \mathbb{R}^{n_y \times (n_y - n_r)}$ and $\mathbf{W}_{\text{PCA2}}^s \in \mathbb{R}^{n_y \times n_y}$ are respectively the matrix of singular values, the matrix of right singular vectors and the separation matrix associated to the residual subspace of the healthy structure.

In the same way, we define the matrix $\mathbf{W}_{\text{PCA}}^u$ using the following equation:

$$\begin{aligned} \mathbf{W}_{\text{PCA}}^u &= \mathbf{I}_{n_y \times n_y} \mathbf{\Gamma}^u (\mathbf{V}^u)^T = \begin{bmatrix} \mathbf{I}_{n_y \times n_r} & \mathbf{I}_{n_y \times (n_y - n_r)} \end{bmatrix} \begin{bmatrix} \mathbf{\Gamma}_1^u & \mathbf{0} \\ \mathbf{0} & \mathbf{\Gamma}_2^u \end{bmatrix} \begin{bmatrix} \mathbf{V}_1^u & \mathbf{V}_2^u \end{bmatrix}^T \\ &= \mathbf{W}_{\text{PCA1}}^u + \mathbf{W}_{\text{PCA2}}^u \end{aligned} \quad (14)$$

The presence of a damage will modify the measurement matrix \mathbf{Y}^s , and consequently the separation matrix $\mathbf{W}_{\text{PCA}}^u$, compared to the matrix $\mathbf{W}_{\text{PCA}}^s$. Therefore, the subspaces generated by $\mathbf{W}_{\text{PCA}}^u$ are deflected to those of $\mathbf{W}_{\text{PCA}}^s$. The idea here is to monitor changes of specific subspaces. Let, $R\{\mathbf{A}\}$, $R\{\mathbf{A}^T\}$ be respectively the range subspace of a matrix $\mathbf{A} \in \mathbb{R}^{n_y \times n_y}$ and its transpose. $\mathbf{P}_{R\{\mathbf{A}\}}$, $\mathbf{P}_{R\{\mathbf{A}^T\}}$ correspond to the orthogonal projection of the range subspace $R\{\mathbf{A}\}$ and $R\{\mathbf{A}^T\}$. One way to define orthogonal projections is to use SVD, *i.e.*

$$\mathbf{\Gamma} = \mathbf{U}^T \mathbf{A} \mathbf{V} = \text{diag}(\sigma_1 \cdots \sigma_{n_y}) \quad (15)$$

The orthogonal projections $\mathbf{P}_{R\{\mathbf{A}\}}$, $\mathbf{P}_{R\{\mathbf{A}^T\}}$ are respectively defined as follow:

$$\mathbf{P}_{R\{\mathbf{A}\}} = \mathbf{U} \mathbf{U}^T, \mathbf{P}_{R\{\mathbf{A}^T\}} = \mathbf{V} \mathbf{V}^T \quad (16)$$

From the definition of the separating matrices $\mathbf{W}_{\text{PCA}}^s$ and $\mathbf{W}_{\text{PCA}}^u$, the matrix of left singular vectors is equal to the identity matrix:

$$\mathbf{U}^s = \mathbf{U}^u = \mathbf{I}_{n_y} \quad (17)$$

Therefore, no information can be derived from the matrix of left singular vectors, thus we will use the matrix of right singular vectors as a feature. To build our proposed damage index, we will use projections on the transpose of matrices $\mathbf{W}_{\text{PCA1}}^s$ and $\mathbf{W}_{\text{PCA1}}^u$ as a damage feature. This is the subject of the following subsection.

The proposed damage index is based on the calculation of the principal angle vectors between the range subspace of the matrix $(\mathbf{W}_{\text{PCA1}}^s)^T$ and $(\mathbf{W}_{\text{PCA1}}^u)^T$. We note $\underline{\boldsymbol{\varphi}}[R\{(\mathbf{W}_{\text{PCA1}}^u)^T\}, R\{(\mathbf{W}_{\text{PCA1}}^s)^T\}]$, the principal angle vectors between the range subspace $R\{(\mathbf{W}_{\text{PCA1}}^u)^T\}$ and $R\{(\mathbf{W}_{\text{PCA1}}^s)^T\}$. Using the SVD tool, the Euclidean norm of the sinus angle is defined as follow [8-6]:

$$\begin{aligned} \left\| \sin \underline{\boldsymbol{\varphi}}[R\{(\mathbf{W}_{\text{PCA1}}^u)^T\}, R\{(\mathbf{W}_{\text{PCA1}}^s)^T\}] \right\|_2 &= \left\| \mathbf{P}_{R\{(\mathbf{W}_{\text{PCA1}}^s)^T\}^\perp} \mathbf{P}_{R\{(\mathbf{W}_{\text{PCA1}}^u)^T\}} \right\|_2 \\ &= \left\| \left(\mathbf{I}_{n_r} - \mathbf{P}_{R\{(\mathbf{W}_{\text{PCA1}}^s)^T\}} \right) \mathbf{P}_{R\{(\mathbf{W}_{\text{PCA1}}^u)^T\}} \right\|_2 \end{aligned} \quad (18)$$

Let be a smart structure with n_y sensors, and define equations (13), (14) and (18).

Damage could be detected by monitoring the following damage index:

$$DI_{PCA} = \frac{\left\| \sin \underline{\varphi} [R\{(\mathbf{W}_{PCA1}^u)^T\}, R\{(\mathbf{W}_{PCA1}^s)^T\}] \right\|_2}{n_r} \quad (19)$$

where n_r is the number of principal components retained.

Figure 4 depicts the DI behavior in term of impact energies. One can see that there exist a sensitivity of the DI regarding the magnitude of the impact energy.

Figure 4: Damage detection results

SUMMARY

The presented paper has addressed a damage detection approach based on principal component analysis, where a damage index based upon the change of the principal angle vectors between subspaces has been proposed. The effectiveness of the proposed approach has been tested on a batch of monolithic composite coupons that have undergone different impact energies and locations with different size of delaminated area. For work under progress, a reliability methodology is underway in order to derive Probability of Detection (POD) for the proposed SHM approach in a fashion that agrees with current nondestructive inspection (NDI) validation requirements.

Abstract: The increasing application of CFRP calls for a Structural Health Monitoring (SHM) system for adhesively bonded CFRP joints. Optical glass fibres carrying Fibre Bragg Gratings (FBG) are a promising technology for such a SHM system. This study investigates the effect of embedding optical glass fibres carrying FBGs directly in the adhesive on the adhesive bond quality and the fibre embedding. Embedding the optical glass fibres in the adhesive bond poses the risk of significantly reducing the bond strength. Optical glass fibres with different cladding diameters (50 μm , 80 μm , 125 μm) and coatings (polyimide (3 - 8 μm) and acrylate ($\sim 35 \mu\text{m}$)) are embedded in structural and repair film adhesives. Without embedded optical glass fibres the film adhesives has a bondline thickness of $\sim 90 \mu\text{m}$ (structural) and $\sim 100 \mu\text{m}$ (repair). The influence of embedding optical glass fibres directly in the adhesive is visually inspected in glass-slate adhesive bonds and microscopically investigated in cross-sectional cuts (CFRP adherents). It is found that embedding optical glass fibres with a total diameter $< 100 \mu\text{m}$ (cladding + coating diameter) doesn't increase the number of air inclusions in the adhesive in a visually detectable amount. Also, the adhesive fully encloses embedded optical glass fibres with a total diameter $< 100 \mu\text{m}$. When embedding optical glass fibres with total diameter $\sim 145 \mu\text{m}$ it is found that the structural film adhesive responds with an increased number of air inclusions. It is concluded that the optical glass fibres with total diameter $\sim 200 \mu\text{m}$ (standard telecommunication glass fibre) is too thick for embedding in the tested film adhesives. Furthermore, it is found that polyimide coatings are suited better for embedding in the tested film adhesives than acrylate coatings.

1. INTRODUCTION

The importance of CFRP in aircraft construction has increased over the past years [1]. Adhesive bonding is better suited for joining CFRP materials than conventional joining techniques like riveting or bolting [2,3]. The aeronautic industry however requires high security

standards. Without a method to identify the condition of an adhesive bond in service adhesive bonding will not be approved by the airworthiness authorities for primary aircraft structures [3]. A structural health monitoring (SHM) system to identify the condition and remaining lifetime of an adhesive bond would be a strong support for reaching airworthiness approval. Due to the dimensions and characteristics of optical fibres carrying Fibre Bragg Gratings (FBGs), they are suitable for structural health monitoring in composite adhesive bonds [4,5,6,7,8,9,10,11]. As shown in Fig. 1 an optical glass fibre consists of a very fragile glass core and cladding that are protected by a polymer coating [12]. The FBG sensor itself is a small portion of the glass fibre core with a periodic variation of the effective refractive index that senses fibre elongation and bending [12,13].

Fig. 1: Schematic sketch of the structure of an optical glass fibre with Fibre Bragg Grating (FBG) (adapted from [14]).

In earlier studies by Jones and Galea [4], Capell et al. [5] and Palaniappan et al. [6,7] the optical fibres carrying the FBGs were embedded in the adherents and standard telecommunication optical glass fibres with a 125 μm cladding diameter were employed. Disbond initiation and crack growth in the adhesive was successfully monitored [5,6,7,8]. In 2014 two studies were published [9, 11] that embedded the optical glass fibre carrying the FBG directly in the adhesive bond. This has the advantage of directly monitoring the stress distribution in the adhesive without signal distorting CFRP layers in between [9]. But embedding the optical fibre directly in the adhesive bears the risk of significantly influencing the bond characteristics and thus strength [10,11]. The intrusive effect of the embedded glass fibre sensor should be minimal. So far, only little attention has been paid to the effect that embedding an optical glass in the adhesive has on the bondline characteristics and quality. Initial investigations were carried out by Da Silva et al. [11] and Canal et al. [10] with SL tensile shear tests. Da Silva et al. [11] investigated the effect of embedding optical glass fibres in SikaForce[®]-7888 L10 adhesive (steel adherents). The authors concluded that embedding optical glass fibres directly in the adhesive can cause a significant reduction of the bond strength. Canal et al. [10] compared the effect of embedding multiplexed FBG arrays in different positions in two component epoxy adhesive Araldite 420 A/B: 1) between the 1st and 2nd CFRP ply, 2) in the adherent-adhesive interface, 3) in the adhesive. No negative effect on joint performance was detected in this study ($n = 4$). Since the possible intrusive effect of embedding optical glass fibres in the adhesive has major impact on reaching airworthiness approval it was decided to pay detailed attention to this problem. In this study, the research is focussed on structural and repair film adhesives commonly used in the aeronautic film industry for bonding load bearing primary structures in the aeronautic industry. Film adhesives pose unique challenges for embedding optical glass fibres. Especially the thin film layer thickness and the fabric carrier in the film adhesive should be

given special attention [15,16]. This paper investigates visually and microscopically the effects of embedding optical glass fibres with different cladding diameters and coatings in structural film adhesive bonds. The visual bondline inspection is performed with the help of transparent glass slate adhesive bonds, the microscopic investigation with cross-sectional cuts from CFRP adhesive bonds. In a consecutive paper the effects of embedding optical glass fibres with different cladding diameters and coatings on the tensile shear strength of structural film adhesive bonds will be investigated and the results will be related to the results from this paper.

The indicators for visually evaluating the bond quality in this study are:

- Fully developed interface between the adhesive and both adherents.
- Even adhesive distribution in the bondline.
- Number of air inclusions in the adhesive.

Air inclusions in the adhesive are related to a significant reduction in bond strength [17]. Bascom and Cottingham [17] discovered a difference in bond strength of up to 30% between specimens with entrapped air in the adhesive in comparison to specimens without entrapped air [17].

The indicators for visually evaluating the fibre embedding in this study are:

- Fibre position in the bondline.
- Full enclosure of the optical glass fibre with adhesive.
- Undamaged fibre and coating after autoclave curing.

The listed factors are critical for the functionality of the FBG sensor.

2. MATERIALS AND METHODS

2.1. Optical glass fibre coatings

The employed fibres are tested with acrylate and polyimide coatings because these are common and commercially available optical glass fibre coatings. Acrylate has a Young's modulus of approximately 100 MPa (compare Tab. 1). It is only deposited on the glass fibre surface and therefore easy to remove [18]. The main drawback is the relatively low thermal stability [19] and distortion of the matrix strain information [18]. Polyimide on the other side has a Young's modulus of approximately 3 GPa, a high thermal stability [20] and is chemically bonded to the glass fibre surface [18]. An advantage is the excellent adhesion of the coating to the glass fibre surface and a relatively precise information transfer from the surrounding host material to the FBG in the glass fibre core [18]. A drawback is the complicated removal of the coating for cleaving and splicing of the fibre [20].

Tab. 1: Comparison of the characteristics of acrylate and polyimide coatings (adapted from [18,19,20]).

Characteristics	Acrylate	Polyimide
Young's modulus	100 MPa	3 GPa
Operating temperature	+85°C/+150°C	+300°C
Bonding to fibre surface	only deposited	chemical bond

2.2. Optical glass fibres

The employed optical glass fibres are manufactured at RISE Acreo Fiberlab (Hudiksvall, Sweden) and have cladding diameters of 50 μm , 80 μm and 125 μm . The protective acrylate or a polyimide coating is applied directly after cooling. Depending on the fibre diameter the acrylate coating is applied with a thickness of 35 – 40 μm , the polyimide with a thickness of 3 – 8 μm . The total fibre diameters resulting from the combination of different cladding diameters and coating types (coating thicknesses) are presented in Tab. 2:

Tab. 2: Glass fibre types employed in this study. Different glass fibre diameters in combination with either polyimide or acrylate coating lead to the listed total fibre diameters.

Glass fibre type	P50	P80	P125	A80	A125
Cladding diameter	50 μm	80 μm	125 μm	80 μm	125 μm
Coating material	Polyimide	Polyimide	Polyimide	Acrylate	Acrylate
Total diameter	54 – 59 μm	95 μm	140 μm	145 μm	200 μm

2.3. Adhesives

The employed adhesives are the industrially available structural film adhesive FM[®] 300K (film thickness: 200 μm) and repair film adhesive FM[®] 300-2M (film thickness: 250 μm) by Cytec Industries Inc. FM[®] 300K is distributed on a wide-open-knit fabric carrier [15]. FM[®] 300-2M is distributed applied on a random matt fabric carrier [16]. The material properties of these film adhesives are stated in the data sheets provided by the manufacturer. The film adhesives are processed and cured according to manufacturer specifications at 121°C (FM[®] 300-2M) and 175°C (FM[®] 300K). After curing the film adhesives have a bondline thickness of ~ 90 μm (FM[®] 300K) and ~ 100 μm (FM[®] 300-2M).

2.4. Glass slate bonds preparation: visual inspection of the adhesive distribution, the number and size of air inclusions and the interface in samples with different embedded optical glass fibres

Specimens are manufactured by bonding two transparent glass slates (100 x 100 x 4 mm) with FM[®] 300-2M and FM[®] 300K film adhesives and embedding one glass fibre per specimen. Specimens are manufactured for all glass fibre diameter and coating combinations. Also, reference specimens without an embedded glass fibre are manufactured. The film adhesive is cut exactly according to the dimensions of the glass slates. The adherents are cleansed with 2-Propanol. After, the pre-cut film adhesive is placed on the lower glass slate (compare Fig. 2). The glass fibre is placed on top of the film adhesive along the centre lines of the glass slate. The second glass slate is placed on top. To achieve an even distribution of the adhesive in the bondline, pressure plates are placed on each specimen. The curing of the specimens takes place in a hot-air autoclave by Scholz Maschinenbau (Coesfeld, Germany) according to the adhesive manufacturer's specifications.

2.5. CFRP slate bonds and cross-sectional cuts preparation: microscopic investigation of the glass fibre position in the bondline and the influence of the glass fibre diameter on the bondline thickness

Specimens are manufactured by bonding two CFRP slates (100 x 100 x 2 mm) with

FM[®] 300-2M and FM[®] 300K film adhesives and embedding one glass fibre per specimen as described in 2.4. Specimens are manufactured for all glass fibre diameter and coating combinations. Also, reference specimens without an embedded glass fibre are manufactured. Deviating from the description in paragraph 2.4 the CFRP specimens are hand sanded prior to bonding and the curing of the specimens takes place under vacuum bagging. Pressure plates are not applied. The cross-sectional cuts are cut from the position indicated by the red dashed line in Fig. 2a with a diamond cutting disc and embedded in two-component epoxy resin EpoFix by Struers GmbH, (Hannover, Germany). The embedded cross-sectional cuts are first grinded with grit sizes ranging from 80 to 4000 and then polished in the following steps: 1. buff MD- Largo, 3 µm suspension + lubricant (300 U/min + 25 N + 3 min); 2. polishing cloth MM414, 1 µm suspension BioDiamant MM 140 (300 U/min + 35 N + 5 min); 3. polishing cloth MD-Chem, 0.25 µm Siliziumoxidsuspension OP-S (150 U/min + 25 N + 2,5 min). Photos are taken with a DMRX Leica light microscope at 25x, 50x, 100x, 200x and 500x magnification.

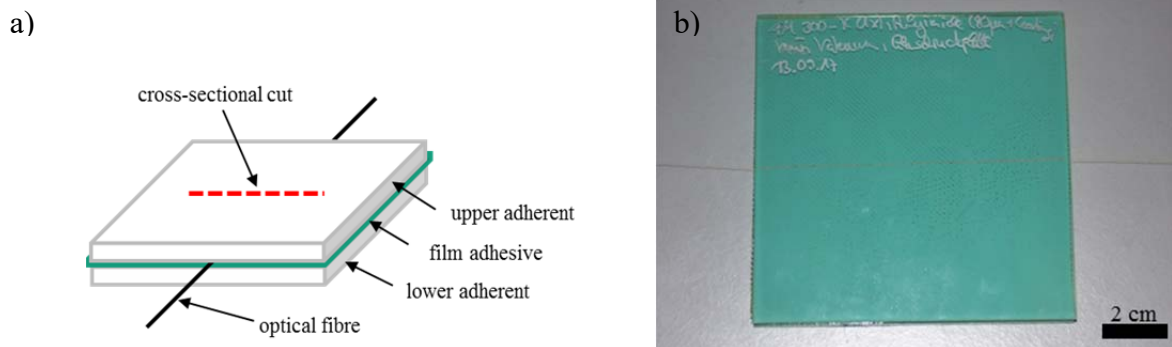

Fig. 2: a) Schematic sketch of the lay-up of a bonded joint specimen with an optical glass fibre embedded in the adhesive. The red dashed line indicates the position where the cross-sectional cuts in paragraph 2.5 are taken from; b) Photography (top view) of a bonded joint glass specimen manufactured as described in paragraph 2.4 with an embedded optical glass fibre. The glass slate adherents allow a visual evaluation of the bonded joint quality.

3. RESULTS

3.1. Glass slate adherents: visual inspection of the adhesive distribution, the number and size of air inclusions and the interface in samples with different embedded optical glass fibres

Photographs of the manufactured bonds between glass slates carrying the different glass fibre diameter and coating combinations are presented in Fig. 4. The FM[®] 300-2M specimens A1, A2 and A4 all show a good adhesive distribution with a small number of air inclusions despite different fibre diameters. The air inclusions are evenly distributed across the bondline. Only the specimens with the polyimide and acrylate and coated 125 µm glass fibres (specimen A3 and A5) show a slightly higher number of air inclusions (compare Fig. 4). On the contrary, in the FM[®] 300K specimens the number and size of air inclusions increase with increasing total optical glass fibre diameter. The FM[®] 300K specimens carrying the polyimide coated 50 µm and 80 µm fibres (B1 and B2) show a good adhesive distribution with a small amount of air inclusions and the air inclusions are evenly distributed across the bondline. In

the FM[®] 300K specimens carrying the polyimide coated 125 µm fibre (B3) and the acrylate coated 80 µm fibre (B4) the number of air inclusions increase in comparison to the specimens B1 and B2 and the distribution of the air inclusions across the bondline is more uneven (compare Fig. 3). A higher number of air inclusions is visible on one side of the embedded glass fibre and a higher number on its other side. This is especially pronounced in the B3 specimen where a higher number of more uneven distributed air inclusions than in B4 are visible and a small darker green patch is found in the lower right corner of the specimen. The described development is even more pronounced in the specimen carrying the acrylate coated 125 µm fibre (B5). This specimen shows a high amount of highly unevenly distributed air inclusions and large dark green patches.

3.2. CFRP slate bonds and cross-sectional cuts: microscopic investigation of the glass fibre position in the bondline and the influence of the glass fibre diameter on the bondline thickness

Photomicrographs of the cross-sectional cuts of the FM[®] 300-2M and FM[®] 300K specimens are presented in Fig. 5. In some of the photomicrographs (A1, A2, A4, A5, B0, B1, B4), fabric carrier fibres from the film adhesive are visible. The cross-sectional cuts (A1, A2, B1, B2) indicate that in both adhesives the polyimide coated 50 µm and 80 µm fibres are intact and enclosed by adhesive. The glass fibre is not positioned in the middle of the bondline but in the upper half of the bondline. The cross-sectional cut of the polyimide coated 125 µm glass fibre in the FM[®] 300K (B3) shows that the glass fibre completely fills the bondline. The polyimide coated 125 µm glass fibre in the FM[®] 300-2M (A3) nearly fills the entire bondline. The cross-sectional cuts of the specimens carrying the acrylate coated glass fibres (A4, A5, B4, B5) indicate that in both adhesives the acrylate coating completely separated from the glass fibre during curing and that the glass fibre itself is damaged. Hollow spaces are visible around the fibre. Fig. 3 pictures a photomicrograph of a larger detail of a FM[®] 300K cross-sectional cut with an embedded polyimide coated 50 µm fibre. The photomicrograph also shows fabric carrier fibres. It is visible that in this cross-sectional cut (as in A1, A2, A5, B1) the optical glass fibre is situated on top of a fabric carrier fibre. Furthermore it is visible that the air inclusions are not located close to one of the interfaces but fill the whole bondline.

Fig. 3: Photomicrographs (100x) of a FM[®] 300K cross-sectional cut (compare Fig. 2a) with an embedded polyimide coated 50 µm fibre. Fabric carrier fibres and air inclusions are visible.

Fig. 4: Photographs (top view) of bonded glass slate joints with different embedded glass fibre types. Visual inspection of the bondline through the glass slate adherents allows the evaluation of the adhesive distribution, air inclusions and fibre position. The left column shows specimens manufactured with FM® 300-2M film adhesive and the right column specimens manufactured with FM® 300K film adhesive. The total fibre diameter increases from the top of to the bottom of both photo columns. Photographs are taken as shown in Fig. 2b.

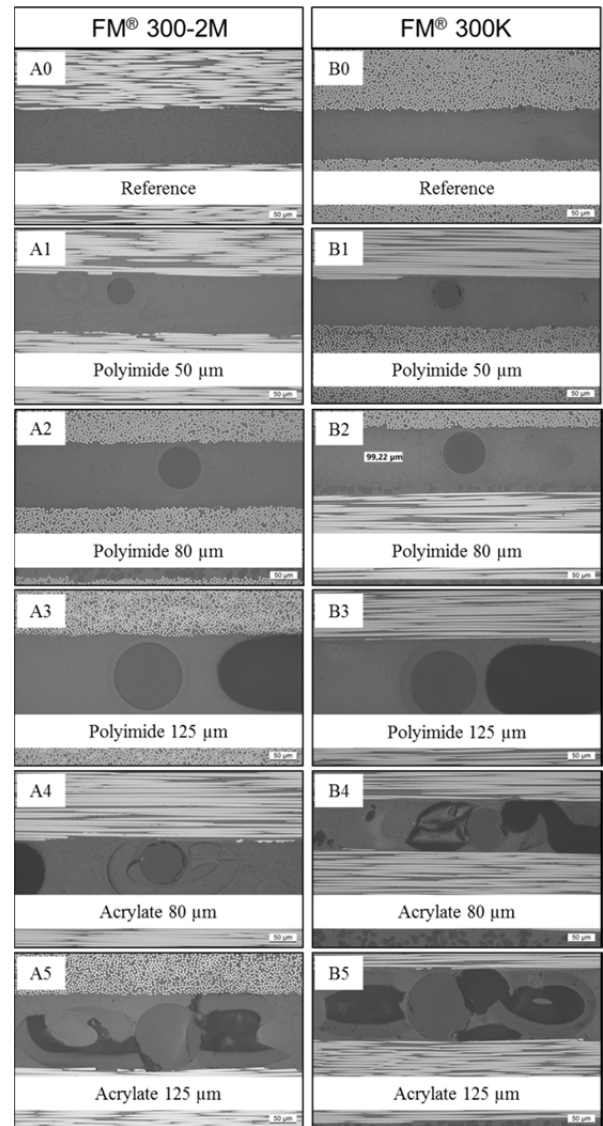

Fig. 5: Photomicrographs (200x) of cross-sectional cuts. The cuts are taken from the position indicated in Fig. 2a. Left column: samples of all fibre types embedded in FM® 300-2M adhesive bonds between CFRP adherents: Polyimide 50 µm (A1), Polyimide 80 µm (A2), Polyimide 125 µm (A3), Acrylate 80 µm (A4) and Acrylate 125 µm (A5). A0 is a reference sample without an embedded optical glass fibre. Right column: samples of all fibre types are embedded in FM® 300K adhesive bonds between CFRP adherents: Polyimide 50 µm (B1), Polyimide 80 µm (B2), Polyimide 125 µm (B3), Acrylate 80 µm (B4) and Acrylate 125 µm (B5). B0 is a reference sample without embedded optical glass fibre.

4. DISCUSSION

Tab. 3 summarizes the results from the visual inspection of the adhesive bondlines in the glass slate samples and the cross-sectional cuts. The evaluation of the results is indicated by the colouring of the table. Green colour indicates a good result. Yellow indicates an acceptable result: the result is not optimal but doesn't impede the employment of the respective fibre type in an SHM system for FM[®] 300-2M and FM[®] 300K film adhesives. Red indicates a not acceptable result: the result impedes the employment of the respective fibre type in an SHM system for the investigated adhesives.

Tab. 3: Results from the visual inspection of the adhesive bondlines in the glass slate samples and the cross-sectional cuts. The colouring of the fields indicates the results achieved in the different categories: green = good result; yellow = acceptable result; red = not acceptable result.

	Sample	Fibre type	Fully developed interface	Even adhesive distribution	Number of air inclusions	Fibre position	Full enclosure of fibre	Fibre damage
FM [®] 300-2M	A0	/						
	A1	P50						
	A2	P80						
	A3	P125						
	A4	A80						
	A5	A125						
FM [®] 300K	B0	/						
	B1	P50						
	B2	P80						
	B3	P125						
	B4	A80						
	B5	A125						

4.1. Polyimide coated 50 µm and 80 µm fibres (A1, A2, B1, B2); total diameter < 100 µm

In both adhesives the best results are achieved by the polyimide coated 50 µm and 80 µm optical glass fibres. Both optical glass fibres achieve in most categories a good result (green). Since the interface between the adherents is fully developed, the adhesive distribution is even and no visible increase in number and size of air inclusions is detected it is expected in accordance with Bascom and Cottingham [17] that the presence of the optical glass fibres doesn't affect the bond strength significantly. Therefore, these categories are evaluated green.

The fibre position is not centred and therefore evaluated yellow. The tendency of the embedded glass fibre to position itself closer to one side of the bond is likely to be caused by the specimen production process where the fibre is placed on top of the film adhesive. The presence of the fabric carrier is suspected to prevent the fibre from moving to the centre of the bondline (compare Fig. 3). It has to be investigated in future experiments how the sensor performance is influenced by the fibre position.

Since both fibres are fully enclosed with adhesive and the fibre remains undamaged after curing the two factors are expected to not affect the sensors functionality and therefore these categories are evaluated green.

4.2. Polyimide coated 125 µm fibres (A3, B3); total diameters ~ 145 µm

The polyimide coated 125 µm fibre achieves acceptable results in the FM[®] 300-2M adhesive bonds (A3). The interface is fully developed and the adhesive evenly distributed. Therefore both categories are rated green. Since a slight increase in air inclusions is visually detectable this category is evaluated yellow. According to Bascom and Cottingham [17] this might cause a reduction in bond strength. It will be investigated in a consecutive paper if a reduction in tensile shear strength is detectable in samples with an increased amount of air inclusions. The category fibre position is also rated yellow because the fibre completely fills the bondline. Big changes in adhesive layer thickness lead to changes in the stress distribution and might thus provoke changes in the crack growth and propagation as described by Lee et al. 2004 [21] for adhesives with included rubber particles. This might cause preliminary interlaminar failure. Therefore, the category fibre enclosure is rated yellow. Since the polyimide coated 125 µm fibre remains undamaged the category fibre damage is rated green.

For the FM[®] 300K adhesive bonds (B3) the results are evaluated as not acceptable. A not fully developed interface, an uneven adhesive distribution and a high increase of air inclusions are detected visually. According to Bascom and Cottingham [17] these factors are expected to reduce the bond strength and therefore the categories air inclusions and adhesive distribution are evaluated red and the category fully developed interface yellow. The categories fibre position and enclosure are evaluated yellow for the same reasons as for the FM[®] 300-2M adhesive bonds. Since the polyimide coated 125 µm fibre remains undamaged the category fibre damage is rated green.

4.3. Acrylate coated 80 µm and 125 µm fibres (A4, A5, B4, B5); total diameters 145 µm - 200 µm

The results for embedding the acrylate coated 80 µm and 125 µm fibres in both tested film adhesives are evaluated as not acceptable.

For the FM[®] 300-2M adhesive bonds, the A4 samples receive a green evaluation in the categories fully developed interface, adhesive distribution and air inclusions. No changes in comparison to the other samples are detected visually. The A5 samples receive a green evaluation in the categories fully developed interface and adhesive distribution and a yellow evaluation for the detected increase of air inclusions.

In the FM[®] 300K adhesive bonds the category fully developed interface is rated green for the acrylate coated 80 µm fibre samples (B4). The B5 samples are the only samples evaluated red in the category fully developed interface. The not fully developed interface is indicated by the dark green patches visible in B5. B4 and B5 show both an increased number of air inclusions and an uneven adhesive distribution. This leads to a yellow (B4) and red (B5) evaluation of the categories even adhesive distribution and number of air inclusions. The formation of the dark green patches and the uneven distribution of air entrapments between the areas left and right of the centrally placed glass fibre indicate that the embedded glass fibre acts as a wedge. Thus, air is entrapped in the interface between the film adhesive and the adherent on that side of the film adhesive where the glass fibre was placed. According to Bascom and Cottingham [17] the air entrapped between the film adhesive and the adherents during bonding is displaced into the resin during the heated curing process. This is confirmed by the findings in Fig. 3.

The embedding in both film adhesives damaged the acrylate coated fibres (acrylate coated 80 μm and 125 μm glass fibre) beyond functionality. In the specimens B4 and B5 (compare Fig. 5) the coating has completely separated from the fibre. It is concluded that the low thermal stability and the non-chemical bond to the glass fibre surface (compare Tab. 2) make the acrylate coating unsuited for embedding in FM[®] 300K and FM[®] 300-2M film adhesives. All fibre-related categories are evaluated red for the acrylate coated fibres. The separation of the acrylate coating might explain why specimen B4 (acrylate coated 80 μm fibre) has a slightly lower number of air inclusions than sample B3 (polyimide coated 125 μm fibre) and although both glass fibres have a similar total diameter of approximately 155 μm before curing. After the separation the acrylate coated 80 μm glass fibre does not have a total diameter of 155 μm anymore and the fibre most likely doesn't wedge open the bond as unevenly as the intact polyimide coated 125 μm fibre in specimen B3.

5. CONCLUSIONS

- 1) The cross-sectional cuts demonstrate that the tested film adhesives fully enclose the embedded glass fibre during the curing process as long as the embedded glass fibre diameter does not exceed a certain total diameter ($< 100 \mu\text{m}$). The not centred position of the optical glass fibre in the bondline leads to a thinner adhesive layer on one side of the optical glass fibre.
- 2) When the embedded optical glass fibre does not exceed a total diameter $< 100 \mu\text{m}$ no increase in air inclusions is detected visually. In FM[®] 300-2M adhesive bonds no increase in air inclusions are detected visually for embedded glass fibres not exceeding total diameters $< 145 \mu\text{m}$.
- 3) The results suggest that the standard telecommunication glass fibre (acrylate coating) with a total diameter of 200 μm is too thick for embedding in FM[®] 300 film adhesives. It causes a significant increase in air inclusions in both adhesives and leads to a not fully developed interface in FM[®] 300K adhesive bonds.
- 4) It is concluded that the acrylate coating is unsuited for embedding in FM[®] 300 film adhesive since it separates from the optical glass fibre during the curing procedure.

6. ACKNOWLEDGEMENTS

The research leading to the results was supported by the DAAD and Fraunhofer Talenta carrier program. We acknowledge RISE Acreo for the manufacturing and providing the optical glass fibres. Furthermore we acknowledge Kerstin Lunkwitz for preparing the cross-sectional cuts.

Key words: structural health monitoring, multifunctional composite, carbon fibre reinforced plastic, carbon nanotubes, interlaminar fracture toughness

Abstract. Multifunctional composites as means of structural health monitoring can parallelly carry structural loads and detect potential damage to the structure. The importance arises from enhanced lifetime and service interval estimations. Via inkjet printed and electrically conductive paths, as integral part of a carbon fibre reinforced plastic, damage assessment is possible by resistance measurements. A promising novel approach is to use carbon nanotubes as conductive elements in an epoxy-based matrix. In the current work, the effect of printed electronics from such materials on the mechanical damage behavior of the multifunctional composites is investigated. Conclusions are drawn from interlaminar fracture toughness values and failure mode distributions obtained from different loading modes applied to precracked specimens. The results create primal understandings of the damage behavior of such multifunctional composites and conclusion how to realize further improvements to this specific printed electronics material.

1 INTRODUCTION

Since most engineering structures, i.e. buildings, aircrafts and wind turbines, are designed to withstand loads over decades, they are subjected to an ageing process [1]. This leads to structural damage which limits the lifetime of the structures. In order to extend the operational life, damage tolerant designs are frequently used [1]. To prevent damage growth and catastrophic failure, visual inspections intervals for the structures are defined in parallel with the design [2]. A major drawback is the interruption of structure's operation.

To overcome this disadvantage, the damage state can be continuously observed by means of structural health monitoring (SHM). Via electronical sensors as integral part of the structure

and through-thickness electrical resistance measurements, information about existence, location and extent of damage are obtained during operation. Fundamental for this approach is the effect of the damage on the electrical properties. Recorded data are transferred via wired or wireless configurations to analysers which evaluate the criticality [3]. Since mass, space and costs are objectives during design, wireless conductive paths are more and more frequently applied to lightweight structures [3].

With respect to the location of the sensors, two different arrangements are possible. Heinrich has shown in [4], that electronics on the surface of a carbon fibre reinforced plastic (CFRP) stiffener can be used to determine a critical damage state. The positioning of the sensors in between the single layers of composite structures is another relevant approach [4]. This has a major effect on the structural damage behavior, since the conductive material becomes an integral part. It must be ensured, that it does not become the starting point for delaminations or other damage.

For both applications, an inkjet printing process is appropriate for additive manufacturing of sensor configurations. Wide ranges of materials are printable in arbitrary patterns on 3D surfaces combined with a small ink consumption [5]. Besides operational requirements like electrical conductivity and suitable mechanical properties, the printability of the ink is a main objective during ink composition.

Since CFRP structures are prone to develop internal non-visible damage, they are highly applicable to the SHM technology. Further, an ink based on carbon nanotubes (CNT) was found appropriate since Huang et. al. [6] proved their high electrical conductivity in epoxy resins. Hedia et. al. [7] found their reinforcing effect on the mechanical properties. Resulting multifunctional composites are appropriate for SHM of engineering structures.

In the current research the mechanical damage behavior of such multifunctional composites from CFRP laminates and printed CNT-based inks is tested. Results are obtained from two tests in a double cantilever beam (DCB) and an end notched flexure (ENF) configuration. Objectives for evaluation are the interlaminar fracture toughness and the failure mode distribution. Due to the novel character of the investigated multifunctional composites, first comparisons to the previous work of Heinrich [8], who used an ink based on silver nanoparticles, can be made. Furthermore, required modifications of the current ink composition can be derived.

2 MECHANICAL DAMAGE BEHAVIOR

As the printed electronics become part of the structure, they form a bonding interface with the CFRP substrates. It is characterized by cohesion forces of the single materials and by adhesion forces along the interface, which directly depend on the interaction between the joined materials [9]. In order to assess the quality of the interface, its peel strength and shear strength are main objectives. DCB and ENF specimens with intentionally precracked interfaces can be used for evaluation. The test procedures are representative for most common crack opening modes in structure operation. In the DCB test the crack is opened with a peeling mode I, see Figure 1 in accordance with Campbell [10]. The crack opening with shear mode II is tested with the ENF specimens. A tearing mode III is typically neglected in research since it is only relevant for thick laminates and torsional loads [11].

Figure 1: Modes of crack opening displacements according to [10]

As outlined in [12] and [13], both referenced tests base on the assumption of a linear elastic, cracked specimen. According to Sharpe [14], the total elastic energy of the quasi-static loaded system includes the work of external forces, the internal stored energy and the fracture energy per area of crack surface. In case of a constant crack length, the system is in equilibrium and the total elastic energy is extremal [14]. Thus, any crack propagation leads to a loss of the systems elastic energy. The critical loss of energy for an infinitesimal small crack propagation is defined as the interlaminar fracture toughness [12]. The higher this value the better is the multifunctional composites resistance to crack propagation. It can be calculated from the specimen geometry, the applied forces and recorded displacements in the DCB and ENF tests, see [12] and [13].

As the precracked interfaces are most likely the weak point, crack propagation is supposed along the adhesive bond. Depending on adhesion and cohesion forces, the crack propagates in areas with the smallest internal strength. Since both forces can vary along the interface due to inhomogeneities, the crack potentially alternate between the substrate surfaces (AF - adhesion failure) and the printed electronics material (CF - cohesion failure). In a subsequent fractography process, CF is characterised by the presence of ink on both fractured surfaces, whereas the ink is absent on one surface in case of AF [15]. The allocation as CF assumes an ideal dispersion of the components in the sintered ink. Since CNT tend to form agglomerations due to high van der Waals forces [16] when the ink is not fully cured, a decomposition potentially occurs during sintering and forms clusters of single ink components [17]. This results in varying cohesion forces and needs to be considered for failure mode identification. Thus, the CF is subdivided as follows: cohesive agglomeration failure (CAF) with CNT agglomerations on both fracture surfaces, cohesive interface failure (CIF) with CNT agglomerations on only one surface and cohesive resin failure (CRF) where no CNT are present on both surfaces. Additionally, unwetted areas (UA) must be recorded. The outlined failure modes are visualised in Figure 2.

Figure 2: Potential failure modes for multifunctional composites from CNT ink

Any AF is not acceptable as the low corresponding fracture toughness increases the risk of in-service delamination which leads to a catastrophic failure of the multifunctional composite. It must be prevented by means of surface treatment. In contrast, the cohesion forces can be improved by use of a modified ink composition and application processes.

3 EXPERIMENTAL SETUP

The following experimental setup describes the methods which are used to prepare and execute the mechanical tests and to evaluate the obtained data.

3.1 Ink formulation

The used inks base on single-walled CNT with an outer diameter of 1.8 ± 0.4 nm and > 5 μm in length. Furthermore, ethyl cellulose (EC) as stabilizing polymer, N,N-dimethylacetamide (DMAc) with a purity of ≥ 99.8 % as dispersion medium and an epoxy resin with an associated hardener are added. An overview of the CNT content in the formulated ink is given in Table 1.

Table 1: Weight fractions of CNT in the formulated inks

ink label	CNT [wt.%]
RED01	0.000
CNT08	0.044
CNT02	0.087

The materials are introduced to each other in a three-step procedure. First, EC (~ 2.5 wt.%), resin and hardener (~ 10.0 wt.%) are fully diluted in DMAc. Second, CNT are added to the clear solution and then vigorously stirred for 10 minutes. Third, the mixture is homogenized in an ice bath using an ultrasonic probe *Sonopuls HD 2070* for 120 minutes at power amplitude of 32 % and cycle value of 8. The dispersed suspension is kept on stirrer plates. Before each printing session, the dispersion is ultrasonicated for 60 minutes under the same conditions.

After homogenization, the ink is filtered in a PTFE (polytetrafluorethylene) membrane with a pore size of 5 μm and then filled into the printing reservoir for inkjet printing.

3.2 Specimen preparation

CFRP laminates from *HexPly M21/35%/268/T800S* prepreg material are fabricated from *Hamburg University of Technology* in a $[0/90_2]_s$ configuration. The substrates are cured for two hours at 180 °C under 7 bar autoclave pressure and 750 mbar vacuum pressure. Following, the laminates are cut to the required geometry of 125 x 10 mm (see Figure 3) using a circular saw with a diamond blade.

Figure 3: Exploded, schematic setup with the precrack on the right side for the DCB specimen in accordance with [12]. The ENF specimen in accordance with [13] is similar but without piano hinges. All measures are given in mm.

The formulated inks are deposited on the surface of CFRP specimens using a piezo-driven inkjet printhead *MD-K-140* from *Microdrop Technologies GmbH* with an inner nozzle diameter of 100 μm . Prior to application, the substrates are cleaned using isopropyl alcohol. Since two substrates are required per specimen, the ink is applied to both substrates to achieve better adhesion. Per substrate, 5 layers of the ink are printed with a drop spacing of 100 μm over an area of 98 x 8 mm which allows the ink to flow during the sinter process without leaking from the bonding gap. About 10 minutes after printing the final layers, the substrates are placed on top of each other so that the printed sides come together. A PTFE parting film of 30 μm thickness is used to assure the precrack. Subsequently, the specimens are placed in a custom-made PTFE fixture, which prevents the substrates from misalignments. A constant pressure is applied via 1 N weight elements. Following, the specimens are sintered for 4 h at 90 °C, 2 h at 110 °C and finally 4 h at 170 °C in a programmable oven.

After the sinter step, the preparation of ENF specimens is finished. For the DCB specimens, according to Figure 3, piano hinges need to be installed to the precracked side. The bonding surfaces are cleaned with isopropyl alcohol. A two-component epoxy glue is mixed and applied to the CFRP side using a paintbrush. The hinges are centrally aligned and the glue is cured at room temperature for 12 h. Additionally, polystyrene stripes are glued on the counterpart of the hinges to improve clamping properties during the test execution [4]. In the last step of the

experimental preparation, the width b of each specimen is measured at four equidistant distances. The mean value is used for further calculations.

3.3 Experimental procedure

For both experiments a tensile testing machine *TIRA TEST 2810* is used. The loads are applied via a moveable upper crosshead with a 100 N load transducer in DCB configuration and a 1 kN load transducer in ENF configuration.

For the DCB test, two clampings are installed to the test apparatus. The prepared specimen is mounted almost horizontally to the clampings using the piano hinges, see Figure 4. For test preparation, the upper crosshead is slowly moved upwards until the crack tip becomes visible with an optical microscope *Keyence VHX-5000*. The initial crack tip position a_0 is marked using a red fineliner and the current displacement δ_0 is recorded. Following, the displacement is set to 0 mm again and a cyclic boundary condition is programmed: The cyclic load is applied via a constant crosshead velocity of 1 mm/min until a first increment of $\delta_0 + 0.1$ mm is reached [8]. A potential new crack tip is marked using a blue fineliner and the displacement is set again to 0 mm. The cycle is repeated with increasing increments $\Delta\delta$ until a final fracture of the interface occurs. Since crack propagation is expected to slow down with progressive crack lengths, $\Delta\delta$ is 0.1 mm for the first 10 increments, 0.2 mm for the next 5 increments and finally 0.3 mm for higher increments. During the complete test, the applied force and the displacement are logged [12].

For the ENF test, setup and procedure are adopted from Heinrich [8]. The lower clamping is substituted by two rigid supports with a radius of 2 mm and 100 mm distance. A mandrel with a radius of 5 mm is installed to the moveable upper crosshead. The ENF specimen is mounted centered in a three-point bending configuration, see Figure 5. The initial crack tip and the bearing point on the precracked side are marked with a red fineliner. To force crack propagation, the specimen is loaded via a constant mandrel displacement. The velocity is set to a value of 1 mm/min. The end of the test is reached when the crack has propagated and then stagnated. The specimen is unloaded and the new clearly visible crack tip position a_f , identified using an optical microscope, is marked with a blue fineliner. Besides the initial fracture test, additional calibration measurements are required [13]. Therefore, five equidistant positions with approximately 5 mm distance are additionally marked with the blue fineliner on the cracked side of the specimen. They serve as new bearing points and thus change the effective crack length. All calibration measurements are carried out equivalently to the fracture test, but with a maximum load of 30 N. The velocity of the mandrel is 1 mm/min. For calculation of the $G_{II,C}$ value, the force and displacement values are logged during all measurements [13]. Since no complete failure of the printed interface occurs, both substrates are separated manually after the test, to observe the present fracture modes.

Figure 4: Mounted DCB specimen

Figure 5: Mounted ENF specimen

3.4 Postprocessing

For the calculation of the interlaminar fracture toughness G_C , a data reduction method needs to be applied. Since only the compliance calibration method is available for both tests, it is used for further calculations [4].

In case of the DCB test in accordance with [12], a plot of the compliance $\log(\delta_i/P_i)$ over the initial crack length $\log(a_i)$ per increment i is created for every specimen. Therein, only increments are considered where the crack has propagated. Via the least-squares fit method a linear regression is obtained. The slope of the function is defined as parameter n . It is required to determine the mode I interlaminar fracture toughness using equation (1) from [12]. Since applied force P for advancing the crack, displacement δ and initial crack length a are recorded for each increment, multiple $G_{I,C}$ values for one specimen can be obtained resulting in a final median value [18].

$$G_{I,C} = \frac{nP\delta}{2ba} \quad (1)$$

In difference, for the ENF test analysis in accordance with [13] a plot of the compliance (δ_i/P_i) versus the cubed crack length $(a_i)^3$ is required including the results of the calibration measurements. A linear regression using a least-square fit leads to the slope m . With equation (2)¹ from [13], the fracture load P_{max} , the initial crack length a_0 and the specimen width b , it is used to calculate the interlaminar fracture toughness under a pure mode II loading. Only one $G_{II,C}$ value is obtainable per specimen.

$$G_{II,C} = \frac{3mP_{max}^2a_0^2}{2b} \quad (2)$$

Beside the calculation of fracture toughness values, a fracture mode analysis is executed. Therefore, microscopic images of both fracture surfaces are taken with a 20x magnification. Diverse appearing areas are allocated to the characteristic fracture modes. In this context, areas with agglomerations of CNT appear darker than adjacent areas, see Figure 6a) and b). They are located, recorded and surveyed via brightness evaluation of the microscope. By use of the image processing program *ImageJ*, such areas from related fracture surfaces can be converted to

¹ Designation of the force is changed compared to the referenced ASTM specification in order to achieve consistency with the DCB test.

binary images with only white and black pixel color values. An overlay of both images shows the overall agglomeration area in black (c). White areas in the overlay are CRF, provided that no UA and AF occurs. CAF areas, with agglomerations on both fracture surfaces, can be determined via multiplication of the binary images (d). Finally, CIF areas follow from subtracting the CAF color properties from the overlay image (e).

Figure 6: Representative evaluation of failure modes: a), b) conversion of fracture surfaces into binary images, c) overlay via addition of pixel color values, d) CAF via multiplication of pixel color values, e) CIF via difference of overlay and CAF

Since observed fracture of the ENF specimens is limited to the length between a_0 and a_f , evaluation of the fracture mode is restricted to this certain area. For the DCB specimens the fracture modes are evaluated for a representative length of 45 mm, which is the largest continuous observable dimension of the used microscope.

4 TEST RESULTS AND DISCUSSION

First test results are obtained from three DCB and ENF specimens fabricated from the inkjet printed CNT02 composition. The resulting interlaminar fracture toughness values are shown in Figure 7. As multiple results are obtainable from a single DCB specimen, $G_{I,C}$ values are displayed as boxplots outlining the median value, the total range and the interquartile range with 75 % of all values. For both tests, the majority of the median interlaminar fracture toughness is within a relatively low range from 2 to 6 N/m. On the other hand, values from a third specimen are significantly higher by a factor of 2 in case of DCB03, respectively factor 5 for ENF01. Allocated to their characteristic failure mode distribution, these specimens correlate with a higher portion of CRF.

Several conclusions are drawn from these results. First, a decomposition of the CNT enriched ink can be observed on the fracture surfaces. This results in clearly visible

agglomerations and in resin rich areas on 30 % to 50 % of the fracture zone. Therefore, the printed interface is found inhomogeneous with a wide range of interlaminar fracture toughness values. The larger the agglomerations, the smaller the CRF portion and the smaller both $G_{I,C}$ and $G_{II,C}$ values. Thus, a weakening effect of the agglomerated CNT is shown.

Figure 7: Interlaminar fracture toughness values and correlation with portion of CRF for valid DCB & ENF specimens for ink composition CNT02

This hypothesis is confirmed by results of two additional test series where the CNT are excluded (RED01) respectively reduced (CNT08). Without CNT the forming of agglomerations during the sinter process is precluded. A complete CRF of the printed interface can be observed, but with inhomogeneities with respect to the thickness distribution due to the DMAc evaporation. Results for each three valid DCB and ENF specimens of the RED01 series show significantly higher interlaminar fracture toughness values as in the previous tests. The median $G_{I,C}$ value is increased by 88 %, the corresponding value for a mode II load is increased by 271 % (see Figure 8).

Diverse results are obtained from the CNT08 series. The halving of the CNT content, compared to CNT02, does not lead to a reduction of the agglomeration area on the fracture surfaces. Contrary, the mean portion is found slightly increased from 62 % to 65 %. Therefore, the CNT fraction inside the agglomerations needs to be decreased and mitigate the local weakening effect. Due to this fact, the median $G_{II,C}$ value, obtained from only two valid specimens, is about 154 % higher than for the CNT02 series. The results from the DCB specimens show a different behavior. The change of the median value is negligible. Since the behavior of the agglomerations can be assumed to be transversal orthotropic with poor out-of-plane properties, the effect of the reduction of the CNT content vanishes for the corresponding mode I load.

Figure 8: Interlaminar fracture toughness values of all ink compositions obtained from DCB specimens (left) and ENF specimens (right)

5 CONCLUSIONS

The CNT enriched inks were found to be prone to form agglomerations. The extent does not vary significantly with the added CNT content which causes several problems. First, the conductive path is very likely to be interrupted by resin rich areas. Further, the intended strengthening effect for the epoxy resin is inverted. Cohesion forces in agglomerations are smaller than in neat resin, which was confirmed with results from the RED01 series.

Furthermore, a negligible effect of the CNT content on the interlaminar fracture toughness value in DCB tests was shown. Since CNT are assumed to be mainly distributed in plane with the printed interface, transversal orthotropic properties are predominant. Thus, an effect was found for the in-plane shear mode II. A local reduction of CNT in the agglomerations improved the corresponding fracture toughness.

Nevertheless, the medians of the fracture toughness values were higher than the average values from Heinrich et. al. [8] investigating a silver particle-based ink, applicable to in-situ monitoring of damage [4]. Thus, the current results have shown the potential of CNT-based printed electronics regarding their enhanced damage behavior.

The objective for future works is the prevention of agglomerations by use of suitable chemical additives. This is fundamental for improved mechanical properties. The fracture toughness from the RED01 series shall be exceeded.

Key words: Shape-Adaptable Structures, Smart Structures, Shape-Memory-Alloy.

Abstract. Shape memory alloys (SMA) are well known for the high stress and the large strain that they can achieve simultaneously and, therefore, have been widely used as actuators in different shape-adaptable structures. While most of the adaptive structures found in the literature using SMAs as actuators have been designed to accomplish only a single type of deformation, we present in this work a novel structural concept able to achieve multiple shapes. The concept consists of a modular sandwich panel composed of rigid cells connected by active joints hosting SMA wires, which are used as actuators. Thanks to their geometry, the joints act both as stroke amplification systems and as bias springs, allowing for multiple actuations of one-way SMA wires. The active joints are placed in pairs both on the upper and on the lower face sheet of the panel and control the distance as well as the orientation of neighbouring panel cells. As a result, it is possible to deform the panel both in-plane and out-of-plane. In this paper, we present the working principle of the proposed concept and of its actuation system. The mechanical behaviour of the active joints is investigated both numerically and experimentally and the results obtained are implemented in a finite element model of the shape-adaptable sandwich panel. Four actuation strategies of the active joints are investigated and the achieved deformations returned by the corresponding simulations are compared with the experimental measurements carried out on a demonstrator.

1 INTRODUCTION

Sandwich panels are a type of construction widely used in lightweight structures due to the high specific stiffness and specific strength and the possibility to integrate additional functions such as thermal or acoustic insulation [1] or even liquid storage [2]. In this work, we want to make a step forward introducing the concept of shape-adaptable sandwich panels. This step is motivated by the growing interest in shape-adaptable lightweight structures by the aerospace

and the automotive industry, which see morphing structures as a possible way to realize reconfigurable lightweight systems or active aerodynamic surfaces able to improve performance and efficiency of the current technologies [3-6].

As underlined by Campanile et al. [7], the design of shape-adaptable lightweight structures tackles an inherent contradiction, since a certain compliance is required in order to accommodate for the changes in shape but, simultaneously, enough stiffness has to be provided to carry operational loads without undergoing excessive deformations and, at the same time, the weight constrain has to be met. In opposition to traditional technologies, which rely on rigid-body mechanisms to solve this problem, novel approaches take advantage of the combination of compliant structures and smart materials [8-12] or deploy a regular arrangement of unit cells and small, distributed actuators to create programmable structures capable of achieving complex changes in shape [13-14].

In this work, we merge these two principles to realize a shape-adaptable sandwich panel. The concept presented is based on the two dimensional arrangement of rigid cells connected with active compliant joints. Each joint hosts an actuation system based on shape memory alloys (SMA), which can be controlled independently. This fact allows us to selectively actuate only specific joints and to obtain multiple shapes from a single panel design.

Figure 1: Geometry (a) of the shape-adaptable sandwich panel investigated, (b) of the active compliant joints and (c) of the stiff cells.

2 INVESTIGATED DESIGN CONCEPT

The shape-adaptable sandwich panel concept presented in this work is depicted in Fig. 1-a and consists of two deformable face sheets made of stiff square platelets connected through active compliant joints (Fig. 1-b). Corresponding platelets on opposite face sheets are connected by truss elements, which form the core of the panel, and, all together, form stiff cells (Fig. 1-c). In this arrangement, each cell is connected to its neighbours through two active compliant joints, which are placed, respectively, between the platelets of the upper and those of the lower face sheet (see Fig. 2-a). The joints consist of leaf springs hosting a pre-strained, one-way SMA wire, which acts as an actuator. When heated up, the SMA wire contracts, deforming the leaf spring, which in turn pushes the neighbouring platelets apart. This actuation principle is similar to the ‘Fish-mouth’ actuator presented by Campanile et al. [15] and relies on the leaf spring to pull back the SMA wire to its initial state, while the latter cools down, allowing us to obtain a result similar to a two-way shape memory effect with a one-way SMA wire.

The morphing capability of the presented concept is based on the placement of the active compliant joints between the platelets of the panel cells and on the possibility of their selective actuation. These two features allow for the control of the distance and of the angle α between neighbouring cells (see Fig. 2) and, therefore, they enable us to obtain both in-plane and out-of-plane deformations according to the actuation strategy of the SMA wires implemented. For example, if we consider two adjacent panel cells, we notice that, when both the upper and the lower active joint are actuated, the displacement between the upper and the lower cell platelets is equal and, therefore, the cells experience an in-plane translation (Fig. 2-a). On the other hand, if only the upper (Fig. 2-c) or the lower (Fig. 2-b) joint is actuated, the relative motion of the platelets is no longer equal and, consequently, the panel cells undergo an out-of-plane rotation. This effect, combined with the periodic arrangement of the panel cells in two dimensions, gives us the possibility to achieve complex 3D shapes, such as half pipes (Fig. 2-d), domes (Fig. 2-e), as well as shapes with multiple curvatures (Fig. 2-f).

Figure 2: Behaviour of two neighbouring cells (a) when both active joints are actuated, (b) when only the upper joint is actuated and (c) when only the lower joint is actuated. Examples of possible shapes achievable by the shape-adaptable sandwich panel concept: (d) half pipe, (e) dome and (f) multi-curvature.

3 METHODS

In order to evaluate the capability of the presented concept to vary its shape, we considered a sandwich panel composed by 3x3 cells (Fig. 3-a). We first investigated the mechanical behaviour of the active compliant joints and we created a simplified numerical model that was later extended to the entire panel. This model was used to compute the deformations of the panel for different actuation strategies of the active joints under the assumption that no external load was acting on the panel. Finally, a demonstrator was manufactured and tested for four selected types of deformations to verify the numerical results.

We considered a design of the active compliant joints based on leaf springs of height $h_l = 32$ mm, width $w_l = 52$ mm, thickness $t_l = 6$ mm and arm thickness $w_a = 2$ mm. The leaf springs were 3D printed (Indimatec) in polyether ether ketone (PEEK) (Zyex, VICTREX PEEK 1.75 mm) with a single outer layer and a 60% rectangular infill. We opted for this material due to its high glass transition temperature, which lies above 140°C [16], in order to reduce the risk of thermal degradation and softening during the actuation of the SMA wires (SAES Group, SmartFlex05). The latter had a diameter $d_w = 0.5$ mm and were fixed to the outer side of the leaf springs using crimps (SAES Group, T Type Crimp) (see Fig. 3-b). Before the definitive fixation of the crimps, leaf springs were compressed of 5 %, so that their spring back could pre-strain the SMA wires and enable their actuation.

Figure 3: (a) Demonstrator of the shape-adaptable sandwich panel and (b) one of the compliant active joints tested.

Five identical active joints were tested in order to identify their average strain. The SMA wires were heated up with a current of 3 A applied with a DC power supply (Keysight, E3631A) for 30 s and then cooled down with a ventilator for 1 min. The contraction of the SMA wire was measured with a digital image correlation (DIC) system (Correlated Solutions, VIC-3D) and the difference between the maximum strain achieved by the SMA when heated up and the minimum strain achieved when cooled down was registered. Each actuation cycle was repeated six times but only the strains achieved in the last five cycles were considered for the calculation of the average strain. The average strain measured was used to estimate the force F generated by the SMA wires to be implemented in the numerical model. Five leaf springs were tested under compression in a universal testing machine (Zwick/Roell, Z005) and the force-strain diagram obtained was compared with the average deformation of the five actuators previously measured in order to estimate the value of F .

A linear FE model of the leaf spring was created in COMSOL Multiphysics® v. 5.4 assuming the material as isotropic and using solid 3D elements with a mesh of size of 1 mm.

The Young's modulus of the 3D printed PEEK was determined following the standard ASTM D790-10, while a Poisson's ratio value of 0.4 was chosen. This FE model was used to assess the force necessary to deform the leaf spring and to establish a comparison with the experimental results of the compression test. The model was then expanded to reproduce the entire panel. The panel cells were modelled as rigid bodies and the actuation of the panel was implemented by applying the previously estimated force F on the selected active joints at the fixation points of the SMA wires. Four different actuation strategies of the active joints were investigated (see Fig. 4). Each of them corresponds to a different type of deformation of the panel: a planar expansion (Fig. 4-a), an out-of-plane deformation with a single curvature (Fig. 4-b), an out-of-plane deformation with a double curvature (Fig. 4-c) and an out-of-plane deformation with both a positive and a negative curvature (Fig. 4-d).

The changes in shape obtained by the numerical model were compared with the measurements carried out on a demonstrator. 24 active compliant joints were printed and assembled to nine panel cells. For the sake of simplicity, the latter were 3D printed (Ultimaker, Ultimaker 2+) in polylactide (PLA) (Swiss 3D Tec, PLA filament, 3 mm) since in this work we did not apply any external load to the panel but only investigated the achievable shapes. The cell's platelets had an edge $l = 46$ mm and a thickness $t_s = 6$ mm. Moreover, they were endowed with four anchor points for the interlocking of the active joints, to which we added two dove tail elements (see Fig. 3-b). The truss core had a thickness $t_c = 20$ mm. Finally, the SMA wires of the active joints were connected in series according to the type of deformation investigated and a speckle pattern was applied on the upper surface of the cell platelets in order to track the deformation of the panel using a DIC system (Correlated Solutions, VIC-3D).

Figure 4: Actuation strategies of the active compliant joints for the four cases considered: (a) planar expansion, (b) single curvature, (c) double curvature and (d) positive and negative curvature (d). The joints actuated are marked in red.

4 RESULTS

The strains achieved by the SMA wires in the active joints tested are reported in Table 1. The average strain achieved was $(1.57 \pm 0.22)\%$, to which it corresponds a standard deviation of 14.01%. Fig. 5-a shows the results of the 3 points bending tests performed to characterize the 3D printed PEEK. The characterisation returned a Young's modulus of 2.859 GPa with a standard deviation of 19.55%. Fig. 5-b compares the results of the simulations of the compression behaviour of a single leaf spring with the results of the mechanical tests. By reading from this figure the values of the force corresponding to the previously determined average strain achieved by the SMA wires, an average force of 22.3 N generated by the SMA wires was estimated and used later in the simulations of the entire panel.

Table 1: Strain difference achieved by the active joints tested.

Sample	Cycle 1	Cycle 2	Cycle 3	Cycle 4	Cycle 5
1	1,47%	1,45%	1,43%	1,42%	1,41%

3	2,01%	2,00%	1,97%	1,96%	1,96%
4	1,66%	1,66%	1,62%	1,61%	1,61%
5	1,44%	1,43%	1,41%	1,41%	1,40%
Average	$(1.57 \pm 0.22)\%$				

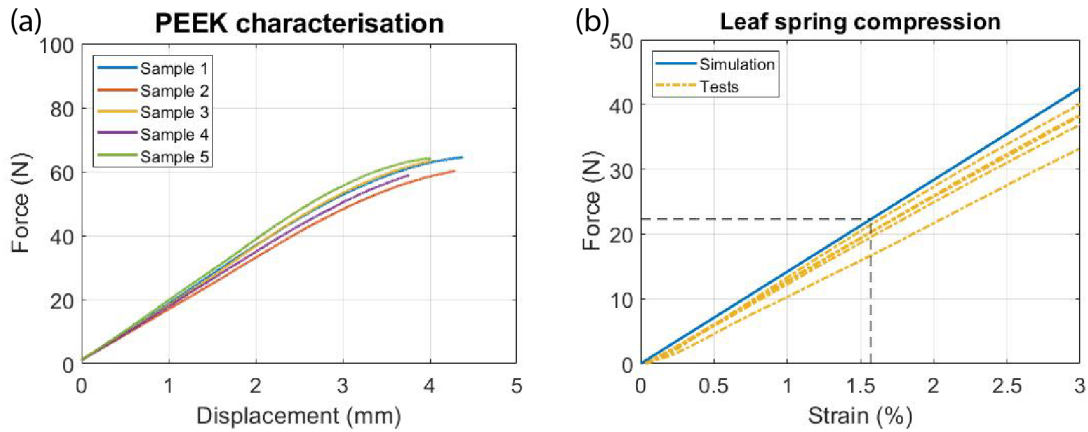

Figure 5: (a) Results of the 3 points bending tests performed on the 3D printed PEEK samples and (b) comparison of the simulated force necessary to compress the leaf spring with the experimental tests.

As far as the panel is concerned, Fig. 6 establishes a comparison between the numerical and the experimental results for the four cases considered. In the following subsections, each type of deformation investigated is treated separately and numerical and experimental results are presented.

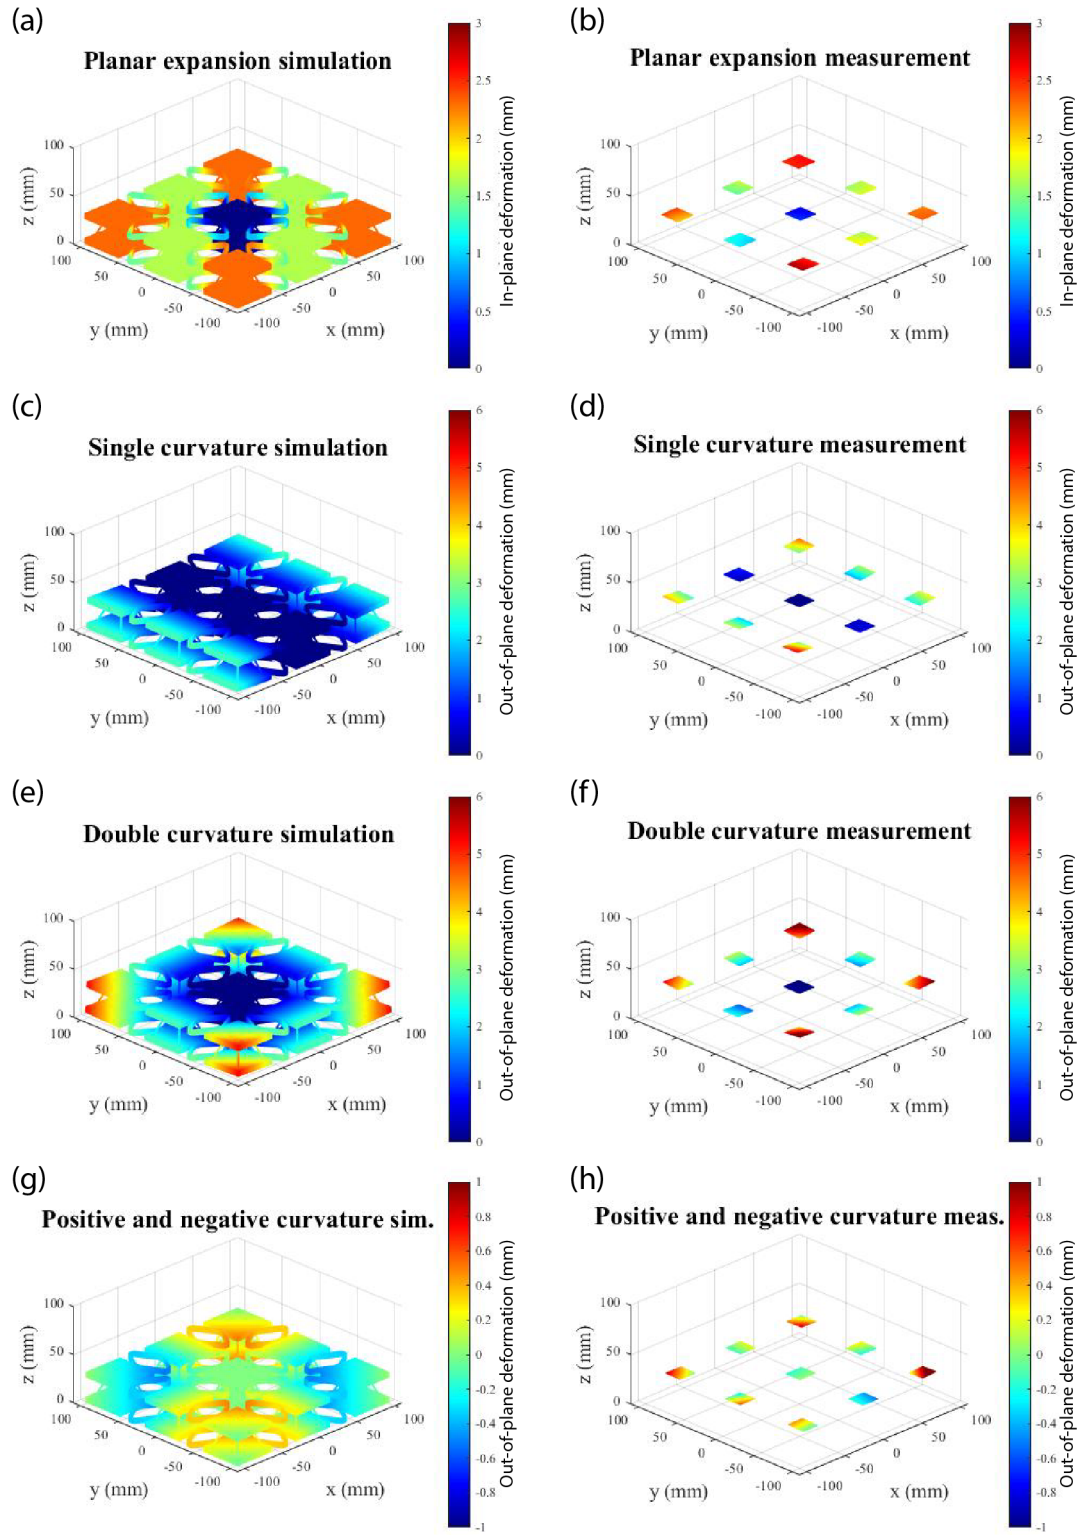

Figure 6: Comparison of the FE results (left) and the DIC measurements (right) for the four cases investigated: (a, b) planar expansion, (c, d) single curvature, (e, f) double curvature and (g, h) positive and negative curvature.

4.1 Planar expansion

The panel undergoes planar changes in shape when corresponding active joints on the upper and on the lower face sheets are actuated at the same time. As it is possible to notice in Fig. 6-a, no rotation of the panel cells occurs but only their planar translation. Moreover, the degree of this translation increases with the increasing distance of the cells from the centre of the panel. These effects can be seen as well in the DIC measurements (Fig. 6-b), which are in good agreement with the numerical results for most of the panel cells.

4.2 Single curvature

In order to obtain a single positive curvature of the panel, only the active joints on the lower face sheet aligned in the same direction were actuated. As a result, the lower face sheets expands in a single direction, introducing a moment in the panel cells, which rotate lifting the neighbouring cells. Both the simulation (Fig. 6-c) and the DIC measurements (Fig. 6-d) show how the central cells of the panel do not displace, while the external cells rotate slightly upwards giving a positive curvature to the panel.

4.3 Double curvature

When all active joints in the lower face sheets are actuated, the latter expands uniformly in both planar directions introducing two perpendicular moments into the structure. Fig. 6-e and Fig. 6-f show how this actuation strategy results in a double curvature of the panel both in the simulation as well as in the DIC measurements, respectively.

4.4 Positive and negative curvature

The results of the numerical calculations and of the DIC measures obtained for the last type of deformation investigated are plotted in Fig. 6-g and Fig. 6-h, respectively. If we consider the profile of the edges of the panel, we notice how the cells on the vertices of the panel rotate in pairs towards the centre or towards the outside of the panel, while the cells in the middle of the edges rotate in pairs around an axis parallel to the x or to the y-axis. As results, the edges of the panel assume a slight s-shape, which witnesses the presence of both a positive and a negative curvature.

5 DISCUSSION

The results of the tests conducted on the active joints demonstrate the proper working of the concept and the possibility to obtain multiple actuation cycles using one-way SMA wires like in [15] but with an easier manufacturing process. On the other side, the results also show that the strain achieved by each active joint tends to slight decrease with the increase in actuation cycles and that the deviation in the strain achieved by different joints tested is about 14%. This deviation might be justified considering the deviation in the Young's modulus of the 3D printed PEEK, which amounts to almost 20%. The difference in stiffness of the 3D printed PEEK can be also distinguished in the results of the compression tests carried out on the leaf springs. In Fig. 5-b, we can clearly notice the difference in the slope of the curves of the different leaf springs tested. Similar leaf springs, printed with the same 3D printer and with the same process parameters, were used to assemble the active joints tested. Therefore, we can expect that the

variation in the Young's modulus of the 3D printed PEEK has a major effect on the performance of the active joints, since the stiffness of the leaf springs affects both the maximum strain that the SMA wires can achieve and the capability of the leaf springs to act as a bias spring. On the other side, Fig. 5-b shows also that for the given geometry of the leaf spring and for the strains achieved by the SMA wires, we can assume a linear behaviour of the active joints and, therefore, the use of a linear model in the simulations of the entire panel is justified.

Considering the observed variance in strain achieved by the active joints, the simulations of the deformation of the entire panel and the DIC measurements carried out on the demonstrator were in good agreement. As is it possible to notice comparing the left and the right column of Fig. 6, some misalignments in the displacement of the panel cells are present and they make the final shape not always perfectly symmetric. Nevertheless, the deformations measured are always close to the numerical predictions and the targeted final shape is clearly distinguishable in all cases investigated. Only in the case of positive and negative curvature the difference between simulations and measurement is larger, but this fact might be attributed to the smaller displacements involved. Indeed, since the out-of-plane deformation shown in Fig. 6-g and Fig. 6-h is an order of magnitude lower than in the other cases and in the range of tenths of millimetre, this higher difference might be related also to small imperfections in the manual assembly of the panel.

6 CONCLUSIONS AND OUTLOOK

The results presented in this paper demonstrate the capability of the presented concept to achieve multiple changes in shape involving both in-plane and out-of-plane deformations with a single design. This versatility derives from the high number of degrees of freedom provided by the distributed actuation system and by the disposition of the active joints on both on the upper and on the lower face sheets of the panel. The results achieved suggest that this concept might find application in highly variable environments, where multiple shapes might be beneficial to optimize the structural performance at the different conditions. As possible applications, we envisage active surfaces for morphing wings or car body panels, or even reconfigurable modular structures for space antennas. When considering possible applications, further specific constraints, such as maximum weight or load carrying capability, have to be taken into account and their effect on the morphing capability of the proposed concept have to be evaluated. Moreover, a robust manufacturing process has to be selected, in order to reduce the variance on performance of the active joints and a suitable control system assuring the independent actuation of each joint has to be developed.

Further work will focus on the improvement of the manufacturing process and particularly on the optimisation of the mechanical properties of the 3D printed components. Moreover, the design of the leaf spring and of the active joints will be optimized selecting a specific application and taking into account the specific requirements. Finally, a proper control system able to actuate each active joint independently will be developed and integrated into the panel design.

ACKNOWLEDGMENTS

The authors would like to thank the ETH board for funding the project. The Digital Image Correlation (DIC) equipment was purchased through the Swiss National Science Foundation R'Equip grant 206021_150729.

Abstract. This paper deals with morphing and energy harvesting analysis of new innovative multifunctional hybrid composite beam structure consisting of conventional fiber reinforced composite as substrate layer, a shape memory alloy fiber reinforced composite layer for the purpose of morphing actuation and a piezoelectric composite layer for the purpose of energy harvesting. One dimensional Tanaka type model using Reuss scheme with multi variant martensite is adopted to model SMA behavior and transformation model of SMA solved numerically as Young's modulus depends on martensite fraction. Multicell micromechanics approach is adopted to calculate effective properties of fiber reinforced composites. The objective of the present work is to analytically investigate the free and forced vibration of this newly proposed hybrid composite beams in pre/post-buckled domains and also to analytically estimate energy harvesting capability.

1 INTRODUCTION

Morphing is defined as the ability of certain wing to change its geometrical form during flight. Morphing concept is inspired from bird wings that are able to change wing shapes during flight at varied surrounding conditions. Such wing will enable the aircraft to accommodate multiple flight regimes and obtain better flight performance [1-3]. There can be several types of morphing possible viz. span, chord, sweep, chord-wise, span-wise and twist etc. Several mechanisms are also reported in literature to achieve particular type of morphing viz. tendon actuated compliant cellular truss, lattice based cellular structure, Parker variable camber wing, number of flap and slat mechanisms, variform wing, compliant mechanism, piezoelectric actuated wing, SMA actuated wing, reconfigurable wing and smart wing [4-13]. Of late multifunctional smart materials are being developed to achieve several functionalities simultaneously. Apart from multiple functionalities these materials can reduce weight of the structure thus enable fuel savings [14]. Shape memory alloy (SMA) and piezoelectric actuators are used for wing morphing in different flight regimes and are reported in literature [15-19].

Similarly, SMA strips and wires in laminated composites structures are also used for mechanism of morphing in aircraft wing structure [20]. In literature many researchers addressed the investigation of camber morphing mechanism [21]. The implementation of an actuator that enables smooth deformation is achieved through the use of SMAs. SMA components not only accommodate but actually induce the chord-wise axial strains in the skin needed for camber changes while preserving structural integrity and providing high stiffness. Many studies focus on analysis of pre/post buckling behaviour, bending behaviour and vibration behaviour of laminated composite structures embedded with SMA wires [22-32]. Modeling of SMA wire can be found in literature [33, 34]. Effective properties of piezoelectric fiber reinforced composites is investigated by Mallik and Ray [35] by strength of materials and method of cells approach. An elaborated demonstration of energy harvesting technologies including vibration based technologies can be found in book by Priya and Inman [36].

Investigation of laminated composite structure embedded with SMA wire for morphing capability and energy harvesting capability is scarce in literature. Hence, morphing and energy harvesting analysis of new innovative multifunctional hybrid composite beam structure consisting of conventional fiber reinforced composite as substrate layer, a shape memory alloy fiber reinforced composite later for the purpose of morphing actuation and a piezoelectric composite layer for the purpose of energy harvesting. One dimensional Tanaka type model using Reuss scheme with single variant martensite is adopted to model SMA behavior and transformation model of SMA solved numerically as Young's modulus depends on martensite fraction. Strength of materials approach is adopted to predict effective properties of piezoelectric composite. The objective of the present work is to analytically investigate the free and forced vibration of this newly proposed hybrid composite beams in pre/post-buckled domains and also to analytically estimate energy harvesting capability.

2 GENERAL SPECIFICATIONS

Present paper deals with morphing and energy harvesting analysis of new innovative multifunctional hybrid composite beam structure consisting of conventional fiber reinforced composite as substrate layer, a shape memory alloy fiber reinforced composite layer for the purpose of morphing actuation and a piezoelectric composite layer for the purpose of energy harvesting.

3 METHODOLOGY

One dimensional Tanaka type model using Reuss scheme with single variant martensite is adopted to model SMA behavior and transformation model of SMA solved numerically as Young's modulus depends on martensite fraction. Strength of materials approach is adopted to predict effective properties of piezoelectric composite. The objective of the present work is to analytically investigate the free and forced vibration of this newly proposed hybrid composite beams in pre/post-buckled domains and also to analytically estimate energy harvesting capability.

3.1 SMA constitutive model

One dimensional constitutive model proposed by Brinson is adopted in the presented study.

Based on this constitutive model quantities stress (σ), strain (ϵ) and temperature (T) are related through martensite fraction (ξ) as:

$$\sigma - \sigma_0 = E(\xi)(\epsilon - \epsilon_0) + \Omega(\xi)\xi_S - \Omega(\xi_0)\xi_{S0} + \theta(T - T_0) \quad (1)$$

Where, θ is thermoelastic modulus related to thermal expansion coefficient α ; Ω is phase transformation modulus; $E(\xi)$ is Young's modulus dependent on martensite fraction (ξ); subscript 0 denotes initial conditions. Young's modulus is predicted using Reuss scheme as

$$E(\xi) = \frac{E_A}{1 + (\frac{E_A}{E_M} - 1)\xi} \quad (2)$$

Where, E_A and E_M are Young's modulus of austenite and martensite phases, respectively. According to multiple variant model, martensite fraction (ξ) is represented as

$$\xi = \xi_S + \xi_T \quad (3)$$

Where, ξ_S and ξ_T are fraction of stress induced martensite or detwinned martensite and fraction of temperature induced martensite, respectively. The transformation modulus is related to Young's modulus as given below and can be determined experimentally by converting all austenite to detwinned martensite at a temperature less than austenite start temperature.

$$\Omega = -\epsilon_L E(\xi) \quad (4)$$

Where, ϵ_L is the maximum residual strain. As proposed by Brinson and Huang after simplification Tanaka type constitutive model can be obtained as

$$\sigma - \sigma_0 = E(\xi)(\epsilon - \epsilon_L \xi_S) + \Omega(\xi)\xi_S + \theta(T - T_0) \quad (5)$$

Based on Brinson model, in martensite to austenite conversion phase for $T > A_s$, $dT > \frac{d\sigma}{C_A}$ and $C_A(T - A_f) < \sigma < C_A(T - A_s)$, the resultant equation for thermally induced martensite fraction ($\xi_T = \xi_{T0} \frac{\xi}{\xi_0}$) and stress induced martensite fractions ($\xi_S = \xi_{S0} \frac{\xi}{\xi_0}$) can be written in terms of cosine function as

$$\xi = \frac{\xi_0}{2} \left[\cos \left\{ \frac{\pi}{A_f - A_s} \left(T - A_s - \frac{\sigma}{C_A} \right) \right\} + 1 \right] \quad (6)$$

Similarly, for austenite to martensite conversion phase for $T < M_s$, $dT < \frac{d\sigma}{C_M}$ and $C_M(T - M_s) < \sigma < C_M(T - M_f)$, the resultant equation for thermally induced martensite fraction ($\xi_T = \xi_{T0} \frac{\xi}{\xi_0}$) and stress induced martensite fractions ($\xi_S = \xi_{S0} \frac{\xi}{\xi_0}$) can be written in terms of cosine function as

$$\xi = \frac{1 - \xi_0}{2} \cos \left\{ \frac{\pi}{M_s - M_f} \left(T - M_f - \frac{\sigma}{C_M} \right) \right\} + \frac{1 + \xi_0}{2} \quad (7)$$

As Young's modulus is dependent on martensite fraction same is calculated numerically. The composite effective properties are calculated based on multicell micromechanics approach [1].

The effective properties of the composite are listed below:

$$E_{11} = E_{sf}(\xi)v_{sf} + E_{1m}v_m \quad (8)$$

$$E_{22} = E_{2m} \left[(1 - \sqrt{v_{sf}}) + \frac{\sqrt{v_{sf}}}{1 - \sqrt{v_{sf}} \left(1 - \frac{E_{2m}}{E_{sf}(\xi)} \right)} \right] \quad (9)$$

$$G_{13} = G_{12} = G_{12m} \left[(1 - \sqrt{v_{sf}}) + \frac{\sqrt{v_{sf}}}{1 - \sqrt{v_{sf}} \left(1 - \frac{G_{12m}}{G_{sf}(\xi)} \right)} \right] \quad (10)$$

$$\mu_{11} = \mu_{12sf}v_{sf} + \mu_{12m}v_m \quad (11)$$

$$\alpha_1 = \frac{v_{sf}\alpha_{sf}E_{sf}(\xi) + v_m\alpha_{1m}E_{1m}}{E_{11}} \quad (12)$$

$$\alpha_2 = \frac{E_{2m}}{E_{22}} \left[\alpha_{2m}(1 - \sqrt{v_{sf}}) + \frac{\alpha_{2m}\sqrt{v_{sf}} - v_{sf}(\alpha_{2m} - \alpha_{sf})}{1 - \sqrt{v_{sf}} \left(1 - \frac{E_{2m}}{E_{sf}(\xi)} \right)} \right] \quad (13)$$

$$G_{sf}(\xi) = \frac{E_{sf}(\xi)}{2(1 + \mu_{12sf})} \quad (14)$$

$$\rho = \rho_{sf}v_{sf} + \rho_mv_m \quad (15)$$

$$v_{sf} + v_m = 1 \quad (16)$$

3.2 Analysis of hybrid beam

Based on first order shear deformation theory, the displacement components of a material point within the domain of hybrid composite can be expressed as

$$u(x, z, t) = u_0(x, t) + z\varphi(x, t) \quad (17)$$

$$w(x, z, t) = w_0(x, t) \quad (18)$$

Where, u_0 and w_0 are midplane displacements and φ is the rotation of the mid-plane. Non-linear Green-Lagrange strain tensor is taken for analysis and represented as under

$$\epsilon_x = \frac{\partial u_0}{\partial x} + \frac{1}{2} \left(\frac{\partial w_0}{\partial x} \right)^2 + z \frac{\partial \varphi}{\partial x} \quad (19)$$

$$\gamma_{xz} = \varphi + \frac{\partial w_0}{\partial x} \quad (20)$$

The linear thermo-elastic constitutive relation for a general k^{th} layer of the hybrid beam with fiber orientation θ^k can be written as:

$$\sigma_x^k = \bar{Q}_{11}^k \epsilon_x^k - \bar{Q}_{11}^k \alpha_x^k \Delta T + \cos^2(\theta^k) v_{sf} \sigma_r^k \quad (21)$$

$$\tau_{xz}^k = \bar{Q}_{55}^k \gamma_{xz}^k \quad (22)$$

$$\alpha_x^k = \cos^2(\theta^k) \alpha_1 + \sin^2(\theta^k) \alpha_2 \quad (23)$$

Where, superscript k indicates layer number; \bar{Q}_{ij}^k are transformed reduced stiffness; α_i^k are the co-efficient of thermal expansion; ΔT is the temperature difference with respect to reference temperature where there is no thermal strain and σ_r is the recovery stress generated by the temperature induced reverse phase transformation of the pre-strained SMA fibers from detwinned martensite to austenite.

In order to derive the equation of motion of the hybrid beam the extended Hamilton's principle is applied given as:

$$\int_{t_1}^{t_2} (\delta K - \delta U - \delta W) dt = 0 \quad (24)$$

Where, δ represents the variational symbol; $[t_1, t_2]$ describes arbitrary time interval; K , U and W are respectively kinetic energy, strain energy and applied external work, defined as below:

$$\delta K = \int_A \int_{-h/2}^{h/2} \rho \{ \dot{w}_0 \delta \dot{w}_0 + (\dot{u}_0 + z \dot{\phi}) (\delta \dot{u}_0 + z \delta \dot{\phi}_0) \} dz dA \quad (25)$$

$$\delta U = \int_A \int_{-h/2}^{h/2} (\sigma_x \delta \epsilon_x + K_S \tau_{xz} \delta \gamma_{xz}) dz dA \quad (26)$$

$$\delta W = \int_A q \delta w_0 dA \quad (27)$$

Where, K_S is the shear correction factor to compensate for parabolic transverse shear stress; A is the surface area of the beam; $q = q(x, t)$ is the external load per unit area. By using equations (17 – 23) and (25 – 27) into extended Hamilton's principle and integrating over the beam thickness, equations of motion of the beam are obtained and given as under:

$$\frac{dN_x}{dx} = I_1 \ddot{u}_0 + I_2 \ddot{\phi}_0 \quad (28)$$

$$Q_{xz} - \frac{\partial M_x}{\partial x} = I_2 \ddot{u} + I_3 \ddot{\phi} \quad (29)$$

$$\frac{\partial}{\partial x} \left(N_x \frac{\partial w_0}{\partial x} \right) + \frac{\partial Q_{xz}}{\partial x} + q = I_1 \ddot{w}_0 \quad (30)$$

Where, $(N_x, M_x, Q_x) = \int_{-h/2}^{h/2} (\sigma_x, z \sigma_x, K_S \tau_{xz}) dz$ and $(I_1, I_2, I_3) = \int_{-h/2}^{h/2} \rho (1, z, z^2) dz$. The quantities are expressed as below:

$$N_x = A_{11} \left[\frac{\partial u_0}{\partial x} + \frac{1}{2} \left(\frac{\partial w_0}{\partial x} \right)^2 \right] + B_{11} \frac{\partial \phi}{\partial x} - N^T + N^r \quad (31)$$

$$M_x = B_{11} \left[\frac{\partial u_0}{\partial x} + \frac{1}{2} \left(\frac{\partial w_0}{\partial x} \right)^2 \right] + D_{11} \frac{\partial \phi}{\partial x} - M^T + M^r \quad (32)$$

$$Q_{xz} = K_S A_{55} \left(\phi + \frac{\partial w_0}{\partial x} \right) \quad (33)$$

Where,

$$(N^T, M^T) = \sum_{k=1}^n \int_{h_{k-1}}^{h_k} (\bar{Q}_{11}^k \alpha_x^k) \Delta T(1, z) dz, (N^r, M^r) = \sum_{k=1}^n \int_{h_{k-1}}^{h_k} \sigma_r^k v_{sf} \cos^2(\theta^k)(1, z) dz,$$

$$(A_{11}, B_{11}, D_{11}) = \sum_{k=1}^n \int_{h_{k-1}}^{h_k} \bar{Q}_{11}^k(1, z, z^2) dz, A_{55} = \sum_{k=1}^n \int_{h_{k-1}}^{h_k} \bar{Q}_{55}^k dz.$$

3.3 Buckling domain

The resultant force in pre and post buckling domains are expressed respectively as $N_x^* = -(N^{T*} - N^{r*})$ and $N_x^* = -\frac{\pi^2 P_1 P_2}{\pi^2 P_1 + P_2}$

Where,

$$N^{T*} = N^{r*} + \frac{\pi^2 P_1 P_2}{\pi^2 P_1 + P_2}, N^{T*} = \frac{N^T}{E_m^{ref} h}, N^{r*} = \frac{N^r}{E_m^{ref} h}, f_1 = \frac{A_{11}}{E_m^{ref} h}, f_2 = \frac{B_{11}}{E_m^{ref} h L}, f_3 = \frac{D_{11}}{E_m^{ref} h L^2},$$

$$g_1 = \frac{A_{55}}{E_m^{ref} h}, P_1 = \frac{f_3 f_1 - f_2^2}{f_1}, P_2 = g_1.$$

3.4 Vibration analysis

Vibration analysis is performed assuming harmonic solution and solving eigen value problem and non-trivial solution is obtained by setting determinant to zero.

3.5 Energy harvesting

Strain on the surface of the piezoelectric patch at a distance of y from the neutral axis can be obtained from following relation:

$$\epsilon(x) = -y \frac{\partial^2 w(x, t)}{\partial x^2} \quad (34)$$

Where, $w(x, t) = \varphi_1(x) \varphi_2(t)$ and the output voltage and power from the patch can be expressed as follows:

$$V\left(\frac{x}{L}\right) = g_{31} E_p \epsilon\left(\frac{x}{L}\right) L_p \quad (35)$$

$$P = \frac{V^2}{R_L} \quad (36)$$

4 RESULTS AND DISCUSSIONS

Figure 1: Variation of Young's modulus with respect to martensite fraction

5 CONCLUSIONS

Present paper demonstrates capability of hybrid sma/piezoelectric composite structure for morphing and energy harvesting.

Key words: Morphing aircraft, Actuation system, Morphing wing, Negative stiffness, Energy balancing

Abstract.

The actuation system of morphing aircraft plays an important role in any promising morphing design. If the structure of the morphing wing needs to be deformed elastically, the actuation system will be required to provide an adequate actuation force while the weight and cost added to the morphing aircraft should be limited to the extent that the performance of the morphing aircraft will not be compromised.

The spiral pulley negative stiffness concept, which uses its stored elastic energy and a negative stiffness mechanism to passively balance the energy requirements of the morphing device, is a promising solution to design the actuation system. The negative stiffness is achieved by the spiral pulley with a spooling cable, which is connected to a pre-stretched spring. The rotation of the spiral pulley can release the energy stored in the spring, and generate the torque to deform the morphing structure. Due to the geometric configuration of the spiral pulley and the kinematic tailoring it provides, negative torque of increasing magnitude is generated as rotation increases, such that the mechanism shows a 'negative stiffness', which will balance the positive stiffness of the morphing structure. Geometry optimisation of the spiral pulley is used to achieve the cancellation. By adopting the negative stiffness mechanism, it is expected that the energy requirement will be balanced, which can significantly reduce the input of external energy and therefore the weight and cost of the actuation system.

In the current study, the spiral pulley negative stiffness mechanism is integrated into a morphing wing employing the Fish Bone Active Camber (FishBAC) morphing concept. The FishBAC wing is actuated by a torque to enable its elastic shape change. The torque requirement to deform the FishBAC wing is measured to identify the positive stiffness. The corresponding negative stiffness is then realised by the optimisation of the geometry configurations of the spiral pulleys, which shows the potential of saving energy of the actuation mechanism.

1 INTRODUCTION

Morphing aircraft have been an important research subject for the last few years. The overall performance of the aircraft can be enhanced by changing the aerodynamic shape actively according to the flight conditions [1-3] .

The idea of changing the aerodynamic shape is not new, indeed it can be traced back to the early period of the aviation age. For example, the wing-warping design was adopted by the Wright brothers' Flyer I for the lateral control [4]. The shape-changing can be achieved through the elastic deformation of the aircraft structure or making use of the novel properties of the smart materials [5, 6], such as the shape memory alloys [7-9] or the piezoelectric materials [10-12] . The wing-warping design is a typical instance of the elastic shape-changing, although it was replaced by the aileron due to the increased flight speeds and the requirement for stiffer structures to avoid aeroelastic failures. The requirement to keep the balance between the flexibility to change shape and the stiffness to carry loads is one of the key factors of a promising morphing aircraft, especially when the weight of the aircraft is also taken in account [13]. A promising morphing aircraft should be capable of changing shape when the aircraft is subject to the corresponding aerodynamic loads, and the morphing structure is usually designed to tailor its stiffness for this purpose.

The actuation system must provide high output force/torque for the minimal system weight, and a high energy efficiency, especially when the shape-changing is achieved by the elastic deformation of the morphing structure. A reduction in actuator mass can potentially be achieved by integrating a negative stiffness mechanism into the structure [14-17]. The negative stiffness mechanism can release the energy stored in a pre-stretched spring and drive the rotation of the spiral pulley, which will provide a negative torque of increasing magnitude against the rotation. The structural stiffness can be balanced by the negative stiffness of the spiral pulley mechanism, which will lead to the zero-stiffness mechanism of the overall system. Since the entire system is balanced and energy is stored in the pre-stretched spring, the energy consumption from external resources can be reduced significantly, which has the potential to reduce the weight of the actuation system and its associated power supply system.

While previous studies have demonstrated this principle in desktop demonstrators [16-18], it has not previously been demonstrated this principle in a true aerodynamic structure. In the current study, the negative stiffness mechanism is integrated into the Fish Bone Active Camber (FishBAC) morphing wing [19-21]. The FishBAC morphing wing is a camber morphing design, which can provide a smooth surface change, and has the potential to increase the lift-to-drag ratio [22, 23]. The shape-changing of FishBAC is generated through the elastic deformation of the bending spine, and servo motors have been adopted to drive the structure. Integration of the negative stiffness mechanism has the potential to improve the performance of the actuation system.

The integration is undertaken in the following steps:

- 1) Initial wing design: considering the installation of the spiral pulley mechanism;
- 2) Measurement of the FishBAC structure stiffness;
- 3) Optimisation of the spiral pulley geometry;
- 4) Static and wind tunnel test.

In this paper, Section 2 gives a brief discussion of the FishBAC design and the spiral pulley based negative stiffness mechanism. Section 3 discusses the experimental setup to measure the

structural stiffness of FishBAC wing, which is used in Section 4 to optimise the geometry of the spiral pulleys, and lays the foundation of the development of a demonstration model.

2 MODEL DEFINITION

Figure 1 shows the schematic of the FishBAC design, which was driven by servo motors [19, 24]. Two tendons are attached to the solid trailing edge section, and the torque generated by the servo motors is transferred onto the spine, which will cause the deformation of the spine. The design, analysis and manufacturing methods have been developed as introduced in the literature and the current study is focused on the integration of the negative stiffness mechanism rather than the FishBAC itself.

Figure 1: Schematic of FishBAC wing actuated by servo motors [21]

A NACA23012 aerofoil section is selected for the integration, and the chord and span are 270mm and 250mm respectively. One of the difficulties of the integration is the space available in the wing, which is very limited due to the low thickness of the aerofoil. The current approach uses the cable from the load pulley to drive the tendons on the FishBAC directly as shown in Figure 2, which simplifies the mechanism but can still demonstrate the potential of the spiral pulley.

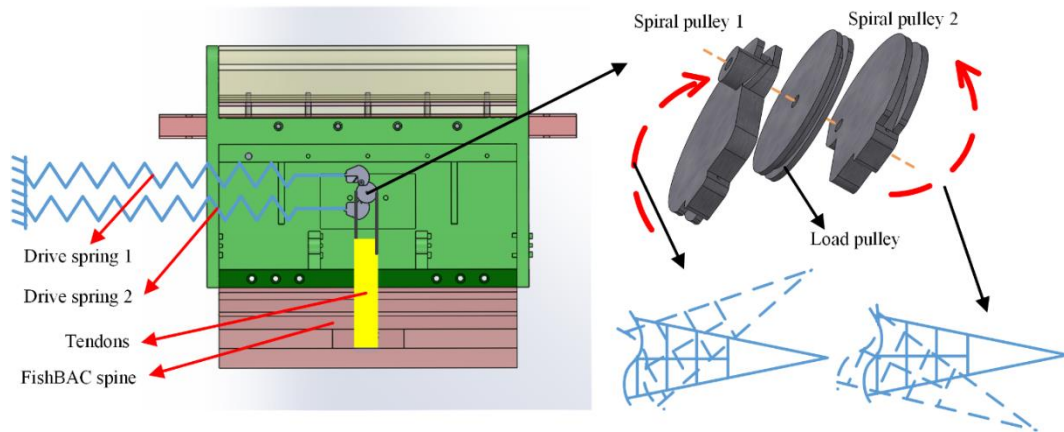

Figure 2: Concept of the integration

The negative stiffness concept used is the bidirectional concept described by Zhang et al. in [17, 18], to assist both positive and negative flap deflections. The drive spring connected to the spiral pulley is pre-stretched with the extension L_0 to store the energy before it is integrated into

the wing. If the stiffness rate of the drive spring is denoted as K , the entire energy stored in the drive spring is then $0.5KL_0^2$; this quantifies the maximum amount of available work that can be provided by the mechanism to assist actuation. Two spiral pulleys are mounted onto one centre shaft, and the bidirectional motion can be achieved through the rotation of the pulleys in the opposite directions.

The planar geometry of the spiral pulley is shown in Figure 3.

Figure 3: Geometry of the spiral pulley

The radius, r , about point O , which is the centre of the rotation shaft can be defined as an exponential function

$$r = r_0 + k_1 e^{k_2(\theta + \delta + \delta_0)} \quad (1)$$

where δ is the rotation angle of the spiral pulley and θ is an associated angle. The parameters k_1 , k_2 are the pre-exponent and exponent terms of the spiral pulley. And the coordinate components of point A , x_{off} , y_{off} , are also needed to fully define the pulley geometry, together with the initial pulley radius r_0 and the initial rotation angle δ_0 .

The drive torque output by the spiral pulley is given by

$$\begin{aligned} T_d &= F_d l_m \\ F_d &= f(\delta, K, L_0, r_0, \delta_0, k_1, k_2, x_{off}, y_{off}) \\ l_m &= g(\delta, r_0, \delta_0, k_1, k_2, x_{off}, y_{off}) \end{aligned} \quad (2)$$

The expression of the drive torque has been derived in [15, 17]. The force caused by the drive spring, F_d , is determined by the rotation angle, the parameters of the spiral pulley geometry and the drive spring. The moment arm, l_m , also varies with the rotation of the spiral pulley. It can be seen that the drive torque is influenced by the geometry parameters of the spiral pulley and the drive spring stiffness and the initial extension. A decreasing torque can be provided against the rotation of the pulley, which leads to the so-called negative stiffness. In the meantime, the load torque, T_l , is required to deform the structure. If the stiffness of the structure can be balanced by the negative stiffness of the spiral pulley mechanism, a zero-

stiffness system can be designed, which means the energy required to deform the structure is provided by the energy stored in the pre-stretched drive springs, and no external energy is needed to deform the structure.

3 STRUCTURE STIFFNESS MEASUREMENT

To design a zero-stiffness mechanism, the relationship between the load torque and the corresponding rotation angle needs to be obtained. The experimental setup is shown in Figure 4. As the focus is the integration of the negative stiffness mechanism, the structure components, including the FishBAC spine, are 3D printed. A baseline load pulley is installed, and the cables from the load pulley are bonded to the tendons of the FishBAC. The baseline load pulley is used to transfer the load torque onto the FishBAC structure in the measurement, and is installed at the same location of the spiral pulley to ensure the integration can be realised. By applying the torque directly onto the load pulley with a torque wrench, the FishBAC spine will be deformed under the specific torque, and the rotation angle is recorded using a protractor.

Figure 4: Schematic of the wing platform for the measurement of the FishBAC structure stiffness

As shown in Figure 5(a), both the upward and downward deflections of the FishBAC are achieved. An external load, which is in the opposite direction of the deflection, is applied to on the structure. The relationship between the measured load torque and the rotation angle is shown in Figure 5(b).

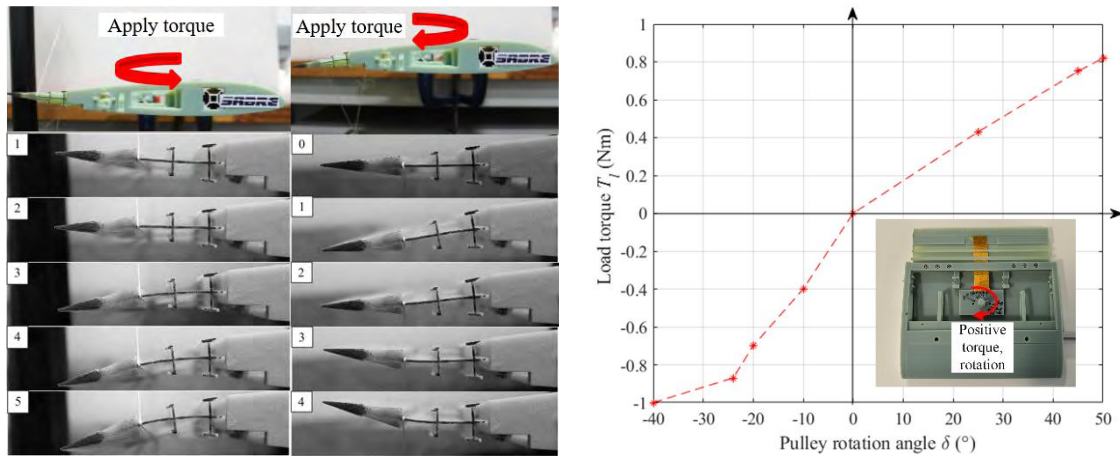

Figure 5: (a) Downward and upward deflection of the FishBAC subject to the load torque, (b) Measured load torque vs the rotation angle of the baseline pulley

The positive torque and rotation angle are defined when they correspond to the upward deflection of the FishBAC tip. It can be seen that the upward and downward deflection of the FishBAC have different stiffnesses, which could be caused by the direction the tendon is aligned, the offset due to the bonding of the tendon, etc. The measurement indicates an approximately linear relationship between the load torque and the rotation angle, although the first data point with the minimum rotation angle is neglected due to measurement errors.

4 OPTIMISATION OF THE SPIRAL PULLEY

To provide a zero-stiffness system, the geometry of the spiral pulley needs to provide the drive torque that can balance the load torque. The geometry parameters are optimised to find the maximum objective defined as

$$\max \eta_e = \frac{E_o}{E_r} \quad (3)$$

where the energy output by the spiral pulley system, E_o , and the energy required by the FishBAC structure, E_r , can be obtained as

$$\begin{aligned} E_o &= \int_0^{\delta} |T_d| d\delta \\ E_r &= \int_0^{\delta} |T_l| d\delta \end{aligned} \quad (4)$$

The ranges of the variables are given by

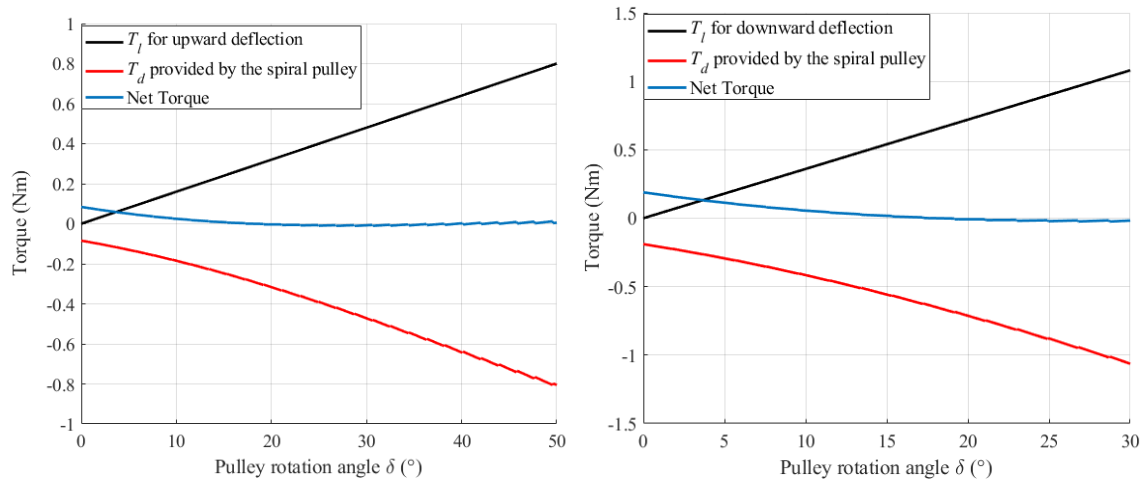

$$\left\{ \begin{array}{l} -30/1000 \leq r_0 \leq 10/1000 \text{ (m)} \\ -0.001 \leq k_1 \leq 0.02 \\ 0 \leq k_2 \leq 1 \\ -50\pi/180 \leq \delta_0 \leq 50\pi/180 \\ -0.05 \leq L_0 \leq 0.4 \text{ (m)} \\ 100 \leq K \leq 1400 \text{ (N/m)} \\ -0.1 \leq x_{off} \leq 0.1 \text{ (m)} \\ -0.05 \leq y_{off} \leq 0.1 \text{ (m)} \end{array} \right. \quad (5)$$

The Matlab nonlinear programming solver, '*fmincon*', is used to perform the optimisation [25]. Two optimisation cases are performed to find the optimal geometry of the two spiral pulleys for the upward and downward deflections separately, and the optimisation results are summarised in Table 1.

The influence of the spiral pulley on the stiffness is shown in Figure 6. It is found that in both spiral pulleys, the drive torque T_d , can balance the load torque T_l , and the net torque is close to zero, which indicates the zero-stiffness of the mechanism.

Table 1. Optimised parameters of the spiral pulley negative stiffness mechanism

Name of the variable	For the upward deflection	For the downward deflection	Unit
Initial pulley radius r_0	-0.029	-0.030	m
Pre-exponent term k_1	0.005	0.016	
Exponent term k_2	0.991	1.000	
Drive spring extension L_0	0.170	0.218	m
Drive spring rate K	567.153	910.891	N/m
Initial rotation angle of the spiral pulley δ_0	-0.814	-0.758	rad
x coordinate to define point A x_{off}	-0.019	-0.064	m
y coordinate to define point A y_{off}	0.069	0.012	m

**Figure 6:** Effect of the optimised spiral pulley on the torque (a) For the upward deflection, (b) For the downward deflection

The influence on the required energy is shown in Figure 7. Obviously, with the spiral pulley mechanism, the external energy, which is required to deform the structure, is reduced significantly, as the energy stored in the pre-stretched spring can drive the mechanism.

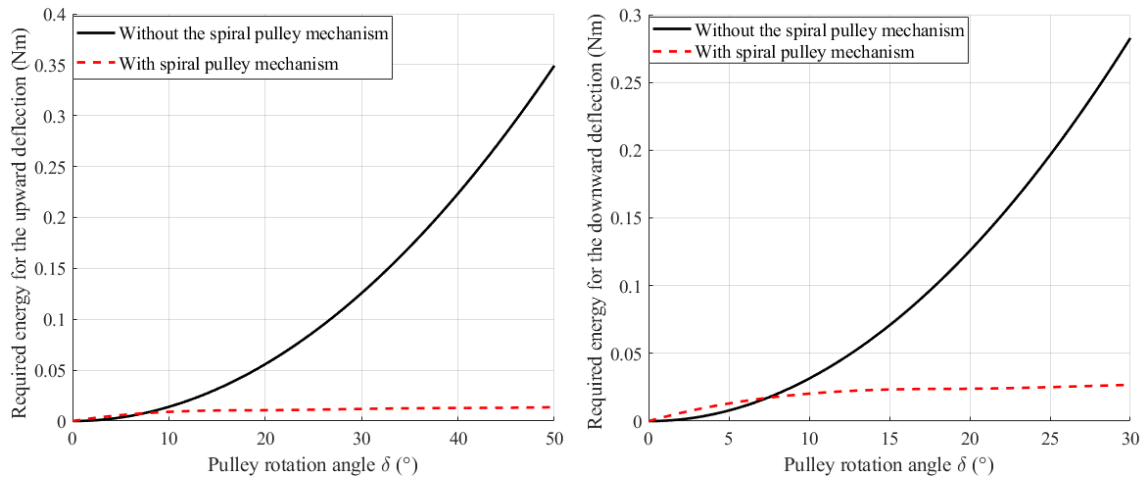

Figure 7: Effect of the optimised spiral pulley on the required energy (a) For the upward deflection, (b) For the downward deflection

5. CONCLUSION

In this paper, the negative stiffness mechanism based on the spiral pulley is integrated into the FishBAC morphing wing.

The load torque, which is required to deform the FishBAC morphing structure, is measured first to obtain the structure stiffness. The geometry parameters of the spiral pulley are then optimised to provide an energy balancing system. The optimisation results indicate that the spiral pulley mechanism is able to provide a negative stiffness against the structure stiffness, which induces a net zero-stiffness of the entire system.

Optimisation work has shown that the spiral pulley is able to provide a high energy efficiency for the morphing structure, and future work will demonstrate a functional model for the static and wind tunnel test.

Abstract. To enable the return to flight of civil supersonic transport (SST) aircraft, configurations must be developed that meet noise and efficiency requirements across a range of operating conditions. A team of researchers, led by Texas A&M University, is investigating real-time geometry changes, driven by compact and lightweight Shape Memory Alloy (SMA) actuators, to minimize boom signatures across all flight phases in response to changing aircraft configurations and environmental conditions. Since 2005 Boeing and Texas A&M, along with numerous industry, academic, and government partners have made significant advances in the area of SMA technology, including improved materials, design and modeling tools, and approved test methods. Many of these advances in SMA technology and tools are now being applied to the development of adaptive aircraft structures as part of NASA's University Leadership Initiative (ULI) led by Texas A&M University titled *Adaptive Aerostructures for Revolutionary Civil Supersonic Transportation*. In this paper the ULI program is described, including its goals and objectives. Strategies for integrated SMA design and design optimization are discussed. Examples of hardware demonstrations of morphing structures for shock wave control in supersonic wind tunnel tests and structural shape control are shown.

1. INTRODUCTION

For years the promise of Shape Memory Alloy (SMA) actuators as an enabling technology has seemed poised to revolutionize the design of adaptive structures and smart systems for aircraft. As far back as 2005 Boeing successfully integrated SMA actuators into the fan nozzle of a 777-300ER GE-115B engine to modify nozzle geometry in flight for community and cruise noise reduction [1-2]. Shape Memory Alloys were an ideal choice for the actuation mechanism for the Variable Geometry Chevron (VGC) flight test. Shape Memory Alloys are active materials that convert thermal energy into mechanical energy. Heating the material above its Austenitic transition temperature activates a crystalline structural phase change causing the material to revert to a previously "remembered" shape. When cooled below the transition temperature the SMA transforms into its more compliant (lower modulus) Martensitic form. It can be easily deformed when a load is applied during transition from Austenite to Martensite

or when in the final Martensite state. The concept for using an SMA to morph the shape of the VGC is shown in **Fig. 1**. The VGC was designed for two modes of operation. Autonomous operation utilizes changes in the ambient temperature from take-off to cruise to activate the chevron shape change. In powered mode internal heaters are used to individually control the VGC temperatures enabling variable immersions and the ability to test a variety of chevron configurations.

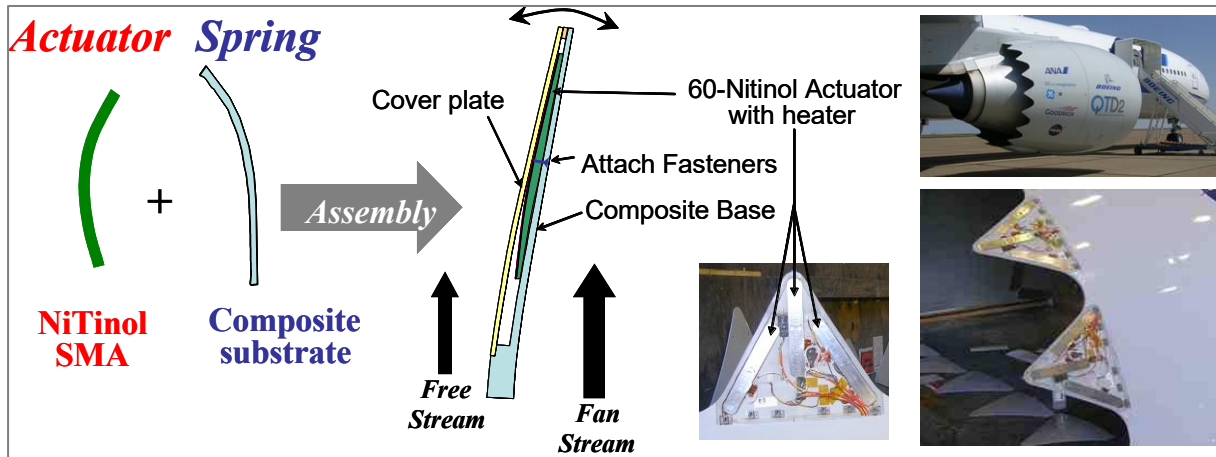

Figure 1: Variable Geometry Chevron Design Concept

2. TECHNOLOGY GAPS, DEVELOPMENT, AND DEMONSTRATIONS

While the Variable Geometry Chevron (VGC) flight tests clearly demonstrated that SMA technology can enable solutions for challenging aerospace applications, it also exposed critical technology gaps and needs that would be essential to advancing SMA technology. Identified needs included:

- Improved tools for modelling, simulation, and design optimization.
- Alloy compositions, processing, and fabrication to increase stability, fatigue, and work output.
- High temperature alloys for stable operation in worldwide thermal environments.
- Improved controller for precise and repeatable load displacement control.

A critical part of the technology development since the VGC program has been regular laboratory and flight demonstrations showing a high technology readiness level (TRL). Key applications and demonstrations are shown in **Fig. 2**.

2.1. The Adaptive Trailing Edge (ATE)

The ATE program was part of a Boeing and Federal Aviation Administration (FAA) collaboration [3]. The ATE program combined advances in SMA actuation and control with the aerodynamic understanding of transport aircraft wing design to demonstrate deployable and controllable trailing-edge elements that improve aircraft performance at all flight conditions. Small SMA actuated control surfaces (miniature flaps) were placed along the wing trailing edge of a 737-700 aircraft demonstrating a simple and effective way to improve aerodynamic performance at multiple configurations that vary with flight segments. Flaps could then be deployed for enhanced takeoff, cruise, or approach performance, and retracted when not needed. Closed loop control of the flap's position, using the SMA actuators, was demonstrated at multiple flight conditions during flight tests.

Figure 2: SMA Applications and Tests Demonstrating Boeing Tools for Design, Simulation, and Control. (a) Actuated Wind Tunnel Models (b) Spanwise Adaptive Wing UAV (c) FAA Adaptive Trailing Edge and (d) F-18 Wing Ground Fold.

2.2. The Spanwise Adaptive Wing (SAW) Flight Test

The SAW project included the development, integration, and test of a compact integrated SMA actuator system to fold the outboard wing sections of the PTERA UAV during flight. High temperature NiTi-20Hf SMA torsional components were processed by Boeing to produce stable actuation at loads up to 45 N*m (400 in-lbs) and 88° of angular range. The SMA components were incorporated into a hinge assembly that mechanically coupled the inboard wing and the outboard folding winglet. Instrumentation was installed to provide position, load, and temperature feedback. A compact on-board control system used angle, torque, and temperature readings to maintain a range of commanded wingtip angles over a wide range of flight and test conditions. An integrated simulation of the SMA actuators was developed to aid in the design of the actuator control system and for preflight performance predictions. The simulation was deployed using compact electronics and integrated into NASA's PTERA flight simulator. This complete actuator system was tested using a combination of bench and wind tunnel testing prior to integration into the PTERA vehicle and flight tests. The performance of the actuator control system, the SMA actuation, and the actuator simulation model were validated during flight tests. Preflight Simulations compared to flight data are shown in **Fig 3**.

2.3. The Spanwise Adaptive Wing (SAW) Ground Test

The SAW ground test demonstrated scale-up of SMA actuators to 2260 N*m (20,000 in*lbs). High temperature NiTi-20Hf SMAs, developed at NASA Glenn, was used for these actuators due to their high strength and high transition temperatures suitable for wing applications. Simply increasing the size of the SMA components may not be a viable solution for larger torques. The cost of manufacturing, limited existing design data, and increased heating and cooling rates can make large tubes impractical. Boeing has demonstrated an SMA actuator design that overcomes the limitations of very large SMA tubes by combining multiple smaller tubes into a single assembly. The design is modular and adaptable, trading output forces and displacements through a simple gearing mechanism. For the large multi-tube actuators material was produced in large scale (>120 lbs batches) and processed into rods from which torque tubes with outer diameters ranging from 0.75 to 1.5 inches were produced. These tubes were used to design and build integrated large scale actuation mechanisms for folding the outer wing section of an F/A-18 wing. The mechanism was tested on a F/A-18 surplus outer wing and was shown to operate at loads up to 2260 N*m (20,000 in*lbs) and angular displacements of up to 90 degrees.

Figure 3: Spanwise Adaptive Wing Model and Flight Test Data Comparison.

2.4. SMA Actuated Wind Tunnel Models

SMA actuated wind tunnel models enable efficient test methods and improved data. Compact and precisely controller SMA actuators have been integrated into models used in high pressure cryogenic wind tunnels. Using traditional fixed parts is expensive due the high cost of tunnel shut down, parts swap, and tunnel restart. Remote actuation can greatly increase productivity and data quality while reducing cost. Shape Memory Alloy technology has been demonstrated as a simple actuator that enables efficient remote actuation of cryogenic wind tunnel models. Previous testing at the European Transonic Wind Tunnel and NASA transonic Cryogenic Tunnel demonstrated actuation under representative loads, precise control and repeatable control as shown in **Fig 4**. Collaboration with leading High Speed wind tunnels has been key to validating the technology and developing new operational methods that will greatly improve testing productivity.

3. University Leadership Initiative (ULI)

Renewed interest in sonic boom noise mitigation in recent years has brought attention to technology development for quiet supersonic aircraft. A multidisciplinary team headed by the Department of Aerospace Engineering at Texas A&M University and Boeing Research & Technology (BR&T) in St. Louis, Missouri, is investigating commercially viable civil supersonic transport aircraft that can modify their shape during flight under a range of conditions to meet noise and efficiency requirements for overland flight. This project is sponsored under NASA's University Leadership Initiative (ULI) program. [4]

Overland flight of supersonic aircraft is limited by the over-pressure on the ground caused by the propagation and coalescence of shock waves generated by the aircraft. The perceived loudness of the resultant sonic boom, depends on many factors including the shape of the aircraft, the aircraft's flight conditions such MACH, angle of attack, and altitude, and atmospheric conditions such as humidity.

The calculation of the sonic boom's perceived loudness (PLdB) is completed in a multi-step process. The various stages of sonic boom loudness calculation are shown in **Fig. 5**. First the pressure signature at a certain distance from the body of the aircraft in what is termed the near-field region is determined. The near-field pressure signature is determined by using a computational fluid dynamics (CFD) solver. The near-field pressure is then propagated through the atmosphere, accounting for relevant atmosphere conditions, to the ground. The ground pressure signature is further analyzed to determine the perceived loudness that results from the over-pressure.

Figure 5: Strategy for Perceived Noise Calculation Based on Aircraft Geometry

Previous studies have shown that small changes in flight conditions, such as Mach or angle of attack, can have an adverse effect on the boom signature [5]. However, to be commercially viable, a supersonic transport must be able to meet low boom noise limits for

all flight conditions. This will require the ability for aircraft to adapt and reconfigure to changing flight conditions to maintain a low boom signature.

As an example, the same near-field pressure was propagated to the ground through two measured atmospheric conditions, one in a humid location, Jacksonville Florida, and one in a dry location, Las Vegas Nevada. The ground pressure signature and the resultant perceived noise is shown in **Fig 6**. A 6 PLdB difference is calculated for the identical aircraft configuration.

Embedded shape memory alloy (SMA) actuators can provide small real-time geometric reconfigurations to the outer mold line (OML) of the aircraft to impact the boom signatures and enable optimal low-boom and low-drag configurations across all environments and flight conditions. The Texas A&M ULI team is combining improved supersonic computational fluid dynamic (CFD) methods, SMA actuator design and optimization tools, and boom propagation models into a multidisciplinary design framework. Modeling and designs are initially being validated in small scale supersonic wind tunnel tests.

Figure 6: Perceived Noise increase due to propagation through high humidity

3.1. Low Boom Predictions and Off Design Flight Conditions.

Initial ULI studies of the off-design low-boom performance have focused on the NASA 25D configuration. A methodology for identifying potential surface morphing locations where SMA solutions can likely improve boom signature under adverse conditions is being developed. CFD studies have shown that Mach number and angle-of-attack can adversely impact perceived boom noise. Additionally atmospheric conditions, particularly humidity, can also adversely impact perceived sonic boom noise on the ground.

The resulting change in ground signature loudness for an initial set of Mach and angle of attack perturbations is shown in **Fig. 7**. It is evident that small perturbations in Mach and angle of attack degrade the designed boom loudness for the NASA 25D model. This implies that appropriate vehicle modifications should be studied to enable greater boom robustness when encountering off-design flight conditions. In this initial analysis the loudness sensitivity to ΔM is more severe than its sensitivity to $\Delta \alpha$. Mach number variations due to temperature gradients and angle of attack variations due to gusts at the design altitude were estimated to within the bounds of Fig. 7 perturbations [6].

Figure 7: Perceived Noise Increase due to Mach and Angle of Attack Changes.

A full simulation including near-field CFD with Cart3D, followed by atmospheric wave propagation with sBOOM and noise assessment with LCASB, was utilized to create a model for PLdB off-design conditions including varying Mach and angle of attack. A surrogate was also created to model the location of maximum ground-signature sensitivity to near-field perturbations. Target regions and areas where surface morphing could improve boom signature in adverse conditions were identified. In particular, a region of the vehicle nose was found to be sensitive to Mach perturbations and an aft region was sensitive to angle of attack perturbations as shown in **Fig. 8**. These results provide insight into the appropriate allocation of SMA actuators for the NASA 25D model.

Both of these regions on the model are therefore candidate locations for SMA actuators to have the most impact on off-design signatures. Future work will explore what type of SMA deformation is best suited for these regions to accomplish robust boom performance.

3.2. Actuated Supersonic Wind Tunnel Model

To explore the feasibility of using SMA actuation to control shock wave characteristics in supersonic flow a SMA-actuated wind tunnel model was designed, built, and tested. The wind tunnel model hardware consists of two coupled panels mounted in the floor of a Mach 2.2 wind tunnel at Texas A&M's National Aerothermochemistry and Hypersonics Laboratory (NAL). SMA torque tubes were integrated into the hinge assemblies and were used to articulate each panel up into the flow. Shock wave formation, location, and characteristics were measured using a Schlieren image system [7].

Figure 9: SMA-actuated wind tunnel model. Torsional actuators are integrated into the hinge between the forward model support and the forward panel and into the hinge between the forward panel and the aft panel.

The wind tunnel model was designed by a Texas A&M undergraduate team. A drawing of the model is shown in **Fig. 9**. The two actuated panels use SMA torsional tube actuators, each independently controlled. Cartridge heaters are used to heat the SMA, varying the actuator's temperature, tube twist, and the panel's angle. The SMA actuators act as hinge pins connecting the forward panel to the forward model support and the aft panel to the

forward panel. One end of each tube is attached to the element upstream of the tube, and the other is attached to the part downstream of the tube as shown in **Fig 10**. The forward panel's angle is directly correlated to the rotation of the forward SMA actuator. The aft panel is mechanically coupled to the forward panel and its angle is the sum of the forward panel angle and the aft SMA actuator's rotation.

The SMA torsional actuators are made from equi-atomic NiTi trained and stabilized to have approximately 5% two-way shear strain shape memory effect (SME). There are no restoring springs or other forces in this actuation design, relying on the two-way SME on cooling to reduce the panel angle.

Figure 10: SMA torsional actuator and cartridge heater left. SMA tubes integrated into wind tunnel model

The model was mounted in the floor of the tunnel as shown in **Fig 11**. Closed loop control of angle was demonstrated on the bench, **Fig 12**, however angle sensor issues limited closed loop control under high Mach conditions, so open loop heating of the SMA was used to control the angle of each ramp. Schlieren images of the shock characteristic for a range of ramp angles is shown in **Fig 13**. Shocks are easily seen originating at the leading edge of each panel. The shock angles vary with ramp angles and the feasibility of controlled the shock waves was demonstrated.

Figure 11: Dual Ramp SMA Actuated Wind Tunnel Model, flow is right to left.

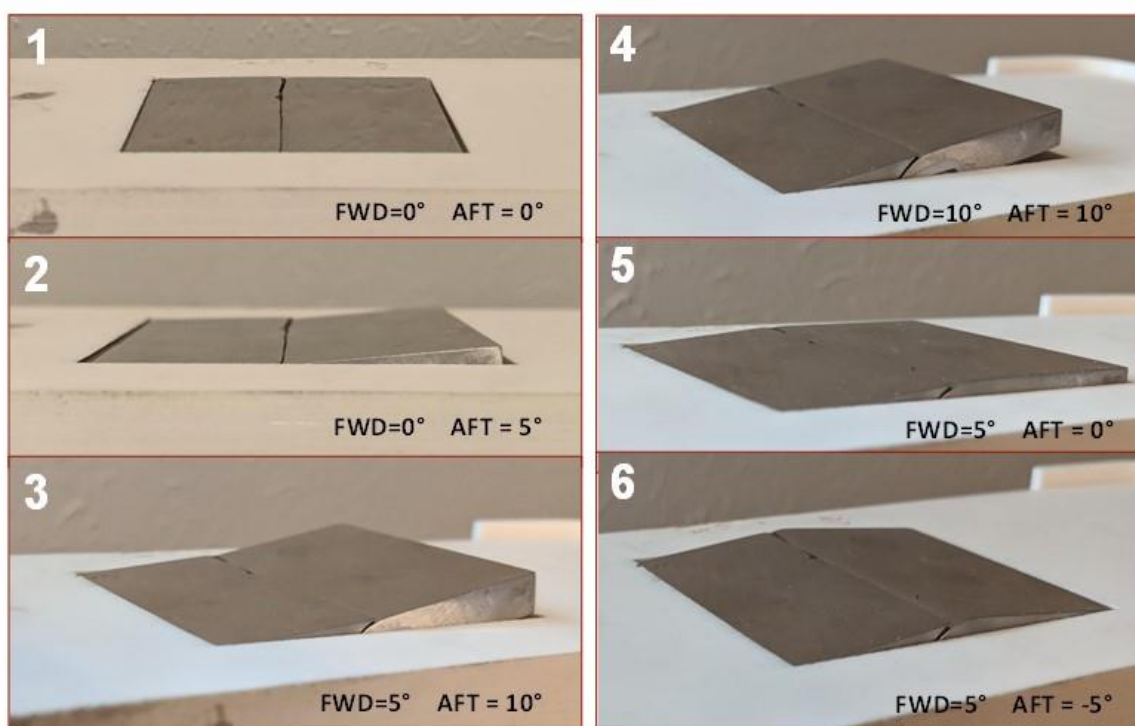

Figure 12: Closed loop angle control of the forward and aft panel during bench-top testing.

Figure 13: Schlieren images of the shock characteristic for a range of ramp angles

An improved wind tunnel model design is currently being fabricated and will be tested summer of 2019. Improvements include accurate angle sensing for closed loop control, measurement of SMA hinge loads, and pressure taps for validation of CFD models.

4. CONCLUSIONS

- Demonstrations of SMA actuator design tools, advanced materials, precise control methods, and aircraft integration have verified the high TRL of SMA actuation.
- The return of commercial supersonic overland flight can be enabled by lightweight SMA actuation to modify aircraft geometry in flight and minimize sonic boom noise in adverse conditions.
- SMA actuated surfaces have been tested in MACH 2.2 flow and the feasibility of controlling shock characteristics has been demonstrated.

Key words: Negative stiffness mechanism; Linear motion; Kinematics tailoring; Energy balancing; Actuator efficiency.

Abstract. Traditional ways to achieve the desired motion of mechanisms or deformation of morphing structures require external energy for actuation. Frequently the use of these actuators to drive the system can cost noteworthy energy for each cycle of operation and the spent energy cannot be recovered. This work investigates a passive energy balancing concept for linear motion systems by strategically using a negative stiffness mechanism. The energy balance concept is achieved by employing a negative stiffness system to couple with the positive stiffness mechanical system to create zero stiffness which can be driven with smaller actuators. The negative stiffness mechanism proposed here uses a pre-tensioned spring to produce a passive torque and therefore to transfer the passive torque through a crankshaft for linear motion. The kinematics of the negative stiffness mechanism is first developed to satisfy the required linear motion and its geometry is then optimised to achieve minimal energy requirements. The performance of the optimised negative stiffness mechanism is evaluated through the net force and the total required energy. Exploiting the negative stiffness mechanism has a significant benefit in the field of energy sensitive applications.

1 INTRODUCTION

Traditional mechanisms and smart structures are designed by using actuators or smart materials to overcome the internal (e.g. structure deformation) resistance and external (e.g. aerodynamic) loads to generate motion of the system. These integrated systems allow shape changes of the structure, and thus control its motion with acceptable precision. In particular, morphing requires deformation against the internal loads, and the frequent use the actuators to drive the system can cost noteworthy energy for each cycle of operation and the spent energy cannot be recovered. In other words, the work done to reach the target state requires the input of energy, while the subsequent dissipation of that energy to recover the initial state generates waste heat. Traditional actuators, such as electromechanical actuation, can be used as linear and rotary actuators, combined with mechanisms to provide a powerful tool for morphing [1]. Moreover, with the development of smart materials, many traditional actuation systems based

on electric motors, hydraulics, or pneumatics may be replaced by smart material systems. For example, piezoelectric materials have been used as actuators to control wing panels [2,3], spanwise deflection [4] and trailing-edge flaps [5,6]. Concepts have been proposed to reduce the required force or torque and therefore to allow smaller and lighter actuators, or even no actuator, to be employed to drive the system. For some typical cases, such as gravity equilibrators, a weight can be carried throughout its range of motion without any external energy by using spring mechanisms or counterweights [7–9]. Such static balancing is described as “zero stiffness” or “neutral stability”, as the system can be moved without operating energy. In general, many systems have force that is purely a function of displacement, as shown in Fig. 1(a), known as an elastic force response. In order to produce a static balancing for such systems with a zero stiffness property, negative stiffness is required to assist the imposed deformation. Figure 1(b) shows a representative nonlinear stiffness property, which has a completely nonlinear behaviour compared to the positive stiffness system and helps to construct an energy balancing system in a certain working range shown in Fig. 1(c). As the actuation is returned to zero, the elastic energy stored in the driven structure will force the negative stiffness system back to its original state, again at zero net actuation force. Therefore, Figure 1 shows that for a system assumed to be perfectly elastic, the negative stiffness can drive required actuation force to zero. Of course, many real systems include significant inelastic forces, which can be rate or history dependent, or due to external disturbances, and these cases represent a more complex problem that will be the subject of future work. In what follows, it is assumed that the driven structure has a purely elastic force displacement response.

Figure 1. Schematic of the energy balancing system force curve. k_p is the stiffness of the load system and k_n is the negative stiffness system. (a) Increasing force system. (b) Nonlinear stiffness system. (c) Energy balancing system in a certain working range.

The negative stiffness mechanism can be coupled to the target positive stiffness system to produce an energy balancing system and the energy required to actuate the existing system can be balanced by the stored energy in the negative stiffness system. Figure 2 shows that a net zero stiffness device may be achieved by adding the negative stiffness system to a positive stiffness system, and the coupled system can therefore be considered as an energy balancing system. Figure 2(a) shows that a traditional way to actuate a system with internal stiffness k_p and the external load L , which requires a high power actuator. However, by coupling the negative stiffness mechanism, the total stiffness of the whole system becomes $k_p + k_n$ and a key benefit is that a small actuator can be used to determine the same output with regards to the same external load L , as shown in Fig. 2(b).

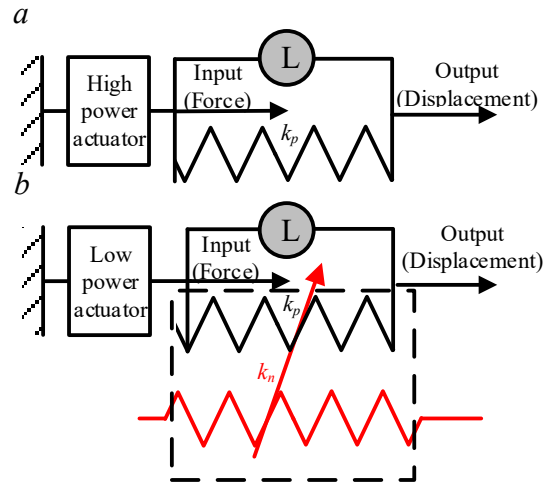

Figure 2. Minimalistic model of a negative stiffness mechanism for energy balancing. L denotes the external load, k_p is the internal stiffness of the load system and k_n is the negative stiffness system. (a) Traditional actuated system. (b) Energy balancing system by adding the negative stiffness mechanism.

It can be assumed that if the required input, such as force or torque, can be completely eliminated by the negative stiffness, then in principle no energy is required to move the system, other than to overcome dissipation. Therefore, the use of negative stiffness systems is likely to benefit energy constrained systems, such as those present in the aerospace and automotive industries.

Many applications have been proposed that use a negative stiffness for passive energy balancing. Clingman and Ruggeri [10] described a negative stiffness nonlinear over-centre linkage used on a tilt-rotor blade for active twist. This negative stiffness linkage mechanism uses the stored energy of a compressed spring to rotate the output shaft, resulting in an effectively softened blade that requires 70% reduction in torque for morphing. In addition, a pulley based balancer has been proposed with a varying radius pulley to preserve moment equilibrium between a constant load and a varying spring length [11,12]. By using such a spiral pulley negative stiffness mechanism, the required torque for the morphing actuation can be satisfactorily matched to create a nearly zero stiffness which requires minimal energy. A bidirectional torsional negative stiffness mechanism by using a series of pre-compressed springs has investigated for energy balancing systems [13]. This integrated BTNS mechanism was then verified to tailor the kinematics of the required torque driving the active camber and the results showed a similar torque-rotation profile can be generated. The proposed device provides actuation to change the state of the system, such as deforming a structure or lifting a mass; hence the energy provided by the actuator transforms into an increased potential energy in the system. Once the system returns to its original state, all of the energy provided by the actuator will be recovered, if the system is conservative. In other words, the work done to reach the target state require the input of energy, while the subsequent dissipation of that energy to recover the initial state generates waste heat.

In a previous work [14], an energy efficient concept for bidirectional morphing aircraft actuation was investigated by using a negative stiffness mechanism. The torsional negative

stiffness with an off centre spring (TNSOCS) mechanism was proposed that uses a pre-tensioned spring to convert the decreasing spring force available in the spring into an increasing output balanced torque. A significant contribution can be provided by the negative stiffness mechanism to balance the positive stiffness rotation motion system. This work extends [14] by applying the torsional negative stiffness mechanism to a linear motion actuation. This paper proceeds as follows. Firstly, a prototype of this energy balancing device is proposed and the kinematics of the bidirectional torque shaft, the linear motion mechanism and rotation angle are investigated. Then, the characteristics of the negative stiffness mechanism is proposed and a linear spring is chosen as the positive stiffness load system for investigation. Finally, the design parameters are optimised to exactly match the requirements of the linear motion requirement.

2 KINEMATIC ANALYSIS

The prototype of this energy balancing device is shown in Fig. 3 with the detailed geometry definition of two mechanisms. The torsional negative stiffness with an off centre spring (TNSOCS) mechanism [14] is developed to produce the actuating force and the slider-crank mechanism is designed to transfer the torque to linear motion actuation. The shaft is centred at O and θ is the shaft rotation angle. A pre-stretched spring is fixed on the shaft and point B is the off centre point for the spring. Then, the slider-crank mechanism is connected to the torsional negative stiffness mechanism and point E is the joint. Therefore, when the pulley rotates, the slider can move in the horizontal direction as denoted by q_m .

Figure 3. Schematic representation of a variable stiffness cam mechanism. In this mechanism k denotes the stiffness of the linear spring, q is the extra output position, θ is the input angle, while q_m denotes the motion of the slider.

In order to investigate the tailored nonlinear negative stiffness mechanism for linear motion, the kinematics of the system should be derived. Two springs are shown here, one is designed as an energy storage device for the negative stiffness system and the other represents the load system. Therefore, the potential energy function of this mechanism is given by:

$$V(\theta, q) = \frac{1}{2}k_1(l - l_0)^2 + \frac{1}{2}k_2(q_m - q)^2 \quad (1)$$

where l_0 is the initial length of the spring and l is the length of the spring at its current position. k_2 is the stiffness of the output system and can be considered as a linear system when k_2 is constant. Then, the additional required moment imposed by the negative stiffness modulating mechanism is

$$M_{in}(\theta, q) = \frac{\partial V}{\partial \theta} = k_1(l - l_0) \frac{\partial l}{\partial \theta} + k_2(q_m - q) \frac{\partial q_m}{\partial \theta} \quad (2)$$

Figure 4. The slider-crank mechanism: displacement q_m of the slider for different λ and θ .

Moreover, the displacement q_m of the slider can be determined as

$$q_m = L \left(\left(\sqrt{1 - \lambda^2 \sin^2 \theta} - 1 \right) + \lambda(1 - \cos \theta) \right) \quad (3)$$

where $\lambda = R/L$ denotes the ratio of the radius of the crank shaft and the length of the connecting rod. Figure 5 shows the displacement of the slider for different λ when the crank shaft rotates. It can be seen that the larger the value of λ , the higher the displacement that can be achieved.

Figure 5. Displacement q_m for different λ and θ .

The kinematics of the torsional negative stiffness shaft is now investigated. Figure 6 shows that the cable is fixed on the shaft and point B is the off centre point for the spring. The Cartesian coordinates can then be defined with the origin at A and the coordinates of any point B' are then defined as

$$x_B = -l_{off} - b \cos \theta \quad (4)$$

$$y_B = b \sin \theta \quad (5)$$

where r is the length of the vector \overline{OB} and l_{off} is the length of the vector \overline{OA} .

Figure 6. Torsional negative stiffness shaft geometry analysis with moment arm details.

Therefore, the length of the vector $\overline{AB'}$ is equal to

$$l = \sqrt{x_B^2 + y_B^2} = \sqrt{(b \sin \theta)^2 + (l_{off} + b \cos \theta)^2} \quad (6)$$

The change of the length l with the shaft rotation angle θ can be calculated as

$$\frac{\partial l}{\partial \theta} = -l_{off} b \sin \theta / \sqrt{(b \sin \theta)^2 + (l_{off} + b \cos \theta)^2} \quad (7)$$

The motion of the slider can also be calculated as

$$\frac{\partial q_m}{\partial \theta} = L \left(\lambda \sin \theta - \lambda^2 \sin \theta \cos \theta / (\sqrt{1 - \lambda^2 \sin^2 \theta}) \right) \quad (8)$$

Therefore, the additional required moment can be obtained by substituting Eqs. (7) and (8) into Eq. (2), to give

$$\begin{aligned} M_{in}(\theta, q) = \frac{\partial V}{\partial \theta} = & k_1 \left(\sqrt{(b \sin \theta)^2 + (l_{off} + b \cos \theta)^2} - l_0 \right) \\ & \times \left(-l_{off} b \sin \theta / \sqrt{(b \sin \theta)^2 + (l_{off} + b \cos \theta)^2} \right) \\ & + k_2 L^2 \left(\left(\sqrt{1 - \lambda^2 \sin^2 \theta} - 1 \right) + \lambda(1 - \cos \theta) - q \right) \\ & \times \left(\lambda \sin \theta - \lambda^2 \sin \theta \cos \theta / \sqrt{1 - \lambda^2 \sin^2 \theta} \right) \end{aligned} \quad (9)$$

In Eq.(9), for an ideal energy balancing system, we require $M_{in}(\theta, q) = 0$, where k_1 , b , l_{off} , L , l_0 , q , λ , k_2 are system constants. For a potential actuation system with known k_2 and q , the parameters can be optimised for passive energy balancing. Moreover, Eq. (9) can be modified by employing $k_1 = 0$ and $q = 0$ to obtain the ordinary required moment to actuate the system without the proposed negative stiffness mechanism as

$$M_r = k_2 L^2 \left(\left(\sqrt{1 - \lambda^2 \sin^2 \theta} - 1 \right) + \lambda(1 - \cos \theta) \right) \times \left(\lambda \sin \theta - \lambda^2 \sin \theta \cos \theta / \left(\sqrt{1 - \lambda^2 \sin^2 \theta} \right) \right) \quad (11)$$

Figure 7 shows the required moment and actuation force for the different input angle, and demonstrates that the required moment has a strong nonlinearity. Moreover, the system will be turned from positive stiffness to negative stiffness at a specific angle.

Figure 7. Required moment and actuation force as a function of input angle.

Therefore, in order to improve the performance of the total system, an initial established angle θ_0 of the bar mechanism is proposed as an additional parameter, as shown in Fig. 4. Then, the displacement q_m of the slider becomes

$$q_m = L \left(\left(\sqrt{1 - \lambda^2 \sin^2(\theta + \theta_0)} - 1 \right) + \lambda(1 - \cos(\theta + \theta_0)) \right) \quad (12)$$

Moreover, the turning point θ_t of the system can be obtained by solving

$$\frac{\partial M_r}{\partial \theta} = 0 \quad (13)$$

In order to evaluate the performance of the energy balancing system, it is useful to establish a force metric. As the system is continuous with limited constants, it is hard to construct a perfect energy balancing system using finite unknown constants. Therefore, an error metric is established to evaluate the performance of the energy balancing system. Figure 8 shows the schematic diagram of the actuation force error for different input angles. The error metric could theoretically integrate this actuation error from a zero angle to the current position and is written as

$$\eta_{err} = \int_0^{\theta} |M_{in}| d\theta \quad (14)$$

Figure 8. Schematic diagram of the actuation force error for the input angle.

This is a meaningful metric to evaluate the error for the passive energy balancing (PEB) system, as this implies the additional energy required during actuation. With this actuation force error metric, the performance of the energy balancing system can be obtained, and the geometric parameters of the system can be optimized using the *fmincon* function in Matlab. The energy conversion efficiency metric η_{err} is used as the objective function to make the torque available from the negative stiffness mechanism match as closely as possible the requirement to actuate the linear motion system over the entire prescribed rotation range.

3 DESIGN CASE

In order to investigate how to use this negative stiffness mechanism for linear motion actuation, a linear spring stiffness $k_2 = 69$ N/m is chosen as the drive load for study and the rotation input angle is between 0 and $\theta_t - \theta_0$. The resulting optimised parameters are shown in Table 1. All the components used here are ubiquitous and already manufactured over a very broad range of scales. The intention of this initial study is therefore to show the considerable energy storage achievable in a moderate size demonstrator.

Table 1. Design parameters for the NS mechanism for linear motion optimisation.

Parameter	Lower bound	Upper bound	Optimised value	Units
Drive spring rate, k_1	0.01	1	0.0238	N/mm
Drive spring length, l_0	10	500	146.186	mm
Off centre length, l_{off}	10	500	124.270	mm
Link bar length, L	10	500	100.000	mm
Shaft length, b	10	500	125.146	mm
Ratio R/L , λ	0.1	1	0.2709	-
Initial established angle, θ_0	0	90	78.9890	degree

With the optimised parameters shown in Table 1, the effectiveness of the optimal negative stiffness mechanism to construct an energy balancing system for the proposed target positive stiffness linear motion spring system can be investigated. Figure 9 shows the linear motion displacement along with the rotation angle provided by the negative stiffness mechanism. While there is a strong nonlinearity in the moment function, the output displacement presents a linear

relationship with respect to the rotation during the optimised operation interval, which can also be seen in Fig. 7. Hence this characteristic implies that the negative stiffness mechanism can provide a suitable linear motion output by careful design and optimisation.

Figure 9. Predicted actuation displacement with rotation.

The performance predicted for the optimised torque shaft profile shows satisfactory matching of the linearised torque requirements. Figure 10 shows that the evolution of torque with rotation for the spring and the linear motion system and the net torque of the whole system. The torque provided by the negative mechanism matches the torque required closely to provide a linear motion, and the maximum torque required by the extra actuator is approximately zero.

Figure 10. Predicted torque with optimised negative stiffness mechanism.

Integrating both the torque versus the rotation angle provides the mechanical energy required to actuate the target spring, and is shown in Fig. 11. By comparing the energy required with and without the negative stiffness mechanism, the negative stiffness mechanism shows a strong ability to passively balance the required torque. Figure 11 shows that the predicted energy reduction is almost 98%, with the energy required reduced from 0.032 J to 0.0005 J. This is the contribution of the energy stored in the extended spring in the initial position.

Figure 11. Comparison of the predicted energy required with and without the negative stiffness mechanism.

The objective error function plotted in Fig. 12 shows that the optimised configuration of the negative stiffness mechanism provides significant benefits in terms of energy efficiency.

Figure 12. Evolution of efficiency with rotation.

Based on this study, it can be seen that the negative stiffness mechanism provides a significant contribution to balancing the positive stiffness system, and can provide a suitable linear motion output by careful design and optimisation. High energy conversion efficiency can be provided by the extension spring and a smaller actuator can be used in the system.

4 CONCLUSION

A new concept using a torsional negative stiffness with an off centre spring (TNSOCS) mechanism for linear motion actuation has been presented. The proposed negative stiffness device is designed to have the capability to passively balance the actuation requirement of systems displaying positive stiffness. The motivation for using such a mechanism was presented and the kinematics of the tailored nonlinear negative stiffness mechanism was introduced. An error metric function was introduced to provide a basis for evaluation and also act as the objective function to optimise the geometry of the tailored nonlinear negative stiffness mechanism. The optimised tailored nonlinear negative stiffness mechanism was shown to be able to generate a torque that matches the required force of a linear spring closely, which means a significant contribution can be provided by the tailored nonlinear negative stiffness mechanism to convert the torque to linear actuation and balance the positive stiffness system. The concept shown here can be extended to many potential actuation design applications which need frequent state switching to reduce the mean power consumption and waste heat dissipation. While the example used in this paper is relatively simple, it provides an insight into the low energy actuation design problem, both in the field of bidirectional morphing aircraft and other fields.

Key words: ball-screw inerter, impact absorption, passive absorber, variable inertance, variable moment of inertia, inertial damping.

Abstract. For over two decades, inerter-based devices are a subject of research papers, patents and engineering reports. Since 2002, when the inerter was introduced as the missing element of mechanical networks, various applications of the inerter have been proposed. They include solutions for earthquake engineering, suspensions of vehicles, aircraft landing gears and even systems improving walking performance of humanoid robots. In contrast to majority of the inerter-based systems, which are mainly developed for vibration mitigation problems, this paper concerns the inerter as the shock-absorber protecting objects excited by the impact. In particular, adaptive performance of the ball-screw inerter with variable moment of the flywheel inertia is investigated. In order to ensure efficient adaptation of the inerter to various excitation conditions, the single reconfiguration technique, which was successfully applied for pneumatic absorber, is now adjusted and implemented in the proposed inertial system. The contribution consists of the concept introduction, discussion of the mathematical model of the system, theoretical as well as numerical analyses. Results of the presented study show that optimal impact absorption can be obtained in semi-passive manner. The properly adjusted geometry of the surface guides for the inertial elements ensure appropriate variability of the flywheel moment of inertia. Variable moment of the flywheel inertia provides optimal deceleration of the amortized object. The calculated moment of inertia depends on the mass of amortized object and friction but it is independent of the impact velocity.

1 INTRODUCTION

Although smart materials and advanced control systems are commonly known and even implemented in commercially produced systems, e.g., magnetorheological suspensions of cars [1], there are some applications for which passive solutions are still preferable, e.g., base isolations for earthquake protections of buildings [2]. As a result, the currently conducted research concerns both design of passive devices [3] and elaboration of control methods for active devices [4, 5]. In recent years the research of many scientists from all over the world was focused on the application of passive mechanical system, which is called the ‘inerter’ [6]. Typically the inerter is implemented in the tuned mass dampers (TMD) and used for mitigation of the forced vibrations amplitudes [7, 8]. Nevertheless, other practical applications of the inerter have been proposed and they include also suspensions of vehicles, aircraft landing gears and even systems improving walking performance of humanoid robots. Moreover, there appear contributions in which inerter-based devices are used for absorption of mechanical impacts [9].

Similarly, this paper relates to the problem of adaptive impact absorption and presents further development of the idea introduced in [10], where the ball-screw inerter is designed in such a way that the optimal deceleration of the amortized object is obtained.

Presented contribution reveals a conceptual solution which is based on two promising ideas: passive system with parameters dependent on the displacement of working element and single reconfiguration technique, which allows to obtain semi-passive, optimal performance of the system. Variable moment of the flywheel inertia is obtained by equipping the inerter flywheel with additional weights, whose position depends on the geometry of the surface mounted in the inerter housing. Shape of the surface varies with the displacement of the screw relative to housing and as a result the moment of the flywheel inertia changes also as a function of the screw displacement. In case the inerter is used for mitigation of impacts exciting objects of different masses the single reconfiguration technique is applied by reshaping of the guiding surface to the identified impact conditions.

2 BALL-SCREW INERTER AS THE SHOCK-ABSORBER

2.1 Problem formulation

Let us consider simple 1-DOF system described by classical equation of motion:

$$m\ddot{x} + F_{abs}(x(t)) = F_{ext}(t) \quad (1)$$

with initial conditions: $\dot{x}(0) = v_0$, $x(0) = 0$.

The first l.h.s. term of (1) is the inertia force of the decelerated object under impact conditions (Fig. 1), F_{abs} is the value of absorber reaction force, F_{ext} is the value of external force acting on the excited system.

Figure 1: Free body diagram of the object decelerated with the use of the ball-screw inerter.

As shown in the free body diagram, in this paper the ball-screw inerter is analyzed and applied to the problem of optimal impact absorption, which can be formulated in general form:

$$\begin{cases} \max_{\mathbf{u}(x(t))} (F_{abs}(x(t)) - F_{ext}(t)) = \min \\ \int_d \mathbf{F}_{abs} d\mathbf{s} = E_{init} + \int_d \mathbf{F}_{ext} d\mathbf{s} \end{cases} \quad (2)$$

where \mathbf{u} is the control vector, d is the inerter stroke and E_{init} is the initial kinetic energy of the object amortized by the inerter. The inerter includes a screw with the thread lead P and a nut with a flywheel of the total moment of inertia I_b . We assume that the housing of the inerter is fixed so additional degrees of freedoms have not be introduced. In presented study the control

will be performed by variable moment of the flywheel inertia I_b which will be changed in passive manner and it will be the function of displacement x .

2.2 Reaction force and optimal change of the moment of the flywheel inertia

In order to obtain adaptive and optimal performance of the ball-screw inerter the problem (1) should be solved for every impact conditions. Nevertheless, it will be shown further that the optimal response of the system is independent from impact velocity and only adaptation to different values of amortized object mass has to be performed. In presented study it is assumed that the control of the moment of flywheel inertia is realized by autonomous mechanism, which utilizes several weights mounted on arms of variable length and guiding surface. Geometry of the surface results in specified change of the distance between weights and the axis of the screw. As a result, it provides change of the flywheel moment of inertia being a function of the screw displacement. The shape of guiding surface should be calculated for predicted or identified online impact conditions in order to ensure appropriate variability of the flywheel moment of inertia. If the guiding surface is appropriately reshaped just before or at the very beginning of the impact absorption process, the optimal response of the inerter will be obtained.

Now, let us derive the model of the ball-screw inerter with variable moment of inertia. Geometric constraints of the ball-screw connection result in kinematic relation between the velocity of impacting object \dot{x} and angular velocity of the flywheel $\dot{\phi}$:

$$\dot{\phi} = \frac{2\pi}{P} \dot{x} \quad (3)$$

The torque acting on the flywheel is equal to the time derivative of the flywheel's angular momentum:

$$M = \frac{d}{dt}(I_b(x)\dot{\phi}) = \frac{2\pi}{P} \left(I_b(x)\ddot{x} + \frac{dI_b}{dx} \dot{x}^2 \right) \quad (4)$$

Simultaneously, the torque is derived from the balance of forces acting on the ball-screw connection and it equals:

$$M = \frac{D \sin \beta - \mu \cos \beta}{2 \cos \beta + \mu \sin \beta} F_{abs} \quad (5)$$

where μ is the friction coefficient, D is the diameter of the ball-screw connection and β is the inclination angle described by simple relation:

$$\tan \beta = \frac{P}{\pi D} \quad (6)$$

The reaction force F_{abs} generated by the inerter with the variable moment of the flywheel inertia $I_b(x)$ is described by the following equation:

$$F_{abs}(x) = \frac{4\pi}{D} \frac{\pi D + \mu P}{P^2 - \pi \mu D P} \left(I_b(x)\ddot{x} + \frac{dI_b}{dx} \dot{x}^2 \right) \quad (7)$$

3 ADAPTATION TO THE IMPACT CONDITIONS

3.1 Adaptation technique

In Fig. 3. the general block diagram describing operation of the proposed ball-screw inerter with variable moment of the flywheel inertia is presented. The adaptation to actual impact conditions is performed according to the principles of Adaptive Impact Absorption (AIA) [11] and the inerter ensures so-called ‘adaptable’ performance [12], which is obtained by adaptation to the identified impact conditions and passive realization of the impact absorption process.

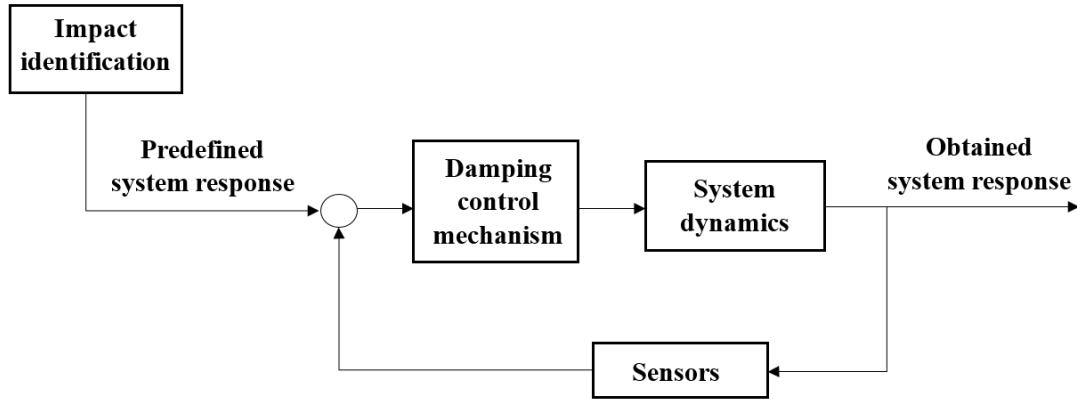

Figure 2: Block diagram of the adaptable system.

Inserting (7) into (1) and assuming that impact conditions are defined by initial velocity v_0 and any external force is not acting on the decelerated object, the particular form of the equation of motion is obtained:

$$\ddot{x} \left(\frac{m}{I_b(x)} + \frac{4\pi}{D} \frac{\pi D + \mu P}{P^2 - \pi \mu D P} \right) + \frac{4\pi}{D} \frac{\pi D + \mu P}{P^2 - \pi \mu D P} \frac{d}{dx} \ln I_b(x) \dot{x}^2 = 0 \quad (8)$$

Assuming that globally optimal response of the system is feasible, the constant value of the object deceleration $\ddot{x} = -\frac{v_0^2}{2d}$ is introduced to (8) and by its solving the optimal change of the flywheel moment of inertia is obtained in the closed-form:

$$I_b(x) = \sqrt{\frac{d}{d-x} \left(\frac{mDP(\pi \mu D - P)}{4\pi(\pi D + \mu P)} - I_{b_0} \right)} + \frac{mDP(\pi \mu D - P)}{4\pi(\pi D + \mu P)} \quad (9)$$

It should be pointed out that the obtained solution is independent from the impact velocity v_0 .

For calculated optimal changed of the flywheel moment of inertia $I_b(x)$ the shaped of guiding surface can be calculated. The particular formula depends on practical implementation of the systems so it will not be discussed in this contribution.

3.2 Numerical case study

In Tab. 1 parameters of the inerter, which were used for numerical simulations are presented.

Table 1: Parameters of the inerter assumed for numerical simulations.

inerter stroke	200	[mm]
diameter of the ball-screw connection	20	[mm]
initial flywheel moment of inertia	100	[kg·mm ²]

Fig. 3 and Fig. 4 present variability of the flywheel moment of inertia, which ensures optimal impact mitigation (minimal, constant deceleration of the object at the entire stroke), for different values of the object mass and dry friction coefficients, respectively.

Figure 3: Moment of the flywheel inertia as a function of screw displacement for different values of the amortized object mass, dry friction coefficient $\mu = 0.01$.

Figure 4: Moment of the flywheel inertia as a function of screw displacement for different values dry friction

coefficient, object mass $m = 10$ kg.

It can be easily noticed that for small values of impacting mass and small values of dry friction coefficient the variability of the flywheel moment of inertia does not change significantly. Nevertheless, for higher values of these parameters the optimal moment of the flywheel inertia becomes noticeably different.

4 CONCLUSIONS

The paper briefly discusses the concept of adaptable ball-screw inerter, which is designed for impact mitigation. Adaptation mechanism is based on the guiding surface, which regulates the distance of the weights mounted on the inerter flywheel and as a result controls the flywheel moment of inertia. Appropriate shaping of the guiding surface is based on the solution of the inverse dynamics problem, in which change of the flywheel moment of inertia is a function of displacement and it is calculated for different values of amortized object's mass. In case of various initial velocities of the impacting object, any additional action is not required because system response is independent from the impact velocity. Presented study is illustrated by numerical example revealing influence of the impacting object mass, as well as influence of the dry friction coefficient appearing at the ball-screw connection.

ANALYSIS AND CONTROL OF DAMPED FLEXIBLE STRUCTURES

YORAM HALEVI

Faculty of Mechanical Engineering (CIMNE)
Technion – Israel Institute of Technology
Haifa 32000, Israel
e-mail: yoramh@technion.ac.il

Key words: Flexible Structures, Damping, Transfer Function, Control, Fractional Order.

Abstract. The paper considers the properties of damped flexible structures and dedicated methods of control. The main tool is an accurate, infinite dimension, transfer function (TF), from actuation to measurement. . In case of undamped systems, or systems with boundary damping, the TF consists of pure time delays and low order rational terms. The paper considers also two types of domain boundary and in those cases the TFs are fractional order in both the delays and the "rational parts". The time domain, e.g. delays and frequency domain, e.g. poles of the systems are investigated. Absolute vibration suppression (AVS) is a dedicated control method for flexible structures which is based on the TFs. The paper gives the resulting AVS controller for each case and discusses the differences between the cases.

1 INTRODUCTION

Spatially continuous flexible structures appear in diverse engineering applications, ranging from MEMS actuators and sensors on the small scale to cranes, air and space systems, robotic arms and even bridges and buildings on the large scale. The main advantage of flexible structures is their light weight. It should be kept in mind that flexible is a relative term, depending both on the excitation bandwidth and the accepted level of vibration. Higher performance (faster maneuvers, better accuracy) requires therefore acknowledging the flexibility in systems that could otherwise be considered as rigid.

The classical models of flexible structures are energy conservative, and this is the basic assumption of the comprehensive modal theory where the notions of natural frequencies and modeshapes are central to the analysis of the time domain behavior [1]. The same is true for the traveling wave approach [2]. However, in practice, the free vibration decays with time due to the presence of damping, both at the supports, and throughout the structure [3].

In a series of publications by the author, [4-8] a comprehensive modeling and control method for flexible structures was presented. The model for a system without domain damping is given in terms of infinite dimension transfer functions, consisting of delays and low order rational terms. Models that recognize domain damping include in their transfer functions elements that are not integer powers of "s" - the Laplace operator [7,8]. These elements represent fractional order differentiation and integration. It turns out that fractional calculus is known almost since the development of the integer order calculus (first credit is

assigned to Leibniz and L'Hospital, 1695). In recent years, fractional calculus has been applied to many fields of science, engineering and mathematics [9,10].

Feedback control has two important tasks in flexible structure design: adding "artificial rigidity" for tracking systems, and absorbing energy. A flexible, light weight, system with carefully designed controller can exhibit the same behavior as a rigid system with larger and heavier damping devices.

The paper uses the Absolute Vibration Suppression (AVS) controller [4,5,7] which belongs to the family of dedicated control approaches, e.g. [11, 12] that use the physical properties of flexible structures. In particular the control strategy can be related to the traveling wave approach [13]. This is in contrast with the approach of generic mathematical control laws that in theory can be applied to all dynamic systems, regardless of their physical origin. In mathematical terms the key point is the infinite dimension transfer functions. In previous publications these transfer functions, were used to design a dedicated control law with boundary actuation that stops the wave reflections, thus achieving absolute vibration suppression (AVS) in the system. Having fractional order models requires the extension of the AVS method and of standard dead time compensation algorithms to such cases.

2 THE MODEL

The case that is used in this proposal to demonstrate the modeling and control methodologies is the taut string shown in Fig. 1 where w is the traverse displacement and Ψ is the distributed load. Clearly the same model applies to a rod in tension or in torsion as well. It was also shown that it applies also each mode of a membrane after a modal decomposition in one dimension [7]. The damping shown in the figure is what we call external distributed domain, but in this paper we consider other configurations as well.

Figure 1: Model of a taut damped string.

The model that is used in the paper is as follows.

$$c^2 w_{xx}(x,t) - w_{tt}(x,t) + \mu \Psi(x,t) = \alpha w_t(x,t) + \beta w_{xt}(x,t) - \gamma c^2 w_{xxt}(x,t) \quad (1)$$

The left-hand side is the classical, undamped wave equation with $c=(T/\rho)^{1/2}$ where T is the tension and ρ is mass per unit length and $\mu=1/\rho$. The right hand side includes three times of (potentially) domain damping mechanisms. It can be shown obvious, based on energy considerations that such the mixed term $\beta w_{xt}(x,t)$ does not provide damping into the system (actually it represents a situation where the progressive and regressive waves have different speed). Therefore it will not be discussed in the sequel. The linear boundary conditions (BC)

consist of lumped inertia, spring and damper and an external point force (later on this will be identified as the control force) at each end.

$$\begin{aligned} -Tw_x(0,t) + (J_0 w_{tt}(0,t) + D_0 w_t(0,t) + K_0 w(0,t)) &= f_0(t) \\ Tw_x(L,t) + (J_L w_{tt}(L,t) + D_L w_t(L,t) + K_L w(L,t)) &= f_L(t) \end{aligned} \quad (2)$$

To show the essentials of the problem a simpler model is used in this paper. The disturbance is assumed to decompose into a product of spatial and time functions, i.e. $\Psi(x,t) = \psi(x)d(t)$. The BC, except for the case of boundary damping will be either free-free (Neumann BC) or free-fixed (mixed Neumann and Dirichlet BC).

2.1 The undamped wave equation with general boundary conditions

This case was treated in detail before in [4,6] and is given here in a concise manner as it forms the basis for the system with domain damping. To derive the transfer functions from the end force $f(t)$ and the domain load $d(t)$ we solve first an auxiliary problem where the only external excitation is a point force $p(t)$ acting at $x=\xi$.

$$c^2 w_{xx}(x,t) + \mu \delta(x-\xi) p(t) = w_{tt}(x,t) \quad (3)$$

Applying Laplace transform with respect to time to (3), assuming zero initial condition, as in the definition of a transfer function, gives

$$w_{xx}(x,s) = \left(\frac{s}{c}\right)^2 w(x,s) - \frac{\mu}{c^2} \delta(x-\xi) p(s) \quad (4)$$

This is an ODE in x and its general solution is

$$w(x,s) = -\frac{\mu p(s)}{4cs} \left(e^{\frac{s|x-x_0|}{c}} - e^{-\frac{s|x-x_0|}{c}} \right) + C_1(s) e^{\frac{sx}{c}} + C_2(s) e^{-\frac{sx}{c}} \quad (5)$$

Applying the (homogeneous!) boundary conditions (2) the coefficients $C_1(s)$, $C_2(s)$, which are linear in $p(s)$ are found. Rearranging, the transfer function from $p(s)$ to a displacement $w(x,s)$ is given by

$$G(x,\xi,s) = \frac{w(x,s)}{p(s)} = \frac{e^{-|\tau_x - \tau_\xi|s} + R_0(s)e^{-(\tau_x + \tau_\xi)s} + R_L(s)e^{-(2\tau - \tau_x - \tau_\xi)s} + R_0(s)R_L(s)e^{-(2\tau - |\tau_x - \tau_\xi|)s}}{2\phi s(1 - R_0(s)R_L(s)e^{-2\tau s})} \quad (6)$$

Where

$$\phi = c\rho, \quad \tau = L/c, \quad \tau_x = x/c, \quad \tau_\xi = \xi/c$$

And

$$R_i(s) = \frac{\phi s - (J_i s^2 + D_i s + K_i)}{\phi s + (J_i s^2 + D_i s + K_i)}, \quad i=0,L \quad (7)$$

Physically the exponents represent delays, resulting from the wave motion at velocity c . The transfer functions $R_i(s)$ can be thought of a dynamic reflection coefficients. It is easily

seen that for a free end $R_i = 1$, and for a fixed end, setting either one of the parameters to infinity, $R_i = -1$. By setting $\xi=0$ we obtain the transfer function from $f(s)$ and using (6) as a Green function the one from the load $d(t)$ is found. Hence

$$w(x, s) = G(x, 0, s)f(s) + G_d(x, s)d(s) \quad (8)$$

Where

$$G(x, 0, s) = \frac{(1 + R_0(s))(e^{-\tau_x s} + R_L(s)e^{-(2\tau - \tau_x)s})}{\phi s(1 - R_0(s)R_L(s)e^{-2\tau s})} \quad , \quad G_d(x, s) = \int_0^L G(x, \xi, s)\psi(\xi)d\xi \quad (9)$$

The transfer function leads to many observations regarding the system, as well as tools for analysis and design [4-8]. In this work we use the fact that the poles can be easily computed from

$$1 - R_0(s)R_L(s)e^{-2\tau s} = 0 \quad (10)$$

The pole at $s=0$ exists if there is a rigid body motion, otherwise it is cancelled out by a zero of the transfer function.

2.2 Boundary damping

This is a particular case of the general one in the previous sub-section. If the only element in the BC is a lumped damper, the reflection coefficients in this case become a constant

$$R_i(s) = \frac{\phi - D_i}{\phi + D_i} \quad , \quad i = 0, L \quad (11)$$

In terms of traveling waves that means that each time the wave hits the boundary it is reflected scaled by that value. Notice that R_i ranges between -1 (fixed) and +1 (free) and that in case the damper has the value ϕ then $R_i=0$, which means no reflection at all. This property, known as impedance matching is discussed in detail in [4,5] and is utilized in the design of the AVS controller.

The poles of the system are easily computed as

$$p_n = \begin{cases} \frac{1}{2\tau} \{ \ln(R_0 R_L) + 2n\pi i \} & R_0 R_L > 0 \\ \frac{1}{2\tau} \{ \ln(|R_0 R_L|) + (2n+1)\pi i \} & R_0 R_L < 0 \end{cases} \quad ; n = 0, \pm 1, \dots \quad (12)$$

They all share an identical real part and their imaginary parts are exactly the natural frequencies of a free-free or a fixed-free undamped system.

2.3 External domain damping

To concentrate of the effect of domain damping we assume in this sub-section that the BC, are either free-free (Neumann BC) or free-fixed (mixed Neumann and Dirichlet BC)

$$-Tw_x(0, t) = f(t) \quad , \quad Tw_x(L, t) = 0 \quad \text{or} \quad -Tw_x(0, t) = f(t) \quad , \quad w(L, t) = 0 \quad (13)$$

The three terms on the RHS of Eq. (1) have different effect and will be treated separately. We start with the “distributed skyhook damping” term $\alpha w_t(x,t)$. To derive the transfer functions in this case we set up an auxiliary problem similar to eq. (3).

$$c^2 w_{xx}(x,t) + \mu \delta(x-\xi) p(t) = w_{tt}(x,t) + \alpha w_t(x,t) \quad (14)$$

Applying Laplace transform gives

$$w_{xx}(x,s) = \left(\frac{\lambda(s)}{c} \right)^2 w(x,s) - \mu \delta(x-\xi) p(s) \quad (15)$$

Where

$$\lambda(s) = \sqrt{s^2 + bs} \quad (16)$$

The general solution of this ODE is

$$w(x,s) = -\frac{\mu p(s)}{4c\lambda(s)} \left(e^{\frac{\lambda(s)|x-x_0|}{c}} - e^{-\frac{\lambda(s)|x-x_0|}{c}} \right) + C_1(s) e^{\frac{\lambda(s)x}{c}} + C_2(s) e^{-\frac{\lambda(s)x}{c}} \quad (17)$$

Since the BC that are used in this sub-section do not include any expression containing explicitly the Laplace variable s , the situation is similar to the case with no domain damping with $\lambda(s)$ replacing ‘ s ’ everywhere.

$$G(x,\xi,s) = \frac{w(x,s)}{p(s)} = \frac{e^{-|\tau_x - \tau_\xi| \lambda(s)} + R_0 e^{-(\tau_x + \tau_\xi) \lambda(s)} + R_L e^{-(2\tau - \tau_x - \tau_\xi) \lambda(s)} + R_0(s) R_L(s) e^{-(2\tau - |\tau_x - \tau_\xi|) \lambda(s)}}{2\phi \lambda(s) (1 - R_0 R_L e^{-2\tau \lambda(s)})} \quad (18)$$

Where

$$\phi = 1/c\mu, \quad \tau = L/c, \quad \tau_x = x/c, \quad \tau_\xi = \xi/c, \quad R_0 = 1, \quad R_L = \pm 1$$

The transfer function from $f(s)$ is given now as (G_d is given by the same integral)

$$G(x,0,s) = \frac{e^{-\tau_x \lambda(s)} + R_L e^{-(2\tau - \tau_x) \lambda(s)}}{\phi \lambda(s) (1 - R_L e^{-2\tau \lambda(s)})} \quad (19)$$

In the undamped case $\lambda(s) = s$, the exponents become pure time delays, and the transfer function coincides with that given in Eq. (7). Most of the components, such as the time constants τ , τ_x and τ_ξ , the impedance ϕ , the reflection coefficients R_0 and R_L and the wave propagation velocity c are independent of the damping α . The components of $G(x,\xi,s)$ that depend on α are the exponents. For $\alpha > 0$ they become nonlinear in s , and the system is of fractional order. Since the exponents are no longer pure delays, they not only shift the input but also distort it.

The denominator roots of $G(x,0,s)$ are the roots of $\lambda(s)$, which are $s = 0$ and $s = -\alpha$, and those of

$$1 - R_0 R_L e^{-2\tau \lambda(s)} = 0 \quad (20)$$

In the free-fixed case the limit of $G(x,0,s)$ at the roots of $\lambda(s)$ is finite, hence $s = 0$ and $-\alpha$ are not open loop poles. In other words, they are cancelled by zeros in the numerator. The poles of $G(x,0,s)$ are therefore given by

$$p_m = \begin{cases} -\frac{1}{2}\alpha \pm j\frac{1}{2}\sqrt{\left(\frac{(2m+1)\pi}{\tau}\right)^2 - \alpha^2} & \text{free - fixed} \\ -\frac{1}{2}\alpha \pm j\frac{1}{2}\sqrt{\left(\frac{2m\pi}{\tau}\right)^2 - \alpha^2} & \text{free - free} \end{cases}, \quad m=0,1,\dots \quad (21)$$

In the free-free case $m=0$ yields two real poles, $p_{01}=0$ and $p_{02}=-\alpha$. All open loop poles of $G(x,0,s)$, except for the pole at the origin (rigid body dof), have a negative real part and are thus located in the open left half plane (OLHP). Most of the poles are complex valued with the same real part. In both settings, as m becomes larger (or for small α) the distance between the imaginary parts approaches π/τ , as for undamped systems. Comparing the real parts, which dictate the convergence rate, we have for a free-free configuration with one relatively small damper on the far side

$$-\frac{1}{2}\alpha = \frac{1}{2\tau} \ln(R_L) = \frac{1}{2\tau} \ln\left(\frac{\phi - D_{eq}}{\phi + D_{eq}}\right) \quad (22)$$

Which gives

$$\frac{D_{eq}}{\phi} = \frac{1 - e^{-\alpha\tau}}{1 + e^{-\alpha\tau}} \quad (23)$$

And for small damping

$$D_{eq} \cong \phi\alpha\tau \quad (24)$$

At high frequencies, where the influence of the damping on the imaginary part becomes negligible, the poles' matching is complete.

2.3 Internal domain damping

We consider now the internal damping (the term 'structural damping' is usually reserved to yet another model) term $\gamma c^2 w_{xx}(x,t)$. To derive the transfer functions in this case we set up an auxiliary problem similar to Eq. (14).

$$c^2 w_{xx}(x,t) + \mu\delta(x-\xi)p(t) = w_{tt}(x,t) - \gamma c^2 w_{xx}(x,t) \quad (25)$$

Applying Laplace transform gives

$$w_{xx}(x,s) = \left(\frac{\sigma(s)}{c}\right)^2 w(x,s) - \mu\delta(x-\xi)p(s) \quad (26)$$

Where

$$\sigma(s) = \frac{s}{\sqrt{1 + \gamma s}} \quad (27)$$

Though the physical nature and the resulting properties are very different than the internal case the derivation is the same with $\sigma(s)$ replacing $\lambda(s)$.

$$G(x,0,s) = \frac{e^{-\tau_x \sigma(s)} + R_L e^{-(2\tau - \tau_x)\sigma(s)}}{\phi \sigma(s) (1 - R_L e^{-2\tau \sigma(s)})} \quad (28)$$

While we kept the format identical with the previous case, due to the nature of $\sigma(s)$ the time constants τ , τ_x and τ_ξ , are no longer proportional to the delay, as will be shown in section 3. The first indication comes from the poles. The denominator roots of $G(x,0,s)$ are the root of $\sigma(s)$, which is $s = 0$ (same situation regarding free or fixed) and those of

$$1 - R_0 R_L e^{-2\tau \sigma(s)} = 0 \quad (29)$$

Straightforward calculation gives the poles for a free-free as

$$p_m = -\frac{m^2 \pi^2 \gamma}{2\tau^2} \pm \sqrt{\left(\frac{m^2 \pi^2 \gamma}{2\tau^2}\right)^2 - \frac{m^2 \pi^2}{\tau^2}} \quad , \quad m = 0, 1, \dots \quad (30)$$

For fixed-free m is replaced by $(m+1/2)$. Here too all open loop poles of $G(x,0,s)$, except for the pole at the origin (rigid body dof), are in the OLHP. However the situation is different from the previous cases. First, the system may have a finite number of complex poles at low frequencies (may not have them at all for a large enough γ) but from a certain index m on all the poles are real with one branch approaching $-\infty$ proportional to m^2 while the other approaches zero proportional to m^{-1} . Contrary to external domain damping, similarity to lumped damping is only at low frequencies but even then the real part is not constant.

3 RESPONSE PROPERTIES AND ANALYSIS

To illustrate the wave motion which is closely related to the structure of the transfer function we consider first a system which is free at the actuating side and has a lumped damper at the other. By long division the transfer function can be written as the infinite series

$$G(x,0,s) = \frac{1}{\phi s} \left\{ e^{-\tau_x s} + R_L e^{-(2\tau - \tau_x)s} + R_L e^{-(2\tau + \tau_x)s} + R_L^2 e^{-(4\tau - \tau_x)s} + \dots \right\} \quad (31)$$

Since $|R_L| < 1$, the series consists of repeated scaled down versions of the fundamental function which is the integral of the force. If the input is finite, with duration $T < 2(\tau - \tau_x)$ the waves do not coincide at point x and each wave can be seen clearly as in Fig. 2. Apart from timing, the response is identical at all points along the domain.

One can perform the same expansion for a system with external domain damping.

$$G(x,0,s) = \frac{1}{\phi \lambda(s)} \left\{ e^{-\tau_x \lambda(s)} + R_L e^{-(2\tau - \tau_x)\lambda(s)} + R_L e^{-(2\tau + \tau_x)s} + R_L^2 e^{-(2\tau - \tau_x)\lambda(s)} + \dots \right\} \quad (32)$$

Where R_L now is either 1 or -1. The question is whether the situation is the same, in other words is there a constant wave speed c and therefore real delays. except for the different. The inverse Laplace transform of each expression, with a general ‘delay’ θ is given by [14]

Figure 2: Response at $x=0.6L$ to finite duration force at $x=0$.

$$v(\theta, t) = L^{-1} \left\{ \frac{1}{\sqrt{s^2 + \alpha s}} e^{-\theta \sqrt{s^2 + \alpha s}} \right\} = e^{-\frac{1}{2}\alpha t} I_0 \left(\frac{1}{2} \alpha \sqrt{t^2 - \theta^2} \right) U(t - \theta) \quad (33)$$

U is the Heaviside function and it indicates that the response in (33) is indeed delayed by θ . I_0 is the zero order modified Bessel function of the first kind. $I_0(0) = 1$, which means that for $\alpha = 0$, the term reduces to pure delay. Detailed analysis leads to the conclusion that for $t \gg \theta$, $v(\theta, t) \approx 1 / \sqrt{\pi \alpha t}$. This means that each term is decaying at a rate inversely proportional to the square root of time. Figure 3 shows the wave reflection process through the velocity response of fixed end. For $\alpha = 0$ the input is simply shifted, but for $\alpha > 0$ it undergoes a distortion as well. The response is shown at four time instants, $t/\tau = 0.2, 0.7, 1.2$ and 1.7 . In the last two the response is after reflection from the fixed end and is therefore flipped.

Seemingly exactly the same procedure can be applied to a system with internal damping, with $\sigma(s)$ instead of $\lambda(s)$. While we do not present an explicit inverse Laplace transform in that case, simulations show that the wave phenomenon is practically destroyed with different parts of the input moving at different speed according to their frequency content.

4 ABSOLUTE VIBRATION SUPPRESSION (AVS) CONTROL

The AVS control law [4,7] is a dedicated control methodology for control of flexible structures. It is a collocated rate feedback at $x=0$ with a concentrated force actuation.

$$f(s) = Mr(s) - H(s)w(0; s) \quad (34)$$

The collocation is essential since non-collocated controllers destabilize the system (move the poles into the RHP) [4]. The actuation at an end enables the main feature of the AVS which is the elimination of a block with infinite number of poles, to be shown below. The controller transfer function is given by

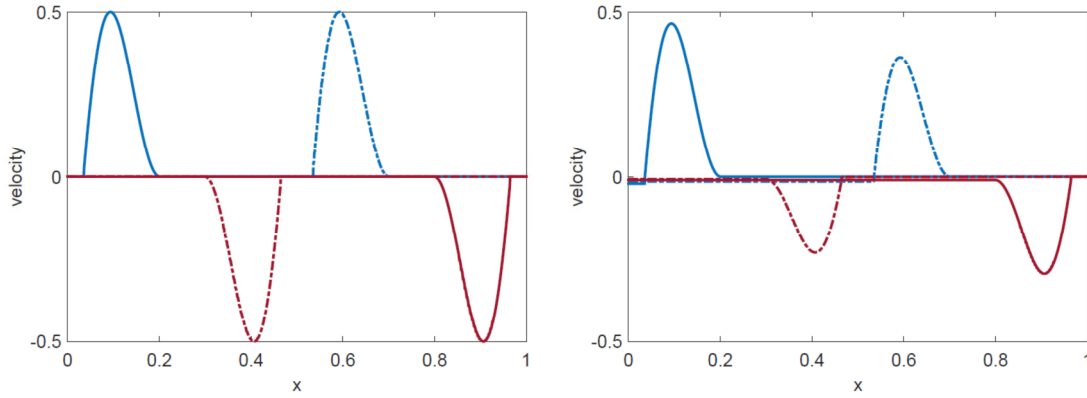

Figure 3: Wave motion in a free-fixed string with (left) and without (right) external domain damping.

$$H(s) = \begin{cases} \phi s & \text{Boundary damping} \\ \phi \lambda(s) & \text{External domain damping} \\ \phi \sigma(s) & \text{Internal domain damping} \end{cases} \quad (35)$$

The closed loop transfer function is then

$$\frac{w(x;s)}{r(s)} = \frac{MG(x;s)}{1 + H(s)G(0;s)} = \frac{M}{2\phi A(s)} \left(e^{-\tau_x A(s)} + R_L e^{-(2\tau - \tau_x)A(s)} \right) \quad (36)$$

$A(s)$ stands for s , $\lambda(s)$ or $\sigma(s)$ according to the case. Hence with the special form of $H(s)$, the AVS controller eliminates all the exponents (delays in the undamped case) from the characteristic equation and the closed loop system. Physically that means that there are no reflections from the left end. M is a scaling factor to guarantee unity gain. The physical interpretation of the action of the AVS controller is impedance matching. It creates, by means of the feedback, an equivalent BC that is identical with the impedance of the domain. Since there is no discontinuity the wave is not reflected and the actuating end becomes a sink.

While the derivation here focused on tracking, i.e. following a reference signal $r(t)$, it can be shown that the controller suppresses, in a similar way, the response to non-steady disturbances and non-zero initial conditions. An example is given in Fig. 4 which depicts the closed versus the open loop responses to a disturbance of finite time duration, for various values of external domain damping. The vibration is absolutely suppressed in closed loop, where for $\alpha = 0$ it happens in finite time.

The controller (35) can be looked at as a rate feedback and that solves the issue of properness. With boundary damping it reduces into a constant rate feedback with a very specific gain. The controller in the two other cases is non-rational which poses theoretical and practical difficulties. Table 1 gives the properties of the normalized rate controllers $\tilde{H}(s) = H(s)/\phi s$ and Figure 5 shows their bode plots. Practically, the controllers should be approximated by a rational transfer function.

Figure 4: Open (top) and closed (bottom) loop responses to disturbance.

Figure 5: Bode plot of $\tilde{H}(s)$ for systems with external (blue) and internal (red) domain

Table 1: Example of the construction of one table

	TF	Magnitude		Angle		Approximation	
		$\omega \rightarrow 0$	$\omega \rightarrow \infty$	$\omega \rightarrow 0$	$\omega \rightarrow \infty$	Low freq.	High freq.
$\tilde{H}(s)$	1	1	1	0	0	1	1
$\tilde{H}_\lambda(s)$	$(1 + \frac{\alpha}{s})^{1/2}$	∞	1	-45	0	$\phi \alpha^{1/2} s^{-1/2}$	$1 + \frac{1}{2} \alpha s^{-1}$
$\tilde{H}_\sigma(s)$	$(1 + \gamma s)^{-1/2}$	1	0	0	-45	$(1 + \frac{1}{2} \gamma s)^{-1}$	$\gamma^{-1/2} s^{-1/2}$

5 CONCLUSIONS

The paper considered the problems of modeling and control of systems with damping. Three configurations were investigated, boundary damping and two mechanisms of domain damping. It was shown that for boundary damping the model is a transfer function that despite being infinite dimension is easy to implement and use since it involves only pure time delays and low order rational terms that act like reflection coefficients. In domain damping those elements become fractional order with irrational terms for both the delays and the coefficient. It is shown that with external domain damping the response and properties are somewhat similar to boundary damping. Internal domain damping on the other hand results in fundamentally different response. The absolute vibration suppression (AVS) controller, which is closely related to the model transfer function is affected by the damping in a similar manner. It is a constant rate feedback for boundary damping but assumes non-standard fractional order forms in the cases of domain damping.

Abstract. Advanced audio applications are more and more demanding with respect to the visual impact of loudspeakers while still requiring more channels for high quality spatial sound rendering. The use of arbitrary plate-like structures driven by electromagnetic actuators or by piezoelectric elements appears as a promising solution to tackle both issues. However, to meet spatial rendering audio constraints (omnidirectional piston-like sources), the generated bending waves must be focused to a certain extent within the host plate. Theoretically, this means being able to invert the spatio-temporal wave propagation operator for the generated bending waves to fit a given target shape. Several methods are here investigated to perform this task depending on the available knowledge of wave propagation in the plate (theoretical, partial spatial and full spatial knowledge) and using several projection bases (modal basis and eigenvalue basis). The various methods are presented in a unified theoretical framework and their performances are compared by means of two key performance indexes (focus localization error and spatial contrast).

1 INTRODUCTION

In the past decades, several studies were performed on the sound restitution using an array of loudspeakers. The main idea is to calibrate each loudspeaker of the array to reproduce with high fidelity the physics and the acoustics of the primary source [1]. Historically, spatial rendering methods such as stereophony (VBAP), binaural rendering or holophony (ambisonic or Wave Field Synthesis (WFS)) are used with electromagnetic loudspeakers. There are many constraints imposed by such methods for them to work properly: a flat and omnidirectional response for the speaker, and several piston-like actuators to avoid spatial aliasing and to cover the whole restitution area [2]. Distributed Mode Loudspeakers (DML) were introduced as a new kind of loudspeaker with a low visual profile [3]. The idea is to produce sound waves by exciting the bending waves of a thin stiff plate through an actuator. This technology was used to render spatial sound by the WFS Method [4, 5]. However, this technology suffers from some drawbacks because of the aliasing caused by joint panels and the modal behaviour at low frequency of the plate which causes distortions of the signal and does not meet spatial audio requirements. Therefore, a new technology using larger plates called MultiActuator Panels (MAP) or much larger called Large MultiActuator Panels (LaMAP) has been designed to overcome these limitations. The main idea is to excite the plate with several actuators driven by different signals to reproduce different sound sources [6].

This technology was successfully used in the context of the wave field synthesis to render spatial sound [7, 8, 9]. However, some drawbacks such as the modal behavior at low frequencies and the interferences between sources causing sound distortions and poor sound quality still exists with this technology.

Particularly in the automotive industry, using spatial sound rendering coupled with flat panel loudspeaker will be very interesting. Indeed, it will allow to alert the users from several dangers and provide high quality spatial sound. Moreover, this approach will decrease weight by replacing electrodynamical loudspeakers with piezoelectric actuators and improve design purposes and visual impact. However, the reconstitution zone is small, with a very limited number of canals and with very complex operational conditions. Considering the previous observations, the focusing of the bending waves on arbitrary plate-like interior parts of the car to create independent sound source appears as the best way to create an array for spatial sound rendering.

In the literature, there are various methods that allow to focus bending waves in a media. The first method called modal control (MC) is based on modal superposition [10]. Indeed, it allows to focus a monochromatic vibro-tactile peak on plates [11, 12], or an audio source on a rectangular plate by computing FIR filters of order 3 [13]. The method is based on a simple approach and is sensitive to modeling error. The second method available in the literature is based on the time reversal (TR) principle, initially described by Fink et al. in [14]. It allows to focus a wave at a specific point in the space by learning partially the waves received at the actuators positions and initiated at the focusing point. Besides, the same author shows that this method can be adapted for acoustic purposes to control precisely acoustic wave propagation in reverberating cavities or in waveguides [15]. Additionally, this method is also used in [16] to focus an audio impulse in a room. Finally, the ease of implementation of the time reversal encouraged many researchers to use it in haptic feedback applications [17]. The third method studied in this paper is the spatio-temporal inverse filtering (STIF), initially studied by [18] and [19] to find a solution to the lack of robustness of the time reversal method. Firstly, the method consists in learning the propagation of the waves in the whole media, then, an inverse filter is created and used as input for each actuator. Then, the method was extended to the time domain [20], and after experimentally applied in heterogeneous, absorbing and highly reverberating medias such as a human skull [21], or to focus acoustic waves in rooms [22]. Finally, another method based on the learning of the large band dynamic behavior of the structure, using the maximization of the contrast between the radiating zone and the whole media. It was initiated for room acoustics in [23], and applied on a plate structure in [24].

The objective of this study is to propose an approach enabling for the localization of bending waves in a defined area of a geometrically complex structure and with arbitrary boundary conditions to make it vibrate as a piston. First of all, this approach should be precise in terms of spatial focusing. Moreover, this method must operate in a wide frequency range and be suitable for the audio restitution. Besides, the method used should also be insensitive to noise and model error. Finally, the method should not rely on too much experimental measurements for practical reasons as the automotive is targeted as the applicative field. Several methods inspired by the previous analysis will be investigated in this study and adapted to perform the focusing task in the audio context. These methods will be presented in a unified formalism and compared numerically to highlight advantages and drawbacks of each method.

2 PROBLEM STATEMENT

Let S denote a plate-like structure of arbitrary shape and with arbitrary boundary conditions. Assuming that this structure lies in the (x, y) plane, the positions of the N piezoelectric actuators bonded on S are given by $\{(x_n, y_n)\}_{n \in [1, N]}$ and the out-of-plane displacement of the bending wave velocity field is denoted $u(x, y, t)$.

Figure 1: Arbitrary shaped-like structure with piezoelectric actuators and localized audio sources

The objective is now, for any input audio signal $a(t)$, to focus the bending wave field $u(x, y, t)$ to fit a given target shape $\phi(x, y)$ using the N actuators through N FIR filters $r_n(t)$ applied to the audio input. Mathematically, this means that we would like to achieve:

$$\forall t \ u(x, y, t) = \phi(x, y) a(t) \quad (1)$$

Or equivalently in the frequency domain, with $U(x, y, f)$ and $A(f)$ the Fourier transforms of the displacement and the audio signal respectively:

$$\forall f \ U(x, y, f) = \phi(x, y) A(f). \quad (2)$$

Assuming the system is globally linear, the contributions $u_n(x, y, t)$ of all the N actuators generating the field $u(x, y, t)$ sum up and can be written as:

$$\forall t \ u(x, y, t) = \sum_{n=1}^N u_n(x, y, t) = \sum_{n=1}^N h_n(x, y, t) * r_n(t) * a(t), \quad (3)$$

where “ $*$ ” stands for the convolution product and $h_n(x, y, t)$ is the spatiotemporal impulse response of the n^{th} actuator. Or equivalently in the frequency domain:

$$\forall f \ U(x, y, f) = \sum_{n=1}^N U_n(x, y, f) = \sum_{n=1}^N H_n(x, y, f) R_n(f) A(f). \quad (4)$$

By combining both expressions (2) and (4) of $U(x, y, f)$, the objective to achieve is then expressed in the frequency domain and independent of the audio input signal $a(t)$ as:

Find $\{R_n(f)\}_{n \in [1, N]}$ such that $\forall f, \phi(x, y) = \sum_{n=1}^N H_n(x, y, f) R_n(f)$.

(5)

This means that the spatiotemporal propagation operators $H_n(x, y, f)$ associated with the N actuators needs to be inverted to design the N FIR filters $R_n(f)$ able to focus the bending wave field on the target shape $\phi(x, y)$ whatever the frequency f .

3 BENDING WAVES FOCUSING METHODS UNIFIED THEORETICAL DESCRIPTION

In this section, several methods able to invert the spatiotemporal propagation operators $H_n(x, y, f)$ are presented. The methods differ depending on the available knowledge of wave propagation in the plate they rely on (theoretical, partial spatial and full spatial knowledge) and on the projection basis they use (modal basis and eigenvalue basis). They are all presented within a unified theoretical framework for comparison purpose.

3.1 Methods relying on a theoretical knowledge of $H_n(x, y, f)$

The first class of methods presented here assumes that a theoretical knowledge of wave propagation within the host structure is known. For bending wave, the out-of-plane displacement $u(x, y, t)$ of the host structure subject to the external point load $p(x, y, t)$ can be expressed as [33]:

$$D\nabla^4 u(x, y, t) + \rho h \ddot{u}(x, y, t) + c \dot{u}(x, y, t) = p(x, y, t) \quad \text{with} \quad D = \frac{Eh^3}{12(1-\nu^2)}. \quad (6)$$

In the above equations, E , ν , and ρ are the Young's modulus, Poisson's ratio, and density of the panel respectively. Additionally, c is the damping constant and h is the panel thickness.

Let $\theta_m(x, y)$ be the theoretical orthogonal modes associated with the structure under study which can be computed analytically or through FEM models. The displacement can be written as a decomposition in the mode shape basis:

$$u(x, y, t) = \sum_{m=1}^{\infty} u_m(t) \theta_m(x, y), \quad (7)$$

where the coefficients $u_m(t)$ denote the modal amplitudes. By reinjecting the displacement expression (7) in the movement equation (6), and by projecting the obtained equation on the M first modes, the orthogonality property allows to get the decoupled equation for each modal displacement $u_m(t)$:

$$\forall m \in [1, M], \quad \ddot{u}_m(t) + c \dot{u}_m(t) + (2\pi f_m)^2 u_m(t) = \frac{1}{S_m} p_m(x, y, t) \quad \text{with} \quad f_m = \frac{1}{2\pi} \sqrt{\frac{D}{\rho h}} k_m^2 \quad (8)$$

In the above equation, f_m is the eigen frequency corresponding to the m^{th} mode and k_m^2 the wave number depending on the geometry. Additionally, S_m is the projection term and $p_m(x, y, t)$ the modal force given by:

$$S_m = \iint_S \rho h \theta_m(x, y)^2 dx dy \quad \text{and} \quad p_m(x, y, t) = \iint_S p(x, y, t) \theta_m(x, y) dx dy. \quad (9)$$

We can then write in the frequency domain, and at the n^{th} actuator:

$$\forall m \in [1, M], \forall f, \quad U_{n,m}(f) = \frac{1}{S_m((2\pi f_m)^2 + (i2\pi f)c + (i2\pi f)^2)} P_{n,m}(x, y, f). \quad (10)$$

In case of piezoelectric actuation (where the area is denoted S_{PZT}), the modal force is given by :

$$P_{n,m}(x, y, f) = \left[\iint_{S_{PZT}} b_n(x, y) \theta_m(x, y) dx dy \right] R_n(f) A(f) = B_n R_n(f) A(f), \quad (11)$$

where $b_n(x, y)$ is a shape function characterizing the spatial distribution of each actuator.

Finally, by summing over all modes and actuators, one obtains:

$$\forall f, \quad U(x, y, f) = \sum_{n=1}^N \left[\sum_{m=1}^M \frac{B_n \theta_m(x, y)}{S_m((2\pi f_m)^2 + (i2\pi f)c + (i2\pi f)^2)} \right] R_n(f) A(f) = \sum_{n=1}^N H_n(x, y, f) R_n(f) A(f) \quad (12)$$

This constitutes a theoretical expression of the spatiotemporal bending wave propagation operator $H_n(x, y)$ that needs to be inverted.

Now, by decomposing the target $\phi(x, y)$ on the host structure mode shapes $\theta_m(x, y)$ as:

$$\phi(x, y) = \sum_m^M \phi_m \theta_m(x, y) \quad \text{with} \quad \phi_m = \iint_S \phi(x, y) \theta_m(x, y) dx dy. \quad (13)$$

We can write the following equation after projecting on each mode ϕ_m :

$$\forall f, \forall m \quad \phi_m = \sum_n^N \left[\frac{\iint_S B_n(x, y) \theta_m(x, y) dx dy}{S_m((2\pi f_m)^2 + (i2\pi f)c + (i2\pi f)^2)} \right] R_n(f). \quad (14)$$

with the number of modes M chosen equal to the number of actuators or superior (potential matrix conditioning problem during the inversion). Moreover, it can be shown [13] that such equation can be easily inverted and expressed in the discrete-time domain as follows:

$$R_n(z) = J_n + K_n z^{-1} + L_n z^{-2}. \quad (15)$$

Where J_n , K_n and L_n can be expressed using the modal parameters $(k_m, \theta_m(x_n, y_n))$ as well as the target shape parameters ϕ_m .

The method described above offers the advantage of not needing any prior experiments. Indeed, only the analytical knowledge of the model is needed. In addition, the computation cost is low because the FIR filter order is 3 and the method is not sensitive to noise, because no prior measures are done. Finally, the method allows to reproduce arbitrary target shapes. However, the advantages listed before are available only for very simple structures. Indeed, only simple structures as rectangular or circular plates with boundary conditions known analytically can be used. Additionally, for an audio purpose the frequency bandwidth is in general large and the number of modes to be addressed might be high. However, the theory assumes that the number of modes controlled is equal to or a bit higher than the number of actuators so that the matrix can be inverted, or pseudo-inverted and matrix conditioning issues can be avoided, but it will not be the case practically.

3.2 Methods relying on a partial spatial knowledge of $H_n(x, y, f)$

Let us now assume that a partial spatial knowledge of the propagation operator is available. More precisely, it is assumed here that the spatiotemporal operator is known for an excitation located at one spatial position (x_i, y_i) and measurements performed at actuator positions $\{(x_n, y_n)\}_{n \in [1, N]}$. Mathematically, what is known in the frequency domain is $\{\hat{H}(x_n, y_n, f)\}_{n \in [1: N]}$ such that:

$$\forall n \in [1, N] \quad \hat{H}(x_n, y_n, f) = \text{conj}[H_n(x_k, y_k, f)], \quad (16)$$

according to the spatial reciprocity principle [15]. Thus, by choosing:

$$R_n(f) = \text{conj}[\hat{H}(x_n, y_n, f)]. \quad (17)$$

One should be able to focus the bending waves in the neighborhood of the location (x_i, y_i) . Using previous notation, this means that the target shape to be reconstructed corresponds here to a Dirac function located at (x_i, y_i) , *i.e.*, $\phi(x, y) = \delta(x - x_i, y - y_i)$.

According to the theory, this method is based on the time invariance principle of partial derivative equations in a non-dispersive media. Moreover, this method is also based on the principle of spatial reciprocity of frequency response functions. Indeed, if a structure is excited at a point A and the wave measured at the point B, therefore the excitation at B and measurement at A gives the same response function. Those two invariances ensure the filter robustness. However, this method maximizes the amplitude at a point in the space, but it does not act on secondary lobes which are in general emphasized. One must extend the method to a wider target shape because for the moment there is no control of the width. Finally, the computation cost must be discussed. Theoretically, impulse responses must be measured between each focus point and actuator. Although it could cost many storage capacities. If the position of the focus area location is known, the number of initial measurements will be very low. The method may also be sensitive to the experimental noise.

3.3 Methods relying on a complete spatial knowledge of $H_n(x, y, f)$

Let us now assume that a complete spatial knowledge of the propagation operator is available. More precisely, it is assumed here that the spatiotemporal operator is known for any actuator $n \in [1, N]$ and that measurements are performed over a complete grid of K points on the structure for positions $\{(x_k, y_k)\}_{k \in [1, K]}$. Mathematically, what is known in the frequency domain is $\{H_n(x_k, y_k, f)\}_{n \in [1, N], k \in [1, K]}$.

The problem to be solved can then be rewritten on the measurement spatial grid as:

$$\phi(x_k, y_k) = \sum_{n=1}^N H_n(x_k, y_k, f) R_n(f). \quad (18)$$

Thus, in the matrix form:

$$\Phi = H(f)R(f). \quad (19)$$

The resulting matrix can first be directly pseudo-inversed in the frequency range of interest by keeping only large enough eigenvalues. This leads directly to the FIR filters $R_n(f)$:

$$R(f) = H(f)^+ \Phi, \quad (20)$$

where “+” denotes the pseudo-inversion operator.

It is important to note that the pseudo-inversion step is sensitive to noise. Hence, during the pseudo-inversion step, the lowest singular values are canceled to deal with those matrix conditioning issues. More details are available in [21].

This method offers several advantages in comparison with the others evoked previously. Firstly, the method is robust because it allows to acquire information about the wave propagation in the whole media. Additionally, the filters size is chosen by the user. Hence, the model takes into account the real structure and its complexity, with eventual losses, and the notion of modal density is not crucial. Finally, this method is very interesting for its ease of implementation. Nevertheless, the points evoked above are also sources of drawbacks. Indeed, it is necessary to realize several experiments between all the points of the structure and the actuators, this complicates numerically the method. Moreover, the model is sensitive to the noise, mainly during the pseudo-inversion step. Thus, it will need a regularization step which is numerically heavy.

4 NUMERICAL STUDY OF THE INVESTIGATED FOCUSING METHODS

4.1 Structures under study

In order to test the previous methods and to compare their performances, a simple and a ribbed clamped polypropylene plate are chosen, a material often used for car passenger garnishments. The dimensions of the plate are given in Figure 2a. Besides, ribs which length of 1 cm and thickness of 3 mm are added to approach as much as possible the surfaces used in the automotive industry. Indeed, the ribs are stiffening the plate, shifting the eigenmodes to higher frequencies and introducing localized modes around the ribs. The goal is to see which method deals best with this configuration.

The material used is polypropylene, with a Young modulus of $E = 1.1\text{GPa}$, a Poisson's ratio of $\nu = 0.33$ and a density of $\rho = 990\text{ Kg/m}^3$. Mode shapes of the structures with piezoelectric actuators glued on it are computed thanks to a finite element model implemented on the software SDT [25] and an experimental modal analysis was performed jointly to identify modal dampings, available in Table 1. The plate is modeled with shell elements. The control algorithms are developed and implemented in Matlab with SDT jointly. The meshes are available Figure 2b and Figure 2c.

Figure 2: (a) Dimensions of the plate and (b) meshes of the studied plate and (c) ribbed plate.

The target shape consists of a rectangle measuring $(0, 15L_x; 0, 2L_y)$ and centered at $(0, 3L_x; 0, 55L_y)$. Moreover, the audio signal to be reconstructed is a sweep sine with a duration of 2 seconds, from 100 Hz to 800 Hz, sampled at 40 kHz. The chosen frequencies allow to excite the 6 first modes. In addition, a set of "NCE51" piezoelectric actuators developed by Noliac are used, with a diameter of 25 mm and a thickness of 1 mm. Indeed, there are 6 used for the simple plate and 9 between each rib for the second structure, placed quasi randomly, and equally spaced along y . One should notice that the number of actuators and their disposition change the final results. Here, an example with few actuators is studied, because in the real applications as in automotive industry, only a small number of actuators can be embedded for reasons of compactness.

Table 1: First eigen frequencies and damping coefficients of the plate

Index	Eigen frequency (Hz)	Damping (%)
Mode (1,1)	120	3,35
Mode (2,1)	212	2,19
Mode (1,2)	277	3,5
Mode (2,2)	350	4,59
Mode (3,1)	360	1,59
Mode (3,2)	476	2,25

4.2 Indicators for the parametric study

Let $u(x, y, t)$ be the out-of-plane displacement of the plate and $U(x, y, f)$ its Fourier transform. Two criterions will be used and described below:

Localization error: given a reconstructed target shape, the first criterion is the measurement between the center of the target shape and the maximum amplitude of the reconstructed shape. Thus, the lower the distance is, the more the shape is localized precisely from a spatial point of view.

Spatial contrast: the second criterion is the computation of the contrast between the energy in the reconstructed area (S_R) and energy of the total area ($S_T = L_x \times L_y$), so that:

$$C(f) = \frac{\int_{S_R} |U(x, y, f)|^2 dS}{\int_{S_T} |U(x, y, f)|^2 dS}. \quad (21)$$

If $C(f) = 1$, then all the energy is present in the target shape and nothing outside, and if $C(f) = 0$, then all the energy is outside the target shape.

5 NUMERICAL RESULTS

5.1 Results localization on a simple structure

The three methods described previously are applied numerically, and compared to a case where no control is imposed, with only the nearest actuator to the target shape actuated.

The spot error and the contrast in the frequency band [100 Hz;800 Hz] for each method are plotted in Figure 3. Firstly, we can observe that the STIF method allows to achieve a very high localization performance, in comparison with others. Indeed, it shows a very low spot error, which is around 12% of the total length in the [100 Hz;210 Hz] region, and lower than 10% above 210 Hz approximately until 540 Hz (Figure 3a). It is important to notice that this frequency corresponds to the limit where the modal density (number of modes/Hz) is very high. Thus, above this frequency the plate could not be described with a modal behavior anymore [7]. Moreover, the contrast drops drastically at modal frequencies, with a peak of the error at 208 Hz and a small around 360 Hz (Figure 3b). It corresponds to the eigenmodes which influences the target shape pattern. Therefore, the STIF method can achieve a precise localization from 100 Hz to 540 Hz, after the algorithm does not focus vibrations anymore. It is interesting to notice that there is the same behavior around 120 Hz and 208 Hz for the MC and for the case without control, also influenced by eigenmodes. Besides, according to the spot error and contrast curves, the MC method can only focus on a narrow bandwidth between 100 Hz and 350 Hz. The time reversal (TR) also operates in a narrow band, around 130 Hz to 300 Hz approximately, with a high influence of the first mode shape. Finally, it is also interesting to note that without any control strategy, the plate localizes vibrations around the actuator even at low frequency, given the material and properties of this example (high damping particularly).

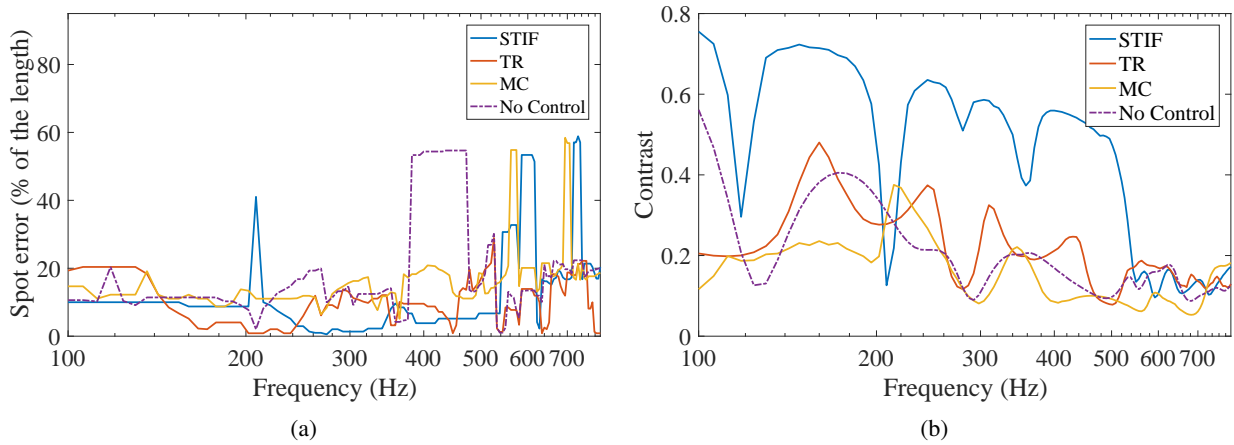

Figure 3: (a) Spot error and (b) contrast for the simple plate.

The results of localization obtained at the frequency band of interest are plotted in Figure 4. Thus, the normalized mean quadratic displacement amplitude of bending waves in the frequency range of interest, defined by:

$$\langle |U(x,y)|^2 \rangle = \frac{1}{f_{max} - f_{min}} \int_{f_{min}}^{f_{max}} |U(x,y,f)|^2 df, \quad (22)$$

is plotted. The MC induces several analytical steps to focus the target shape. However, the Figure 4c shows that it localizes very poorly the bending waves with this actuators configuration. Indeed, the

method is very sensitive to the mode shapes of the structure, and the deformation mode of the PZT. On the other side, the STIF is based on the learning of the propagation operators between each observation point and actuator. Hence, this method is easier to implement than the MC but requires much more computation time. This means that the STIF allows to focus far better bending waves in the frequency band of interest, as shown in Figure 4a. In contrast, the TR based on a partial knowledge requires less computation time than the STIF, but in this case is less performing and gives poorer localization precision (Figure 4b). Indeed, the TR needs to be used in a high reverberating media to catch the whole dynamics, here the plate is very damped. Finally, when there is no control, the energy stays around the actuator due to the high damping ratio (Figure 4d). It is very important to point out that the results depend on the number of actuators. With more actuators, the STIF can localize more effectively. This parameter must be taken into account to obtain the best compromise.

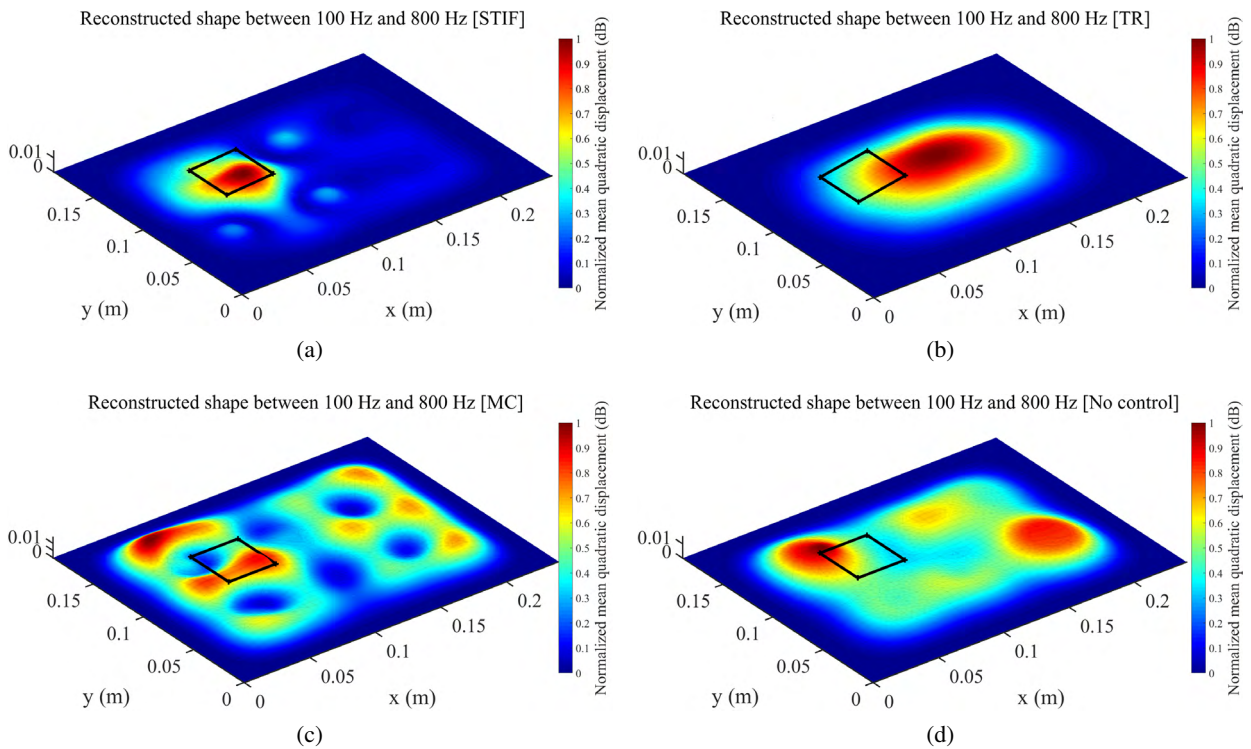

Figure 4: Reconstructed shapes with (a) STIF, (b) TR, (c) MC and (d) without control.

5.2 Results localization on a structure with ribs

The studied structure is now the plate as introduced above with ribs fixed on it. The main idea is to see which method will still work on a more complex structure. Moreover, the modal frequencies are higher than before, from 154 Hz to 590 Hz, and the modal amplitudes are localized between ribs.

The Figure 5 shows the spot error and the contrast. On the frequency band between 100 Hz and 800 Hz, the STIF localizes the energy on the target area, compared to the simple case with 6 actuators (Figure 6a). Additionally, the contrast drops at frequencies where modes appear. However, the higher values of the error between 270 and 380 Hz correspond to high amplitude vibrations on actuators around the target area but the shape is still reproduced with high contrast. In addition, the TR can focus the

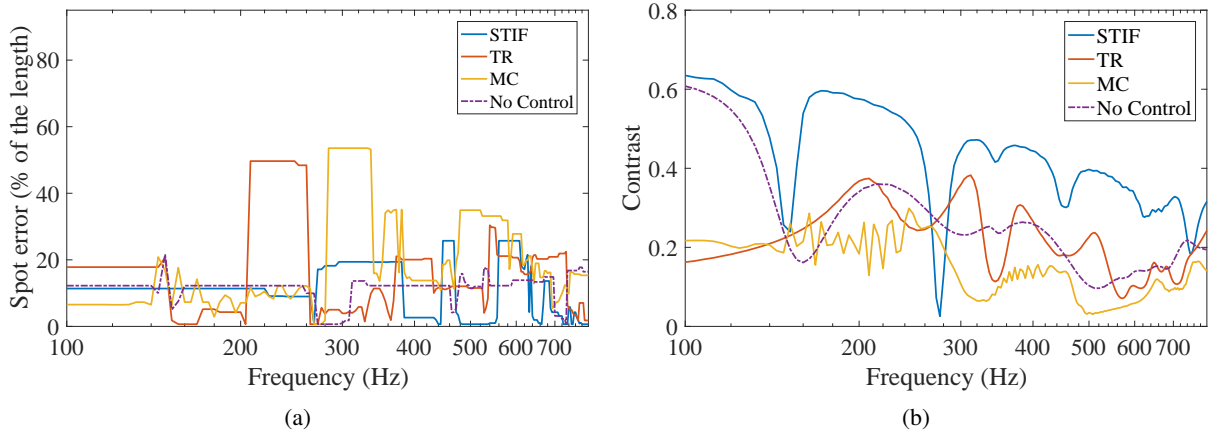

Figure 5: (a) Spot error and (b) contrast for the plate with ribs.

waves in the frequency band (Figure 6b), but it does not maintain the target shape for each frequency. Similarly, the MC localizes the energy alternatively next to the target shape and between ribs (Figure 6c), but does not work well since the mode shapes are not conventional flexural modes but a mixture of global and local modes. Finally, without control strategy, the energy is also confined between the ribs near the target shape and shows better precision than MC and TR (Figure 6d). The initial learning of the dynamic behavior allows to have better focusing precision by considering the local modes in the dynamics, in a wider frequency band. When the number of actuators is higher, it increases the localization capabilities.

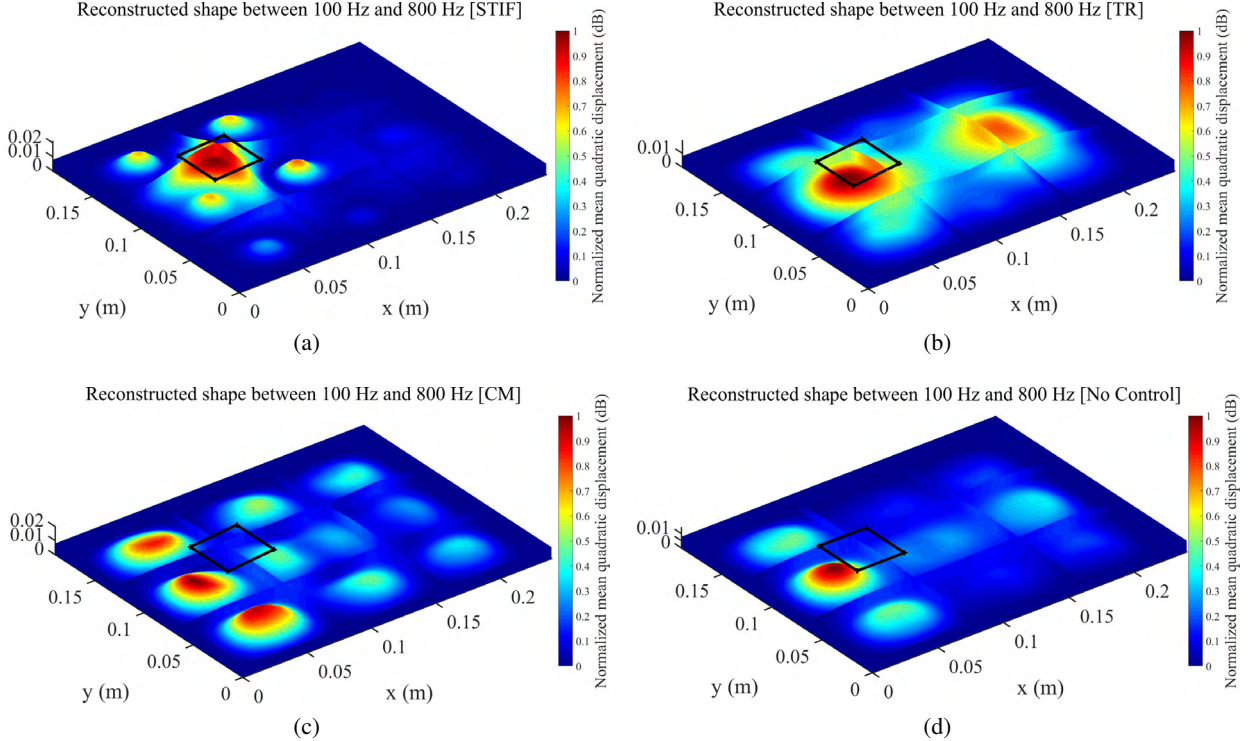

Figure 6: Reconstructed shapes with (a) STIF, (b) TR, (c) MC and (d) without control.

6 CONCLUSION

To conclude, three focusing wave methods were tested and adapted for bending wave in the case of sound reproduction. Within the context of automotive industry and spatial sound rendering, it is obvious that the spatio-temporal inverse filtering method is easier to implement and gives better results compared to others, even on a complexe structure. Indeed, the filters are computed without prior knowledge about boundaries or theoretical dynamic behavior. However, the computation cost is higher, because the structure dynamic must be learned before. Above a certain frequency where the methods focus poorly, only exciting the actuator located near the target shape would be enough. Mainly for higly damped structures and at high frequencies. Finally, several parameters as the number of actuators and the boundary conditions have been studied but not presented here, influence the localization results, and must be taken into account, regardless of the complexity of the structure.

Abstract. In the field of haptic, some researches focus on localized stimulations on screens. To that end, a velocity field is generated, where high velocities are produced within a chosen region at a given time. Time reversal or phased array have been studied on screens equipped with piezoelectric ceramics. However, these solutions can lack robustness or sharpness.

Closed loop (CL) control of the mode transients may address these issues. Therefore, we propose to use the modal basis to reproduce a specified velocity field with a predefined transient. In this paper, a preliminary proof of concept toward CL is presented. We propose a methodology to select the modes and practically synthesize the voltages to achieve an open-loop controlled focusing in a prescribed time. The experimental results show the versatility of the method and a good agreement with the theory. Both realization of the field distribution and localization are observed. Moreover, preliminary haptic tests shows a consistent detection thresholds for a simulated button click despite the open loop conditions.

1 INTRODUCTION

Tactile displays are now ubiquitous, e.g smartphones or tablets, but they also have a great potential to realize virtual control panel for such machine tools or automotive applications. At the moment though, the main feedback channel toward the user is visual, which can be incompatible with secure operations. So far, tactile or auditive feedback are crude, although it is commonly admitted and demonstrated that multiple sensory channels can enhance task performances and usability [1, 2]. Hence, part of the researches aim at reducing the cognitive overload induced by visual confirmation during human machine interaction by stimulating the fingertip [3].

For that purpose, elastic waves are interesting in the sense that they propagate, and thus, the actuators may not be colocated to the active region, which is an obvious constraint in the case of a screen. Moreover, if the actuators are glued piezoelectric patches, the modification to the whole design is minimal thanks to good factor form. Some applications already exploit standing or traveling waves to modulate friction on a screen [4, 5, 6], in such examples, the whole surface is active. In the case where localized stimuli are required, such as in virtual button or switches, several approaches using wave focusing have been proposed such as phased array [7, 8] or time-reversal[9, 10]. In these techniques however, the focus

pattern and its transient are not controlled, moreover external parameters can mitigate the effects [11]. In this paper, a truncated modal decomposition is used to design a specified velocity field. By defining, high low speed regions, an approached focusing is obtained which has been proven to generate stimuli [12]. First, we present the method to specify the time evolution to specify a given velocity field. The second part, voltages are optimized to avoid saturation of the power supply. In the third part, we demonstrate experimentally the validity and present evidences that a "click" effect can be produced. Finally, the last section is devoted to conclusion.

2 PRINCIPLES

2.1 Projection

The general set-up consists in an elastic media, on which piezoelectric patches are glued. Considering that low deformation are used, the approach relies on the well-known results of linear elasticity. In particular, noting T_{ij} the stress tensor components and \mathbf{u} the displacement vector, it is well known that the elastic vibration problem of an elastic body occupying volume Ω at rest given by [13]:

$$T_{ij,j} = \rho \ddot{u}_i \quad (1)$$

with specified kinematic conditions on some portions Γ_k on the boundary:

$$\mathbf{u} = 0 \quad (2)$$

and no load applied defines a Sturm-Liouville problem. Therefore it admits an infinity of so-called eigenfrequencies ω_k , each corresponding to a mode shape (the degenerate cases are not considered here). Denoting the later $\bar{\Phi}_k$ after mass normalization (the index $k \in \mathbb{N}^*$ denotes the k^{th} solution), the main result used here is the orthogonality of the modes, and the decomposition theorem [14] which states that any arbitrary shape that fulfils the kinematic constraints (2) can be given by the following infinite time varying linear combination:

$$\mathbf{u}(\mathbf{x}, t) = \sum_{k=1}^{\infty} \bar{\Phi}_k(\mathbf{x}) \eta_k(t) \quad (3)$$

This equation implies that the modal shapes $\bar{\Phi}_k$ form a basis. The $\eta_k(t)$ are referred to modal coordinates in the sequel, and the method described here aims at defining their evolution as a function of time. More precisely, we are interested in reaching a specified configuration at a given time t_f , that is:

$$\mathbf{u}(t_f) = \mathbf{u}^* \quad (4)$$

Since the modes shapes are orthogonal and normalized, they satisfy:

$$\int \rho \bar{\Phi}_j \cdot \bar{\Phi}_k d\Omega = \delta_{jk} \quad (5)$$

where δ_{jk} is the kronecker symbol. Hence, combining (3) and (5) one can obtain the modal coordinates of the target shape using the inner product:

$$\eta_k^* = \int_{\Omega} \rho \bar{\Phi}_k \mathbf{u}^* d\Omega \quad (6)$$

2.2 Time evolution and modal forces

In the case of a mechanical loading $\mathbf{p}(\mathbf{x}, t)$ on a subset of the boundary Γ_p , projecting the equation (1) on the modal basis results in eliminating the spatial dependence of the equation and the problem is transformed into an infinite set of dynamic ordinary differential equation of the second order [13]:

$$\ddot{\eta}_k + \omega_k^2 \eta_k = \psi_k(t) \quad (7)$$

with

$$\psi_k(t) = \int_{\Gamma_p} \mathbf{p}(\mathbf{x}, t) \cdot \bar{\boldsymbol{\Phi}}_k(\mathbf{x}) d\Gamma \quad (8)$$

the modal forces.

The deformed configuration being known, it remains to specify the time evolution of the modal coordinates. Since the objective is to simulate a "click", in other word, a fast transient leading from rest configuration to the specified one must be realized to suggest the behavior of a pressed button. It should be noted though that the objective here is not a realistic rendering. It is rather a metaphor that the user can accept as a mechanical confirmation at the tip of his finger when interacting via an interface (the tactile screen). It has been observed in previous works [12] that the velocity is more relevant for that purpose. So the choice here is to impose $\dot{\eta}_k(t)$. Since $\dot{\mathbf{u}} = \sum_{k=1}^{\infty} \bar{\boldsymbol{\Phi}}_k(\mathbf{x}) \dot{\eta}_k(t)$, the procedure discussed above remains valid.

Considering the eq. (7), and modifying to take into account the modal damping ξ_k , one gets:

$$\ddot{\eta}_k + 2\xi_k \omega_k \dot{\eta}_k + \omega_k^2 \eta_k = \psi_k(t) \quad (9)$$

Taking the Laplace transform of the equation:

$$\frac{(s + a_k)^2 + b_k^2}{s} \mathcal{L}[\dot{\eta}_k](s) = \mathcal{L}[\psi_k](s) \quad (10)$$

with $a_k = \xi_k \omega_k$ and $b_k = \sqrt{1 - \xi_k^2} \omega_k$. The core idea is to compute by "inverse filtering" in the modal basis by specifying $\mathcal{L}[\dot{\eta}_k](s)$. To compute a causal modal force, attention must be paid when specifying the modal velocities, namely $\deg \mathcal{D}(s) \geq \deg \mathcal{N}(s)$ where $\mathcal{D}(s)$ and $\mathcal{N}(s)$ denote respectively the denominator and numerator appearing on the left hand side of the previous equation. In this work, the modal velocity are defined as a modulated envelop, at the mode frequency ω_k :

$$\dot{\eta}_k(t) = f_k(t) \sin(\omega_k t) \quad (11)$$

The consideration behind this choice is that the energy supplied to the system is minimized since it is at resonance. By setting, for instance:

$$f_k(t) = A_k e^{\gamma_k a_k t}$$

where γ_k is a scaling factor introduced to tune the growth of the mode, and A_k , the amplitude, will be used later to realize the initial condition.

Using the Laplace transform, one can write:

$$\frac{(s + a_k)^2 + b_k^2}{s} \mathcal{L}[f_k(t) \sin(b_k t)] = \mathcal{L}[\psi_k(t)]$$

yielding:

$$\mathcal{L}[\psi_k(t)] = A_k \frac{(s + a_k)^2 + b_k^2}{(s - \gamma_k a_k)^2 + b_k^2}$$

So the modal force is:

$$\psi_k(t) = \Psi_k e^{a_k \xi_k \omega_k t} [C_k \sin(b_k t) + D_k \cos(b_k t)] + E_k \quad (12)$$

with :

$$\begin{aligned} \Psi_k &= A_k \frac{a_k (\gamma_k + 1)}{a_k^2 \gamma_k^2 + b_k^2} \\ C_k &= (a_k^2 \gamma_k (\gamma_k + 1) + 2b_k^2) \\ D_k &= a_k b_k (\gamma_k - 1) \\ E_k &= b_k \frac{a_k^2 + b_k^2}{a_k^2 \gamma_k^2 + b_k^2} \end{aligned}$$

To compute the various constants above, we finally set the transient duration. Defining $\Delta t_k = t_f - t_k$ where t_k is the time when the excitation for a given mode is started, we set $\omega_k \Delta t_k = \frac{\pi}{2} + 2\pi N_k$. This condition ensure that a focusing time t_f , all the modal forces are synchronized at their maximum. A_k is such that:

$$\dot{\eta}_k^* = A_k e^{\gamma_k \xi_k \omega_k \Delta t_k}$$

Similarly, the differential equation could also be directly used for more general envelop.

2.3 Practical considerations

The actual device is supposed to be an elastic structure with several piezoelectric patches glued on its surface. In such case, the modal forces are actually the superimposition of the contribution of each patch. Each contribution is proportional to the voltage applied to the ceramic considered. Hence, supposing that the devices features n_p patches, the modal force corresponding the k^{th} is given by:

$$\psi_k = \sum_{i=1}^{n_p} \alpha_{ik} U_i \quad (13)$$

The coefficient α_{ik} depend on the geometry and the material properties of the considered patch i but also on its location relatively to the mode shape k [15, 16]. It is thus theoretically possible to choose the various parameters to have a decoupling such that one voltage controls directly one mode. In practice however, it is a difficult task given the standard dimensions of patches available. So, the approach here is to take advantage of all the voltages. To do so, the voltages U_i are rewritten as a linear combination of the modal forces calculated by eq. 12, and assuming that n_m are used to realize a given vector field:

$$U_i(t) = \sum_{k=1}^{n_m} m_{ik} \psi_k(t)$$

where the weights m_{nk} are used to allocate the desired modal force among the ceramics. Thus, the modal dynamic equation is now:

$$\ddot{\eta}_k + \omega_k^2 \eta_k = \sum_{i=1}^{n_p} \alpha_{ki} \left(\sum_{k=1}^{n_m} m_{ik} \psi_k(t) \right) \quad (14)$$

Assuming that the modes can be excited separately owing to the frequency selectivity, we require the conditions:

$$\sum_{i=1}^{N_b} \alpha_{ki} m_{ik} = 1 \text{ for } k = \{1, \dots, n_m\} \quad (15)$$

to ensure that the necessary modal force is indeed applied. Then, the weight can be tuned to reduce the voltages U_i actually applied to the ceramics by stating the following optimization problem:

$$\begin{aligned}
 & \underset{m_{ik}}{\text{minimize}} && \| \mathbf{M} \boldsymbol{\Psi} \| \\
 & \text{subject to} && |U_i| \leq U_{\max}, i = 1, \dots, n_p. \\
 & \text{and to} && \sum_{i=1}^{n_p} \alpha_{ki} m_{ik} = 1 \text{ for } k = \{1, \dots, n_m\}
 \end{aligned} \tag{16}$$

where \mathbf{M} is the matrix of the weights (which coefficients are the m_{ik} , $\dim(\mathbf{M}) = n_p \times n_m$). $\boldsymbol{\Psi}$ is a matrix which k -th row vector is constituted by ordered samples of the modal forces $\psi_k(nT_s + t_0)$. The number of samples N_s and the sampling should be chosen such that $N_s T_s + t_0 = t_f$, and to cover a time interval where the modal forces ψ_k become large with respect to the voltages rating. In this work, the Frobenius norm was used.

3 EXPERIMENTAL RESULTS

3.1 Experimental set-up

Figure 1: Picture of the experiment: **A)** Staple shaped aluminum beam, the velocity is controlled within a rectangular region on the upper part; **B)** Fixture of the beam to realize clamp-clamp boundary conditions; **C)** Mirror showing the ceramics; **D)** Reflection revealing some of the ceramics fixed beneath the beam. The second ceramic from the left is split as explained in the text; **E)** Electrical connections of transducers allowing the reconfiguration according to the set of ceramics used; **F)** Laser spot positioned at one of the corner of the studied region.

The demonstrator is a clamped staple-shaped aluminium beam equipped with piezoelectric patches Noliac NC51 with dimensions $(9 \times 5 \times 0.5) \text{ mm}^3$ as visible on the picture in fig. 1. This peculiar shape was chosen because i) it reduces the surface to be scanned hence the velocities cartography are considerably faster to realize; ii) it demonstrates that the method is usable even if actual solutions to the eigen problem are not known. As discussed above, the ability of a voltage U_i to excite the k -th mode depends on the α_{ik} coefficient eq (13) which depends on the geometry and location of the patches. To avoid to use several ceramics geometries, the electrodes were actually splitted (e.g second ceramic from the left).

By properly choosing these cuts, it is possible to evenly excite the modes.

The identification was realized using a white noise identification procedure. The surface of the staple is scanned by fixing the set-up on a x-y positioning table and measuring the velocities thanks to laser vibrometer (OFV 505 Polytec). The velocity vs input voltage frequency response function was recorded at points defined on a regular grid on the upper part of the beam. The mapped region was defined between the limits of the curved parts, with a step small enough with regard to the smallest spatial wavelength. During the process the end ceramics were used in conjunction (same voltages) or in opposition (opposite voltages), to excite the even and odd modes respectively, because they are able to excite all the bending modes in the 100 Hz-80 kHz band. During these measurements, the other ceramics are in short-circuit conditions. Modes were selected using the resonance peaks. Knowing the phase and amplitude at resonant frequencies at each measured point, the mode shapes were reconstructed. When the signal to noise ratio was too low, the mode shapes were more precisely mapped at resonance choosing ceramics with more effective participation coefficients.

The orthogonality of the measured modes, however, is only approximatively verified because the scanning cannot cover the whole structure, but only a rectangular area on the top. Indeed, finite element simulation shows that for low frequency modes (having large wavelength) the corners of the staple where acting as clamps, i.e. the modes are located on the top of the staple only. As the frequency increases, modes progressively tend to occupy the whole staple. To address this problem, the modes are re-orthogonalized using a Gram-Schmidt procedure to construct a truncated basis. The time synthesis of the voltages discussed previously requires a fair knowledge of the damping of a mode, which was done by measuring the -3 dB bandwidth. It was verified that the quality factor were high enough to validity the frequency selectivity of modes assumption. Finally, the participation coefficients were estimated from the measurement of the velocity at resonance obtained when supplying each ceramic individually (the other being short-circuited).

3.2 Validation of the voltages assignement

First, the effectiveness of the methodology to assign the voltages and excite the mode independently is illustrated. As explained, the voltages deduced from the prescribed modal forces given by eq. (12) can be "mixed" between the patches using a linear combination (15). Here, the scenario examined is to control modes 1 and 3 (with resonant frequencies $f = 364$, and 2240 Hz) simultaneously, and reach at a prescribed focusing time velocities of 20 mm s^{-1} for the modes φ_1 and φ_3 at the center of the experimental set-up (i.e a total velocity of 40 mm s^{-1} at focusing time). Moreover, a speed up of $\gamma_1 = 4$ and $\gamma_3 = 1$ over the natural decaying speed of modes φ_1 and φ_3 is imposed. Finally, φ_1 and φ_3 should achieve the focusing within $N_1 = 10$ and $N_3 = 25$ oscillations respectively. For the purpose of the demonstration, two set of patches were selected. The first one (denoted set 1 in the sequel) has a strong effect on φ_1 , but a very weak effect on the second, while the second set is more balanced with a prominent effect on φ_3 . This results in the voltages depicted in fig. 2 (bottom).

To assess the effect of "mixing" the voltages, a second run consisted in applying the optimisation procedure in order to conceal the voltages amplitude below 50 V as long as possible during the transient. The resulting voltages (named case 2), depicted in fig. 2 (middle graph), are indeed respecting the constraint as far as possible. Due to the poor ability of patch 1 to energize the second mode, the optimization procedure favors the use of the second patch to reduce the voltage amplitudes. This is clearly visible on the spectra of fig. 3. This figure also confirms that the bandwidth of the excitation signal is well controlled since the second, 4th and 5th modes (at $f = 963$, 3907 and 5719 Hz) are not excited. The transients are still very similar as expected, and the velocity at focusing time is still realized.

Figure 2: Validation of the voltages allocation strategy: (a) velocity measurement with "one mode one patch" strategy (case 1 black) and mixed voltages between patches (case 2 dark grey). The corresponding voltages applied to the patches set are depicted in the case 1 (b) and case 2 (c).

Figure 3: Spectra of the voltages and velocity at the center for case 2: since set 1 of ceramics is poorly coupled to the 3rd mode, the optimization requires that the set 2 is used also to excite mode 1, hence reducing the voltages as shown in fig. 2

3.3 Velocity field control

The main experiments presented here aimed at testing the viability of the approach to reproduce a specified shape on the top of the "staple". As an illustration, the velocity map for the out of plane component of the velocity is defined as follows:

$$\dot{w}(t_f) = \begin{cases} A \exp\left(-\frac{1}{1-\left(\frac{x-x_c}{a}\right)^2}\right) & \text{if } x \in (-a+x_c, a+x_c) \\ 0 & \text{otherwise} \end{cases} \quad (17)$$

known as the bump function and where A is a scaling factor, x_c the center coordinate, and a controls the width. This function has interesting continuity properties and its Fourier transform is rapidly decaying [17]. Intuitively, there exists an analogy between the Fourier transform and the modal projection, hence a limited number modes is expected. The reference field is windowed with a Kaiser window having a sharp transition to ensure a nil value at the boundary as required by the kinematic constraints at the end of the beam.

For practical reason, the modal projection must be truncated. To select the modes, a criterion is defined. Considering that twice the kinetic energy is given by:

$$\mathcal{K} = \int_{\Omega} \rho \dot{\mathbf{u}} \cdot \dot{\mathbf{u}} d\Omega = \int_{\Omega} \rho \bar{\Phi}^T \bar{\Phi} d\Omega \dot{\eta}_k^2 = \sum_{k=1}^{\infty} \dot{\eta}_k^2 \quad (18)$$

one can define the τ -score criterion for a truncation order N_m :

$$\tau = \left(1 - \sum_{k=1}^{N_m} \frac{\dot{\eta}_k^2}{\mathcal{K}^2}\right)^{\frac{1}{2}} \quad (19)$$

where \mathcal{K} can be determined directly from the specified velocity field \dot{w} . The τ -score is thus a measure of the residue resulting from the truncation.

For each test, the velocity field was measured, projected on the modal basis and compared to the specified modal coordinates resulting from the truncation. The criterion \mathfrak{v} -score, used to assess the "misalignment" of the obtained shape compared to the specified one, is defined as:

$$\mathfrak{v} = \frac{\text{cov}[\dot{\mathbf{w}}^*(x_m), \dot{\mathbf{w}}(x_m, t_f)]}{\sqrt{\text{var}[\dot{\mathbf{w}}^*(x_m)] \times \text{var}[\dot{\mathbf{w}}(x_m, t_f)]}} \quad (20)$$

where var and cov are the variance and the covariance respectively, x_m are the location where the velocities are sampled. $\dot{\mathbf{w}}^*$ and $\dot{\mathbf{w}}$ are considered as vectors of reference and measurement of the out of plane component in this case. The criterion is chosen to evaluate the discrepancies between the truncated modal projection and the experimental modal projection, regardless of the error on the amplitude which can be due to some miscalibration. In this way, one can appreciate whether the obtained shape is similar to the (truncated) reference up to a scaling factor.

Five different focusing locations, equidistantly distributed on the beam, were tested at $x_c = -46, -24, 0, 24$ and 46 mm of the high velocity zone (25 mm of width at mid-height of the active area) are presented in fig. 4. For each test, the specified, the approached and the measured velocities at focusing time along the center line in the y direction are presented (left column). The approached reference velocity field results from the truncation of the actual modal decomposition. The τ -score, which dictates the choice for the truncation, and the \mathfrak{v} scores, which validate the experimental focused velocity field, are summed up in Tab. 1. The results demonstrate the validity of method. Note that the poorer τ -scores on the outermost points are due to the trade-off on the number of modes used in the truncation.

Pulse center	P_1	P_2	P_3	P_4	P_5
τ -score	0.8285	0.9727	0.9544	0.9816	0.8717
\mathfrak{v} -score	0.9877	0.9953	0.9911	0.9609	0.9973

Table 1: Effect of the truncation (τ -score) and synthesis accuracy (\mathfrak{v} -score) for the various location studied.

3.4 Haptic evaluation

To mimic a "click, the previous set-up is fixed to a force sensor that measure the force applied in the vertical direction. The hypothesis tested in this experiment is that the user can be lured by triggering the focus at a consistent level of pressure. By doing so, it is expected that an unconscious association with the real-life experience "pressure implies movement of the button" can be suggested.

Data were collected from 15 healthy volunteers aged between 22 and 62 (4 females). Participants were wearing noise-cancelling headphones in order to prevent potential interference from auditory cues. All participants gave written informed consent. The investigation conformed to the principles of the Declaration of Helsinki and experiments were performed in accordance with relevant guidelines and regulations. The purpose of this experiment was 1) to assess the proposed idea 2) to evaluate the detection threshold. To do so, the participants were first asked to answer "yes" or "no" to the question "Do you feel a click when pressing on the surface of the device?" when they pressed at the center of the beam. As a preliminary tuning, different levels of the velocity field between 0 mm s^{-1} up to 240 mm s^{-1} using a dichotomy. The procedure was repeated 4 times to ensure the consistency of the results, and then confirmed by a one-down two-up procedure. In all cases, the threshold for each participant could be confirmed within 10 %. Based on these preliminary test, a set of samples was generated and presented randomly. During a test, 6 levels around the participant anticipated threshold were tested, as well as the extreme values, each level appearing five times. The test was repeated three times for a participant.

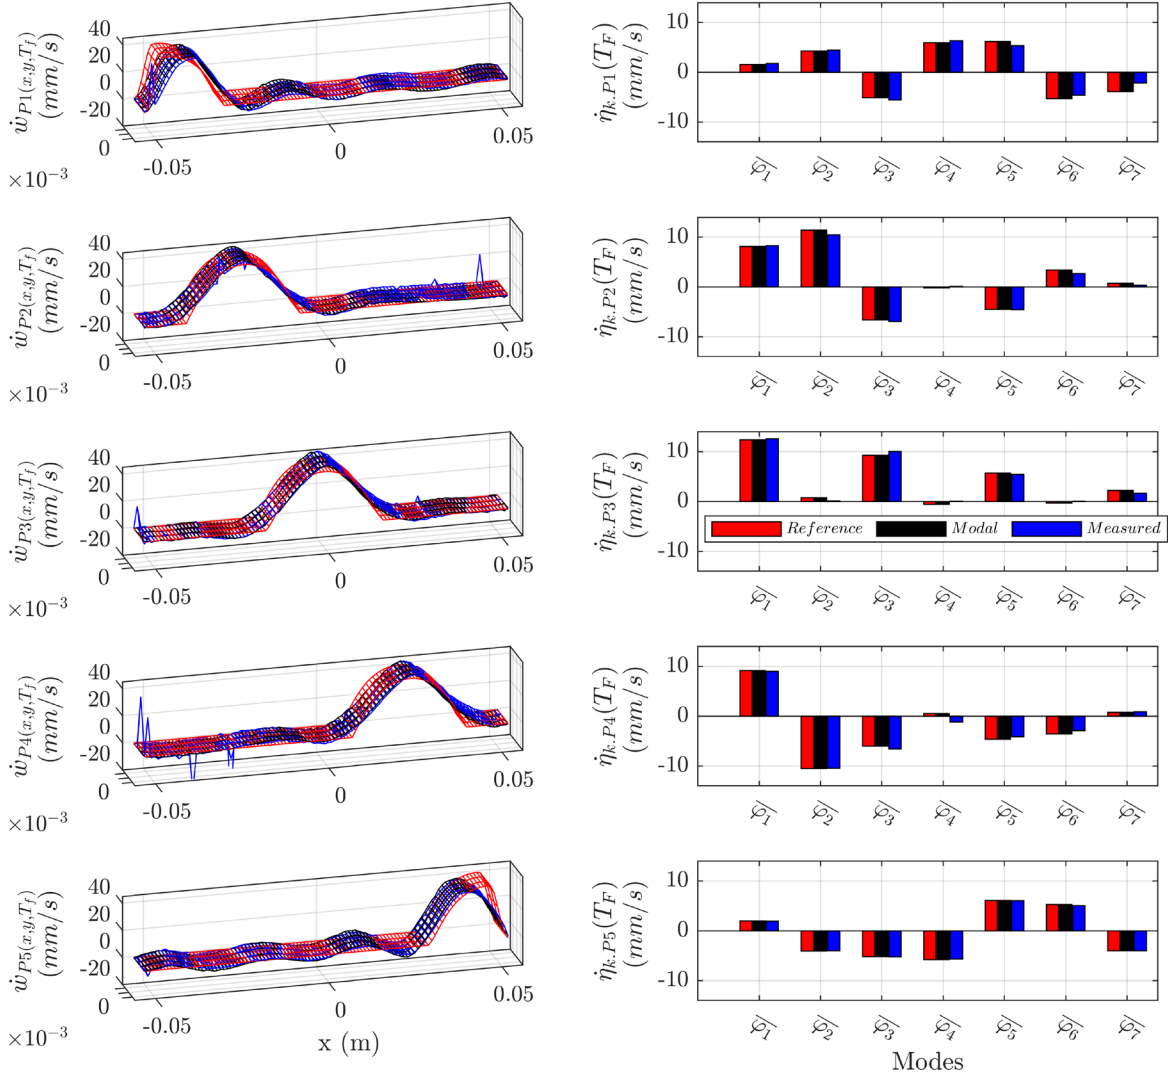

Figure 4: Test results of approximated bump velocity profiles at location points -46 , -24 , 0 , 24 and 46 mm, on the left velocity fields for the references, the approached ones and the measured velocities (resp. red, black and blue) and their respective modal projection (right). The truncation includes 7 modes, based on the distortion criteria.

For each level tested, the probability of detection is estimated supposing a binomial law. Then, a log normal cumulative probability density was fitted between the previously obtained probabilities to yield a "per-level" detection probability. The result of the procedure is depicted on the graph of fig 5 for seven of the participant (for clarity). The detection threshold is clear for every participant and generally lying between 10 mm s^{-1} and 50 mm s^{-1} . Only one outlier had a threshold of 140 mm s^{-1} . It should also be noted that all the participant were able to detect the "click".

Figure 5: Estimation of the 50 % probability detection threshold.

4 CONCLUSIONS

A methodology to realize a reference velocity field in an elastic equipped with piezoelectric patches has been presented. Unlike previous methods, such as time reversal, the velocity field can be arbitrarily defined as long as it verifies the kinematic conditions. Since the study was in open loop, the voltages are computed, and an optimization procedure has been proposed to mix the voltages among the patches in order to respect the technological limitation (saturation).

Experimental were verified against newly defined criteria and the effectiveness of the methodology has been verified both for the ability to synthesize a given velocity field and to efficiently distribute the voltages.

Finally, a preliminary study to assess the "click" haptic rendering has showed that most participant do have a clear detection threshold within a consistent velocity interval. This latest result is surprising and promising since closed loop should improve repetability by mitigating the perturbation introduced by the participants finger.

Abstract. This paper describes the comparison of three different types of piezoelectric actuators for application in sound emitting panels so-called load-bearing surface loudspeaker. The first actuator is a piezoelectric ring glued directly to a polypropylene surface of dimension 300 x 200 x 3 mm³. The other two are mechanically amplified piezoelectric actuators of the flat and the cymbal flextensional-type tested in a reactive configuration on the same sized polypropylene panel. Those actuators are compared in terms of vibration response measured with a laser vibrometer and audio response measured with a microphone.

1 INTRODUCTION

In the foreseeable future, the adoption of multifunctional car structure (MCS) will offer the potential to radically upgrade the abilities of vehicles in terms of ecological requirements emerging from the social and legal environment. Integrating car structures with functional systems that monitor structural integrity and aging, change shape at local level, act as sound sources and tackle noise vibration harshness issues will eliminate many of the weight, volume, and signature penalties associated with the current approach of designing, manufacturing and maintaining vehicles and functional systems separately. One type of MCS that appears as very promising and which we propose to investigate in this paper is a Load-bearing Loudspeaker Structure (LLS). A LLS refers to structures that are equipped with active elements such as piezoelectric elements that allow for music reproduction and 3D sound spatialization. We consider the fact that the passenger cabin of cars consists of many large surrounding surfaces such as door panels, roof trim panel, trims and dashboards, which can act as membranes. The objective is thus to design surface loudspeaker able to efficiently reproduce sound in the low, medium and high frequency range depending on the sound panel size. Piezoelectric transducers chosen because of their small size, low weight and high force output are investigated in this paper. They are coupled to mechanical amplification units to increase displacement amplitudes to overcome the lack of low frequency sound production [1,2] and are compared to a piezoceramic ring. The goal is to efficiently excite the full audio spectrum.

2 PIEZOELECTRIC ACTUATORS

Piezoelectric materials used in this work are ceramic perovskite materials made from lead zirconate titanate (PZT) that expands or contracts when an electrical charge is applied, generating motion and force called the inverse piezoelectric effect. Piezoelectric actuators use this motion to provide very short high force strokes with high frequency and fast response times at small size giving them a significant power-to-size ratio. Bulk piezo ceramics with external electrodes provide deformations in the range of 300 ppm with fields of 600 kV/m requiring high driving voltages. Multi-layer piezoelectric ceramics have been developed with the aim to reduce the required voltage by reducing the PZT layers to 50 to 100 μm thickness placed between internal electrodes. Those materials can be driven with a maximum electric field up to 2 MV/m with a voltage of less than 200 V achieving a deformation of about 1000 ppm.

Depending on the application, piezoelectric ceramics can be glued directly to a surface or a structure introducing a bending-type deformation. Alternatively, the high output force can be transformed into an amplified deformation at the expense of the size of the actuator due to the required amplification unit. If the amplification unit is rigidly coupled to the piezoceramic, these actuators are called flextensional actuators. Three different actuator types are described in the next sections:

- Piezoelectric rings
- Flat flextensional piezoelectric actuators
- Cymbal-type flextensional piezoelectric actuators

3.1 Piezoelectric ring

The first prototype of a sound-emitting panel uses a piezoceramic ring of dimension OD50 mm, ID20 mm, and TH 0.5 mm. It is made of a hard Navy I-type material called Pz26 from Meggitt Ferroperm with good coupling factors, high Curie temperature, high mechanical quality factor, low dielectric loss and very good stability over time. Table 1 shows the material characteristics. This piezoceramic ring is glued centered to a 300 x 200 x 3 mm³ plate made of polypropylene, a material often used for car passenger garnishments. The plate is screwed via a spacer (thickness 6.7 mm) to another stiffer plate made of Delrin creating a closed housing. The final assembly is shown in Figure 1.

Table 1: Material parameters Meggitt Pz26.

Relative dielectric permittivity k33	-	1300
Curie temperature	°C	230
Piezoelectric charge coefficient d33	pC/N	300
Density	kg/m ³	7700

Figure 1: Polypropylene plate with centered piezoelectric ring (left) and prototype speaker with housing (right).

3.2 Flat flextensional piezoelectric actuator

Flat flextensional piezoelectric actuators transform the high output force of piezoelectric ceramics into an amplified displacement. The actuator used in this work is called “Amplified Piezoelectric Actuator” (APA) developed by Cedrat Technologies based on a low voltage piezoelectric ceramics stack. The mechanical amplification is obtained due to an external monolithic shell of elliptic shape made of stainless steel, which magnifies the stack deformation in normal direction. This elliptical frame preloads the piezoelectric ceramic stack and protects it from tensile force. This kind of mechanical amplifiers is especially well-suited for dynamic drive conditions and provide relatively high force and large displacement while being compact in size. The APA400MML model has been chosen because of its good compromise between force and displacement output. Characteristics are given in Table 2. For the experimental tests, the actuator has been screwed in a reactive configuration centered between two plates. The sound emitting membrane of size 300 x 200 x 3 mm³ is made of polypropylene and the back plate is made of Delrin (thickness 6.7 mm) as shown in Figure 2.

Table 2: Characteristics of an APA400MML from Cedrat Technologies.

Max. no load displacement	μm	295-434
Blocked force	N	171-231
Stiffness	N/μm	0.547
Resonance frequency (blocked-free)	Hz	634
Capacitance	μF	10
Drive voltage	V	0-120
Dimensions	HxLxW in mm	24x78x11.5
Mass	g	47.5

Figure 2: APA400MML from Cedrat Technologies (left) and surface speaker prototype with centered actuator (right).

3.3 Cymbal-type flextensional piezoelectric actuator

The cymbal transducer consists of a piezoelectric or ceramic disc (either in single layer or multilayer form) sandwiched between two metal endcaps, each having a truncated conical shape. These metal endcaps serve as a mechanical transformer for converting and amplifying the lateral displacement of the ceramic into an axial motion of the endcaps. Both the d_{33} and d_{31} piezoelectric coefficients contribute to the axial displacement of the composite. Displacement increases exponentially with increasing cavity diameter and increases linearly with increasing cavity depth. Displacement is inversely proportional to the endcap thickness. Displacement and generative force show a position dependent behavior.

TDK PowerHap™ piezoelectric actuators provide high performance in terms of acceleration, force, and response time. They are made of multilayer piezo plates with copper inner electrodes. This allows the actuators to be driven with relatively low operating voltages up to 120V. Once activated, the piezo plates only expand minimally in the z axis, but due to the constant volume of the piezo effect contract simultaneously in both the x and y axes. The actuators employ cymbals on both sides of the plate as levers to amplify the contraction by a factor of 15 in the z axis. The biggest actuator of the PowerHap™ series, the PowerHap™ 15G, is used in this paper with its characteristics given in Table 3. The actuator is also fixed in a reactive configuration between two plates of dimensions 300 x 200 mm³.

Table 3: Characteristics of the TDK PowerHap 15G actuator.

Max. no load displacement	μm	200
Blocked force	N	20
Stiffness	N/mm	100
Resonance frequency (blocked-free)	kHz	8
Drive voltage	V	0-120
Capacitance	μF	3.6
Dimensions	LxWxH in mm	26x26x2.4

4 EXPERIMENTAL TEST SET-UPS

Dynamic displacement measurements have been carried out using a laser vibrometer to

investigate the dynamic behavior of the actuators. Figure 4 shows the experimental test set-up using a Polytec OFV-5000 laser vibrometer with an OFV-534 laser head mounted on a 3-axes cartesian robot. This experimental set-up allows to measure the dynamic displacement response of a single point on an actuator or a surface as well as the scanning of a complete surface to determine the mode shapes of the vibrating plate.

Acoustic characterizations are carried out in a semi-anechoic chamber (i.e. whose floor is not covered with foam) in order to not alter the acoustic signal recorded by the microphone (Figure 4). The prototype plate is on a stand, at the same height and a distance of 1 m from the microphone, itself on a tripod (1 m from the ground). An APEX220 microphone from Apex Electronics is used for the measurements connected via an XLR cable to a Focusrite Scarlet2 6i6 soundcard connected via USB to the computer. Each set of measurements begins with a "blank" measurement of the room, with a sound level meter, to determine the sound level (about 29 dB within the room in general). The amplified piezoelectric actuators in this paper are driven with a Piezomechanik LE 150/100 EBW amplifier. It generates voltages between 0 V and 150 V to be obtained with a preset offset voltage from a 0 V to 5 V input. The gain is x30 and its no load bandwidth extends up to 70 kHz. The amplifier can supply up to 350 mA continuously and 1200 mA peak. This leads to a rapid decrease in its bandwidth with increasing load. The piezoceramic ring is driven with an ELBATEC T-500 symmetrical high-voltage amplifier. It generates voltages of ± 200 V from a ± 10 V input. The maximum current is 400 mA and the no-load bandwidth extends up to 100 kHz.

Figure 4: Set-up for displacement measurements with a laser vibrometer (left) and acoustic measurements in a semi-anechoic chamber (right).

5 MEASUREMENT RESULTS

5.1 Piezoelectric ring

First, the displacement behavior at the center of the plate is measured with the laser vibrometer. Therefore, a 400 Vpp sine sweep is applied to the piezoelectric ring element. The loudspeaker is screwed to the base of the scanning table as shown in Figure 4 to prevent any unintended movement. Figure 5 shows the result for an excitation frequency from 50 Hz to 20 kHz. It can be seen that the absolute displacements are in the low micrometer range from 0.3 μm to 25 μm decreasing towards higher frequencies.

Next, the sound pressure level of the piezoelectric ring speaker has been characterized from 100 Hz to 20 kHz for a driving voltage of 400 Vpp. The sound pressure level (SPL, the reference level corresponds to the threshold of hearing, 20 μ Pa) is shown in Figure 6 measured in the semi-anechoic chamber. A 1/12 octave filter has been applied to the SPL curve. Due to the low capacitance of the ring actuator, high frequencies with relatively low power consumption can be attained. However, the low frequency range is quite limited. Despite of a few acoustic holes an average SPL of 80 dB is emitted up to 20 kHz. The lower cut-off frequency with this polypropylene plate is around 400 Hz reaching a SPL of 75 dB.

Figure 5: Displacement response of the PZT ring speaker measured at the center of the plate.

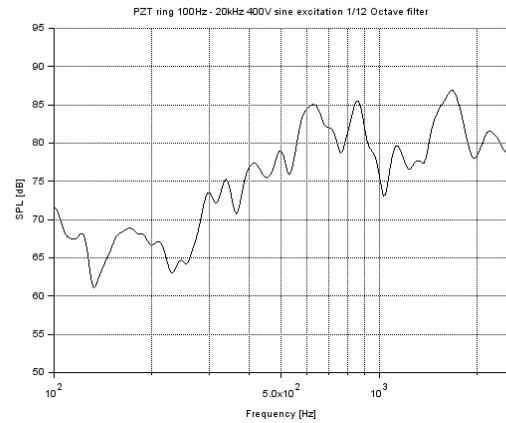

Figure 6: SPL of the PZT ring speaker measured at 1 m at 400 Vpp.

5.2 Flat flextensional piezoelectric actuator

As for the piezoelectric ring, laser vibrometer displacement measurements have been carried out for the APA400MML actuator. First, the frequency response has been measured for frequencies from 20 Hz to 20 kHz for the actuator only. A 7.5 Vpp sine sweep (offset 3.75 V) was applied to the piezoelectric actuator with a duration of 2 s. The result is shown in Figure 7. It can be seen that the APA400MML actuator has linear displacement behavior up to its first resonance frequency indicated at 634 Hz by the supplier. Figure 8 shows the displacement frequency response for a 150 Vpp (offset 75 V) sine sweep from 100 Hz to 500 Hz. This is the maximum driving voltage that can be applied to the actuator. At those driving voltages, the actuator cannot be actuated on its first resonance, which would cause failure to the ceramic due to excessive tensile stress. The supplier indicated a mean maximum peak to peak displacement amplitude of 368 μ m up to the first resonance frequency. It has to be noted that one of the three piezoelectric ceramics composing the APA400MML actuator was electrically damaged and has been electrically removed from the actuator. Driven with only two ceramics the measured peak displacement amplitude is around 150 μ m before the first resonance frequency but the voltage amplifier can now fully charge the actuator up to 500 Hz.

Next, the Cedrat Technologies APA400MML speaker has been characterized in the semi-anechoic chamber. A 7.5 Vpp sine sweep of 5 s has been applied to the actuator and measured with the microphone. In Figure 9, the 1/12 octave filtered sound pressure level from 100 Hz to 20 kHz is shown. It can be seen that even at very low driving voltages relatively high levels can

be attained in the range from 400 Hz to 2 kHz. For higher frequencies, the membrane material as well as the characteristics of the actuator induce damping lowering the maximum sound pressure level. Figure 10 shows the transfer function for a 150 Vpp (75 V offset) sine sweep excitation from 100 Hz to 500 Hz. As described earlier, this kind of actuator cannot be driven in resonance, which would lead to breakdown of the ceramics. It can be seen that SPLs exceeding 75 dB can be achieved from 1500 Hz to 600 Hz using this kind of actuators and the current surface size. It may be convenient to increase the size of the membrane to achieve higher levels at lower frequencies.

Figure 7: Displacement amplitude frequency response of the APA400MML actuator for a 7.5 Vpp driving voltage (2 s sine sweep) from 10 Hz to 20 kHz.

Figure 8: Displacement amplitude frequency response of the APA400MML actuator for a 150 Vpp driving voltage (2 s sine sweep) from 100 Hz to 500 Hz.

Figure 9: SPL from 100 Hz to 20 kHz of the APA400MML speaker at 7.5 Vpp.

Figure 10: SPL from 100 Hz to 500 Hz of the APA400MML speaker at 150 Vpp.

4.3 Cymbal-type flexensional piezoelectric actuator

Finally, the displacement amplitude of the TDK PowerHap 15G actuator has been measured. Figure 11 shows the peak displacement amplitude from 100 Hz to 20 kHz with an almost linear

zone below the first resonance frequency around 8 kHz. The mean peak amplitude at 7.5 V is around 10 μm . Figure 12 shows the frequency response for a 2 s sine sweep from 100 Hz to 1 kHz at 120 Vpp with an offset of 60 V (maximum driving voltage). The almost horizontal plateau has a peak displacement amplitude of 80 μm . This actuator can be fully charged up to 1 kHz by the amplifier used in this paper.

The sound pressure level of the TDK PowerHap 15G speaker has been characterized in the semi-anechoic chamber. A 120 Vpp (offset 60 V) sine sweep of 5 s has been applied to the actuator and measured with the microphone. Figure 13 shows the sound pressure level from 100 Hz to 20 kHz. Relatively high SPLs are achieved between 500 Hz and 2.5 Hz. There is a small hole present in the transfer function from 1.2 kHz to 1.6 kHz due to the insufficient charging of the actuator by the amplifier (limited to 1 kHz for this actuator). Next to the APA actuators, this actuator is an interesting candidate to excite the car structures because of its compact geometry, relatively low power consumption and high displacement amplitude.

Figure 11: Displacement amplitude frequency response of the TDK PowerHap 15G actuator for a 7.5 Vpp driving voltage (2 s sine sweep) from 100 Hz to 20 kHz.

Figure 12: Displacement amplitude frequency response of the TDK PowerHap 15G actuator for a 120 Vpp driving voltage (2 s sine sweep) from 100 Hz to 1 kHz.

Figure 13: SPL of the TDK PowerHap 15G speaker at 120Vpp.

6 DISCUSSION

The study revealed that the piezoceramic ring can be used for exciting the medium to high frequency audio range. In practice, lower maximum voltages will be applied reducing the sound pressure level and thus affecting primarily the lower end of the excited frequencies. This will shift the addressable audio range to higher frequencies. This can be partially compensated by using multiple piezoceramic actuators. The advantage if these actuators is their minimal size requirement and surface conform integration.

The amplified piezoelectric actuators can address the medium low frequencies from 150 Hz to 2.5 kHz. The APA series can easily be adapted to a targeted audio range but may introduce actuators of bigger size. The PowerHap actuators stand out by their small size and relatively high output displacement. Output force may be an issue depending on the LLS stiffness. In both cases, the voltage amplifiers are the main limitation factor for speaker applications. Using different membrane materials with higher Young's modulus and lower damping than the polypropylene material used in this paper can increase the sound pressure level but may introduce coloration to the created sound. In general, to achieve a proper radiation efficiency and radiated sound power, the Young's modulus cannot be too low. A tradeoff between Young's modulus and the density needs to be found to design efficient LLS.

Compared to classical electrodynamic speaker, the piezoelectric actuators are not visible and can be applied to structures that have initially other functions than creating sound. After equalization, LLS performance could be similar to electrodynamic speaker, at least subjectively. The process of equalization basically cancels out the lack of certain frequency band, and thus, is no longer affecting the performance. The use of sophisticated control schemes applied by a digital signal processor when using multiple actuators could significantly improve sound quality even on complex structures. The implementation of piezoelectric actuators is then a good choice because they can be more easily controlled than electrodynamic exciter technology.

7 CONCLUSIONS

Three different actuators have been compared in this paper in terms of maximum displacement amplitude and maximum sound pressure level on 300 x 200 x 3 mm³ speaker surfaces. A flat piezoelectric ring glued to a surface is compared to amplified piezoelectric actuators. The ring actuator produces good sound pressure levels at frequencies higher than 400 Hz but excites confuse mode patterns due to the stiff ceramic glued to the surface making control schemes more challenging. The other two actuators have been tested in a reactive configuration (fixed between two plates) to overcome the diffuse mode patterns created by a piezoceramic disc or ring glued to a surface. Highest output displacements can be obtained with the APA400MML flextensional actuator from Cedrat Technologies, which is limited to a maximum frequency of around 500 Hz due to its first mechanical resonance. Due to the high capacitance, this actuator is relatively power consuming. Its maximum output force of 200 N is not necessary for the speaker surface used in this paper but gives much design space for applications with complex and stiff structures. A smaller piezoceramic stack could be used to reduce power consumption. The flat cymbal actuator from TDK named PowerHap 15G produces a force of 20 N, which is enough to displace the membrane. Good acoustic power is

produced between 500 Hz and 2.5 kHz. Power consumption is reduced by a factor of three compared to the APA400MML actuator because of the lower capacitance (3.6 μ F compared to 10 μ F). The very compact design (26 x 26 x 2.4 mm³) could make this actuator a good choice for medium frequencies in car applications. The limiting factor for high frequency sound generation using those amplified piezoelectric actuators is the availability of high-power electric amplifiers. In order to cover a large audio spectrum, the combination of simple piezoelectric ceramics with amplified piezoelectric actuators on the same loudspeaker panel can be advantageous to maintain low power consumption.

Abstract. This article is devoted to space truss-like structures commonly used for solar panel installations or telecommunication antennas. Such structures have obvious advantage of beneficial ratio of their stiffness to mass. One of challenges in satellite engineering is focused on special design of ultra-light structures, compacted during transportation to the orbit, able to deploy into large cantilever with e.g. photovoltaic panels (being on the orbit). This approach allows for better withstands the launch loads in compact configuration. The proposed smart topology (SMARTOP) of the structure enables for easy, zero-energetic transformation from the compact, two-dimensional form into the final, tree-dimensional configuration, making use of stored pre-stress energy, released with use of specially controlled clutches. Main innovations are in specially design topology and so-called smart clutches performing controlled release of stored strain energy in a proper timing. Numerical simulations of the SMARTOP structure functionalities are presented.

1 INTRODUCTION

The aim of this paper is to present specially designed, self-deployable rod-cable structure, applicable in satellite engineering, where the structure has to be launched into the orbit in a compact form (due to protection against high accelerations) and then, deployed into the very extended, flexible form (due to low gravitation and mass saving).

The structures on the orbit are subjected to thermal loads or can oscillate shortly after self-deploying. Therefore, an effective technique, in order to suppress the transient vibrations in low frequency range, is a very appealing solution. To this end, active (for example utilizing a force feedback control algorithm presented in [1]) and semi-active approaches (e.g. friction-based dampers [2-3]) have been developed by researchers. Mitigation of vibrations in the presented structure can be done utilizing by control of slacking and prestressing the cables embedded into the truss.

2 GENERAL CONCEPT OF THE DEPLOYABLE STRUCURE

The structural topology (Fig. 1a), according to the patent pending claim [4], allows switching from the stable, functional form (as a supporting isostatic truss structure) into the collapsed, compact form (Fig. 1d) ready for transportation with high overloading. Both configurations are switchable. The compact form of the structure can be fixed due to prestressed actuators and blocking devices, where release of them causes automatically structural development into the flexible truss form. Stability of this final form is guaranteed by strings located inside, along selected rod-tube elements (1 and 2) and by blocking of hinge devices (3).

Figure 1: The SMARTOP configuration forms during sequential folding: (a) operational (initial) configuration; (b) configuration with folded the lower section; (c) configuration with folded the lower and middle sections; (d) fully folded configuration.

The truss topology (Fig. 1a) allows applying three pairs of rod-cable elements: $A_3B_4-B_3C_4$, $B_2A_3-C_2B_3$ and $A_1B_2-B_1C_2$ (one pair in each segment), realization of the planned modification of structural configuration. Rods (1) contain cable strings (2) inside and the controllable hinge mechanism (3) – blocked or released. When cables are pre-tensioned and hinge mechanism released, the sections collapse. After section collapsing, the hinge mechanism becomes blocked again. The structural configuration, after bottom section collapsing (deactivation of hinge mechanisms Q_1 and P_1 needed) is shown in Fig. 1b, while after bottom and middle section collapse (deactivation of hinge mechanisms Q_1-P_1 and Q_2-P_2 necessary) – on Fig. 1c. Finally, deactivation of all hinge mechanisms leads to the configuration shown on Fig. 1d. The sequence of collapsing sections to the 2D format can be arbitrary planned.

Simultaneous release of trigger springs initiating vertical movement up of all three levels of the structure together with deactivation of hinge mechanisms for pairs: Q_1-P_1 , Q_2-P_2 , and Q_3-P_3 , lead to rebuilding of the functional configuration of the structure. However, fixing of this configuration requires again initiation of cable pre-tensioning and hinge mechanisms reactivation.

Finally, three properly controlled smart devices: triggering springs, prestressing cables and blocking hinges allow automatic realization of two scenarios: controlled collapse and deployment of the structure.

3 BASIC DYNAMIC ANALYSIS

The vibrations of the structure were numerically tested. Firstly, the influence of the prestressing state in cables on modal parameters was investigated, and next the dynamic behaviour during unfolding was simulated. To this end, in both cases the following structural parameters were assumed:

- The truss structure composed with carbon fibers elements have pipe cross-sectional area with the wall thickness of 1mm and the outer diameter 10 mm. The applied elements have length: 0.60 m (horizontal element in the unfolded structure) and 0.85 m (remaining elements). The Young's modulus and density are equal to 60 GPa and 2100 kg/m^3 , respectively.
- The steel cable elements, placed inside selected truss elements (Fig 1a), with circular cross-section area with radius of 3 mm. The Young's modulus and density are equal to 200 GPa and 7850 kg/m^3 , respectively.
- Free-free structure only for modal analysis.

The numerical model and analyses were performed utilizing Abaqus software.

3.1 Eigenfrequencies and eigenmodes

Modal analysis was preceded by the computations of the statically loaded truss structure caused by the prestressed cables located as shown in Fig 2a (red lines). There were considered three prestressing states in the cables (out of structure): 20 kPa, 50 MPa and 200 MPa. The longitudinal stresses in the truss elements computed for the prestressed cables at level of 50 MPa are presented in Fig 2b. It is clearly visible, that the most loaded elements are co-located with the cables, whereas the remaining elements are slightly stressed. The displacement map of

the structure along the vertical axis (Z-axis) determined for this case is illustrated in Fig. 2c.

Next, taking into account the above mentioned prestressing levels, the modal analyses were performed. The obtained eigenfrequencies for the different prestressing states in the cables are shown in the Tab. 1. The first six modes corresponding to the rigid motions were omitted. For comparison, the results calculated for slackened cables were also included in the Tab. 1. The gathered results show the significant influence of the presence of prestressed state in the cables for the structural eigenfrequencies. On the other hand, the initial prestressing level is of secondary importance. Comparison of the overlapped corresponding mode shapes obtained for non-tensioned structure (black lines) and prestressed one (50 MPa, blue lines) are presented in Fig. 3.

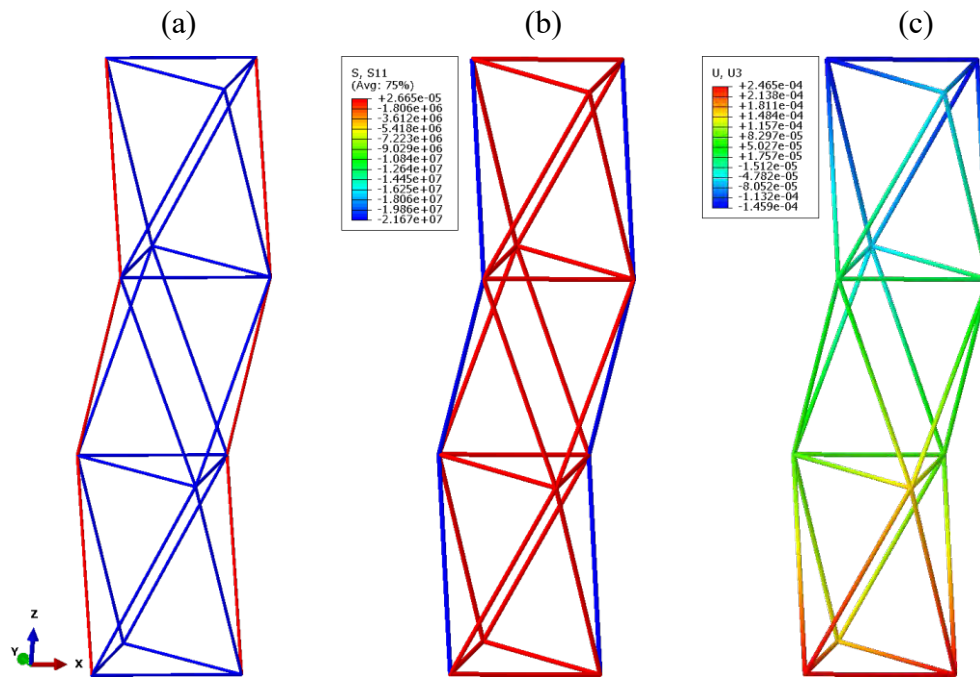

Figure 2: Statically prestressed structure (initial stress in the cable: 50 MPa): (a) tendon locations (red lines); (b) axial stress in the truss elements; (c) displacement map along Z-axis.

Table 1: List of the first six eigenfrequencies (corresponding to non-rigid mode shapes) obtained for non-tensioned and prestressed structures.

Mode number	Eigenfrequencies [Hz]			
	Non-tensioned	Prestressed 20 kPa	Prestressed 50 MPa	Prestressed 200 MPa
7	178.45	188.02	188.06	188.18
8	191.60	194.80	194.93	195.30
9	224.52	234.48	234.49	234.51
10	300.15	301.33	301.30	301.21
11	311.27	340.50	340.67	341.17
12	368.62	381.33	381.45	381.81

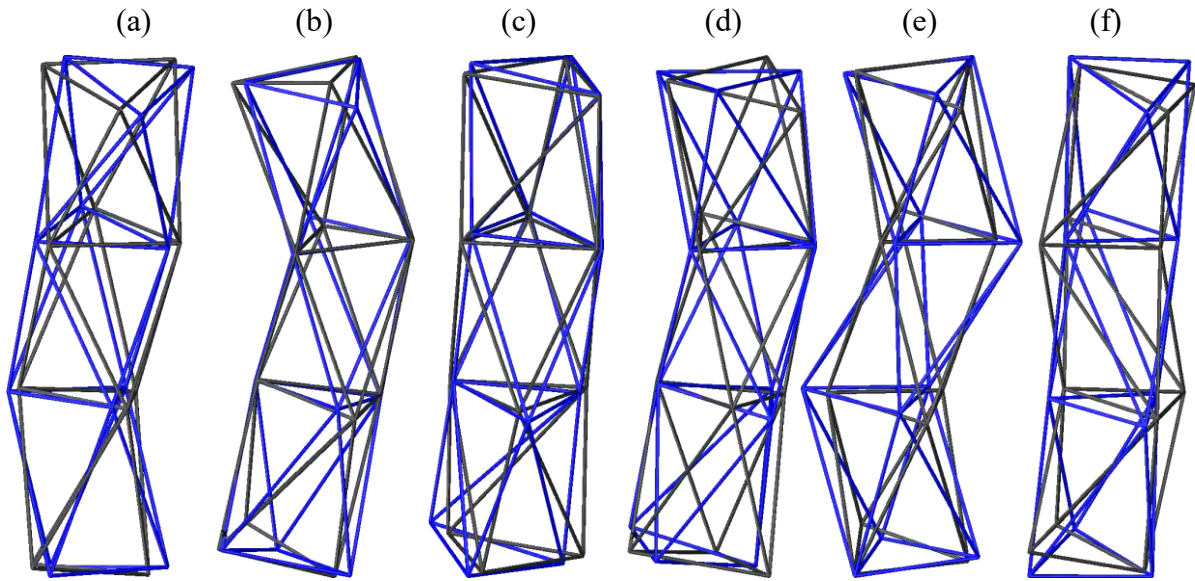

Figure 3: The eigenmodes (7-12) obtained for the non-tensioned and prestressed (50 MPa) structures.

3.2 Unfolding-induced vibrations

For testing purposes of the unfolding dynamics a single section of the structure was considered. Additionally, the structure was simply supported at the nodes (nos. 1, 2, 3) in the bottom section as shown in Fig. 4. Initially, the remaining nodes of the structure was clamped in the folded mode (Fig. 4a). Releasing the clamped nodes (nos. 4-8) and simultaneously imposing initial velocities at nodes of upper section (nos. 4-6) the structure is transformed into the operational form. The transformation requires a change of pin-joints (nos. 7, 8) into a rigid joints in a proper time. This approach generates excessive structural vibrations as well as bending moments and transversal forces in the elements adjacent to the switchable joints. Therefore, these elements have to be considered as beams during the transformation process.

For mitigation such effects an appropriate strategy during unfolding of the structure has to be applied. The further research work will be focused on:

- damping of unfolding-induced vibrations utilizing the switchable cable between the slackened and prestressed states,
- minimization of the bending moments and transversal forces in the structural elements caused by a status change of the switchable joints.

4 CONCLUSIONS

In this article a concept of a deployable truss structure was presented. The structure has a special designed topology allowing for easy transformation from folded mode (transportation mode) into operational mode as well as allowing for damping vibrations. The structural mode change is possible thanks to application of switchable joints blocked at the final stage of the

unfolding process. The second attribute – damping vibration – can be performed utilizing *on–off* switching the prestressed states in the cables. The presented numerical results show the significant modification of the modal parameters of the structure.

Figure 4: Two stages of the single section unfolding: (a) initial stage, (b) close to final stage.

Key words: Fluidic Artificial Muscles, Pressure Control Circuits, Working Fluid Comparison

Abstract. There is currently an increased interest in extending the application of McKibben actuators for a range of working fluids. Extensive efforts have already established force response models for pneumatically driven McKibben actuators that are independent of working fluid material properties, however the model's independence to working fluid choice has yet to be validated with empirical evidence. This paper experimentally investigates the effect of working fluid choice on the quasi-static pressure dependent force-contraction response of McKibben actuators, and tests the hypothesis that FAM actuation force is dependent on inflation pressure while being independent of all other working fluid properties. Using air or water as the working fluid, characteristic isobaric force-contraction response curves are compared for a small scale McKibben actuator. To ensure truly isobaric force-contraction characterizations, hydraulic and pneumatic pressure systems were developed to provide precise and accurate control of pressure. Experimental testing showed that using air or water as a working fluid resulted in nearly identical isobaric force-contraction response curves, and demonstrated that the quasi-static force of McKibben actuators is independent of working fluid. This establishes that the previously developed force response models for pneumatic McKibben actuators can now be easily extended to use with other permissible liquid or gaseous fluids. With the conclusion of this research, McKibben actuators can be readily adapted to a wider range of uses with working fluid choice catered to application requirements independent of their force response.

1 INTRODUCTION

An increasingly diverse number of applications are utilizing McKibben actuators due to their many desirable characteristics. Previous work established McKibben actuators as an ideal form of actuator when compliant, high force-to-weight ratio actuation is desired [4, 5, 14]. McKibben actuators, known more generally as fluidic artificial muscles (FAMs), have often been operated using air (PAMs). Research efforts have also been focused on the accuracy and fidelity of modeling pneumatic FAMs for control purposes. Using empirical test data, semi-mechanistic models that achieve a high degree of accuracy have been developed for pneumatic FAMs.

Research efforts for FAMs have recently expanded to use with different working fluids as the FAM's source of internal pressure. Although FAMs have typically been operated pneumatically, applications of FAMs also include water [6, 15], and aerospace applications [2, 9] making it necessary to study working fluids that are best suited to these environments.

Few researchers have studied hydraulically powered FAM actuators [1, 6, 8, 10, 11, 12] while even fewer have directly compared FAM actuators pressurized with air or water [3, 7, 13]. Tiwari tested the assumption made in pneumatic FAM (PAM) models that indicate pneumatic and hydraulic powered FAMs should provide the same force response independent of the choice of working fluid in quasi-static operation. Tiwari used a 3.18 mm (1/8 in) FAM to conduct constant pressure tests with water and air, with results showing substantial discrepancies between their force response. The difference in the force response of the two working fluids was cited as likely being a result of inaccurate control of the fluid pressure.

This research describes the effect of working fluid selection on the quasi-static pressure dependent force-contraction response of FAMs. Testing either air or water as the working fluid, characteristic isobaric force-contraction response curves are compared for a small scale McKibben actuator. Improving upon the work done by Tiwari, where inaccurate pressure control resulted in an inconclusive comparison between pressurization using air or water, in this study hydraulic and pneumatic pressure systems were developed to provide precise and accurate control of pressure to ensure a dependable comparison between the two working fluids. Consecutive testing using water and then air is conducted to show the independence of working fluid choice on the quasi-static response of FAMs, and demonstrates that pressure is the independent variable.

Pneumatic FAM models have been developed and refined through the years to provide an accurate representation of their quasi-static force response. A semi-mechanistic model based on a force balance approach was recently updated to include empirically fit coefficients that represent the material properties of the elastomeric bladder [9]. This force response model is a function of the working fluid pressure, P , and the PAM actuator length, L , and is given as follows:

$$F(P, L) = \frac{P}{4\pi N^2} (3L^2 - B^2) + \sigma_z \left(\frac{V_b}{L} \right) - \sigma_c \left(\frac{tL^2}{2\pi RN^2} \right) \quad (1)$$

where the number of turns of a single braid fiber about the actuator's diameter, N , the length of that braid fiber, B , and the volume of the incompressible bladder, V_b , are set values that describe the geometry of the FAM actuator. The thickness of the bladder, t , radius of the actuator, R , and the longitudinal bladder stress, σ_z , and circumferential bladder stress, σ_c , are values that are functions of the instantaneous actuator length, L . Inspection of this model shows that actuation force is a function of only the PAM's geometry, materials, and working fluid pressure. With no reliance on fluid properties other than pressure, it is assumed that this model can be transferrable to use with FAMs for other working fluids besides air. This study was performed to validate the accuracy of this assumption, and to then extend the use of the force response models used for PAMs more generally to use with FAMs independent of the chosen working fluid.

2 EXPERIMENTAL TEST SETUP

The FAM was experimentally tested with either air or water as the working fluid. The routine of characterizing the actuator's isobaric force-contraction response was adopted from previous PAM characterization testing [4]. The FAM is slowly stroked at 5.1 mm/sec (0.2 in/sec) from its resting length to its zero force length at constant pressure. The FAMs were stroked at set pressures of 138-689 kPa (20-100 psi) in 138 kPa (20 psi) increments.

Testing for this study was conducted in a MTS material testing machine that strokes the FAM while recording inputs from a pressure transducer (Omega PC209-200G5V) and load cell (Honeywell Model 31 Mid). The FAM is tested with each working fluid consecutively to ensure retention of the FAMs reference length state and alignment. Fixtures to connect the FAM to the MTS machine were fabricated to be adaptable to the hardware necessary for either air or water testing without requiring removal of the FAM from the testing machine.

2.1 FAM Test Specimens

A small scale FAM (4.8 mm (3/16 in) diameter) was fabricated for comparison testing of air and water powered actuation to ensure size independence of observed phenomenon (Fig. 1). This FAM typically produces a maximum force in the blocked force condition of about 222 N (50 lbf), and can achieve a maximum/free contraction of 25-35%.

Figure 1: 22.2 mm FAM (top) versus the 4.8 mm FAM (bottom) used in this test

2.2 FAM Test Specimens

An accurate comparison between air and water working fluids requires precise and accurate control of the pressure supplied to the FAM to maintain a true isobar for each stroke cycle test of the FAM. Careful regulation of pressure is required to ensure that any difference between the FAM force response for each working fluid could be correctly attributed to the working fluid and not by any imprecision in feed pressure. This drove the decision to develop pressure control systems for water and air. The water pressure systems for each working fluid are detailed in the following sections.

2.2.1 Pneumatic Pressure System

The air pressure system for pneumatic FAM testing, shown in Fig. 2, is the same as what has been used for previous PAM testing with the addition of a proportional valve to more precisely

regulate airflow. An air compressor (DeWalt D55146) was used to store and provide pressurized air. A pressure regulator (Excelon R73G) was used to set a constant supply pressure of 793 kPa (115 psi), 103kPa (15 psi) above the maximum pressure to be tested. A proportional control valve (Enfield Technologies LS-V05s) was used to directly control FAM pressure. An Arduino was used as a controller to direct proportional valve actuation to control pressure. The Arduino received pressure state values for controller feedback through a pressure transducer (Omega PX209-200G5V) mounted to the fixture just above the air inlet of the FAM. A 4448 N (1000 lbf) load cell (Honeywell Model 31 Mid) was placed in line with the FAM to measure the contraction force of the FAM.

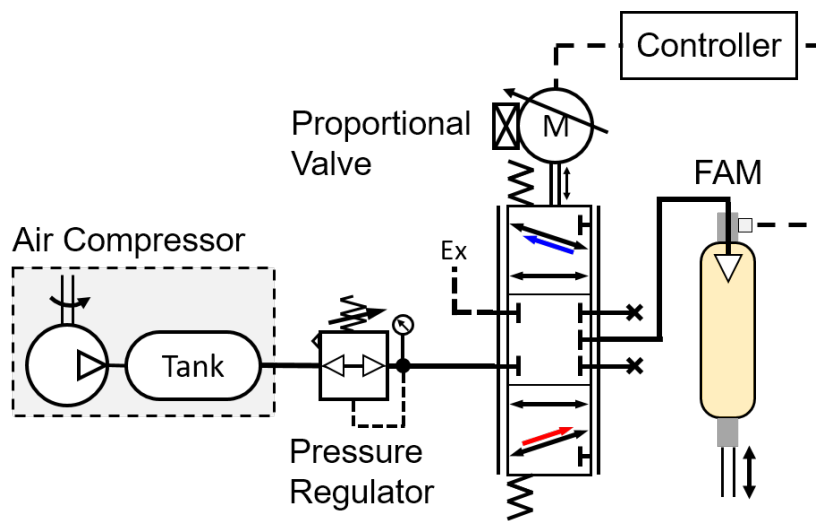

Figure 2: Pneumatic pressure system schematic

2.2.2 Hydraulic Pressure System

Testing the FAM with water required the development of a hydraulic pressure system (Fig. 3). The incompressibility of water, as well as the limited number of water compatible components, resulted in a hydraulic system that is very different in nature from the pneumatic system. The hydraulic system uses a continuously running, variable-speed pump. A fixed displacement gear pump (Fluid-o-Tech FG204) uses a fluid reservoir as the water source. To avoid damaging hydraulic hammer effects from requiring the motor to constantly switch directions about a pressure set point, the FAM was made open at each end to allow continuous flow of water in a single direction through the FAM. To buildup pressure in the system, flow is restricted downstream of the FAM using a needle valve. An adjustable relief valve (Watts LF 530-C STD) was positioned between the pump and FAM to relieve pressure if it exceeds 758 kPa (110 psi). Pump speed is controlled using an Arduino to achieve the desired isobaric pressure.

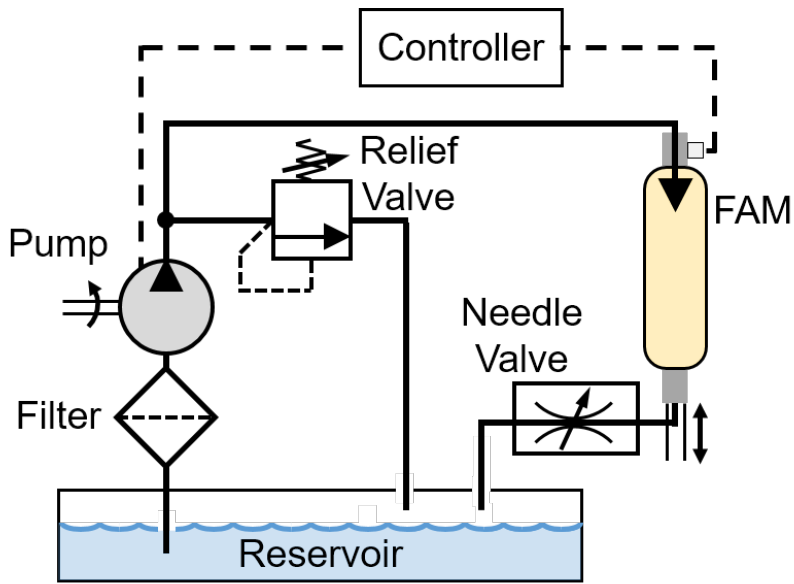

Figure 3: Hydraulic pressure system schematic

2.3 Pressure Control System

A proportional-integral (PI) closed-loop feedback controller was used to regulate each pressure system to the desired isobar. The controller input acts to minimize the error, $e(t)$ between the desired set pressure, P_{set} , and the actual pressure, P_{meas} . The controller receives a pressure sensor voltage as input, and outputs a control signal in the form of a 5V pulse width modulation (PWM) signal. The Arduino produces a command value of 0-255 as a digital representation of the PWM output that translates to a 0-100% duty cycle. This enables the digital based Arduino to output the 0-5V analog input values required for control of the proportional valve and pump. The controller was tuned for the pneumatic and hydraulic pressure circuits for the FAM resulting in two gains, the proportional gain, K_p and the integral gain, K_i , which were tuned through iterative testing.

3 TEST RESULTS

Accurate pressure control was achieved for both the hydraulic and pneumatic pressure systems, resulting in a high fidelity comparison of the response of the two tested working fluids. The results of the pressure control, as well as the characterization of the FAM response with air and water working fluids are detailed in the following sections.

3.1 Pressure Control Results

Results for the measured pressure during characterization testing are given in Table 1 below. Average pressure and standard deviation values are given for both air and water testing. Together, these values provide a depiction of how well the pressure systems provided a true isobar for each set pressure test to enable a good comparison between each working fluid. Although there is a slight offset in the set pressure versus the test pressures, the average pressures when

using air or water correlated very closely with one another with a minimum deviation from the set pressures.

Table 1: Average pressure and standard deviation for the force response characterization test at each test pressure

Commanded Set Pressure	138 kPa	276 kPa	414 kPa	552 kPa	689 kPa
Average Pressure, Air (kPa)	145.17	284.37	422.34	561.16	699.82
Average Pressure, Water (kPa)	145.13	284.17	422.13	560.55	699.18
Standard Deviation, Air (kPa)	1.58	1.24	1.42	1.77	1.99
Standard Deviation, Water (kPa)	1.04	1.02	1.52	1.97	1.41

3.2 Characterization Results

Figure 4: Results of each isobaric force-contraction characterization test for the 4.8 mm FAM

Characterization testing of the FAM with each working fluid showed nearly identical results when using either air or water for all tested pressures. Results from each characterization test are plotted in Fig. 4. To provide a quantitative comparison of the force response difference between the two working fluids, the root mean squared error (RMSE) between the two responses was calculated for each pressure. The root mean squared error was calculated using the following equation:

$$RMSE_{avg} = \sqrt{\frac{1}{N_i} \sum_i ((F_i)_{air} - (F_i)_{water})^2} \quad (2)$$

where F is the experimental force for each test, and N is the total number of data points of each test with i representing each respective measurement point from 1 to N . RMSE values for both working fluids at each pressure are given in Table 2.

Table 2: Root-mean-square error (RMSE) at each test pressure

	138 kPa	276 kPa	414 kPa	552 kPa	689 kPa	Overall Average
4.8 mm Dia. (N)	0.85	1.20	2.00	2.05	3.34	1.82

4 Conclusion

This study examined the effect of working fluid choice on the quasi-static force response of FAMs. Past studies showed that the working fluid can affect the dynamic behavior and efficiency of FAMs, but none conclusively demonstrated the assumption that the quasi-static force response is independent of the working fluid used to power it. To study this assumption, a small scale FAM was fabricated, and had its force response characterized using water and air as the working fluid. To ensure an accurate comparison between using air and water, control systems were developed to precisely control fluid pressure for each isobaric force-contraction characterization test. Testing of each working fluid resulted in nearly identical isobaric force-contraction response curves. This confirms that the FAM's quasi-static force response is independent of working fluid, allowing force response models previously developed for PAMs to be adopted for use with FAMs with any working fluid, and motivates the use of FAMs with an expanded range of application dependent working fluids.

Abstract. This research deals with computer modelling in finite element software ACELAN-COMPOS of multiscale two-phase magnetoelectric (piezomagnetoelectric) bulk composites that consist of piezo-magnetic and/or piezoelectric fractions of irregular structures. The proposed technique is based on the models of micro- and nanoscale materials with interface or surface effects, the effective moduli method, the modelling of representative volumes, and the use of finite element technologies for solving the problems in the representative volumes.

1 INTRODUCTION

In the present paper, as active materials we will understand the materials in which sufficiently noticeable deformations can be caused by external nonmechanical influences. Such materials are piezoelectric, magnetoelectric, pyroelectric and other materials with coupling between mechanical fields and fields of a different nature: electric, magnetic or thermal. These materials are widely used in modern engineering as active elements of transducers, sensors, actuators and other devices. Recently, new materials with improved characteristics are being intensively developed to improve the efficiency of these devices. Especially important are the problems of developing active composite materials consisting of materials of different phases. Methods of mathematical and computer modelling help us to predict the effective properties of composite materials depending on the characteristics of the initial phases, their percentage ratio and the peculiarities of the internal structure.

The problems of determining effective properties, also called homogenization problems, can be solved on the basis of various approaches known in the mechanics of composite materials. For active materials whose behavior is described by a sufficiently complicated system of differential equations, it is convenient to use the method of effective moduli. For example, for piezoelectric composites according to this method, it is necessary to solve a set of boundary-value problems of piezoelectricity (electroelasticity) with special boundary conditions providing for homogeneous materials the exact solutions with constant field gradients (strains, stresses, electric field and electrical induction). In a non-uniform representative volume, these gradients, naturally, will not be constant, but their averaged integral characteristics will permit to determine the effective moduli of the composite material [14, 15].

For nanostructured composites, in which inclusions or pores have nanodimensions, the nanoscale effect can be taken into account in the framework of the theory of surface stresses ([4, 6, 22, 23], et al)

and its generalizations to the problems with coupling fields ([3, 5, 19, 24], et al). In the theory of surface stresses for the interfaces of materials with different phases, the special equations are written that relate stress jumps in volumes with fields for surface stresses. Finally, in recent years, the technologies have been proposed for creating the new materials composed of piezoelectric matrix and of inclusions from other materials or pores, on which interface boundaries the particles of third type materials are deposited [20].

To solve the homogenization problems for all active composites described in this paper, the specialized software was developed, which is based on the finite element solution of boundary problems in representative volumes and takes into account the main features of the internal structure of composites.

Namely, the program systems written in the APDL ANSYS language were created, which allow in the automated mode to solve in the ANSYS package the homogenization problems for active composites of various types and determining their effective moduli. To generate the structures of representative volumes in addition to the simple random ANSYS algorithm, external programs that implement various algorithms were created [14, 15, 16]: 3-x algorithm implemented by S.V. Bobrov, supporting the connectivity of finite elements of the first phase, up to 90 % of inclusions of the second phase; 3-0 algorithm with a regular structure of connectivity of the first phase in three axial directions and with a closed structure of the elements of the second phase; cluster algorithms implemented by V.V. Remizov (Witten-Sander method, cluster of the second phase method; method of "growth out of the plane"; method of initial concentration, etc.)

However, in the ANSYS package there were no basic means for solving the problems of magnetoelectricity and there were no piezoelectric and magnetoelectric shell finite elements. In this regard, at the Department of Mathematical Modelling of Southern Federal University, a specialized finite element package ACELAN-COMPOS was developed. The ACELAN-COMPOS package is focused on solving the homogenization problems with coupled mechanical and electromagnetic fields. In this package, implemented new algorithms 3-3 connectivity [9, 12], supporting the connectivity of the two phases; algorithm 3-0 connectivity, creating the granular structures [10, 12]; and algorithm 1-3 connectivity, creating the structures with rod elements in a matrix [11, 12].

For all these models of representative volumes, the algorithms have been developed for the automated search for finite elements located at the interphase boundaries and placing shell elements on them that simulate the presence of surface effects for nanoscale inclusions or pores. For transversely isotropic materials, an algorithm was additionally implemented for the plate surface elements, parallel to the coordinate axes, with the material properties that inherit the anisotropy structure of the neighboring volume elements.

The models of magnetoelectricity and the models of representative volume elements of the ACELAN-COMPOS package are briefly presented in this paper. Other means of ACELAN-COMPOS and a more detailed presentation of models, algorithms and results are presented in [8, 9, 10, 11, 12, 17], et al.

2 SETTING OF HOMOGENIZATION PROBLEMS

The technology of homogenization problem solving implemented in ACELAN-COMPOS is applicable for a fairly wide class of composite materials of various stochastic structures with coupling physico-mechanical fields. It is only important that linear stationary equations of divergent type should be considered. For example, let Ω be the representative volume of a piezomagnetoelectric (magnetoelectric) composite body consisting of two materials. We assume that this volume is filled with materials of two types (phases): $\Omega = \Omega^{(1)} \cup \Omega^{(2)}$. These phases can have various coupled fields. Thus, the phase $\Omega^{(1)}$ can have piezoelectric properties, while the phase $\Omega^{(2)}$ can be piezomagnetic. Another case is the active

materials with inclusions or pores. Then, the first phase of the main fills up the volume or set of volumes $\Omega^{(1)}$, and the second phase (inclusions or pores) fills the volume or set of volumes $\Omega^{(2)}$. Here, for a porous material, the phase $\Omega^{(1)}$ should be connected.

For modelling of nanoscale effects in the framework of the Gurtin–Murdoch theory and its generalizations, surface fields are set on the interfaces of the two phases $\Gamma^s = \partial\Omega^{(1)} \cap \partial\Omega^{(2)}$. The external boundary of the representative volume $\Gamma = \partial\Omega$ will be used to specify the boundary conditions in the homogenization problems.

In accordance with the effective moduli method, we will consider in the volume Ω the following boundary value problem of the static theory of magnetoelectroelasticity with respect to the displacement functions $\mathbf{u}(\mathbf{x})$, the electric potential $\varphi(\mathbf{x})$ and the magnetic potential $\phi(\mathbf{x})$:

$$\mathbf{L}^*(\nabla) \cdot \mathbf{T} = 0, \quad \nabla \cdot \mathbf{D} = 0, \quad \nabla \cdot \mathbf{B} = 0, \quad \mathbf{x} \in \Omega, \quad (1)$$

$$\mathbf{T} = \mathbf{c} \cdot \mathbf{S} - \mathbf{e}^* \cdot \mathbf{E} - \mathbf{h}^* \cdot \mathbf{H}, \quad \mathbf{D} = \mathbf{e} \cdot \mathbf{S} + \mathbf{\kappa} \cdot \mathbf{E} + \mathbf{\alpha} \cdot \mathbf{H}, \quad \mathbf{B} = \mathbf{h} \cdot \mathbf{S} + \mathbf{\alpha}^* \cdot \mathbf{E} + \mathbf{\mu} \cdot \mathbf{H}, \quad (2)$$

$$\mathbf{S} = \mathbf{L}(\nabla) \cdot \mathbf{u}, \quad \mathbf{E} = -\nabla\varphi, \quad \mathbf{H} = -\nabla\phi, \quad (3)$$

$$\mathbf{L}^*(\nabla) = \begin{bmatrix} \partial_1 & 0 & 0 & 0 & \partial_3 & \partial_2 \\ 0 & \partial_2 & 0 & \partial_3 & 0 & \partial_1 \\ 0 & 0 & \partial_3 & \partial_2 & \partial_1 & 0 \end{bmatrix}, \quad \nabla = \begin{Bmatrix} \partial_1 \\ \partial_2 \\ \partial_3 \end{Bmatrix}, \quad (4)$$

$$\mathbf{L}^*(\mathbf{n}) \cdot [\mathbf{T}] = \mathbf{L}^*(\nabla^s) \cdot \mathbf{T}^s, \quad \mathbf{n} \cdot [\mathbf{D}] = \nabla^s \cdot \mathbf{D}^s, \quad \mathbf{n} \cdot [\mathbf{B}] = \nabla^s \cdot \mathbf{B}^s, \quad \mathbf{x} \in \Gamma^s, \quad (5)$$

$$\mathbf{T}^s = \mathbf{c}^s \cdot \mathbf{S}^s - \mathbf{e}^{s*} \cdot \mathbf{E}^s - \mathbf{h}^{s*} \cdot \mathbf{H}^s, \quad \mathbf{D}^s = \mathbf{e}^s \cdot \mathbf{S}^s + \mathbf{\kappa}^s \cdot \mathbf{E}^s + \mathbf{\alpha}^s \cdot \mathbf{H}^s, \quad \mathbf{B}^s = \mathbf{h}^s \cdot \mathbf{S}^s + \mathbf{\alpha}^{s*} \cdot \mathbf{E}^s + \mathbf{\mu}^s \cdot \mathbf{H}^s, \quad (6)$$

$$\mathbf{S}^s = \mathbf{L}(\nabla^s) \cdot \mathbf{u}^s, \quad \mathbf{u}^s = \mathbf{A} \cdot \mathbf{u}, \quad \mathbf{A} = \mathbf{I} - \mathbf{n} \otimes \mathbf{n}, \quad \mathbf{E}^s = -\nabla^s \varphi, \quad \mathbf{H}^s = -\nabla^s \phi, \quad \nabla^s = \nabla - \mathbf{n}(\partial/\partial n), \quad (7)$$

$$\mathbf{u} = \mathbf{L}^*(\mathbf{x}) \cdot \mathbf{S}_0, \quad \varphi = -\mathbf{x} \cdot \mathbf{E}_0, \quad \phi = -\mathbf{x} \cdot \mathbf{H}_0, \quad \mathbf{x} \in \Gamma. \quad (8)$$

Here $\mathbf{T} = \{\sigma_{11}, \sigma_{22}, \sigma_{33}, \sigma_{23}, \sigma_{13}, \sigma_{12}\}$, $\mathbf{S} = \{\varepsilon_{11}, \varepsilon_{22}, \varepsilon_{33}, 2\varepsilon_{23}, 2\varepsilon_{13}, 2\varepsilon_{12}\}$ are the arrays of the stress components σ_{ij} and the strain components ε_{ij} ; \mathbf{D} and \mathbf{E} are the vectors of the electrical induction or the electric displacement and of the intensity electric field; \mathbf{B} and \mathbf{H} are the vectors of magnetic induction and of the intensity magnetic field, respectively; $\mathbf{c} = \mathbf{c}^{E,H}$ is the 6×6 matrix of stiffness moduli; $\mathbf{e} = \mathbf{e}^H$ is the 3×6 matrix of piezomoduli; $\mathbf{h} = \mathbf{h}^E$ is the 3×6 matrix of magnetostriction moduli or piezomagnetic moduli; $\mathbf{\kappa} = \mathbf{\kappa}^{S,H} = \mathbf{\varepsilon}^{S,H}$ is the 3×3 matrix of dielectric permittivity moduli (dielectric constants); $\mathbf{\alpha} = \mathbf{\alpha}^S$ is the 3×3 matrix of magnetoelectric coupling coefficients; $\mathbf{\mu} = \mathbf{\mu}^{S,E}$ is the 3×3 matrix of magnetic permeability moduli; \mathbf{S}_0 , \mathbf{E}_0 and \mathbf{H}_0 are constant six-dimensional array, and three-dimensional vectors, respectively; the superscripts of the moduli indicate for which constant fields they were calculated; $(\dots)^*$ is the transpose operation.

Interface relations (5)–(7) on the interphase surface Γ^s are used only for modelling of composites at the nano-level. In (5)–(7), the surface fields and moduli are marked with superscript s ; $[(\dots)] = (\dots)^{(1)} - (\dots)^{(2)}$ is the jump of the corresponding quantity across the interphase boundary; \mathbf{n} is the unit normal vector to Γ^s , external to the domain $\Omega^{(1)}$.

If the interface boundary conditions (5)–(7) are missing, then the problem (1)–(4), (8) is the homogenization problem for piezomagnetoelectric composite with usual phase sizes (inclusions or pores).

In the case of a composite of arbitrary anisotropy class to determine the full set of its effective moduli $c_{\beta\zeta}^{\text{eff}}$, $e_{i\zeta}^{\text{eff}}$, $e_{i\zeta}^{\text{eff}}$, κ_{ij}^{eff} , α_{ij}^{eff} , μ_i^{eff} , it is required to solve the twelve problems (1)–(8), differing in boundary conditions (8), in which only one of the components $S_{0\gamma}$, E_{0k} , H_{0k} ($\gamma = 1, \dots, 6$; $k = 1, 2, 3$) should be set not equal to zero:

— cases I – VI ($\zeta = 1, 2, \dots, 6$)

$$S_{0\gamma} = S_0 \delta_{\zeta\gamma}, \quad \mathbf{E}_0 = 0, \quad \mathbf{H}_0 = 0 \Rightarrow c_{\beta\zeta}^{\text{eff}} = \langle T_\beta \rangle / S_0, \quad e_{i\zeta}^{\text{eff}} = \langle D_i \rangle / S_0, \quad h_{i\zeta}^{\text{eff}} = \langle B_i \rangle / S_0, \quad (9)$$

cases VII – IX ($j = 1, 2, 3$)

$$\mathbf{S}_0 = 0, \quad E_{0j} = E_0 \delta_{jk}, \quad \mathbf{H}_0 = 0 \Rightarrow e_{j\beta}^{\text{eff}} = -\langle T_\beta \rangle / E_0, \quad \kappa_{ij}^{\text{eff}} = \langle D_i \rangle / E_0, \quad \alpha_{ji}^{\text{eff}} = \langle B_i \rangle / E_0, \quad (10)$$

cases X – XII ($j = 1, 2, 3$)

$$\mathbf{S}_0 = 0, \quad \mathbf{E}_0 = 0, \quad H_{0j} = H_0 \delta_{jk} \Rightarrow h_{j\beta}^{\text{eff}} = -\langle T_\beta \rangle / H_0, \quad \alpha_{ij}^{\text{eff}} = \langle D_i \rangle / H_0, \quad \mu_{ji}^{\text{eff}} = \langle B_i \rangle / H_0, \quad (11)$$

where $\beta = 1, 2, \dots, 6; i = 1, 2, 3$;

$$\langle (\dots) \rangle = \frac{1}{|\Omega|} \left(\int_{\Omega} (\dots) d\Omega + \int_{\Gamma^s} (\dots)^s d\Gamma \right). \quad (12)$$

As we can see from (9)–(12), taking into account the interface conditions leads to the necessity of calculation of the averaged field characteristics not only by the volume Ω , but also by the interface boundary Γ^s . Since the interface boundaries complicate the internal structure of the representative volume, it is possible to solve boundary-value homogenization problems only numerically, for example, by the finite element method described below.

3 FINITE ELEMENT APPROXIMATIONS

In order to solve the problems of magneto-electroelasticity I – XII for an inhomogeneous composite material in a representative volume Ω , one can proceed to their weak statements and use the classical technique of finite element approximations. Let Ω_h be the region occupied by a finite element mesh, $\Omega_h \subset \Omega$, $\Omega_h = \Omega_h^{(1)} \cup \Omega_h^{(2)}$, $\Omega_h^{(j)} \subset \Omega^{(j)}$, $\Omega_h^{(j)} = \cup_k \Omega_{ek}^{(j)}$, where $\Omega_{ek}^{(j)}$ is a separate finite element with the number k and with the material properties of the phase $j = 1, 2$. Let also Γ_h^s be a grid of the surface finite elements, conforming with the volume mesh Ω_h , $\Gamma_h^s = \partial\Omega_h^{(1)} \cap \partial\Omega_h^{(2)}$, $\Gamma_h^s = \cup_m \Gamma_{em}^s$, while Γ_{em}^s is a separate surface finite element with number m , which is a common face of the corresponding volume elements $\Omega_{ek}^{(j)}$ on the phase interface ($\Gamma_h^s \approx \Gamma^s$).

We will use Lagrangian or serendipity finite elements with degrees of freedom of nodal displacements, electrical potentials and magnetic potentials. It is important that, due to the structure of the surface fields (5)–(7), we can use membrane elements with degrees of freedom of nodal displacements, electrical potentials and magnetic potentials (without degrees of freedom of the rotation angles). Then approximate solutions of $\mathbf{u}_h \approx \mathbf{u}$, $\varphi_h \approx \varphi$, $\phi_h \approx \phi$ on the finite element mesh Ω_h can be searched in the form

$$\mathbf{u}_h = \mathbf{N}_u^* \cdot \mathbf{U}, \quad \varphi_h = \mathbf{N}_\varphi^* \cdot \Phi, \quad \phi_h = \mathbf{N}_\phi^* \cdot \Psi, \quad (13)$$

where \mathbf{N}_u^* is the matrix of basis or form functions for displacements; \mathbf{N}_φ^* , \mathbf{N}_ϕ^* are the row vector of basis functions for electric and magnetic potentials; \mathbf{U} , Φ , Ψ are the vectors of nodal displacements, electric potentials and magnetic potentials.

In accordance with the classical finite element technique, we approximate the continual weak formulation of the problems I – XII in the finite dimensional spaces associated with the basis functions from (13). Substituting (13) and similar representations of the projection functions \mathbf{u}_h , φ_h , θ_h into weak statements of magneto-electroelastic problem, we obtain the following finite element system

$$\mathbf{K} \cdot \mathbf{a} = \mathbf{F}, \quad (14)$$

$$\mathbf{K} = \begin{bmatrix} \mathbf{K}_{uu} & \mathbf{K}_{ub} \\ \mathbf{K}_{ub}^* & -\mathbf{K}_{bb} \end{bmatrix}, \quad \mathbf{a} = \begin{bmatrix} \mathbf{U} \\ \mathbf{b} \end{bmatrix}, \quad \mathbf{F} = \begin{bmatrix} \mathbf{F}_u \\ -\mathbf{F}_b \end{bmatrix}, \quad (15)$$

$$\mathbf{K}_{bb} = \begin{bmatrix} \mathbf{K}_{\varphi\varphi} & \mathbf{K}_{\varphi\phi} \\ \mathbf{K}_{\varphi\phi}^* & \mathbf{K}_{\phi\phi} \end{bmatrix}, \quad \mathbf{K}_{ub}^* = \begin{bmatrix} \mathbf{K}_{u\varphi}^* \\ \mathbf{K}_{u\phi}^* \end{bmatrix}, \quad \mathbf{b} = \begin{bmatrix} \Phi \\ \Psi \end{bmatrix}, \quad \mathbf{F}_b = \begin{bmatrix} \mathbf{F}_\varphi \\ \mathbf{F}_\phi \end{bmatrix}, \quad (16)$$

Vectors \mathbf{F}_u , \mathbf{F}_φ , \mathbf{F}_ϕ in (15), (16) appear when taking into account the essential boundary conditions (8), and they are differ for various boundary conditions from (9)–(11).

In (14)–(16) the matrices contain both usual for the problems of the magnetoelectroelasticity the matrices, calculated on the volumes of finite element mesh, and the additional matrices, calculated on the interface boundaries. For example, the stiffness matrix \mathbf{K}_{uu} has the following structure:

$$\mathbf{K}_{uu} = \mathbf{K}_{uu\Omega} + \mathbf{K}_{uu\Gamma}, \quad \mathbf{K}_{uu\Omega} = \int_{\Omega_h} \mathbf{B}_u^* \cdot \mathbf{c} \cdot \mathbf{B}_u d\Omega, \quad \mathbf{K}_{uu\Gamma} = \int_{\Gamma_h^s} \mathbf{B}_u^{s*} \cdot \mathbf{c}^s \cdot \mathbf{B}_u^s d\Gamma, \quad (17)$$

$$\mathbf{B}_u = \mathbf{L}^*(\nabla) \cdot \mathbf{N}_u^*, \quad \mathbf{B}_u^s = \mathbf{L}^*(\nabla^s) \cdot \mathbf{A} \cdot \mathbf{N}_u^*. \quad (18)$$

Note that the matrix \mathbf{K} of the system of linear algebraic equations (14) is symmetric. In addition, by virtue the properties of positive definiteness of the volume and surface energies, the matrix \mathbf{K}_{uu} and \mathbf{K}_{bb} will be at least non-negative definite. Therefore, the symmetric matrix \mathbf{K} in (14) will have the properties of a quasi-defined matrix, typical for the problems with a saddle point.

In this connection, in ACELAN-COMPOS package we use an effective algorithms for symmetric positive definite and quasi-definite matrices for solving the system of linear algebraic equations (14) [1, 2, 21]. All basic procedures that we need in finite element manipulations, such as the degree of freedom rotations, mechanical, electric and magnetic boundary condition settings, etc., we can also provide in a symmetric form.

4 MODELS OF REPRESENTATIVE VOLUMES AND SOME RESULTS

In ACELAN-COMPOS package the representative volume element (RVE) is simulated in the form of a cubic array of finite elements, where the elements also have cubic shapes. In accordance with the accepted structure of second phase, we assign the properties of the skeleton material of the first phase to some part of the finite elements, and assign the properties of the second phase to the remaining part of the elements.

In ACELAN-COMPOS there are the opportunities to create different types of representative volumes. Examples of representative volumes, created by different algorithms of the ACELAN-COMPOS package, are shown in Fig. 1–4. In all cases, the percentage of occurrence of the second phase was approximately the same (about 15 %), and the order of RVE is the same and equal $16 \times 16 \times 16$. Everywhere in Fig. 1–4, *a*) the whole RVE is shown, in Fig. 1–4, *b*) the elements of the first phase are shown, in Fig. 1–4, *c*) the elements of the second phase are shown, and in Fig. 1–4, *d*) the surface elements are shown.

In the first case, the finite elements of second phase are selected by a random number generator (Fig. 1). It is obvious that the model created by using a simple random number generator is easy to build. However, such model does not support the connectivity of the elements for the first phase and does not reflect the connectivity structure of the elements for the second phase.

Two other algorithms in ACELAN-COMPOS create the structures of the two-component materials with the connectivity for both phases (3–3 connectivity) [9, 11, 12]. In the case of porous composites, the 3–3 connectivity algorithms generate materials with open porosity. In these algorithms, the representative volumes consist of domains with $8 \times 8 \times 8$ finite elements. Number 8 for the domain size was chosen

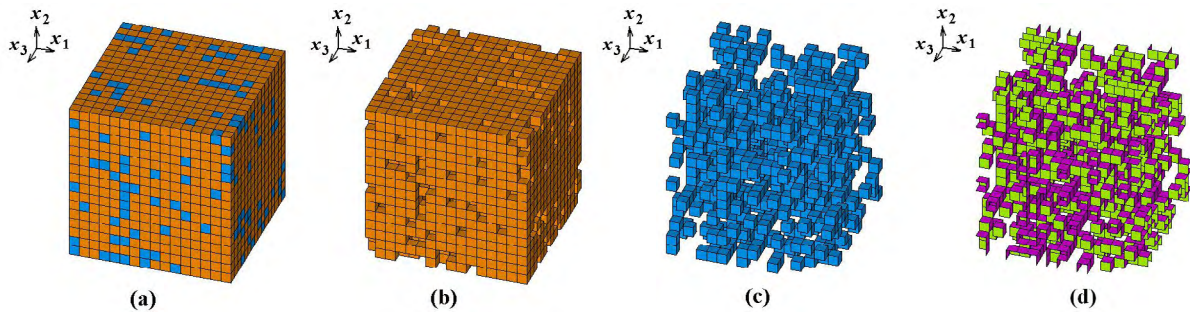

Figure 1: Example of RVE of with a random arrangement of the elements of the second phase

for the convenience of implementing numerical procedures to verify the phase connectivity and generate different data structures. In a direct version of the 3–3 algorithm, the process of the domain generation is implemented in such way that the connectivity of the elements of the first phase is maintained through the domain vertices, and the connectivity of the structure of the second phase is maintained through the elements located approximately in the midpoints of the domain edges. In the inverted version of this algorithm, the first phase and the second phase are interchanged.

Each domain is created by a partially random way, and the representative volumes of $8n \times 8n \times 8n$ order are formed as a result of generating the sequence of n domains along each of three coordinate axes. Thus, generally speaking, each resulting domain differs from the other. Nevertheless, it maintains the connectivity of both phases and the connectivity of the total volume structure, being formed either by a direct 3–3 algorithm or by an inverse 3–3 algorithm.

Figure 2: Example of RVE with 3–3 connectivity (direct algorithm)

A detailed description of these algorithms is given in [9, 12]. Some examples of the representative volumes with the porosity $p \approx 15\%$ for $n = 2$ (eight domains) are shown in Fig. 2 for direct algorithm and in Fig. 3 for inverse algorithm, respectively. As can be seen from Fig. 2, the direct algorithm distributes a significant amount of the framework elements (elements of the first phase) near the domain edges. On the contrary, the inverse algorithm gathers the most part of the framework elements (elements of the first phase) in the central part of the domain. For a larger number of domains ($n = 3$, $n = 4$, etc.), these effects are leveled, since some parts of the domain boundaries become located inside of the representative volume.

For simulate the element of second phase as granules, consisting of one or more structural elements not connected with other granules, in ACELAN-COMPOS package the 3–0 algorithm exists [10, 11, 12]. In the case of porous composites, the 3–0 connectivity algorithms generate materials with closed porosity.

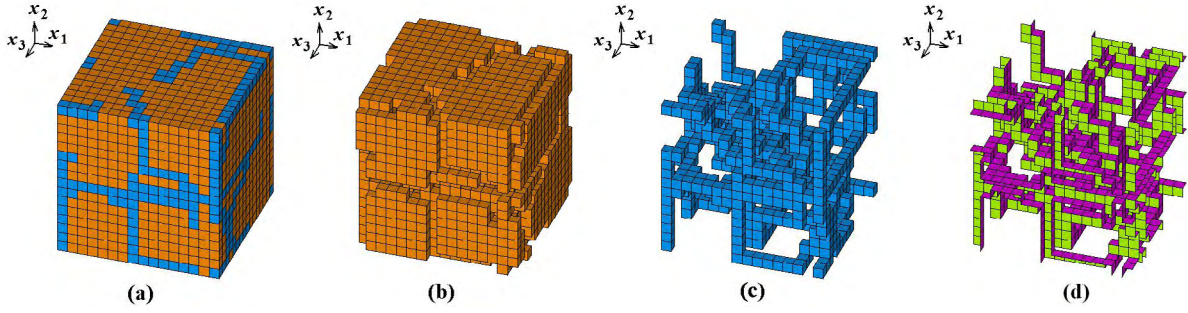

Figure 3: Example of RVE with 3–3 connectivity (inverse algorithm)

In this algorithm, the representative volumes also consist of domains with $8 \times 8 \times 8$ elements. The input user data are the granule size and the maximum quantum of inclusions. Random choice of the supporting elements for the granules ensures in the result the partially stochastic distribution of the elements of second phase in the RVE. The granule grows in the domain according to an algorithm that allows the granule to be shaped as possible close to the ball, while avoiding highly elongated elements.

As in 3–3 algorithms, each domain in 3–0 algorithm is created by a partially random way, and the representative volumes of $8n \times 8n \times 8n$ order are formed in the result of generating the sequence of domains along three coordinate axes. Thus, here each resulting domain differs from the other. Nevertheless, it maintains the connectivity of the elements of the main first phase. A detailed description of the 3–0 algorithm is contained in [10, 12]. One example of the RVE for $n = 2$ (eight domains), constructed by the 3–0 algorithm, is shown in Fig. 4.

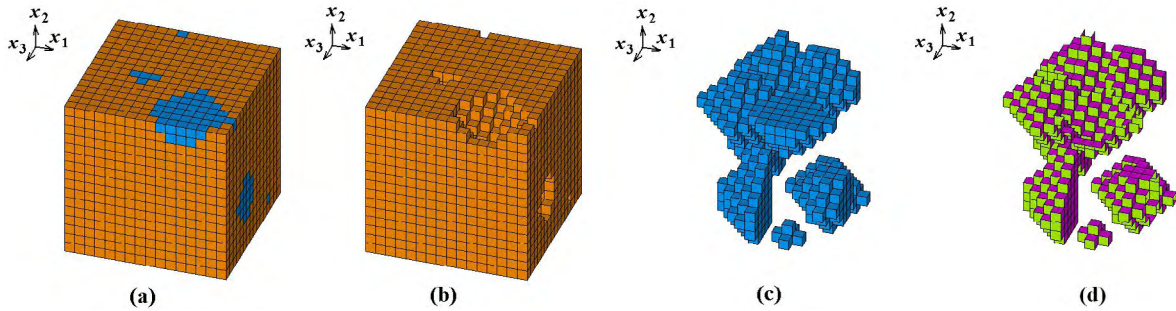

Figure 4: Example of RVE with 3–0 connectivity

In 1–3 (3–1) algorithm of the ACELAN-COMPOS package, the representative volume contains rods placed in the skeleton of the main material. This is a simple algorithm based on placing two-dimensional pattern on the bottom of the volume and extruding it through the body [8, 12].

For nanostructured composites, for all variants of representative volumes, it is possible to automatically find the interphase boundaries Γ^s and place on them the shell (membrane) finite elements that simulate the surface effects (Fig. 1–4, *d*). For the shell elements it is necessary to insure the anisotropy type, which corresponds to the anisotropy of the volume finite element. This correspondence was implemented only for transversely isotropic phases and for elements parallel to the Ox_1x_2 plane (painted in light green in Fig. 1–4, *d*) or x_3 axis (painted in crimson in Fig. 1–4, *d*).

For representative volumes shown in Fig. 1–4, we will present here as an example the calculation results of solving the homogenization problem for a porous piezoceramic material without taking into

account the surface effects (Table 1) and taking into account only uncoupled surface stresses according to the methodology presented in [7, 13] (Table 2). For RVE of this composite the domain $\Omega^{(1)}$ occupied by the dense piezoceramics and the domain $\Omega^{(2)}$ occupied by the pores: $c_{\alpha\beta} = c_{\alpha\beta}^{E(i)}$, $e_{j\beta} = e_{j\beta}^{(i)}$, $\kappa_{jj} = \epsilon_{jj}^{S(i)}$ for $\mathbf{x} \in \Omega^{(i)}$, $i = 1, 2$.

In Tables 1, 2 we give the relative values of the effective material moduli $r(c_{\alpha\beta}) = c_{\alpha\beta}^{\text{eff}}/c_{\alpha\beta}$, $r(e_{j\beta}) = e_{j\beta}^{\text{eff}}/e_{j\beta}$, $r(\kappa_{jj}) = \kappa_{jj}^{\text{eff}}/\kappa_{jj}$ and $r(d_{j\beta}) = d_{j\beta}^{\text{eff}}/d_{j\beta}$ for porous piezoceramics PZT-5. Here $c_{\alpha\beta} = c_{\alpha\beta}^{E(1)}$, $e_{j\beta} = e_{j\beta}^{(1)}$, $\kappa_{jj} = \epsilon_{jj}^{S(1)}$ and $d_{j\beta} = d_{j\beta}^{(1)}$ are the corresponding values for the dense piezoceramics, $\mathbf{d} = \mathbf{e} \cdot \mathbf{c}^{-1}$.

For dense piezoceramics PZT-5 we take the following mechanical, dielectric and piezoelectric constants: $c_{11}^{E(1)} = 12.1 \cdot 10^{10}$; $c_{12}^{E(1)} = 7.54 \cdot 10^{10}$; $c_{13}^{E(1)} = 7.52 \cdot 10^{10}$; $c_{33}^{E(1)} = 11.1 \cdot 10^{10}$; $c_{44}^{E(1)} = 2.11 \cdot 10^{10}$ (N/m²); $e_{33}^{(1)} = 15.8$; $e_{31}^{(1)} = -5.4$; $e_{15}^{(1)} = 12.3$ (C/m²); $\epsilon_{11}^{S(1)} = 916\epsilon_0$; $\epsilon_{33}^{S(1)} = 830\epsilon_0$; $\epsilon_0 = 8.85 \cdot 10^{-12}$ (F/m). For the pores, we set negligibly small elastic moduli $c_{\alpha\beta}^{E(2)} = \eta c_{\alpha\beta}^{E(1)}$, $\eta = 1 \cdot 10^{-10}$, piezomoduli $e_{j\beta}^{(2)} = \eta$ (x1 C/m²) and $\epsilon_{jj}^{S(2)} = \epsilon_0$. For the case of nanoporous piezoceramics with uncoupled surface stresses we accept the size of cube finite element $a = 10^{-10}$ (m), $c_{\alpha\beta}^s = a c_{\alpha\beta}^{E(1)}$, $e_{j\beta}^s = 0$, $\kappa_{jj}^s = 0$.

Table 1: Effective moduli of porous piezoceramics PZT-5 without surface stresses

Material moduli	SR, $p = 14.99$	3–3 (direct), $p = 14.84$	3–3 (inverse), $p = 15.21$	3–0, $p = 15.04$
$r(c_{11})$	0.76	0.71	0.69	0.66
$r(c_{12})$	0.72	0.65	0.62	0.61
$r(c_{13})$	0.71	0.64	0.61	0.58
$r(c_{33})$	0.75	0.69	0.68	0.64
$r(c_{44})$	0.81	0.79	0.78	0.77
$r(e_{31})$	0.73	0.66	0.64	0.56
$r(e_{33})$	0.84	0.83	0.83	0.81
$r(e_{15})$	0.80	0.77	0.77	0.74
$r(\kappa_{11})$	0.85	0.85	0.84	0.84
$r(\kappa_{33})$	0.84	0.83	0.83	0.83
$r(d_{31})$	0.95	0.92	0.92	0.88
$r(d_{33})$	0.99	0.98	0.99	0.98
$r(d_{15})$	0.98	0.98	0.98	0.96
$ \Gamma^s / \Gamma $	1.91	1.32	1.13	0.68

It can be noted that even with the same porosity for the simple random (SR) algorithm, the area of interface boundaries $|\Gamma^s|$ is larger than for the 3–3 connectivity direct algorithms, the area of interface boundaries for the 3–3 direct algorithms is larger than for the 3–3 inverse algorithms, and the area of interface boundaries for the 3–3 inverse algorithms is larger than for the 3–0 algorithms. So, as we can conclude from Tables 1, 2, for the representative volumes with SR distribution of inclusions and with 3–3 or 3–0 connectivity for various interphase areas we obtain different values of the effective moduli, moreover the SR model is slightly stiffer and more electromechanical active than the 3–3 models, and the 3–3 connectivity models are stiffer and more electromechanical active than the 3–1 model.

Accounting for surface stresses here is equivalent to the placement of elastic membrane elements on the interface boundaries. Therefore, when taking into account surface stresses, the size of the interface

Material moduli	SR, $p = 14.99$	3–3 (direct), $p = 14.84$	3–3 (inverse), $p = 15.21$	3–0, $p = 15.04$
$r(c_{11})$	1.09	0.98	0.93	0.77
$r(c_{12})$	0.93	0.85	0.80	0.70
$r(c_{13})$	0.92	0.84	0.79	0.66
$r(c_{33})$	1.09	0.98	0.92	0.75
$r(c_{44})$	1.08	1.00	0.98	0.88
$r(e_{31})$	0.84	0.78	0.74	0.63
$r(e_{33})$	0.84	0.83	0.83	0.81
$r(e_{15})$	0.83	0.80	0.79	0.76
$r(\kappa_{11})$	0.84	0.83	0.83	0.83
$r(\kappa_{33})$	0.83	0.82	0.82	0.82
$r(d_{31})$	0.59	0.63	0.66	0.75
$r(d_{33})$	0.60	0.66	0.69	0.83
$r(d_{15})$	0.76	0.80	0.81	0.87
$ \Gamma^s / \Gamma $	1.91	1.32	1.13	0.68

area has a very significant effect on the effective stiffness moduli (Table 2). Thus, we can conclude that the internal structures of nanoporous composites can have a significant effect on the effective stiffness moduli values. Meanwhile, from a comparison of Tables 1 and 2, we can infer that the uncoupled surface stresses have much less effect on the effective piezomoduli $e_{j\beta}^{\text{eff}}$ and almost do not influence on the dielectric permittivities κ_{jj}^{eff} .

Note that using the described approaches in [7, 8, 9, 10, 14, 15] et al, the of homogenization problems were solved for different structures of representative volumes. Anisotropic elastic and piezoelectric composites were investigated, both on ordinary scale levels and on nanoscale. It was found that the types of connectivity and the internal structure of a composite can have a significant influence on effective moduli (see also Tables 1, 2), and taking into account surface or interface effects can even lead to a change in the decreasing properties of moduli on their growth and even lead to superiority of effective moduli compared to moduli of initial phases (Table 2).

An analysis of the advantages and disadvantages of various algorithms for the formation of representative volumes is given in [12]. Additionally, it can be noted that the piezoceramic finite elements of all types of representative volume structures can be automatically equipped with their elemental coordinate systems rotated relative to the initial Cartesian coordinate system in accordance with the direction of the non-uniform polarization fields [14, 15, 18], and for 3–0 connectivity models the algorithms for the account of electrode surfaces for metallized interfaces have been developed [17, 18].

Abstract. Dual lead zirconate titanate (PZT) transducers have recently been developed for structural health monitoring (SHM) applications. These transducers have been shown to be a suitable option for decomposing a guided Lamb wave response that contains a mixture of the fundamental symmetric (S0) and antisymmetric (A0) modes. This ability to decompose the wave response, or more accurately, to highlight an individual mode, is applied in this experimental work for damage localization using a sparse transducer array. For this paper, studies were performed on a section of an aluminum alloy skin plate of a Piper Cherokee wing. The skin plate is supported by structural features common to most aircraft such as stringers, ribs, and rivets. Such features often pose a challenge to guided wave SHM over a large area due to scattering effects, mode conversion, and attenuation of the guided waves. Damage was simulated using magnets of various strengths and shapes placed on either side of the wing skin. Sparse array images were constructed using baseline-subtracted signals from all possible sensor actuator pairs using ellipse summation and correlation algorithms. This work shows that dual PZTs can potentially be used to improve sparse array imaging techniques due to the transducers' mode decomposition capability. Specifically, preliminary results suggest that the decomposed S0 mode can be used at certain frequencies and farther damage locations where neither the A0 or S0 mode are as effective with single element transducers. Also, this study provides a general comparison between the A0 and S0 modes and their damage localization capability with the given experimental setup. Furthermore, this work demonstrates that if a baseline is used, structural features such as stringers and ribs in the present configuration do not significantly affect the localization capabilities of the proposed sparse array method.

1 INTRODUCTION

Structural health monitoring (SHM) refers to the broad field regarding topics such as autonomous detection and characterization of damage in a system, usage monitoring, remaining life calculation, and autonomously prescribed maintenance. This work focuses on the autonomous detection and characterization of damage category of SHM and particularly emphasizes localization of damage. One class of damage detection and localization methods

makes use of Lamb waves, or in real structures, guided Lamb Waves (GLW). These elastic waves are a type of vibration in plates and have been well studied for their potential applications in SHM particularly for aircraft [1,2]. In order to excite and measure Lamb waves in a practical structure, in-situ transducer networks must be installed as part of the system. Use of lead zirconate titanate (PZT) transducers as the excitation and sensing devices are common due to their simplicity, efficiency, and relatively well-understood properties. Given an excitation voltage and a relatively low excitation frequency, for an isotropic material such as aluminum, a PZT bonded to the surface will excite both the fundamental symmetric (S_0) and antisymmetric (A_0) Lamb wave modes. However, for many GLW localization algorithms, a structural response consisting of one mode is ideal. One solution to this is to bond collocated transducers on either side of a plate in order to selectively excite or decompose a mode of interest [3]. But it is difficult to collocate transducers accurately, and this practice is impractical for aerospace applications where sensors interfering with an aircraft's outer mold line are not ideal. One could also take advantage of the PZT tuning curve to excite the guided waves at frequencies where one mode is dominant, but this cannot perfectly generate only one mode, and it limits the excitation frequencies which can be used significantly [4]. As an alternative to collocated PZTs, a dual PZT transducer concept was developed [5,6]. These transducers are constructed from a pair of concentric ring and disc PZT-5A elements and thus can be mounted on one side of a plate and allow for highlighting of the constitutive A_0 and S_0 modes in a GLW signal.

The sparse array GLW method makes use of a large, spatially distributed network of transducers and is ideal for monitoring a large surface area, such as the skin of an aircraft. This method usually requires a baseline or pristine condition dataset. Baseline-free methods have been developed due to the drawbacks of relying on a baseline such as varying temperature environments and other unknown operating conditions [7,8]. However, due to the complexity of as-built aircraft structures, methods employing a baseline provide better localization capability if environmental influences can be controlled. Lamb wave theory depends on infinite flat plates, so the introduction of structural features such as stringers, ribs, and rivets creates significant challenges. Riveted structures and plate edges cause a GLW scattering effect, and reflections from plate edges and other features make GLW signals in these structures complex [9,10].

In this study, a sparse array was constructed using dual PZT transducers and was installed on a section of a Piper Cherokee skin plate. Damage to this structure was simulated with magnets in various cases. The GLW signal S_0 and A_0 modes were highlighted using the dual PZT mode decomposition process, and signals were compared to a baseline set of data. Sparse array imaging techniques were employed, and the damage localization results are shown here. An analysis of the impacts of mode decomposition and complex structural features is also presented.

2 METHODOLOGY

2.1 Dual PZT Transducers and Mode Decomposition

The basis for using dual element PZT transducers for GLW SHM applications is rooted in the tuning curves of PZT wafers. Specifically, lamb wave amplitudes change at different rates for different sized PZT wafers. Manipulation of this property allows for Lamb wave mode decomposition without requiring collocated sensors on two sides of a plate. For this work an

array of five dual PZTs was constructed. The placement of this array is explained in further detail in the experimental setup section. In order to decompose the fundamental Lamb wave A0 and S0 modes for a given transducer pair and excitation frequency, two types of pitch-catch signals are needed. For the first signal, $RD_{ij}(t)$, the ring portion of the i^{th} transducer is excited and the inner disc section of the j^{th} transducer measures the GLW response. The other signal, $DD_{ij}(t)$, is formed when the inner disc portion of the i^{th} transducer is excited and the inner disc section of the j^{th} transducer measures the GLW response. Figure 1 shows the dimensions of the PZT-5A transducers used for this work as well as a diagram illustrating the signal nomenclature.

Figure 1 : Dual PZT dimensions and signal nomenclature (the active PZT elements are highlighted above).

For this work, only these two signals were necessary for adequate highlighting of the constitutive modes however a total of 9 signals can be collected if desired. In order to decompose the individual A0 and S0 modes, the ring and disc signals were combined and scaled according to equations 1 and 2.

$$A0_{ij}(t) = RD_{ij}(t) - C_{A0,ij}DD_{ij}(t) \quad (1)$$

$$S0_{ij}(t) = RD_{ij}(t) + C_{S0,ij}DD_{ij}(t) \quad (2)$$

The scaling factors, $C_{A0,ij}$ and $C_{S0,ij}$ were determined experimentally by comparing the magnitudes of particular modes in the ring and disc signals. For example, the scaling factor $C_{A0,ij}$ was determined by measuring the ratio of the magnitudes of the S0 mode first arrivals for $RD_{ij}(t)$ and $DD_{ij}(t)$. Thus, applying equation 1 with this scaling factor essentially removes the S0 mode from the signal, and the opposite is true applying equation 2. An example of this decomposition is shown in Fig. 2. Here the signal, $DD_{12}(t)$, is used as the reference undecomposed signal since it is essentially equivalent to a signal that would be found using more common single element PZT discs. The figure shows that the dual PZT processing method is at a minimum able to highlight the first arrival and edge reflections of a particular mode.

Figure 1 : Actuator-sensor pair 1-2 undecomposed (black) and decomposed A0 (red) and S0 (blue) mode signals with an excitation frequency of 100 kHz.

2.2 Sparse Array Technique

Damage maps were constructed using the sparse array technique. This method relies on an approximation of the group velocities for the item under test which can be obtained experimentally or analytically if the material properties are known *a priori*. This method is also dependent on baseline subtraction of damage signals due to the complexity of the aircraft structure. Baseline subtraction highlights the scattered portions of the signal from any damage introduced after the baseline was taken. These portions of the signal are then converted from the space domain to the time domain using the group velocity of a particular mode. The signal must be assumed to predominantly consist of only one mode for this conversion to be successful. In our case, the decomposed signals are used providing a potentially more accurate result. This space domain conversion is repeated for all points in time and all sensor-actuator pairs yielding a triangulation effect at points of damage.

For this work, two triangulation methods were used, these being summation and correlation algorithms. These algorithms are described in more detail in [11,12]. The correlation algorithm provides greater clarity by focusing more on ellipse intersections; however, it can be prone to false alarms and missed detections if faux intersections outweigh the intersection at an actual damage location or if there are multiple damage locations present in the inspection area. A higher number of transducers tends to produce a better result for both methods. For the localization algorithms, the experimentally determined group velocities shown in Fig. 3 were used. For the frequency range of interest (40-200 kHz), a PZT bonded to an aluminum plate will excite only the A0 and S0 modes.

2.3 Experimental Setup

Experimental work for this study used a Piper Cherokee wing section as the test specimen. The panel of interest was constructed from a 1-mm thick aluminum alloy skin plate and was

built up with various stringers, ribs, and a spar. These features were generally riveted to the skin plate, and no other bonding materials were used. The five-element transducer array was constructed in the shape of a spiral as a non-axisymmetric distribution was desired for optimal performance. The array was positioned on the bottom of the wing just aft of the leading edge as shown by Fig. 4. Damage was simulated to the wing skin using a strong pair of magnets placed on either side of the skin. This generates a localized force on the plate which is strong enough to produce GLW scattering similar to an actual crack.

3 RESULTS AND DISCUSSION

A series of studies assessed the capabilities and limitations of the mode decomposition technique combined with the sparse array method. Three case studies are presented here, each testing different aspects to the present method including range, individual mode effectiveness, and the influence of complex structural features such as ribs, stringers, and lap joints.

3.1 Case Study 1 - Damage Distant from the Array

The first study examined the range of damage detection and potential influences of a rib mounted to the skin plate by placing simulated damage over 0.5 m from the center of the sparse array with a rib joint in the direct path to the damage. Due to the dispersion of the A0 mode and the relatively long distance of the damage from the array, this mode did not accurately locate damage as its reflections were likely too weak. Thus, the decomposed S0 mode summation and correlation images are shown in figure 5. Both algorithms show damage at the appropriate location using the experimentally determined S0 mode group velocity. This figure also highlights the difference between the two algorithms for a single damage location case. Henceforth, only the correlation algorithm images are shown since the summation algorithm images are typically similar but less clear. In general, this study demonstrates the advantage of using the S0 mode for maximum inspection range, and it shows that using the decomposed signal, reflections from damage are not too attenuated at over 0.5 m from the array.

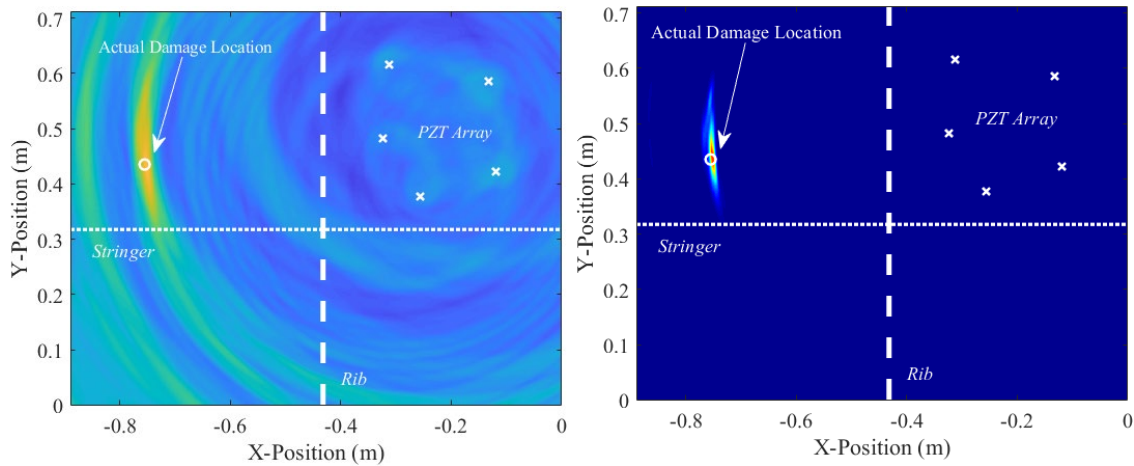

Figure 5: S0 Decomposed 140 kHz excitation summation algorithm image (left) and correlation algorithm image. The damage location is represented by a white circle.

3.2 Case Study 2 - Damage within the Array

For the next case study damage was placed near the center of the array, as this could pose potential problems with first arrival packet interference. Additionally, the proximity to the array implies that both the S0 and A0 reflections should be relatively strong, and an assumption that the signal is predominantly one mode may not provide ideal results in all frequency cases. Figure 6 demonstrates this by showing the damage maps for the undecomposed and decomposed S0 mode signals using the S0 mode group velocity. On the left, the undecomposed signal has dominant A0 mode reflections, so use of the faster S0 mode group velocity provides an inaccurate damage location. By using the decomposed S0 signal, the spurious A0 mode reflections are clearly removed, and use of the S0 group velocity yields a damage image that accurately locates damage. This case study demonstrates that the decomposed S0 mode signal can be used for damage detection close to the array where A0 reflections are typically dominant. Mode decomposition removes these spurious reflections if using the S0 group velocity.

Figure 6: S0 undecomposed 120 kHz excitation correlation algorithm image (left) and S0 decomposed correlation algorithm image (right). The damage location is represented by a white star.

3.3 Case Study 3 - Damage Across Lap Joint

The third case study examines the influence of a lap joint on damage detection capabilities. This lap joint connects two skin plate sections with rivets, and this discontinuity is expected to reduce the amplitude of GLW reflections. To study this, simulated damage was placed just below the lap joint on a separate plate section from the array. Due to the distance from the array, the A0 mode decomposed signal was not effective in locating this damage, so figure 7 examines the effectiveness of S0 mode decomposition. In this figure, the solid line parallel to the dashed stringer line represents the lap joint, and the star represents the damage location. Without mode decomposition, the S0 mode reflections due to introduced damage are not strong enough to locate this damage. With mode decomposition, the image correctly shows damage at the damage location with a few spurious reflections. This case study suggests that the decomposed S0 mode signal can increase the damage detection sensitivity, and that mode decomposition makes damage detection across lap joints possible.

Figure 7: S0 undecomposed 120 kHz excitation correlation algorithm image (left) and S0 decomposed correlation algorithm image (right). The damage location is represented by a white star.

4 CONCLUSIONS

In this paper, a previously developed damage decomposition method using dual element PZT transducers [5,6] was applied to a sparse array GLW damage localization scheme. Experimental studies were performed with an aluminum Piper Cherokee wing since it imposes additional, realistic challenges that are not present when testing with an ideal simple plate. Several cases showed that the sparse array method using dual PZTs to decompose the GLW modes was effective at localizing simulated damage. It was shown that the S0 mode was more effective in localizing damage in cases farther away from the array (greater than 0.5 m) likely due to its lack of dispersion. Additionally, the results suggest that the decomposed S0 mode may be used in almost all cases, and this signal is more sensitive to damage at long distances when compared to the undecomposed signal. Finally, the results suggest that if a baseline data set is used and measurements are made in a consistent environment, structural features do not

significantly influence the damage localization results. The only significant influence is signal attenuation over longer distances and transmission through multiple lap joints. For the cases shown, no structural features prevented damage from being localized accurately. Thus, these results suggest that the presented method can be used to locate crack-like damage in a relatively large section of a wing, likely greater than 1 m². An array that is distributed over a larger area and not restricted to a featureless section of the plate as presented here may allow for damage detection over an even larger area.

Key words: Fabric-reinforced shape memory polymer composite plate (FSMPCP), Shape memory constitutive model, Stiffness homogenization, Tension-compression asymmetry.

Abstract. Fabric-reinforced shape memory polymer composite plate (FSMPCP) with high levels of stiffness, strength and shape memory property are important stimuli-controlled smart materials which have significant potential to be applied in large size smart structures. Shape memory property and the corresponding mechanical constitutive model of FSMPCP are the essential issues to be addressed before utilizing the material. In this work, a long carbon-fiber reinforced FSMPCP was developed via vacuum infiltration molding process (VIMP) to investigate the shape memory process and further to establish the constitutive model. Mechanical experiments including tension and compression were carried out firstly, where the anisotropy and the tension-compression asymmetry were detected. Then, the thermal shape memory property in bending case was investigated through a typical four-step shape memory experiments. To establish an effective shape memory constitutive model of FSMPCP, a bi-phasic description was used where the stiffness was considered to be contributed by an active-phase and a frozen-phase. A homogenization process using representative volume element (RVE) was conducted to obtain the effective elastic properties. Besides, a linear two-modulus model was applied to depict the asymmetry of tension-compression. To validate the constitutive model, numerical simulation method was also developed based on the UMAT in ABAQUS. Finally, finite element simulations of bending shape memory experiments were carried out using the proposed constitutive model. The comparison between numerical and experimental results revealed that the constitutive model was effective to depict the anisotropy, the tension-compression asymmetry and the shape memory process of the FSMPCP.

1 INTRODUCTION

Fabric-reinforced shape memory polymer composite plates (FSMPCPs) have drawn a wide

range of interests due to its superior performance in stiffness, strength and the special shape memory ability. Compared with the shape memory ceramic composites, FSMPCPs behave better in larger deformation and could be easily fabricated. Compared with the shape memory alloy, FSMPCPs are more economical and have more design flexibility. In this case, FSMPCPs can be applied in composite hinges [1], morphing skins [2] and large space deployable structures [3, 4]. Before the utilization of FSMPCs, shape memory property and corresponding constitutive model are fundamental issues to be addressed.

There are usually two method to take the shape memory effect (SME) and heterogeneity of FSMPCPs into account when considering the constitutive model. The first method is directly numerical method, where the composite structure of FSMPCPs including the fabrics and matrix is directly built in finite element model, then the SME is introduced by assigning the matrix as shape memory viscoelastic polymer [5, 6]. The second method is homogenization method, where the heterogeneity is considered by a homogenization process, then the material is regarded as anisotropic material and the SME is introduced by regarding the homogenized material as viscoelastic material [7, 8]. The first method could depict the mechanical properties accurately but is very limited to be used in analysis of large scale structures since the number of element is too big to be processing in a normal finite element analysis program. The second method has reduced the size of global matrix by homogenization across scales, however, the FSMPCPs are not viscoelastic material but elastic material [9, 10]. Therefore, this work will utilize homogenization method to evaluate the heterogeneity of FSMPCPs. Then a bi-phasic description of the material constituent will be used to consider the SME effect in order to establish effective constitutive model for FSMPCPs which is nearly elasticity, where the stiffness was considered to be contributed by an active-phase and a frozen-phase.

The work was organised as follows, the material introduction and experiments were presented firstly, based on which the shape memory constitutive model was established and then validated through finite element simulation. At last, future works and conclusions were briefly listed.

2 MATERIAL AND EXPERIMENT

2.1 Specimen preparation

Carbon fiber FSMPCPs lamina with thickness of 0.8mm was manufactured by vacuum resin transfer molding (VTRM) process, where the mixture of epoxy monomer E44 and poly-bis-ether [11] were poured into the mold to infiltrate the T800-12 K carbon-fiber cloth with 3-up-1-down woven pattern. Then the air was evacuated through the exit of the mold and the infiltrated carbon fiber cloth was cured at 100°C. The woven patterns were plotted in Figure 1 (planform view) and Figure 2 (cross section view) while the geometrical parameters of the elliptic yarn were listed in Table 1. As the glass transformation point (T_g) was determined to be 56.5°C for warp direction and 56.2°C for weft direction, the mechanical experiments of tension and compression were chosen to be 25°C and 85°C, which were corresponded to glassy state and rubbery state of the material, respectively. The initial FSMPCPs was processed to be rectangle specimens using the milling machine with high smoothness processing level. Tension and compression experiments were carried out using UTM-4000 universal testing machine (Produced by Shenzhen SANSEI). Dimensions of specimen for tension experiment was

20mm × 200mm. When considering the compression experiment, the length-width ratio was reduced to avoid buckling effect during the test. Therefore, the dimension for compression experiment was 30mm × 70mm.

2.2 Mechanical and shape memory experiments

(1) Tension experiments

In the uniaxial tensile experiments, the clamped length of specimens was 50mm in each side and the gauge length was 100mm. Specimen was firstly clamped on the fixtures and the tank temperature was set to be the expected value. Then the heat module was started and all the heating and loading devices were hold about 40 minutes to make the thermal field steady in the tank room. After which, the extension was applied to the specimen with constant rate of 1mm/min. Tensile displacement, force and time were recorded in the experiment. The stress-strain curves were plotted in Figure 3 using nominal strain and nominal stress. As presented in the stress-strain curves, the response was nearly linear elasticity in both glassy state and rubbery state. However, the tensile modulus in warp direction was always larger than that in weft direction. Meanwhile, the modulus in rubbery state was significantly smaller than that in glassy state. As a result, the average tensile-modulus in warp and weft directions were 16.5 GPa and 13.7 GPa at 25°C of glassy state. For the rubbery state, the average tensile modulus in warp and

weft directions were 4.9 GPa and 3.3 GPa at 85°C.

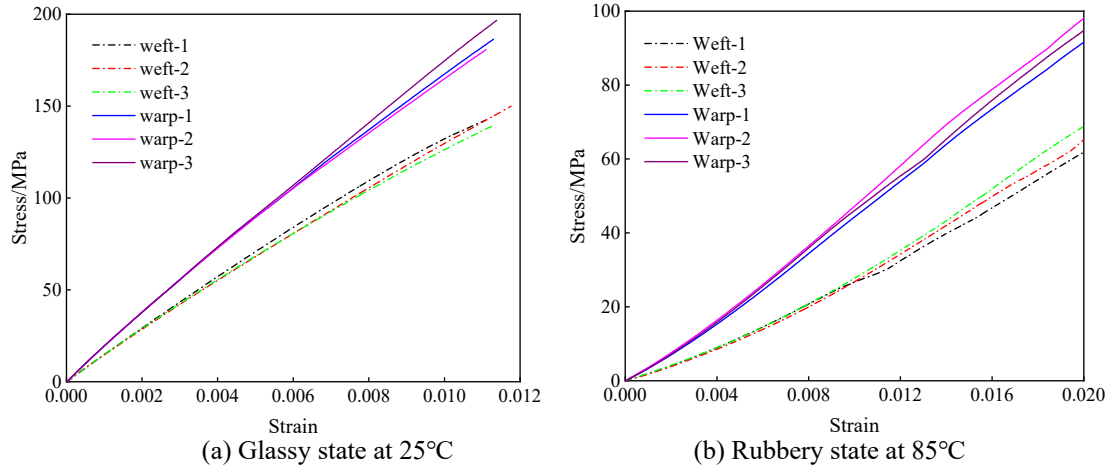

Figure 3: Stress-strain of uniaxial tension experiments in warp and weft directions

(2) Compression experiments

Uniaxial compression experiments were carried out using a dedicated compression test fixture for the local buckling effect using conventional ASTM test fixture. The compression test fixture was consisted by two housing blocks and two matched cover plates, used to prevent the thin woven composite from premature buckling. One could see the details of the fixture in our former work [12]. The temperature control steps were same to the tension experiments, where a thermal balance time of 40 minutes were adopted before loading and the compression rate was also 1mm/min. In this case, the average compression modulus in warp and weft directions were 5.6 GPa and 4.4 GPa at 25°C, while the values were 1.5 GPa and 1.1 GPa at 85°C. Overall, the compression modulus were about one third of tensile modulus for both warp and weft directions.

Figure 4: Stress-strain of uniaxial compression experiments in warp and weft directions

(3) Shape memory experiments

Shape memory experiments in three-point bending mode were carried out using DMA-Q800

equipment according to the typical four step shape memory process: i. Apply the deformation at temperature above T_g ; ii. Cool down the temperature with the displacement constraints; iii. Release the constraints at temperature below T_g and most of the deformation would retain except for the elastic bounce; iv. Heat the specimen and the shape would recovery to the original state. In the experiments, the heating and cooling rates were set to be $3^\circ\text{C}/\text{min}$. Dimension of specimens were $10\text{mm} \times 30\text{mm}$, where the span of the supporting in three-point bending was 20mm . Except for free recovery, the constraint recovery case was also measured, where the displacement freedom degree was constrained in the heating step. The experiment results were plotted in Figure 5, where the force value of unit width was plotted as Z axis.

Figure 5: Deflection and loading force during the shape memory process

3 CONSTITUTIVE MODELLING

There are two issues in the shape memory modelling of FSMPCPs, the mechanical modelling which considering the composite properties and the thermal modelling which considering the memory process. Here the mechanical modelling was carried out by a homogenization process, where the inner-fabric-structure was considered. The thermal modelling was carried out by a phase-transition concept proposed by Liu et al. [13].

3.1 Homogenization and tension-compression asymmetry

Two scale linear elasticity homogenization analysis was firstly carried out to evaluate the anisotropic properties caused by the inner-composite-structure of FSMPCPs. Details of the homogenization process were referred to Fish [14], where the analysis was divided into two steps. Firstly, a unit cell problem with multiple right-hand sides was solved and the stress influence functions were obtained. Then the overall constitutive tensor components were evaluated by volume averaging. When conduct the homogenization process, properties of the yarn were firstly calculated and inputted as initial parameters with the properties of the polymer matrix, which were listed in Table 2. In this case, the matrix was considered to be isotropic material and yarns were assumed to be transversely isotropic homogenous material. The overall constitutive tensor components \mathbf{D} were obtained in Table 3. According to the stiffness matrix \mathbf{D} , the tensile modulus could be calculated to be 17.2GPa and 14.35GPa , with deviation of 3.8%

and 4.6% with the results in tensile experiments at 25°C.

Table 2: Material properties (25°C) used in homogenization analysis

Parameters	E_t /GPa	E_a /GPa	G_a /GPa	ν
Matrix	1.41		0.52	0.34
Fiber	294.0		113.1	0.30
Yarn	158.1	4.98	1.85	0.32

Table 3: Overall constitutive tensor components

Indices	1	2	3	4	5	6
1	18.37	2.53	1.95	0.00	0.00	0.01
2	2.53	15.47	1.93	0.00	0.00	0.00
3	1.95	1.92	3.78	0.00	0.00	0.00
4	0.00	0.00	0.00	1.18	0.00	0.00
5	0.00	0.00	0.00	0.00	1.06	0.00
6	0.02	0.00	0.00	0.00	0.00	1.05

Then it came to the tension-compression asymmetry, a linear two-modulus model as plotted in Figure 6 was utilized here, where the compression modulus was about 1/3 of the tensile modulus. In the calculations, material stiffness matrix was inputted as initial parameters and the stress state of the material point was firstly judged, if the point was in compression state, the corresponding characters in stiffness matrix would be reduced with a reduction coefficient of 1/3.

Figure 6: Linear two-modulus model for FSMPCPs

3.2 Shape memory effect

The concept of two-phase material model of Liu [13] was utilized here, where the material was regarded as anisotropic homogeneous material with frozen phase and active phase. When temperature was at high temperature ($\gg T_g$), the material would be made up by the frozen constituent. When temperature was at low temperature ($\ll T_g$), the material would be made up by the active constituent. In the phase transition process, both active and frozen constituents would coexist in the material and transfer to each other according to the thermal environment. In the shape memory process, total strain $\boldsymbol{\varepsilon}$ was divided into elastic strain $\boldsymbol{\varepsilon}_E$, storage strain $\boldsymbol{\varepsilon}_S$ and thermal strain $\boldsymbol{\varepsilon}_T$. The overall stress components can be calculated by equation (1). The storage strain which control the shape storage and recovery was related to the temperature by equation (3), where f_s was a volume ratio of the frozen constituent and a function of temperature. In order to make the model more flexibility and accurate to depict the shape memory process, the material stiffness tensor was also split into two part as equation (4), where the subscript "f" and "a" denoted the frozen and active constituents, respectively.

$$\boldsymbol{\sigma} = \mathbf{D} \cdot (\boldsymbol{\varepsilon} - \boldsymbol{\varepsilon}_S - \boldsymbol{\varepsilon}_T) \quad (1)$$

$$\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}_E + \boldsymbol{\varepsilon}_S + \boldsymbol{\varepsilon}_T \quad (2)$$

$$\boldsymbol{\varepsilon}_S = (\boldsymbol{\varepsilon} - \boldsymbol{\varepsilon}_T) \cdot f_s \quad (3)$$

$$\mathbf{D} = \mathbf{D}_f \cdot f_f + \mathbf{D}_a (1 - f_f) \quad (4)$$

Both f_s and f_f were temperature-dependent functions. In a typical four-step free recovery shape memory process, by inserting the constitutive model into the boundary and thermal conditions, the stress and strain evolution in shape memory process could be calculated [15]. Then f_s could be obtained from the strain evolution of the recovery step, while the f_f could be obtained from the stress evolution of the cooling step. In this work, the above constitutive model was coded into ABAQUS as a UMAT, based on which we can carry out the simulation of shape memory process.

4 FINITE ELEMENT SIMULATION

Shape memory experiments were simulated using the above constitutive model, where the specimen was meshed with 3D cubic element named as C3D8. All the thermal conditions and displacement boundaries were same to the experiments, where the temperature revolution inputted in the model was measured from the experiments. Both free and constrained recovery shape memory process were simulated. Results with derivation less than 10% were obtained as plotted in Figure 7. Due to the linear elastic assumption was utilized in modelling the mechanical response of FSMPCPs, the nonlinear response in loading step was not considered here. As indicated in the loading step, bending stiffness was appropriately considered using the tension-compression asymmetry model.

Figure 7: Simulation results using the constitutive model

5 CONCLUSIONS

FSMPCPs would behavior both heterogeneity and shape memory properties, of which the constitutive modelling could be divided into two steps, including the homogenization and the thermal modelling. As inducted in this research, the RVE homogenization analysis and phase-transition concepts could be successfully adopted to established the shape memory constitutive model of the FSMPCPs in elastic regime.

Key words: Sandwich, Piezoelectricity, Viscoelasticity, Shunted Damping, Multiobjective Optimization

Abstract. This paper addresses vibration and noise reduction in laminated sandwich plates using both viscoelastic and piezoelectric elements, using the capabilities of the commercial software programme ANSYS. In the low frequency range, noise and vibration damping is accomplished through piezoelectric patches bonded to the surfaces of the sandwich panels, using passive RL damping circuits. For higher frequency ranges, damping is obtained from viscoelastic materials that are used as the core of the sandwich panels. The sound transmission characteristics of the panels are evaluated by computing their radiated sound power, using the Rayleigh integral method. Optimization of thicknesses, fibre orientation of the composite layers and location of the piezoelectric patches is also conducted for minimization of weight and radiated sound power. Results are presented to illustrate the performance of the optimized sandwich panels in terms of weight and noise reduction efficiency.

1 INTRODUCTION

In the transportation industry, sandwich composite panels may represent an optimized solution for both sound radiation and structural vibration in most frequency ranges. Viscoelastic materials are an efficient way of reducing structural vibrations and providing noise attenuation, which allied to piezoelectric elements may lead to broader control capabilities regarding acoustic emissions. The use of commercial software programmes allows for an acceleration in the design cycles, but due to some limitations in these codes when dealing with material viscoelastic behaviour combined with piezoelectric elements, it is sometimes necessary to develop user codes that can overcome these limitations [1]. Recently, Iurlova et al. [2] developed an algorithm that solved the natural frequency problem of electro-viscoelastic structures with electric circuit through the extraction of global FE matrices from ANSYS. Control of vibrations and noise reduction have also been addressed recently by Larbi et al. ([3], [4]), with the use of RL shunt circuits.

In the present work thicknesses, fibre orientation of the composite layers and location of the piezoelectric patches are optimized in an electro-viscoelastic sandwich panel with the objective of noise reduction.

Commercial software ANSYS is used together with Matlab to achieve this purpose.

2 STRUCTURAL MODEL

2.1 Electro-viscoelastic sandwich panel

The addressed structure is a sandwich plate. The core is made of a viscoelastic material, and the top and bottom faces are made of carbon fibre composite laminates. Piezoelectric patches are bonded to the top of the plate, and a shunted RL circuit is connected to each patch. This forms the electro-viscoelastic sandwich panel as shown in Figure 1.

Figure 1: Electro-viscoelastic sandwich panel

2.2 Orthotropic elastic material

Each lamina of the composite laminated faces of the sandwich plate can be modelled as an orthotropic elastic material. The constitutive equation of an orthotropic material, in its principal material directions is

$$\begin{Bmatrix} \epsilon_1 \\ \epsilon_2 \\ \epsilon_3 \\ \epsilon_{23} \\ \epsilon_{13} \\ \epsilon_{12} \end{Bmatrix} = \begin{bmatrix} s_{11} & s_{12} & s_{13} & 0 & 0 & 0 \\ s_{12} & s_{11} & s_{13} & 0 & 0 & 0 \\ s_{13} & s_{13} & s_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & s_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & s_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & s_{66} \end{bmatrix} \begin{Bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \sigma_{23} \\ \sigma_{13} \\ \sigma_{12} \end{Bmatrix} = \begin{bmatrix} \frac{1}{E_1} & -\frac{\nu_{12}}{E_1} & -\frac{\nu_{13}}{E_1} & 0 & 0 & 0 \\ -\frac{\nu_{12}}{E_1} & \frac{1}{E_2} & -\frac{\nu_{32}}{E_3} & 0 & 0 & 0 \\ -\frac{\nu_{13}}{E_1} & -\frac{\nu_{32}}{E_3} & \frac{1}{E_3} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{G_{23}} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{G_{13}} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{G_{12}} \end{bmatrix} \begin{Bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \sigma_{23} \\ \sigma_{13} \\ \sigma_{12} \end{Bmatrix} \quad (1)$$

where ϵ_{ij} are the elastic strain components, σ_{ij} are the corresponding stress components in the principal material directions and s_{ij} are the components of the compliance matrix, also represented in terms of the usual engineering moduli E_i , G_{ij} and ν_{ij} .

2.3 Viscoelastic material

Using the elastic-viscoelastic equivalence principle, a problem with viscoelastic materials in the frequency domain can be solved as an elasticity problem [5], where the complex moduli are given by

$$E_i(j\omega) = E'_i(\omega) (1 + j\eta_{E_i}(\omega)) \quad (2a)$$

$$G_{ij}(j\omega) = G'_{ij}(\omega) (1 + j\eta_{G_{ij}}(\omega)) \quad (2b)$$

$$\nu_{ij}(j\omega) = \nu'_{ij}(\omega) (1 + j\eta_{\nu_{ij}}(\omega)) \quad (2c)$$

and where primed (') quantities denote storage moduli and η denotes the material loss factor. The product between the storage modulus and the loss factor is the loss modulus.

2.3.1 Fractional derivative models

Classical viscoelastic models deal only with spring and dashpot elements, meaning integer order time derivatives are involved, while fractional derivative models are a more powerful way to describe viscoelastic behaviour since they allow the use of non-integer derivatives. Therefore, more accurate behaviour of viscoelastic materials can be captured with the use of these models.

A model that describe well the overall behaviour of a viscoelastic material is the five parameter fractional model developed by Pritz [6]. According to this model, the frequency dependent shear modulus for a viscoelastic isotropic material becomes

$$G(j\omega) = G_0 + G_0(d-1) \frac{(j\omega\tau)^\alpha}{1 + (j\omega\tau)^\beta} \quad (3)$$

where $d = \frac{G_\infty}{G_0}$ is the ratio of high-frequency limit value of the dynamic shear modulus, G_∞ , to the static shear modulus, G_0 , the order of the derivatives of strain and stress are α and β , respectively, and τ is the relaxation time. For more details the reader is referred to reference [6].

2.4 Piezoelectric material

For a transversely isotropic piezoelectric material the constitutive equations are given by

$$\begin{Bmatrix} \sigma_x \\ \sigma_y \\ \sigma_z \\ \sigma_{yz} \\ \sigma_{xz} \\ \sigma_{xy} \end{Bmatrix} = \begin{bmatrix} c_{11} & c_{12} & c_{13} & 0 & 0 & 0 \\ c_{12} & c_{11} & c_{13} & 0 & 0 & 0 \\ c_{13} & c_{13} & c_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{66} \end{bmatrix}^E \begin{Bmatrix} \epsilon_x \\ \epsilon_y \\ \epsilon_z \\ \epsilon_{yz} \\ \epsilon_{xz} \\ \epsilon_{xy} \end{Bmatrix} - \begin{bmatrix} 0 & 0 & 0 & 0 & e_{15} & 0 \\ 0 & 0 & 0 & e_{15} & 0 & 0 \\ e_{31} & e_{31} & e_{33} & 0 & 0 & 0 \end{bmatrix}^T \begin{Bmatrix} E_1 \\ E_2 \\ E_3 \end{Bmatrix} \quad (4a)$$

$$\begin{Bmatrix} D_1 \\ D_2 \\ D_3 \end{Bmatrix} = \begin{bmatrix} 0 & 0 & 0 & 0 & e_{15} & 0 \\ 0 & 0 & 0 & e_{15} & 0 & 0 \\ e_{31} & e_{31} & e_{33} & 0 & 0 & 0 \end{bmatrix} \begin{Bmatrix} \epsilon_x \\ \epsilon_y \\ \epsilon_z \\ \epsilon_{yz} \\ \epsilon_{xz} \\ \epsilon_{xy} \end{Bmatrix} + \begin{bmatrix} \epsilon_{11} & 0 & 0 \\ 0 & \epsilon_{11} & 0 \\ 0 & 0 & \epsilon_{33} \end{bmatrix}^S \begin{Bmatrix} E_1 \\ E_2 \\ E_3 \end{Bmatrix} \quad (4b)$$

in which σ_{ij} are the components of the stress vector, c_{ij}^E are the components of the elasticity matrix evaluated at constant electric field, e_{ij} are the components of the piezoelectric coefficient matrix (which couples the structural and electric fields), E_i denotes the components of the electric field vector, ϵ_{ij} are the components of the strain vector, D_i are the components of the electric displacement vector and ϵ_{ij}^S are the components of the dielectric matrix, evaluated at constant strain.

2.5 Shunted damping

Shunted damping is a type of structural damping that consists of an electrical circuit, with a resistance R and an inductor L , connected to the electrodes of a piezoelectric material. In this work an RL resonant

shunt is used, consisting of an RL circuit with the resistance and the inductor in series. This circuit is then connected to the piezoelectric patch, which acts as a capacitor, as depicted in Figure 1. This assembly forms the well known LRC circuit, that one can take advantage of by tuning its resonant electrical frequency to the mechanical resonant frequency of the system. Knowing the system natural frequency of interest ω_n , the inductor value L can be calculated by

$$\omega_n = \frac{1}{L_i C_{pi}^S} \Leftrightarrow L_i = \omega_n^2 C_{pi}^S \quad (5)$$

where C_{pi}^S is the capacitance of the piezoelectric patch. In [7], Hagood et al. derived an expression for the resistance to obtain the optimal system damping:

$$R_i = \frac{\sqrt{2K_{ij}^2}}{C_{pi}^S \omega_n (1 + K_{ij}^2)} \quad (6)$$

where K_{ij} is the generalized electromechanical coupling coefficient, which can be calculated easily through the short-circuit (SC) and open-circuit (OC) natural frequencies, using the following expression:

$$K_{ij}^2 = \frac{(\omega_n^{OC})^2 - (\omega_n^{SC})^2}{(\omega_n^{SC})^2} \quad (7)$$

2.6 Radiated sound power

When subjected to external excitation, the sound power that is radiated through an area S of the sandwich panel in a semi-infinite rigid baffle is given by:

$$\Pi = \frac{1}{2} \Re \left\{ \int_S p(G) v_n^H(G) dS \right\} \quad (8)$$

where S is the area of the radiating panel, G is a point on the plate surface, p is the sound pressure in the fluid and v_n^H is the complex conjugate of the normal velocity of the surface of the plate. While the velocity can be obtained almost automatically from the displacement (nodal solution) of the finite element model, if the fluid is not discretized one can use the Rayleigh integral to calculate the pressure [8]:

$$p(\omega, M) = \rho_0 \frac{i\omega}{2\pi} \int_S v_n(\omega, G) \frac{e^{-ikr}}{r} dS \quad (9)$$

where ρ_0 is the fluid density, k is the wave number given by $\frac{\omega}{c_0}$, c_0 is the sound speed in the fluid domain, M is a point inside the external acoustic domain and $v_n(\omega, G)$ is the normal velocity at point G . One way to calculate this integral is through the elementary radiators method. Using this technique, the plate is divided into elementary subdomains (as in the finite element method) and the velocities and pressures used in the calculations are the ones in the center of the elements. Equation (8) becomes:

$$\Pi = \frac{S_e}{2} \Re \{ \mathbf{v}_n^H \mathbf{p} \} \quad (10)$$

where S_e is the area of each elementary radiator. Expanding the pressure, the last equation becomes

$$\Pi = \mathbf{v}_n^H \mathbf{R} \mathbf{v}_n \quad (11)$$

where the radiation resistance matrix is given by:

$$\mathbf{R} = \frac{\omega^2 \rho_0 S_e^2}{4\pi c_0} \begin{bmatrix} 1 & \frac{\sin(kr_{12})}{kr_{12}} & \dots & \frac{\sin(kr_{1R})}{kr_{1R}} \\ \frac{\sin(kr_{21})}{kr_{21}} & 1 & \dots & \frac{\sin(kr_{2R})}{kr_{2R}} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\sin(kr_{R1})}{kr_{R1}} & \frac{\sin(kr_{R2})}{kr_{R2}} & \dots & 1 \end{bmatrix} \quad (12)$$

and r_{ij} is the distance between the centers of elements i and j .

2.7 ANSYS finite element model

The material used for the face layers of the sandwich is carbon fibre, with properties: $E_1 = 130.8$ GPa, $E_2 = 10.6$ GPa, $E_3 = 10.6$ GPa, $\nu_{12} = 0.36$, $\nu_{23} = 0.767$, $\nu_{13} = 0.36$, $G_{12} = 5.6$ GPa, $G_{23} = 3.0$ GPa, $G_{13} = 4.2$ GPa and $\rho = 1543$ kg/m³. Three layers are considered for each face of the sandwich, with symmetric layup.

The parameters for the viscoelastic core material are: $d = 570$, $\alpha = 0.566$, $\beta = 0.558$, $\tau = 7.23 \times 10^{-10}$, $G_0 = 0.8$ MPa, the Poisson's ratio is $\nu = 0.49$ and the mass density is $\rho = 1300$ kg/m³.

Regarding the piezoelectric material, its properties are: $c_{11} = 126$ GPa, $c_{22} = 126$ GPa, $c_{33} = 117$ GPa, $c_{13} = 84.1$ GPa, $c_{23} = 84.1$ GPa, $c_{12} = 79.5$ GPa, $c_{44} = 23$ GPa, $c_{55} = 23$ GPa, $c_{66} = 23.3$ GPa; $e_{15} = 17$ C/m², $e_{24} = 17$ C/m², $e_{33} = 23.3$ C/m², $e_{31} = -6.5$ C/m², $e_{32} = -6.5$ C/m²; $\epsilon_{11} = 150.3 \times 10^{-10}$ F/m, $\epsilon_{22} = 150.3 \times 10^{-10}$ F/m, $\epsilon_{33} = 130 \times 10^{-10}$ F/m; $\rho = 7500$ kg/m³.

The sandwich has fixed in-plane dimensions of 200×300 mm² and is modelled in ANSYS with a solid-shell element, SOLSH190, and the piezoelectric elements are modelled with SOLID5 elements. Both elements have 8 nodes. SOLSH190 has 3 degrees of freedom at each node (3 translations) and SOLID5 has 4 nodal degrees of freedom (3 translations and 1 electric potential). To model the electric circuit elements CIRC94 is used, which is a line element with 2 nodes and 1 degree of freedom at each node (electric potential). Different element options are used depending on the type of electric component (resistance or inductance).

The sandwich plate structure is simply supported, and has a pressure load of 200 Pa applied to the bottom face.

3 SANDWICH PANEL OPTIMIZATION

With the aim of reducing the levels of acoustic emission of the sandwich structure a first optimization will be conducted. With the objective of reducing the acoustic levels without the addition of any external elements (e.g. without piezoelectric patches), the radiated sound power (RSP) will be minimized in a given frequency range. This will be accomplished by choosing the objective function to minimize as the length of the radiated sound power curve in that frequency range. The design variables in this first optimization will be the thicknesses of the core and laminated carbon fibre layers and also the orientation angles of the layers of the carbon fibre plies.

Mathematically, the optimization problem can be formulated as

$$\begin{aligned} \min_{\mathbf{x} \in \Omega} \quad & f(\mathbf{x}) \\ \text{s.t.} \quad & 1.016 \text{ mm} \leq \mathbf{x}_{\text{CoreThickness}} \leq 10.030 \text{ mm}; \\ & 0.17 \text{ mm} \leq \mathbf{x}_{\text{PlyThickness}} \leq 1.02 \text{ mm}; \\ & -89^\circ \leq \mathbf{x}_{\text{Angle}} \leq 90^\circ; \end{aligned} \quad (13)$$

where f is the length of the RSP curve and the vector \mathbf{x} is the vector of design variables. The design variables include the three angles and three thicknesses corresponding to the three plies of carbon fibre in each face, plus the thickness of the viscoelastic core (see Figure 2). In total, 7 design variables are considered. Note that the number of plies of the carbon fibre is fixed to three and a symmetric stacking sequence is kept.

The constraints are the lower and upper limits of the angles: -89° and $+90^\circ$ respectively; the lower and upper limits of the thicknesses: 0.17 mm and 1.02 mm for the carbon fibre, and 1.016 mm and 10.03 mm for the viscoelastic core.

Figure 2: Sandwich structure to be optimized: geometry, boundary conditions and loads.

3.1 Implementation

A Matlab program was developed to control the optimization process through the `patternsearch` function. To use this function, it is necessary to provide the value of the length of the RSP curve, given the values of the design variables. Initial point and constraints are optional. At the end of the optimization, the `patternsearch` function outputs the optimum set of design variables and the respective value of the objective function.

Besides the lower and upper limits that were imposed to these variables, in order to reduce the computational time, the design variable space was transformed from continuous to discrete. Basically, the thickness of the core varies in multiples of 0.127 mm and the thickness of the carbon fibre in multiples of 0.170 mm. In the case of the angles, they are set to take integer values between -89° and 90° .

In using the pattern search algorithm, it is important to assure that all the variables are properly scaled. For instance, it would be inadequate to have the algorithm using angle values in degrees mixed with lengths in millimeters. Hence it was decided that each of the 7 design variables would be scaled to vary between 0 and 1.

To scale the objective function, the length of the RSP curve is multiplied by a large number (in the present work, 10^6). Then a residual number is subtracted, the length of the frequency range multiplied by 10^6 . For example, if the range of the curve is from 2 Hz to 500 Hz, the value to be subtracted is 498×10^6 .

Due to the different order of magnitudes of the sensitivities of the objective to the design variables, a three step optimization approach is taken. The first step is the optimization of only the angles. After this an optimization of the thicknesses is made, starting from the optimal angle values from the first step. Finally, starting with the optimum of the last optimization step, all 7 variables were considered simultaneously in the last optimization stage. The results and details can be observed in the next section. Regarding the finite element mesh, a 20×30 in-plane discretization is used with three elements through

the thickness, one for each different sandwich component (one for each face and one for the core).

3.2 Results

A summary of the optimization results can be found in Table 1. It can be seen that the design variable vector \mathbf{x} has a different number of entries depending on the optimization. In the last optimization it has 7 entries, with the first three being the angles and the last 4 the thickness multiplication factors, the first three corresponding to the thickness of the carbon fibre plies and the last one to the thickness of the core. Note that the thickness is obtained by multiplying the multiplication factors by 0.170 mm for the carbon fibre and by 0.127 mm for the core. For the initial point the objective function value is $f_{obj} = 1240.535$

Table 1: Sandwich optimization results

Optimization	Design Variables	Initial Point	Final Point	f_{obj}
1st Step	$[\theta_1, \theta_2, \theta_3]$	$[0^\circ, 90^\circ, 45^\circ]$	$[-85^\circ, 19^\circ, -1^\circ]$	461.213
2nd Step	$[t_1, t_2, t_3, t_c]$	$[3, 3, 3, 20]$	$[2, 2, 2, 79]$	10.134
3rd Step	$[\theta_1, \theta_2, \theta_3, t_1, t_2, t_3, t_c]$	$[-85^\circ, 19^\circ, -1^\circ, 2, 2, 2, 79]$	$[-86^\circ, 21^\circ, -1^\circ, 2, 2, 2, 79]$	10.132

The RSP curves resultant from each optimization stage can be found in Figure 3.

Figure 3: Comparison of the final points of each optimization.

Just by looking at the values in the table, one is able to see that the optimization is much more sensitive to changes in values of the thicknesses. The changes in fibre orientation introduced some improvement in the first optimization, but when compared with optimization of the thicknesses, the latter allowed a larger change in the shape of the curve. It is visible that the value of the thickness of the viscoelastic core reached its highest possible value in the first time that the thicknesses are optimized, which was expected due to the fact that this increase in the core thickness promotes the damping capabilities of the sandwich. In Figure 3 it can be seen that the change in the thicknesses had an effect of reducing the resonant frequencies as well as reducing its the amplitudes.

4 OPTIMIZATION OF THE PIEZOELECTRIC MATERIAL DISTRIBUTION

In this section the performance of the previously optimized sandwich plate with respect to attenuation of acoustic emissions will be further improved by using piezoelectric patches with RL shunt circuits

tuned to the first resonant frequency. The problem is formulated as determining the optimal distribution of the piezoelectric patches in order to reduce the length of the RSP curve, with all the RL circuits targeted for the first resonant frequency. This optimization problem is a binary problem in which, using a finite element mesh, each sandwich shell element can have a piezoelectric element above it (1) or not (0), depending on the optimizer output. Figure 4 illustrates this idea.

Figure 4: Correspondence between design variables matrix and the sandwich structure

While adding more piezoelectric material will decrease the radiated sound power response, the mass of the structure will increase. A compromise between mass and acoustic response can be achieved by using multiobjective optimization. The number of piezoelectric regions can also be taken into account and minimized, as each region represents one electroded patch with equipotential conditions imposed on the electrodes, having its own RL circuit. Hence, minimizing the number of regions or patches is the same as minimizing the number of RL circuits. This results in 3 objectives to minimize: the added mass of the piezoelectric patches, the acoustic response and the number of regions. This problem can be formulated as follows:

$$\begin{aligned} \min_{\mathbf{x} \in \Omega} \quad & F(\mathbf{x}) \equiv (f_1(\mathbf{x}); f_2(\mathbf{x}); f_3(\mathbf{x}))^T \\ \text{s.t.} \quad & x_i \in \{0, 1\} \end{aligned} \quad (14)$$

in which f_1 is the length of the RSP curve in a given frequency range, f_2 is the total mass of the structure, and f_3 is the number of different piezoelectric patch regions.

4.1 Implementation

Regarding the optimization of the piezoelectric patches, a Matlab program was developed to control the optimization process, in which the function `paretosearch` was used. Similarly to the single-objective optimization described before with the `patternsearch` function, the optimization is controlled by this function, with the user having to supply only the objective function values for each point in the design space and, if needed, initial points and some constraints. The dimension of the design variables vector is the number of elements of piezoelectric finite elements in the model. For instance, if the structure is discretized with a 10×10 mesh, the design variables vector will have dimensions 100×1 , in which each entry can take values between 0 and 1 (1 means there is a piezoelectric element and 0 its absence). The majority of the times, the values will not be integer, since the algorithm works with continuous variables. Therefore, if the value is below 0.5 it gets rounded to 0, and otherwise, it is rounded to 1. Figure 5 represents a flowchart describing the procedure used to calculate the objective function

values.

Due to the fact that a RL shunt circuit is implemented, the values of the resistance and inductance need to be known *a priori*. Using Equations (5) and (6), the optimal values of the resistance and inductance for a particular resonance can be obtained from the values of ω_n^{OC} , ω_n^{SC} and C_{pi} . Therefore, before conducting the harmonic analysis, two modal analysis have to be done (one with the piezoelectric patches in short-circuit and another in open-circuit) to get the natural frequencies, and a static analysis has to be done in order to get the capacitance. Note that due to the fact that in modal analysis viscoelastic materials are not allowed in ANSYS, a programming loop takes place to get the converged properties of the viscoelastic material at the natural frequency to be obtained, as can be observed in Figure 5.

The added mass is obtained simply by counting the number of piezoelectric elements and then multiplying this number by the volume of each element and the respective density. The calculation of the RSP curve length is conducted as before and the number of regions can be calculated by considering the elements that are adjacent to one another.

Some approaches were used in order to reduce the computational time. For instance, whenever the number of regions was equal or higher than 5, the value of the objective functions were increased several orders of magnitude above the normal values, penalizing these solutions. This avoids running ANSYS to evaluate these points. Another approach to decrease computational time was the reduction of the range of the harmonic analysis: it was decided that only the neighborhood of the targeted frequency would be analysed: $f_{oc} - 20 < f_{oc} < f_{oc} + 20$ Hz, where f_{oc} is the fundamental resonant frequency in open circuit, in Hz. Also, in this work, a mesh of 6×6 elements was used to generate a first approximation of the solution. The generated solutions were then used as initial points for an optimization using a 12×12 mesh. Then, the resultant points were used as initial points for the final optimization using the most refined 24×24 mesh discretization. This procedure allows the faster convergence of the solutions for larger patch regions. It was also taken advantage of the symmetry of the problem. In fact, by looking at the first mode of vibration of the sandwich, it can be seen that it is symmetric. Hence, the design variables were reduced to $\frac{1}{4}$ of the maximum number of piezoelectric elements.

4.2 Results

As a result of the multiobjective optimization, a set of non-dominated points was obtained, forming the Pareto front. Having 3 objective functions, resulted in a 3D Pareto surface. The evolution of the Pareto front with the different meshes is shown in Figure 6. It is clear that the Pareto front moves to improved solutions with the refinement of the mesh.

A more detailed analysis can be made by choosing 11 distinct Points of the Pareto front, as a better understanding of the behavior of the structure can be inferred in this way. In Figure 7(a) these points can be observed in the projection of the Pareto front in the plane formed by Objectives 1 and 2. Their RSP curves are displayed in Figure 7(b). These selected points and their design parameters are shown in Table 2. Looking at the results, it can be seen that for less mass the region that starts to be covered by the piezoelectric elements is the centre of the plate which was expected, given the high strain energy in that location for the first mode. It is also important to note that, generally, with more piezoelectric elements a tendency of the frequencies to increase is observed. This is explained by the fact that the stiffness effect introduced dominates the added mass effect. For the configurations with lower mass the R and L values presented are really high, even impracticable in the case of inductance. This changes when the added mass increases and the values become more feasible. Even though the first mode was the original target, the other modes get influenced by the added mass. In fact, for configurations 50, 52 and 29, the peak of the second resonant frequencies is almost as high as the magnitude of the first resonant frequency.

5 CONCLUSIONS

With the aim of reducing its acoustic response a sandwich structure was optimized with respect to the laminate fibre orientation and ply thicknesses, as well as to its viscoelastic core thickness. To further reduce the acoustic response, piezoelectric patches with resonant RL shunts were introduced in a multiobjective optimization. The location of the piezoelectric elements were the design variables and the objective functions were the mass, the acoustic response, and the number of shunt circuit regions. The implementation was described and the results were analysed, allowing us to conclude that the proposed methodologies and implementations are efficient and adequate to solve the problem.

Table 2: Chosen solutions from the multiobjective optimization

#	Mass	No.Regions	R [Ω]	L [H]	f_{sc} [Hz]	f_{oc} [Hz]

Key words: Lead-free composite, piezoelectric, flexoelectricity, nonlocal and nonlinear effects, electrostriction, finite element analysis

Abstract. Lead-free piezocomposites represent an environmentally friendly route for sensing mechanical stimuli and for interconversion of electrical and mechanical energy. Current lead-free composites lag state-of-the-art lead-based composites in terms of performance. A major approach to bridge this gap is to devise design strategies to enhance the piezo-response of lead-free composites. Fundamental to this is the understanding of the roles of various physical processes which are conventionally overlooked. From a modelling perspective, it is necessary to develop refined models which account for non-local and non-linear effects, which could have significant roles in deciding the response of the composite. This paper develops such refined electro-elastic models considering the flexoelectric and electrostrictive contributions to the piezo-response in addition to the linear piezoelectric response. The roles of these non-local and non-linear contributions are studied on a simple architecture consisting of a BaTiO₃ inclusion within a polymer matrix. Insights obtained through this model will be further used to develop efficient piezoelectric composites.

1 INTRODUCTION

Piezoelectric composites generally consist of piezoelectric crystalline inclusions embedded in a polymer matrix. This enables the optimal combination of electrical and elastic properties of both the matrix and the filler, resulting in a composite material that can be designed to suit specific application needs. For example, by embedding highly rigid piezoelectric crystalline inclusions, such as BaTiO_3 , PZT and so on, with polymer matrices, it is possible to make piezoelectric composites which are flexible [1]. The recent interest in such composite materials stems from the fact that there is a need to develop lead-free materials which can perform at par with the state-of-the-art lead-based composites [1]. The development of such materials is important from the point of view of sustainable green technology, with current materials posing long-term ecological threats [1, 2]. A second motivation to study such materials is the ease with which the associated devices can be fabricated using the emerging scalable methods such as 3D printing which offer detailed resolutions down to the micrometer scale in the material distribution [3]. The gap in the performance between these two classes of materials is due to the intrinsic properties of the piezoelectric inclusions and therefore most design strategies involve tuning the electro-elastic properties of the surrounding matrix to enhance the piezoelectric response. These approaches involve either hardening the matrix [4] to improve the coupling of mechanical stimuli to the embedded inclusions or improving the permittivity of the matrix [5] to allow easy flow of the generated electric flux to the electrodes enclosing the composite. Recent efforts in material design and modelling have explored these avenues to tune these electro-elastic properties of the matrix to improve the piezo-response. However, these models overlook some physical processes which could significantly control the piezoelectric response. Some of these processes include (a) flexoelectricity – non-local generation of electric flux by strain-gradients as opposed to linear piezoelectricity where a homogeneous strain generates electric flux and (b) electrostriction – non-linear coupling between the strain and the electric field. Flexoelectricity can occur even in non-centrosymmetric materials [6] and electrostriction is a common process in most dielectrics [7]. Although such effects might often be negligible at the macroscopic level, they can influence the overall design principles of composite materials, created on the basis of hierarchically architected microstructures, for 3D printing and subsequent applications. Moreover, possible defects and agglomerations of added nanoparticles in such composite materials under certain conditions may create an environment for flexoelectricity to play a more pronounced role. Both these aspects hint the possibility of even the matrix materials contributing to the piezoelectric response. Further, lead-free materials such as BaTiO_3 have flexoelectric coefficients which are relatively larger compared to other piezoelectric materials [8], thus offering a possible route to enhancing the performance of the composite. Therefore, our focus in this contribution is on the design and modelling issues of lead-free piezoelectric composites, amenable to 3D printing, in order to achieve their higher performance. Although the developed modelling framework is quite general and can be applied to other materials, as an example, our results are discussed in the context of barium titanate piezoelectric inclusions embedded into a polymeric matrix. In what follows, we will first provide the details of the electro-elastic model which includes these non-local and non-linear effects. Following this, we will discuss some preliminary results which can provide important insights relating to the contributions of these effects to the overall material performance.

2 ELECTRO-ELASTIC MODEL

In this section, we will provide the details of the mathematical framework that describes the electroelastic behavior of piezoelectric composites, accounting for flexoelectric (strain-gradient) and electrostrictive contributions. The constitutive relations are obtained from the electrical Gibbs free energy density defined as follows [6, 9, 10]:

$$G = \frac{1}{2}c_{ijkl}\varepsilon_{ij}\varepsilon_{kl} - \frac{1}{2}\epsilon_{ij}E_iE_j - e_{kij}E_k\varepsilon_{ij} - \frac{1}{2}B_{kl ij}E_kE_l\varepsilon_{ij} - \mu_{ijkl}E_i\varepsilon_{j,kl} \quad (1)$$

The terms on the right-hand side of (1) are contributions to the free energy density from the elastic, electric, linear piezoelectric, electrostrictive, and flexoelectric processes, respectively. Here, c_{ijkl} , ϵ_{ij} , e_{ijk} , B_{ijkl} , and μ_{ijkl} are the elastic, permittivity, piezoelectric, electrostrictive, and flexoelectric coefficients. Additionally, the field variables include the strain tensor components ε_{ij} , the electric field components E_i and the strain-gradient components $\varepsilon_{i,jk}$.

The constitutive relations describing electro-elastic behavior are obtained as follows:

$$\begin{aligned} \sigma_{ij} &= \frac{\partial G}{\partial \varepsilon_{ij}} = c_{ijkl}\varepsilon_{kl} - e_{kij}E_k - \frac{1}{2}B_{kl ij}E_kE_l, \\ \hat{\sigma}_{ijk} &= \frac{\partial G}{\partial \varepsilon_{ij,k}} = \mu_{lij k}E_l, \\ D_i &= -\frac{\partial G}{\partial E_i} = \epsilon_{ij}E_j + e_{ijk}\varepsilon_{jk} + B_{ijkl}E_j\varepsilon_{kl} + \mu_{ijkl}\varepsilon_{jk,l}. \end{aligned} \quad (2)$$

In (2), $\hat{\sigma}_{ijk}$ and D_i are the higher order stress components and electric flux density components, respectively. These constitutive relations are further subjected to the governing balance laws given by:

$$\begin{aligned} (\sigma_{ij} - \hat{\sigma}_{ijk,k})_{,j} + F_i &= 0, \\ D_{i,i} &= 0, \end{aligned} \quad (3)$$

where F_i represent the components of the body forces, which are assumed to vanish in our model. This model is applied to a simple architecture consisting of a BaTiO₃ inclusion within a PDMS polymeric flexible matrix, illustrated in Figure 1. The boundary conditions applied to the composite architecture are also schematically illustrated in the Figure 1. The model is reduced to two dimensions in the x_1 - x_3 plane [5, 11].

Figure 1 – The schematic of the RVE studied here along with the boundary conditions used.

The material properties adopted for this study are summarized in Table 1. It is to be noted that the electrostrictive coefficients entered in the table need to be transformed into a different form before using them in the constitutive equations. This transformation is given by $[B] = [C][M]$, where the matrix $[M]$ has the electric field-related electrostrictive coefficients [12]. Typically, experimental values of these coefficients are in terms of the polarization density, the conversion into the electric-field-related version of which requires the following transformation [13]:

$$M_{ijkl} = Q_{opkl} \eta_{oi} \eta_{pj}, \quad (4)$$

where Q_{opkl} represent the polarization-related electrostriction coefficients in the units of m^2C^{-4} , M_{ijkl} represent the electric-field-related electrostriction coefficients in the units of m^2V^{-2} , and the η_{oi} are the components of the dielectric susceptibility tensor of the material.

Table 1 – Electro-elastic material properties used in the simulations. Typical values of electrostrictive coefficients are considered for the polymer matrix ($M_{33} \approx 1 \times 10^{-17} \text{m}^2\text{V}^{-2}$ in conjunction with equation 4)

3 RESULTS AND DISCUSSION

The current analysis in this paper centers around microscale inclusions in a polymer matrix. Under such conditions, the flexoelectric effect has negligible effect. The plots of the volume averaged electric flux density in the x_3 direction, shown in Figure 2(a), demonstrate this with the two curves obtained from the linear piezoelectric model alone and the model with

flexoelectric contributions almost coinciding. However, the contributions due to the non-linear effects are non-trivial. Although non-linear effects due to electrostriction have contributions to the generated electric flux which are negligible at small strains ($\varepsilon_{app} \approx 10^{-6}$) but show considerable increases at larger strains (for example at $\varepsilon_{app} = 10^{-2}$). This is illustrated in the volume averaged electric flux density plotted in the Figure 2(a), with and without the electrostrictive contributions. This shows that as the applied strain increases, while the linear piezoelectric model predicts a constant response, the presence of non-linear effects shows an increased volume averaged flux generation. This increase stems from the electrostrictive contributions in both the matrix and the inclusion, as seen from the increased flux density D_3 both in the inclusion and in the matrix (Figure 2(b) and (c)). These initial results clearly demonstrate the role of non-linear and non-local effects in deciding the electro-elastic response of lead-free piezoelectric composites.

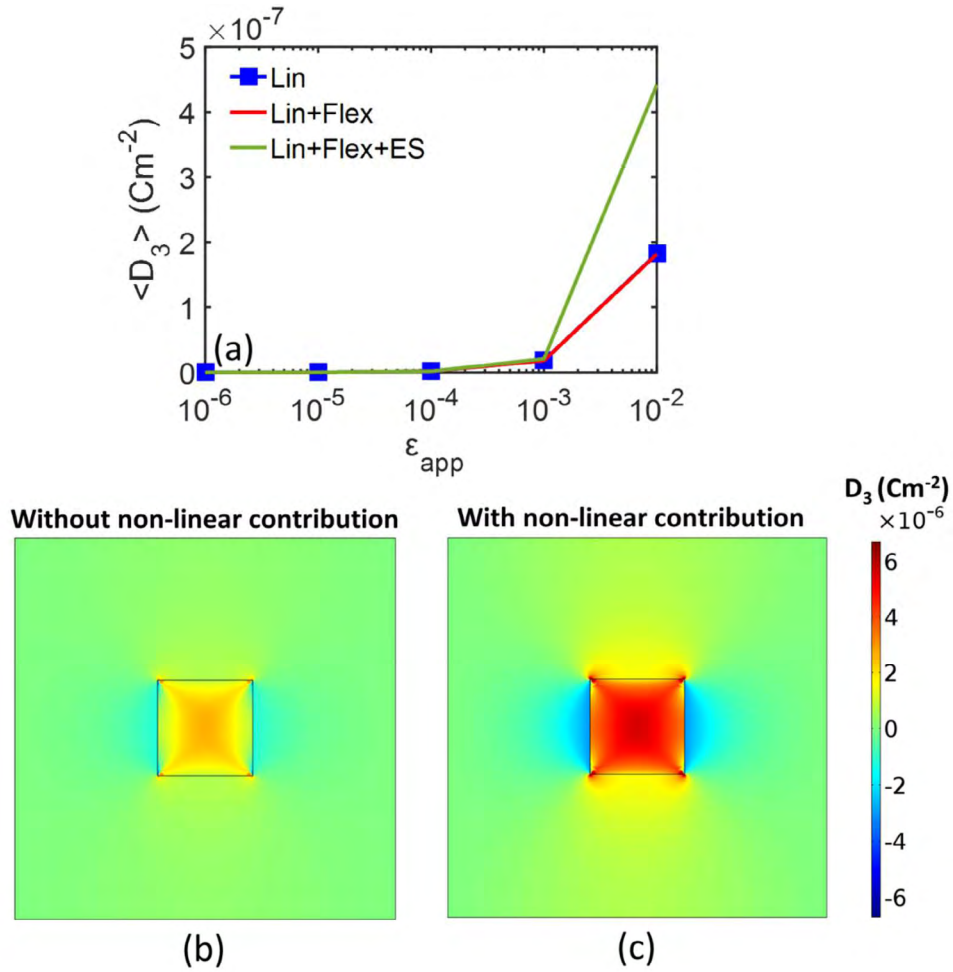

Figure 2 – (a) The volume averaged x_3 -component of the generated electric flux density with (i) linear piezoelectric model (Lin), (ii) linear model with flexoelectric contributions (Lin+Flex), (iii) Linear model with flexoelectric model and non-linear electrostrictive contributions (Lin+Flex+ES), (b) and (c) show the distribution of the D_3 flux density component with and without non-linear contributions, respectively.

4 CONCLUSIONS

We have developed a modeling framework for piezo-composites which accounts for the non-local flexoelectric effects and non-linear electrostrictive effects, with specific focus on lead-free BaTiO₃ based piezocomposites with polymer matrices, which are amenable to scalable 3D printing and additive manufacturing. On studying the implication of these effects in lead-free piezocomposites, we see that with microscale inclusions, while the flexoelectric effect has only negligible contributions, the non-linear electrostriction has considerable contributions which are more pronounced at higher operational strains. These findings clearly emphasize the need to consider these physical effects in the modelling-based design of high-performance environmentally friendly piezoelectric composite materials.

Key words: Piezoelectricity, 3D Vibration Analysis, Laminated Piezoelectric Plate, Sampling Surfaces Method.

Abstract. This paper focuses on implementation of the sampling surfaces (SaS) method for the 3D vibration analysis of laminated piezoelectric plates. The SaS formulation is based on choosing inside the layers the arbitrary number of SaS parallel to the middle surface to introduce the displacements and electric potentials of these surfaces as basic plate variables. Such choice of unknowns allows the presentation of the laminated piezoelectric plate formulation in a very compact form. The feature of the proposed approach is that all SaS are located inside the layers at Chebyshev polynomial nodes that improves the convergence of the SaS method significantly. The use of outer surfaces and interfaces is avoided that makes possible to minimize uniformly the error due to Lagrange interpolation. Therefore, the strong SaS formulation based on direct integration of the equations of motion and the charge equation can be applied efficiently to the obtaining of exact solutions for laminated piezoelectric plates, which asymptotically approach the 3D solutions of piezoelectricity as the number of SaS tends to infinity.

1 INTRODUCTION

The exact vibration analysis of laminated piezoelectric plates was first carried out by Heyliger and Brooks [1], and Heyliger and Saravanos [2] using the Pagano approach. The most popular state space approach was utilized for the free vibration of simply supported electroelastic plates in works [3-7]. Messina and Carrera [8] proposed to employ the transfer matrix method to solve the ordinary differential equations in terms of the displacements and electric potential derived from the system of partial differential equations through the separating variable procedure. The dynamic response of laminated piezoelectric plates by a Taylor series expansion through the thickness was studied in papers [9-11]. The SaS approach was also used for the free vibration analysis of piezolaminated plates [12].

The SaS method [13] has been applied effectively to the 3D stress analysis of laminated piezoelectric structures by Kulikov and Plotnikova [14-17]. According to this method, we choose the arbitrary number of SaS throughout the layers parallel to the middle surface and located at Chebyshev polynomial nodes in order to introduce the displacements and electric potentials of these surfaces as basic plate unknowns. Such choice of unknowns with the consequent use of Lagrange polynomials in the through-thickness distributions of displacements, strains, electric potential and electric field leads to a robust laminated

piezoelectric plate formulation. The above works are based on the variational SaS formulation, which requires including the interfaces into a set of SaS. However, it is important to take all SaS located at Chebyshev polynomial nodes due to the convergence criterion [18].

The present paper is intended to extend the variational SaS formulation for the free vibration of laminated piezoelectric plates [12] to the strong SaS formulation. The latter is based on the choice of all SaS inside the layers at Chebyshev polynomial nodes and direct integration of the equations of motion and the charge equation. The use of interfaces is avoided that allows one to minimize uniformly the error due to the higher-order Lagrange interpolation [19-22]. Thus, the strong SaS formulation can be applied efficiently to the 3D vibration analysis of piezolaminated plates.

2 BASIC ASSUMPTIONS

Consider a laminated piezoelectric plate of the thickness h . Let the middle surface Ω be described by Cartesian coordinates x_1 and x_2 . The coordinate x_3 is oriented in the thickness direction. According to the SaS concept, we choose inside the n th layer I_n SaS $\Omega^{(n)1}, \Omega^{(n)2}, \dots, \Omega^{(n)I_n}$ parallel to the middle surface (see Figure 1), where $n=1, 2, \dots, N$; N is the number of layers and $I_n \geq 3$. The transverse coordinates of SaS of the n th layer located at Chebyshev polynomial nodes (roots of the Chebyshev polynomial of order I_n) are written as

$$x_3^{(n)i_n} = \frac{1}{2}(x_3^{[n-1]} + x_3^{[n]}) - \frac{1}{2}h_n \cos\left(\pi \frac{2i_n - 1}{2I_n}\right), \quad (1)$$

where $x_3^{[0]} = -h/2$, $x_3^{[N]} = h/2$; $x_3^{[m]}$ are the transverse coordinates of interfaces $\Omega^{[m]}$; $h_n = x_3^{[n]} - x_3^{[n-1]}$ is the thickness of the n th layer; the index $m=1, 2, \dots, N-1$ identifies the belonging of any quantity to the interface; the indices $i_n, j_n = 1, 2, \dots, I_n$ identify the belonging of any quantity to the SaS of the n th layer.

Figure 1: Geometry of the laminated piezoelectric plate

The through-thickness SaS approximations can be expressed as

$$[u_i^{(n)}, \varepsilon_{ij}^{(n)}, \sigma_{ij}^{(n)}, \varphi^{(n)}, E_i^{(n)}, D_i^{(n)}] = \sum_{i_n} L^{(n)i_n} [u_i^{(n)i_n}, \varepsilon_{ij}^{(n)i_n}, \sigma_{ij}^{(n)i_n}, \varphi^{(n)i_n}, E_i^{(n)i_n}, D_i^{(n)i_n}], \quad (2)$$

where $u_i^{(n)}, \varepsilon_{ij}^{(n)}, \sigma_{ij}^{(n)}, \varphi^{(n)}, E_i^{(n)}, D_i^{(n)}$ are the displacements, strains, stresses, electric potential, electric field and electric displacements of the n th layer; $u_i^{(n)i_n}, \varepsilon_{ij}^{(n)i_n}, \sigma_{ij}^{(n)i_n}, \varphi^{(n)i_n}, E_i^{(n)i_n}, D_i^{(n)i_n}$ are the displacements, strains, stresses, electric potential, electric field and electric displacements of SaS of the n th layer $\Omega^{(n)i_n}$; $L^{(n)i_n}(x_3)$ are the Lagrange basis polynomials of degree $I_n - 1$ corresponding to the n th layer:

$$L^{(n)i_n} = \prod_{j_n \neq i_n} \frac{x_3 - x_3^{(n)j_n}}{x_3^{(n)i_n} - x_3^{(n)j_n}}. \quad (3)$$

3 STRONG SAS FORMULATION

For simplicity, we consider the case of linear piezoelectric materials given by

$$\sigma_{ij}^{(n)} = C_{ijkl}^{(n)} \varepsilon_{kl}^{(n)} - e_{kij}^{(n)} E_k^{(n)}, \quad (4)$$

$$D_i^{(n)} = e_{ikl}^{(n)} \varepsilon_{kl}^{(n)} + \varepsilon_{ik}^{(n)} E_k^{(n)}, \quad (5)$$

where $C_{ijkl}^{(n)}, e_{kij}^{(n)}$ and $\varepsilon_{ik}^{(n)}$ are the elastic, piezoelectric and dielectric constants of the n th layer. Here, the summation on repeated Latin indices is implied.

The equations of motion and the charge equation of the laminated piezoelectric plate are written as

$$\sigma_{ij,j}^{(n)} = \rho_n \ddot{u}_i^{(n)}, \quad (6)$$

$$D_{i,i}^{(n)} = 0, \quad (7)$$

where ρ_n is the mass density of the n th layer; $\ddot{u}_i^{(n)}$ is the second order derivative of displacements with respect to time t ; the symbol $(\dots)_{,i}$ stands for the partial derivatives with respect to coordinates x_i .

The boundary conditions on bottom and top surfaces are defined as

$$u_i^{(1)}(-h/2) = w_i^- \text{ or } \sigma_{i3}^{(1)}(-h/2) = p_i^-, \quad \varphi^{(1)}(-h/2) = \phi^- \text{ or } D_3^{(1)}(-h/2) = Q^-, \quad (8)$$

$$u_i^{(N)}(h/2) = w_i^+ \text{ or } \sigma_{i3}^{(N)}(h/2) = p_i^+, \quad \varphi^{(N)}(h/2) = \phi^+ \text{ or } D_3^{(N)}(h/2) = Q^+, \quad (9)$$

where $w_i^-, p_i^-, \phi^-, Q^-$ and $w_i^+, p_i^+, \phi^+, Q^+$ are the prescribed displacements, surface tractions, electric potentials and electric charges at the bottom and top surfaces.

The continuity conditions at interfaces are

$$u_i^{(m)}(x_3^{[m]}) = u_i^{(m+1)}(x_3^{[m]}), \quad \sigma_{i3}^{(m)}(x_3^{[m]}) = \sigma_{i3}^{(m+1)}(x_3^{[m]}), \quad (10)$$

$$\varphi^{(m)}(x_3^{[m]}) = \varphi^{(m+1)}(x_3^{[m]}), \quad D_3^{(m)}(x_3^{[m]}) = D_3^{(m+1)}(x_3^{[m]}). \quad (11)$$

Satisfying equations of motion (6) and charge equation (7) at inner layer points $x_3^{(n)m_n}$ by using the SaS approximations (2), the following differential equations are obtained:

$$\sigma_{i1,1}^{(n)m_n} + \sigma_{i2,2}^{(n)m_n} + \sum_{i_n} M^{(n)i_n}(x_3^{(n)m_n}) \sigma_{i3}^{(n)i_n} = \rho_n \ddot{u}_i^{(n)m_n}, \quad (12)$$

$$D_{1,1}^{(n)m_n} + D_{2,2}^{(n)m_n} + \sum_{i_n} M^{(n)i_n}(x_3^{(n)m_n}) D_3^{(n)i_n} = 0, \quad (13)$$

where $M^{(n)i_n} = L_3^{(n)i_n}$ are the derivatives of the Lagrange basis polynomials whose values at SaS $\Omega^{(n)m_n}$ are presented in papers [14, 15]; $m_n = 2, 3, \dots, I_n - 1$.

Next, we satisfy the boundary conditions on bottom and top surfaces

$$\sum_{i_1} L^{(1)i_1}(-h/2) u_i^{(1)i_1} = w_i^- \text{ or } \sum_{i_1} L^{(1)i_1}(-h/2) \sigma_{i3}^{(1)i_1} = p_i^-, \quad (14)$$

$$\sum_{i_1} L^{(1)i_1}(-h/2) \varphi^{(1)i_1} = \phi^- \text{ or } \sum_{i_1} L^{(1)i_1}(-h/2) D_3^{(1)i_1} = Q^-,$$

$$\sum_{i_N} L^{(N)i_N}(h/2) u_i^{(N)i_N} = w_i^+ \text{ or } \sum_{i_N} L^{(N)i_N}(h/2) \sigma_{i3}^{(N)i_N} = p_i^+, \quad (15)$$

$$\sum_{i_N} L^{(N)i_N}(h/2) \varphi^{(N)i_N} = \phi^+ \text{ or } \sum_{i_N} L^{(N)i_N}(h/2) D_3^{(N)i_N} = Q^+,$$

and the continuity conditions at interfaces

$$\sum_{i_m} L^{(m)i_m}(x_3^{[m]}) u_i^{(m)i_m} = \sum_{i_{m+1}} L^{(m+1)i_{m+1}}(x_3^{[m]}) u_i^{(m+1)i_{m+1}}, \quad (16)$$

$$\sum_{i_m} L^{(m)i_m}(x_3^{[m]}) \sigma_{i3}^{(m)i_m} = \sum_{i_{m+1}} L^{(m+1)i_{m+1}}(x_3^{[m]}) \sigma_{i3}^{(m+1)i_{m+1}},$$

$$\sum_{i_m} L^{(m)i_m}(x_3^{[m]}) \varphi^{(m)i_m} = \sum_{i_{m+1}} L^{(m+1)i_{m+1}}(x_3^{[m]}) \varphi^{(m+1)i_{m+1}}, \quad (17)$$

$$\sum_{i_m} L^{(m)i_m}(x_3^{[m]}) D_3^{(m)i_m} = \sum_{i_{m+1}} L^{(m+1)i_{m+1}}(x_3^{[m]}) D_3^{(m+1)i_{m+1}}.$$

Thus, the proposed strong SaS formulation deals with $4N_{\text{SaS}}$ governing equations (12)-(17) for obtaining the same number of SaS displacements $u_i^{(n)i_n}$ and SaS electric potentials $\varphi^{(n)i_n}$, where $N_{\text{SaS}} = I_1 + I_2 + \dots + I_N$ is the total number of SaS. These differential and algebraic equations have to be solved to describe the dynamic response of the laminated piezoelectric plate.

4 FREE VIBRATION OF SIMPLY SUPPORTED PIEZOELECTRIC PLATE

In this section, we consider a laminated piezoelectric rectangular plate with simply supported edges. The boundary conditions on the edges are written as

$$\begin{aligned} \sigma_{11}^{(n)} = u_2^{(n)} = u_3^{(n)} = \varphi^{(n)} = 0 \text{ at } x_1 = 0 \text{ and } x_1 = a, \\ \sigma_{22}^{(n)} = u_1^{(n)} = u_3^{(n)} = \varphi^{(n)} = 0 \text{ at } x_2 = 0 \text{ and } x_2 = b, \end{aligned} \quad (18)$$

where a and b are the length and width of the plate.

To satisfy boundary conditions (18), we seek the analytical solution of the problem in the following form:

$$\begin{aligned} u_1^{(n)i_n} &= u_{1rs}^{(n)i_n} e^{i\omega_{rs}t} \cos \bar{r}x_1 \sin \bar{s}x_2, & u_2^{(n)i_n} &= u_{2rs}^{(n)i_n} e^{i\omega_{rs}t} \sin \bar{r}x_1 \cos \bar{s}x_2, \\ u_3^{(n)i_n} &= u_{3rs}^{(n)i_n} e^{i\omega_{rs}t} \sin \bar{r}x_1 \sin \bar{s}x_2, & \varphi^{(n)i_n} &= \varphi_{rs}^{(n)i_n} e^{i\omega_{rs}t} \sin \bar{r}x_1 \sin \bar{s}x_2, \end{aligned} \quad (19)$$

where $\bar{r} = r\pi/a$, $\bar{s} = s\pi/b$; r and s are the half-wave numbers in x_1 and x_2 directions; $u_{irs}^{(n)i_n}$ and $\varphi_{rs}^{(n)i_n}$ are the amplitudes of displacements and electric potentials of SaS; ω_{rs} is the circular frequency; $i = \sqrt{-1}$ is the imaginary unit.

Using (19) in relations between the SaS variables [12], one finds

$$\begin{aligned} (\varepsilon_{11}^{(n)i_n}, \varepsilon_{22}^{(n)i_n}, \varepsilon_{33}^{(n)i_n}, \sigma_{11}^{(n)i_n}, \sigma_{22}^{(n)i_n}, \sigma_{33}^{(n)i_n}) &= (\varepsilon_{11rs}^{(n)i_n}, \varepsilon_{22rs}^{(n)i_n}, \varepsilon_{33rs}^{(n)i_n}, \sigma_{11rs}^{(n)i_n}, \sigma_{22rs}^{(n)i_n}, \sigma_{33rs}^{(n)i_n}) e^{i\omega_{rs}t} \sin \bar{r}x_1 \sin \bar{s}x_2, \\ (E_3^{(n)i_n}, D_3^{(n)i_n}) &= (E_{3rs}^{(n)i_n}, D_{3rs}^{(n)i_n}) e^{i\omega_{rs}t} \sin \bar{r}x_1 \sin \bar{s}x_2, \\ (\varepsilon_{13}^{(n)i_n}, \sigma_{13}^{(n)i_n}, E_1^{(n)i_n}, D_1^{(n)i_n}) &= (\varepsilon_{13rs}^{(n)i_n}, \sigma_{13rs}^{(n)i_n}, E_{1rs}^{(n)i_n}, D_{1rs}^{(n)i_n}) e^{i\omega_{rs}t} \cos \bar{r}x_1 \sin \bar{s}x_2, \\ (\varepsilon_{23}^{(n)i_n}, \sigma_{23}^{(n)i_n}, E_2^{(n)i_n}, D_2^{(n)i_n}) &= (\varepsilon_{23rs}^{(n)i_n}, \sigma_{23rs}^{(n)i_n}, E_{2rs}^{(n)i_n}, D_{2rs}^{(n)i_n}) e^{i\omega_{rs}t} \sin \bar{r}x_1 \cos \bar{s}x_2, \\ (\varepsilon_{12}^{(n)i_n}, \sigma_{12}^{(n)i_n}) &= (\varepsilon_{12rs}^{(n)i_n}, \sigma_{12rs}^{(n)i_n}) e^{i\omega_{rs}t} \cos \bar{r}x_1 \cos \bar{s}x_2, \end{aligned} \quad (20)$$

where

$$\begin{aligned} \varepsilon_{11rs}^{(n)i_n} &= -\bar{r}u_{1rs}^{(n)i_n}, & \varepsilon_{22rs}^{(n)i_n} &= -\bar{s}u_{2rs}^{(n)i_n}, & 2\varepsilon_{12rs}^{(n)i_n} &= \bar{s}u_{1rs}^{(n)i_n} + \bar{r}u_{2rs}^{(n)i_n}, \\ 2\varepsilon_{13rs}^{(n)i_n} &= \bar{r}u_{3rs}^{(n)i_n} + \beta_{1rs}^{(n)i_n}, & 2\varepsilon_{23rs}^{(n)i_n} &= \bar{s}u_{3rs}^{(n)i_n} + \beta_{2rs}^{(n)i_n}, & \varepsilon_{33rs}^{(n)i_n} &= \beta_{3rs}^{(n)i_n}, \\ \beta_{irs}^{(n)i_n} &= \sum_{j_n} M^{(n)j_n} (x_3^{(n)i_n}) u_{irs}^{(n)j_n}, \\ E_{1rs}^{(n)i_n} &= -\bar{r}\varphi_{rs}^{(n)i_n}, & E_{2rs}^{(n)i_n} &= -\bar{s}\varphi_{rs}^{(n)i_n}, & E_{3rs}^{(n)i_n} &= -\sum_{j_n} M^{(n)j_n} (x_3^{(n)i_n}) \varphi_{rs}^{(n)j_n}. \end{aligned} \quad (21)$$

In the case of the piezoelectric material with $4mm$ symmetry, the constitutive equations (4) and (5) can be written in terms of SaS variables

$$\sigma_{ijrs}^{(n)i_n} = C_{ijkl}^{(n)} \varepsilon_{klrs}^{(n)i_n} - e_{kij}^{(n)} E_{krs}^{(n)i_n}, \quad (22)$$

$$D_{irs}^{(n)i_n} = e_{ikl}^{(n)} \varepsilon_{klrs}^{(n)i_n} + \epsilon_{ik}^{(n)} E_{krs}^{(n)i_n}. \quad (23)$$

For the vibration analysis of piezoelectric plates with stress-free and voltage-free external surfaces, the boundary conditions (14) and (15) are used with $p_i^\pm = 0$ and $\phi^\pm = 0$. Substituting (19)-(23) in governing equations (12)-(17), we arrive at the homogeneous system of linear equations

$$\left(\begin{bmatrix} \mathbf{K}_{rs}^{uu} & \mathbf{K}_{rs}^{u\varphi} \\ \mathbf{K}_{rs}^{\varphi u} & \mathbf{K}_{rs}^{\varphi\varphi} \end{bmatrix} - \omega_{rs}^2 \begin{bmatrix} \mathbf{M}_{rs} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \right) \begin{bmatrix} \mathbf{U}_{rs} \\ \mathbf{\Phi}_{rs} \end{bmatrix} = \mathbf{0}, \quad (24)$$

where \mathbf{K}_{rs}^{uu} , $\mathbf{K}_{rs}^{u\varphi}$, $\mathbf{K}_{rs}^{\varphi u} = (\mathbf{K}_{rs}^{u\varphi})^T$ and $\mathbf{K}_{rs}^{\varphi\varphi}$ are the mechanical, piezoelectric and dielectric stiffness matrices; \mathbf{M}_{rs} is the mass matrix; \mathbf{U}_{rs} is the SaS displacement vector of order $3N_{\text{SaS}}$; $\mathbf{\Phi}_{rs}$ is the SaS electric potential vector of order N_{SaS} given by

$$\mathbf{U}_{rs} = [\mathbf{U}_{1rs}^T \mathbf{U}_{2rs}^T \mathbf{U}_{3rs}^T]^T, \quad (25)$$

$$\begin{aligned} \mathbf{U}_{irs} &= [u_{irs}^{(1)1} u_{irs}^{(1)2} \dots u_{irs}^{(1)I_1} u_{irs}^{(2)1} u_{irs}^{(2)2} \dots u_{irs}^{(2)I_2} \dots u_{irs}^{(N)1} u_{irs}^{(N)2} \dots u_{irs}^{(N)I_N}]^T, \\ \mathbf{\Phi}_{rs} &= [\varphi_{rs}^{(1)1} \varphi_{rs}^{(1)2} \dots \varphi_{rs}^{(1)I_1} \varphi_{rs}^{(2)1} \varphi_{rs}^{(2)2} \dots \varphi_{rs}^{(2)I_2} \dots \varphi_{rs}^{(N)1} \varphi_{rs}^{(N)2} \dots \varphi_{rs}^{(N)I_N}]^T. \end{aligned} \quad (26)$$

Eliminating the vector $\mathbf{\Phi}_{rs}$ from (24), one gets

$$\mathbf{\Phi}_{rs} = -(\mathbf{K}_{rs}^{\varphi\varphi})^{-1} \mathbf{K}_{rs}^{\varphi u} \mathbf{U}_{rs}. \quad (27)$$

Inserting (27) in the first row of (24), the following reduced homogeneous system is obtained

$$(\mathbf{K}_{rs} - \omega_{rs}^2 \mathbf{M}_{rs}) \mathbf{U}_{rs} = \mathbf{0}, \quad (28)$$

which has a non-trivial solution only if

$$\det(\mathbf{K}_{rs} - \omega_{rs}^2 \mathbf{M}_{rs}) = 0, \quad (29)$$

where $\mathbf{K}_{rs} = \mathbf{K}_{rs}^{uu} - \mathbf{K}_{rs}^{u\varphi} (\mathbf{K}_{rs}^{\varphi\varphi})^{-1} \mathbf{K}_{rs}^{\varphi u}$ is the stiffness matrix of order $3N_{\text{SaS}} \times 3N_{\text{SaS}}$.

The polynomial equation (29) has to be solved to obtain the circular frequencies $0 < \omega_{rs}^{(1)} < \omega_{rs}^{(2)} < \dots < \omega_{rs}^{(3N_{\text{SaS}}-6N)}$ arranged in an increasing order. The number of frequencies $\omega_{rs}^{(q)}$ for each set of SaS depends on the number of zero rows in a mass matrix \mathbf{M} , where the superscript $q = 1, 2, \dots, 3N_{\text{SaS}} - 6N$ stands for the number of through thickness modes. The eigenvectors $\mathbf{U}_{rs}^{(q)}$ associated with the corresponding eigenvalues $\lambda_{rs}^{(q)} = (\omega_{rs}^{(q)})^2$ can be evaluated by using the linear system (28).

5 FORCED VIBRATION OF SIMPLY SUPPORTED PIEZOELECTRIC PLATE

Here, we study forced vibrations of the simply supported laminated piezoelectric rectangular plate with boundary conditions on the bottom and top surfaces

$$\begin{aligned} \sigma_{13}^{(1)} = \sigma_{23}^{(1)} = \sigma_{33}^{(1)} = \varphi^{(1)} = 0 \text{ at } x_3 = -h/2, \\ \sigma_{13}^{(N)} = \sigma_{23}^{(N)} = 0, \quad \sigma_{33}^{(N)} = p_3^+, \quad \varphi^{(N)} = \phi^+ \text{ at } x_3 = h/2. \end{aligned} \quad (30)$$

Consider time-harmonic loading distributed on the top surface as follows:

$$\text{Problem A: } p_3^+ = p_0 e^{i\omega t} \sin \frac{\pi x_1}{a} \sin \frac{\pi x_2}{b}, \quad \phi^+ = 0; \quad (31)$$

$$\text{Problem B: } p_3^+ = 0, \quad \phi^+ = \phi_0 e^{i\omega t} \sin \frac{\pi x_1}{a} \sin \frac{\pi x_2}{b}, \quad (32)$$

where ω is the forcing frequency.

To satisfy boundary conditions (18), we seek the analytical solution of the problem in the following form:

$$\begin{aligned} u_1^{(n)i_n} &= u_{10}^{(n)i_n} e^{i\omega t} \cos \frac{\pi x_1}{a} \sin \frac{\pi x_2}{b}, \quad u_2^{(n)i_n} = u_{20}^{(n)i_n} e^{i\omega t} \sin \frac{\pi x_1}{a} \cos \frac{\pi x_2}{b}, \\ u_3^{(n)i_n} &= u_{30}^{(n)i_n} e^{i\omega t} \sin \frac{\pi x_1}{a} \sin \frac{\pi x_2}{b}, \quad \varphi^{(n)i_n} = \varphi_0^{(n)i_n} e^{i\omega t} \sin \frac{\pi x_1}{a} \sin \frac{\pi x_2}{b}, \end{aligned} \quad (33)$$

where $u_{i0}^{(n)i_n}$ and $\varphi_0^{(n)i_n}$ are the amplitudes of displacements and electric potentials of SaS of the n th layer.

The described algorithm was performed with the Symbolic Math Toolbox, which incorporates symbolic computations into the numeric environment of MATLAB. This makes possible to obtain the analytical solutions for free and forced vibrations of the simply supported laminated piezoelectric rectangular plate in the framework of the SaS formulation, which asymptotically approaches the 3D exact solutions of electroelasticity as the number of SaS goes to infinity.

As a numerical example, we consider a simply supported two-ply square plate [0/90] made of the graphite epoxy composite and covered with PZT-4 piezoelectric layers at the bottom and at the top. Therefore, we deal here with a hybrid four-layer plate [PZT/0/90/PZT] with ply thicknesses $[0.25h/0.25h/0.25h/0.25h]$. The material properties of the PZT-4 [12] polarized in the thickness direction are $E_1=E_2=81.3$ GPa, $E_3=64.5$ GPa, $G_{12}=30.6$ GPa, $G_{13}=G_{23}=25.6$ GPa, $\nu_{12}=0.329$, $\nu_{13}=\nu_{23}=0.432$, $e_{311}=e_{322}=-5.2$ C/m², $e_{333}=15.08$ C/m², $e_{113}=e_{223}=12.72$ C/m², $\epsilon_{11}=\epsilon_{22}=13.06$ nF/m, $\epsilon_{33}=11.51$ nF/m and $\rho=7600$ kg/m³. The material properties of the graphite epoxy [12] are $E_1=172.5$ GPa, $E_2=E_3=6.9$ GPa, $G_{12}=G_{13}=3.45$ GPa, $G_{23}=1.38$ GPa, $\nu_{12}=\nu_{13}=0.25$, $\nu_{23}=0.35$, $\epsilon_{11}=0.031$ nF/m, $\epsilon_{22}=\epsilon_{33}=0.027$ nF/m and $\rho=1800$ kg/m³.

To evaluate the results effectively, we introduce the dimensionless frequency [12]

$$\bar{\omega} = \omega a^2 \sqrt{\rho_0 / E_0} / h \quad (34)$$

and dimensionless basic variables at crucial points as functions of the thickness coordinate

$$\begin{aligned} \bar{u}_3 &= 10^9 u_3(a/2, a/2, z) / h, \quad \bar{\sigma}_{11} = \sigma_{11}(a/2, a/2, z) / p_0, \\ \bar{\sigma}_{13} &= \sigma_{13}(0, a/2, z) / p_0, \quad \bar{\sigma}_{33} = \sigma_{33}(a/2, a/2, z) / p_0, \\ \bar{\varphi} &= \varphi(a/2, a/2, z) / \phi_0, \quad \bar{D}_3 = 10^9 \phi_0 D_3(a/2, a/2, z) / ap_0, \quad z = x_3 / h, \end{aligned} \quad (35)$$

where $a=1$ m, $h=0.1$ m, $E_0=81.3$ GPa, $\rho_0=7600$ kg/m³, $p_0=1$ Pa and $\phi_0=1$ V.

Figures 2 and 3 display the distributions of displacements, stresses, electric potential and electric displacement (35) through the thickness of the plate for the forcing frequencies $\bar{\omega} = 0, 0.8\bar{\omega}_0, 0.95\bar{\omega}_0$ and $1.05\bar{\omega}_0$ using seven SaS inside each layer, where $\bar{\omega}_0 = 6.0932$ is the fundamental frequency in the case of stress-free and voltage-free external surfaces [12]. It is seen that the boundary conditions on bottom and top surfaces for the transverse stresses and the continuity conditions at interfaces for the transverse stresses and electric displacement are satisfied correctly. Note also that the displacements and stresses become larger as the forcing frequency approaches the fundamental frequency.

Key words: Node-dependent kinematic, global-local, Carrera Unified Formulation

Abstract. The present paper presents a multidimensional model for the global-local analysis of smart layered structures. The use of the Carrera Unified Formulation has lead to a general framework for the development of one-, two- and three-dimensional models. The use of the node-dependent kinematic approach makes it possible to easily connect elements with incompatible kinematics, that is, refined kinematic elements can be connected with classical elements without the need of *ad hoc* connection strategies. The capabilities of this numerical model have been exploited to develop enhanced global-local models for smart layered structures where high-fidelity models are used only in those areas where complex phenomena appear, e.g. around a piezo-patch. The results show the accuracy and efficiency of the present approach and make it suitable for future applications in the design of smart structures.

1 INTRODUCTION

The design of smart structures requires numerical models able to deal with complex phenomena with reasonable computational cost. Smart structures, such as piezoelectric devices, are usually built by a classical structure, acting as a substrate, with a number of patches or layers locally applied to provide sensor/actuator capabilities. Finite element models are widely used for the design of such complex structures but the accuracy required to catch the behavior of the active material may lead to very expensive models. 3D brick elements for piezoelectric modeling were presented by [1], and [2]. Since solid elements are computational costly when used to model thin piezoelectric layers, various 2D and 1D models were proposed as alternative choices. As shown by Kim *et.al.* [11] the use of global-local approaches may lead to an efficient modeling approach that uses the refined models only in those areas where it is necessary, exploiting the efficiency of the classical finite elements approach elsewhere. This approach requires to couple elements with different kinematic fields such as beam or plate elements with three-dimensional elements. Different coupling approaches have been presented in literature. Surana [15, 16] proposed an approach to couple three and two-dimensional elements. The connection between solid and shell elements was also investigated in [12] and [7]. The work by Gmur [9] deals with the connection of solid isoparametric and super-parametric shell elements, while the connection between one- and three-dimensional elements was investigated in [10]. McCune *et.al.* [13] and Monaghan *et.al.* [14] introduced a mixed-dimensional coupling scheme, based on geometrical assumptions, while Garusi and tralli [8] used a transition element to develop solid-to-beam and plate-to-beam connections.

The present work aims to extend the use of the multi-dimensional modeling approach presented by the authors in [17, 4] to refine locally those models that could not provide an adequate accuracy level

for multi-field analyses. The structural models have been derived in the frameworks of the Carrera Unified Formulation [3] that allows the kinematic field to be refined in a unified and efficient fashion. The node-dependent kinematic approach presented in [5] and recently extended to the piezo-electric problem [6], will be exploited to switch between models with different kinematics without the need on any *ad hoc* formulation or compatibility equations. The results obtained from the solution of well known benchmarks show that the present approach may be used to reduce the computational costs without affecting the accuracy of the solution.

2 NODE-DEPENDENT KINEMATIC ELEMENTS

The development of refined one- and two- and three-dimensional finite element models requires to derive the stiffness/mass matrix for each kinematic approximation adopted. Moreover, the introduction of the node-dependent kinematics formulation would ask for an *ad-hoc* formulation of the matrices for each element. A general and unified approach for the derivation of the matrices for any kinematic model has been proposed by [3] and will be used to derive the NDK elements formulation.

The generic three-dimensional solution of the problem can be written as follows:

$$\mathbf{u} = \mathbf{u}(x, y, z). \quad (1)$$

where $\mathbf{u}(x, y, z)$ is a three-dimensional function solution of the problem. The vector \mathbf{u} contains the three displacement components when the mechanical problem is considered. The if piezo-mechanical problem is considered \mathbf{u} has four components, the three-displacements and the electric potential:

$$\mathbf{u}(x, y, z)^T = \{u_x, u_y, u_z, \phi\} \quad (2)$$

When all the three dimensions of the structure are comparable it is not possible to reduce the dimension of the problem, that is, a three-dimensional problem should be solved. When the structure has a dimension, z , which can be neglected with respect to the others, x and y , it is possible to introduce a plate/shell model, in this case the Equation 2 can be reduced to:

$$\mathbf{u} = \mathbf{u}_\tau(x, y)F_\tau^{1D}(z), \quad \tau = 1 \dots M, \quad (3)$$

where F_τ^{1D} represents a generic function expansion used to approximate the displacement field through the thickness, and M is the number of terms in the expansion. If two dimensions, x and z , are negligible with respect to the other, y , it is possible to reduce Equation (2) in the form:

$$\mathbf{u} = \mathbf{u}_\tau(y)F_\tau^{2D}(x, z), \quad \tau = 1 \dots M \quad (4)$$

where F_τ^{2D} represents the function expansion used to approximate the solution over the cross-section of the beam model, and M is the number of terms in the expansion. Whatever is the problem considered, one- or two-dimensional, the functions F_τ can be assumed *a priori*. The choice of F_τ depends on the structural model to be used in the analysis. The function u_τ is the unknown of the structural problem. The solution of the problem can be obtained introducing the FE model. Therefore the domain is discretized in a finite number of elements where the solution is approximated using the shape functions, N_i . The generic displacement field can be written as:

$$\mathbf{u} = \mathbf{u}_{i\tau}N_iF_\tau, \quad \tau = 1 \dots M; \quad i = 1 \dots N_n. \quad (5)$$

Where the index i comes from the FE model and the index τ comes from the kinematics used in the structural model approximation. N_n is the number of nodes in the finite element. $\mathbf{u}_{i\tau}$ is the coefficient of

Figure 1: A three-node one-dimensional element with node-dependent kinematics.

the expansion and it is also the unknown of the problem. The indicial form showed in Equation (5) is common for all the structural models, the choice of N_i and F_τ makes the difference:

$$3D \longrightarrow \mathbf{u} = \mathbf{u}_i N_i^{3D}(x, y, z) \cdot 1 \quad (6)$$

$$2D \longrightarrow \mathbf{u} = \mathbf{u}_{i\tau} N_i^{2D}(x, y) F_\tau^{1D}(z) \quad (7)$$

$$1D \longrightarrow \mathbf{u} = \mathbf{u}_{i\tau} N_i^{1D}(y) F_\tau^{2D}(x, z) \quad (8)$$

Where N_i^{2D} and N_i^{1D} are the FEM shape functions of the two- and one-dimensional model respectively, while F_τ^{1D} and F_τ^{2D} are the expansion used thorough-the-thickness of the two-dimensional element or over the cross-section of the one dimensional model. The choice of F_τ depends on the structural model used. In the following sections are reported the kinematic assumptions used in the present paper for the one- and two-dimensional model while the three-dimensional model does not require any approximation other than the FEM. In the case of node-dependent kinematics models, NDK, each node of the FEM discretization can assume a different kinematic, see Figure 1.

The displacement field of an element with node-dependent kinematics can be written including two main novelties:

$$F_\tau(x, z) \longrightarrow F_\tau^i(x, z) \quad (9)$$

$$M \longrightarrow M^i \quad (10)$$

The first equation, Eq. 9, states that the function expansion is not a property of the element, but of the nodes, that is, the index i is included in the notation. Eq. 10 remarks that the number of terms in the expansion, M , can be different at each node, and the notation M^i is used to underline this aspect. The generic displacement field can be written as:

$$3D \longrightarrow \mathbf{u} = \mathbf{u}_i N_i^{3D}(x, y, z) \cdot 1, \quad i = 1 \dots N_n. \quad (11)$$

$$2D \longrightarrow \mathbf{u} = \mathbf{u}_{i\tau} N_i^{2D}(x, y) F_\tau^{i,1D}(z), \quad \tau = 1 \dots M^i; \quad i = 1 \dots N_n. \quad (12)$$

$$1D \longrightarrow \mathbf{u} = \mathbf{u}_{i\tau} N_i^{1D}(y) F_\tau^{i,2D}(x, z), \quad \tau = 1 \dots M^i; \quad i = 1 \dots N_n. \quad (13)$$

3 MULTI-DIMENSIONAL MODELS

The assembly of multidimensional models required to impose the displacement continuity at the interface. In this work the capabilities of Lagrange models have been exploited to easily connect models

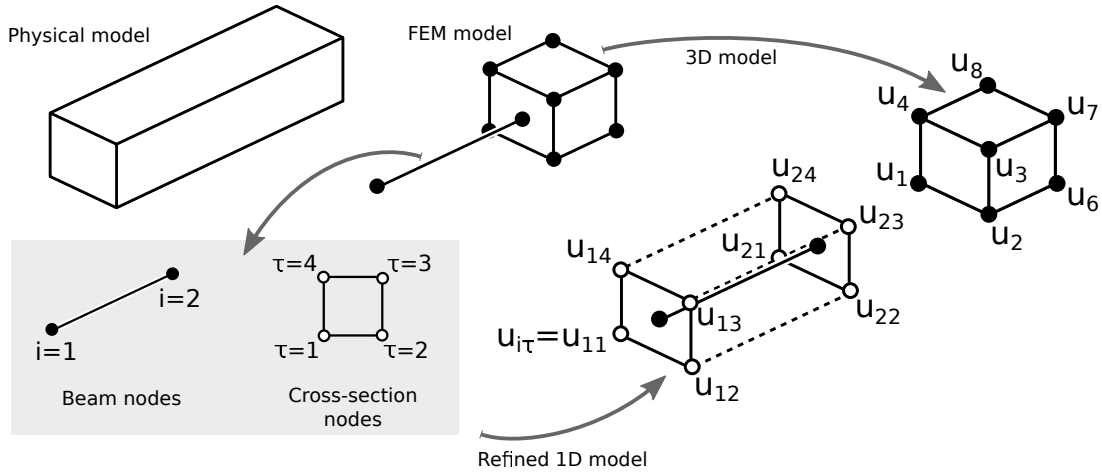

Figure 2: Example of a multi-dimensional model: connection between a beam and a solid elements.

with incompatible kinematics. When Lagrange models are used, does not matter if a one-, two- or three-dimensional model is considered, the unknown vector contains only pure displacements and the electric potential as unknown. This property make it possible to connect plate, beam and solid elements without any ad hoc technique.

3.1 The assembling procedure

To explain the assembling procedure, the simple configuration shown in Figure 2 is considered. A prismatic structure has to be modelled with a beam and a solid element. The beam uses a four node Lagrange element over the cross-section and a two node beam element along the axis. Figure 2 shows that the refined beam model has four node in each cross-section where the displacements are the unknown, u_{11} to u_{14} in the section on the first axial node and u_{21} to u_{24} in the second node. At the same time, the solid element has eight nodes in which the displacements have to be defined. Since both models have the same unknowns, the imposition of compatibility between the shared nodes is straightforward:

$$\mathbf{u}_{21} = \mathbf{u}_1, \quad \mathbf{u}_{22} = \mathbf{u}_2, \quad \mathbf{u}_{23} = \mathbf{u}_3, \quad \mathbf{u}_{24} = \mathbf{u}_4; \quad (14)$$

The conditions shown in Equation 14 can be used during the assembly procedure to identify the nodes that have to be connected. The matrices of the two elements can be used to build the global matrix of the whole structure simply summing the contributions of the shared nodes.

3.2 Governing Equations

The governing equations can be derived by applying the principle of virtual displacement (PVD). Consider the energy of the system:

$$\delta L_{int} = \int_V \delta \bar{\mathbf{\epsilon}}^T \bar{\boldsymbol{\sigma}} dV = \delta L_{ext} \quad (15)$$

where V is the volume of the integration domain, and δL_{int} is the internal energy and δL_{ext} is the external work. $\bar{\boldsymbol{\epsilon}}$ and $\bar{\boldsymbol{\sigma}}$ are the generalized strain and tress vectors that include both the mechanical and the electrical quantities. By considering the geometrical relations, constitutive equations, end the generic displacement field, the internal work can be written as:

Figure 3: Example of a global-local modeling of a beam with a piezo-patch.

$$\delta L_{int} = \delta \mathbf{q}_{js} \int_V N_j F_s^j \mathbf{D}^T \tilde{\mathbf{H}} \mathbf{D} F_\tau^i N_i dV \mathbf{q}_{i\tau} \quad (16)$$

In a compact form, the above expression can be written as:

$$\delta L_{int} = \delta \mathbf{q}_{js}^T \mathbf{k}_{ij\tau s} \mathbf{q}_{i\tau} \quad (17)$$

where $\mathbf{k}_{ij\tau s}$ represents the electromechanical *fundamental nuclei* (FNs), which is a core unit of the generalized stiffness matrix:

$$\mathbf{k}_{ij\tau s} = \int_V N_j F_s^j \mathbf{D}^T \tilde{\mathbf{H}} \mathbf{D} F_\tau^i N_i dV \quad (18)$$

Actually, $\mathbf{k}_{ij\tau s}$ can be further written as:

$$\mathbf{k}_{ij\tau s} = \begin{bmatrix} \mathbf{k}^{uu} & \mathbf{k}^{u\phi} \\ \mathbf{k}^{\phi u} & \mathbf{k}^{\phi\phi} \end{bmatrix}_{ij\tau s} \quad (19)$$

in which the mechanical stiffness FN \mathbf{k}^{uu} is a 3×3 matrix, while the electromechanical coupling FNs $\mathbf{k}^{u\phi}$ and $\mathbf{k}^{\phi u}$ are 3×1 and 1×3 , respectively. The dimension of the pure electric part $\mathbf{k}^{\phi\phi}$ is 1×1 .

3.3 Global-local models for layered smart structures

The capability to build multidimensional models, as well as, the possibility to vary the kinematic within the same element make it possible to derive efficient global-local approaches. The present work proposes to use the NDK approach to refine the kinematic where required and to impose a compatible kinematic at the interface between elements with different dimensions. A cantilevered beam with a piezo-patch is considered as an example. Figure 3 shows two different modeling approach. The first uses a full three-dimensional model that ensure a high-fidelity solution but could require a large computational cost. The second approach aims to preserve the three-dimensional model accuracy in the patch area but, through the 1D NDK element, allows classical beam elements to be used for the substrate where the patch is not present.

4 NUMERICAL RESULTS

A simple beam clamped at both the ends has been considered to assess the present approach. The geometry is reported in Fig. 4. The substrate is built in aluminum while the piezoceramic material PZT-H5 has been used for the patch. Three different modeling approaches have been used. The first approach

Figure 4: Geometry and models description.

Model	$u_z \times 10^{-6}$ [m]	DOFs	$\Delta u_z(\%)$
Full 3D	1.919	1026	-
3D-2D	1.923	858	0.21
3D-1D	1.923	618	0.21

Table 1: Vertical displacement at the beam mid-span.

considers a full three-dimensional model. The second approach uses a three-dimensional model in the patch area and a plate model elsewhere, a FSDT model has been considered. The third model beams, based on a Taylor expansion of the first order, instead plate elements in the area where the patch is not applied. The deflection due to a potential of 5V applied to the patch has been evaluated.

Table 1 reports the displacements at the mid-span of the beam. It can be seen that the models that used plate and beam elements are able to reproduce the three-dimensional solution. The use of a global-local approach leads to a reduction of the computational costs and, in the case of the $3D - 1D$ model, 618 DOFs are required instead 1026, that is a reduction of the 40% is guaranteed.

Figure 5 report the maps of the vertical displacement field for all the three models considered.

Figure 5: Vertical displacement evaluated with the three models.

5 CONCLUSIONS

The present paper presents an innovative approach in the global-local analysis of layered smart structures. The capabilities of the node-dependent kinematic models, developed in the framework of the Carrera Unified Formulation, have been successfully exploited to connect classical 1D and 2D structural models to 3D models. The approach has been assessed considering a beam under the action of a piezopatch. The results obtained with the present global-local approach can be considered as accurate as the full-three-dimensional solution but a significant reduction in the computational cost has been obtained. The use of the present approach does not require any ad hoc connection technique and ensures a continuous displacement field even in the transition zone. The present approach could find future applications in the design of smart devices such as energy harvester, sensors or MEMS.

Abstract. This paper addresses the issue of vibration and noise reduction in laminated sandwich plates using piezoelectric patches with passive shunted damping. A finite element implementation of a laminated sandwich plate with viscoelastic core and surface bonded piezoelectric patches is used to obtain the frequency response of the panels. The sound transmission characteristics of the panels are evaluated by computing their radiated sound power using the Rayleigh integral method. RL (Resistor and Inductor) shunt damping circuits are used to add damping to the sandwich panels. The optimal location of the surface bonded piezoelectric patches is then obtained, along with the RL circuits resistance and inductance, using Direct MultiSearch (DMS) optimization to minimize added weight, number of patches and noise radiation. Trade-off Pareto optimal fronts and the respective optimal patch configurations are obtained.

1 INTRODUCTION

The generalized introduction of lightweight composites in the automotive and aerospace industries, while leading to significant weight reductions and associated fuel savings, pose a serious problem of low acoustic performance when these structures are subjected to mechanical or acoustic excitations. Passive damping technologies are nowadays frequently used to control sound and vibration levels through the use of viscoelastic materials, while active devices such as surface bonded piezoelectric patches can also be effectively used to control these undesired sound and vibration levels in lightweight composite structures. Sandwich composite panels may represent an optimized solution for both sound radiation and structural vibration for most frequency ranges. Viscoelastic materials are an efficient way of reducing structural vibrations and providing noise attenuation, which allied to piezoelectric elements may lead to broader damping capabilities regarding acoustic emissions.

The open literature regarding the subject of vibration and sound radiation from passive or active composite and sandwich structures is quite scarce. Regarding the vibration control using passive tech-

Figure 1: The sandwich plate with the piezoelectric patch and associated RL circuit

nologies, previous works have been presented for mechanical vibration suppression [1] and sound level attenuation [2–5]. The vibroacoustic problem has been recently addressed by Larbi et al. in smart piezoelectric composite and sandwich plates [6, 7] and also in double-wall sandwich panels [8].

In the present work we apply a layerwise sandwich finite element model, previously developed by the authors [9], with frequency dependent viscoelastic core, composite laminated skin layers and piezoelectric patches with associated RL circuits. The model is used to calculate the frequency response of sandwich panels and the structural results from the model are then used to calculate the radiated sound power of the panel.

In this paper we present a multiobjective approach for the optimal distribution of surface bonded piezoelectric patches in composite laminated panels. The objective is to obtain designs that simultaneously minimize weight and maximize damping using the minimum number of RL circuits. A topological optimization approach is used along with the DMS (Direct MultiSearch) solver. DMS [10] is a solver for multiobjective optimization problems which does not use any derivatives of the objective functions. It is based on a novel technique called direct multisearch, developed by extending direct search from single to multiobjective optimization. It was recently used to solve the problem of minimum weight and maximum damping of a viscoelastic sandwich plate [11], simultaneously minimizing weight and material cost and maximizing modal damping [12] and to find the optimal positioning of surface bonded piezoelectric sensors and actuators for active damping maximization in a given frequency range [13]. An application to a clamped rectangular sandwich panel is described and some Pareto front solutions are analyzed.

2 SANDWICH PLATE MODEL

The *layerwise* sandwich finite element model is briefly described here, to analyze sandwich laminated plates with a viscoelastic (v) core, two composite laminated face layers (e_1 , e_2) and piezoelectric patch or layer (p) bonded to the top outer surface of the plate (Figure 1).

The basic assumptions in the development of the sandwich plate model are: The origin of the z axis is the medium plane of the core layer; No slip occurs at the interfaces between layers; The displacement is C^0 along the interfaces; Elastic and piezoelectric layers are modeled with first order shear deformation theory (FSDT) and viscoelastic core with a higher order shear deformation theory (HSDT); All materials are linear, homogeneous and orthotropic and the elastic layers (e_1) and (e_2) are made of laminated com-

posite materials; For the viscoelastic core, material properties are complex and frequency dependent; The top piezoelectric layer has an RL circuit attached to its top and bottom electroded surfaces, consisting of a resistance and an inductor in series (Figure 1).

After enforcing displacement continuity at the layer interfaces we retain 17 mechanical unknowns. For more details on the model and its validation, the reader is directed to [9].

2.1 Constitutive relations

We consider that fibre-reinforced laminae in elastic multi-layers (e_1) and (e_2), viscoelastic core (v), and piezoelectric (p) layer are characterized as orthotropic. However, due to the different nature of the displacement fields in the face layers and in the core, the constitutive relations are going to be different.

For the laminas in the elastic laminated face layers or in the piezoelectric layer, constitutive equations for each lamina may be expressed in the principal material directions, assuming zero transverse normal stress as in [14].

For the viscoelastic core, a full 3D orthotropic stiffness matrix is used in the principal material directions [15] and the stiffness coefficients are complex quantities, since the complex modulus approach was used in this work, using the elastic-viscoelastic correspondence principle [16].

2.2 Finite element formulation

The equations of motion for the plate are obtained by applying the extended Hamilton's principle, the solution of which was obtained through the finite element method, using an eight node serendipity element with 17 mechanical degrees of freedom per node, and one electric potential degree of freedom per piezoelectric layer. The system equilibrium equations are obtained in the usual way through assembly of the element equations, yielding:

$$\begin{bmatrix} \mathbf{M}_{uu} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{u}} \\ \ddot{\phi} \end{bmatrix} + \begin{bmatrix} \mathbf{K}_{uu} & \mathbf{K}_{u\phi} \\ \mathbf{K}_{u\phi}^T & \mathbf{K}_{\phi\phi} \end{bmatrix} \begin{bmatrix} \mathbf{u} \\ \phi \end{bmatrix} = \begin{bmatrix} \mathbf{F}_t \\ \mathbf{Q}_t \end{bmatrix} \quad (1)$$

where \mathbf{u} , $\ddot{\mathbf{u}}$, ϕ and $\ddot{\phi}$ are mechanical degrees of freedom and corresponding accelerations, electric potential and corresponding second time derivatives, respectively. \mathbf{M}_{uu} and \mathbf{K}_{uu} are the mass and complex stiffness matrices, respectively, corresponding to purely mechanical behavior, while $\mathbf{K}_{\phi\phi}$ is the dielectric stiffness matrix, $\mathbf{K}_{u\phi}$ is the stiffness matrix that corresponds to the coupling between the mechanical and the piezoelectric effects, \mathbf{F}_t is the externally applied mechanical load vector, and \mathbf{Q}_t is the electrical charge vector, both in the time domain.

The electric potential difference ϕ_i across the electrodes of the piezoelectric patch i can be related to the the resistance R_i and inductor L_i values as:

$$\phi_i = -R_i \dot{Q}_i - L_i \ddot{Q}_i \quad (2)$$

where \dot{Q}_i and \ddot{Q}_i are the first and second time derivatives of the surface charge Q_i of patch i , respectively. Assuming harmonic vibrations, this relation can be written for all the potential degrees of freedom of all np patches in vector form as:

$$\phi = -\mathbf{G}\mathbf{Q} \quad (3)$$

where \mathbf{Q} is the vector of charge amplitudes and G is a diagonal matrix:

$$\mathbf{G} = \begin{bmatrix} j\omega R_1 - \omega^2 L_1 & 0 & \cdots & 0 \\ 0 & j\omega R_2 - \omega^2 L_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & j\omega R_{np} - \omega^2 L_{np} \end{bmatrix} \quad (4)$$

where j is the imaginary unit.

By condensing the degrees of freedom of electric potential in the system equilibrium equations (1) and using equation (3), the final equilibrium equation, assuming harmonic vibrations, can be written as:

$$[\mathbf{K}^*(\omega) - \omega^2 \mathbf{M}_{uu}] \mathbf{U} = \mathbf{F} \quad (5)$$

where the condensed stiffness matrix is given by:

$$\mathbf{K}^*(\omega) = \mathbf{K}_{uu}(\omega) - \mathbf{K}_{u\phi} \mathbf{G} [\mathbf{I} + \mathbf{K}_{\phi\phi} \mathbf{G}]^{-1} \mathbf{K}_{u\phi}^T \quad (6)$$

where $\mathbf{K}_{uu}(\omega)$ is a complex matrix, \mathbf{I} is the identity matrix, and \mathbf{U} and \mathbf{F} are the vectors of the amplitudes of displacement and applied mechanical force, respectively.

It is worthwhile noting that when electroded surfaces exist in a given patch or layer, equipotential conditions should be imposed before condensing the electric degrees of freedom.

The forced vibration problem is solved in the frequency domain, which implies the solution of the following linear system of equations for each frequency point:

$$[\mathbf{K}^*(\omega) - \omega^2 \mathbf{M}_{uu}] \mathbf{U}(\omega) = \mathbf{F}(\omega) \quad (7)$$

where $\mathbf{F}(\omega) = \mathcal{F}(\mathbf{F}_t(t))$ is the Fourier transform of the time domain force history $\mathbf{F}_t(t)$.

3 ACOUSTIC INDICATOR

When subjected to external excitation, the sandwich plate radiates noise into the surrounding acoustic medium. For a light fluid, the fluid mass may be neglected and both acoustic and structural problems can be solved independently, whereas for heavy fluids the problem is more complex owing to strong acoustic radiation damping and added mass effects which may significantly change the inertia of the coupled structure. In the present work we are concerned mainly with radiation involving light fluids such as air. Hence, the fluid loading is neglected in the present approach, and in order to evaluate the acoustic performance of the active sandwich panels, the radiated sound power (Π) is the acoustic indicator chosen in this work.

The sound power that is radiated through an area S of the panel is given by:

$$\Pi = \frac{1}{2} \Re \left(\int_S p(G) v_n^*(G) dS \right) \quad (8)$$

where G is a point on the plate surface, p is the sound pressure applied as an external loading and v_n is the normal velocity. The complex conjugate is denoted by $*$ and \Re denotes the real part of the integral.

For a flat plate embedded in an infinite rigid plane baffle and radiating in a semi infinite fluid, the pressure p can be obtained using the Rayleigh Integral [17]:

$$p(\omega, M) = \rho_0 \frac{i\omega}{2\pi} \int_S v_n(\omega, G) \frac{e^{-ikr}}{r} dS \quad (9)$$

where ρ_0 is the mass density of the external acoustic domain, $k = \omega/c_0$ is the wave number, where c_0 is the speed of sound in air, M is a point inside the external acoustic domain and $v_n(\omega, G)$ is the normal velocity at point G , which is easily obtained from the finite element formulation presented in the previous sections.

In this work, the finite element method is used to obtain the normal velocity distribution, assuming a sufficient number of discrete radiating elements, according to the smallest wavelength to be observed. The transverse vibration of the plate is specified in terms of the normal velocities at the center positions of each one of the rectangular finite elements in the mesh. We assume that the dimensions of these elements are small when compared to the structural and acoustic wavelengths, so that the total radiated sound power in Equation (8) can be expressed as the sum of the powers radiated by each element:

$$\Pi = \frac{S_e}{2} \Re(\mathbf{v}_n^H \mathbf{p}) \quad (10)$$

where the superscript H denotes the hermitian transpose, \mathbf{v}_n and \mathbf{p} are the vectors of complex amplitudes of the normal velocity and acoustic pressure in all elements, respectively, and S_e is the area of each element. The pressure on each element is generated by the vibrations of all elements of the panel. The vector of sound pressure can therefore be obtained using the impedance matrix:

$$\mathbf{p} = \mathbf{Z} \mathbf{v}_n \quad (11)$$

where \mathbf{Z} is the (symmetric) impedance matrix with components $Z_{ij} = (i\omega\rho_0 S_e / 2\pi r_{ij}) e^{-ikr_{ij}}$ and r_{ij} is the distance between the centers of elements i and j . Substituting Equation (11) in Equation (10), we obtain:

$$\Pi = \frac{S_e}{2} \Re(\mathbf{v}_n^H \mathbf{Z} \mathbf{v}_n) = \frac{S_e}{4} \Re(\mathbf{v}_n^H [\mathbf{Z} + \mathbf{Z}^H] \mathbf{v}_n) = \mathbf{v}_n^H \mathbf{R} \mathbf{v}_n \quad (12)$$

where \mathbf{R} is the radiation resistance matrix for the elementary radiators which is given by:

$$\mathbf{R} = \frac{\omega^2 \rho_0 S_e^2}{4\pi c_0} \begin{bmatrix} 1 & \frac{\sin(kr_{12})}{kr_{12}} & \dots & \frac{\sin(kr_{1R})}{kr_{1R}} \\ \frac{\sin(kr_{21})}{kr_{21}} & 1 & \dots & \frac{\sin(kr_{2R})}{kr_{2R}} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\sin(kr_{R1})}{kr_{R1}} & \frac{\sin(kr_{R2})}{kr_{R2}} & \dots & 1 \end{bmatrix} \quad (13)$$

This method can be applied to any plane surface in an infinite baffle, independently of the boundary conditions, as it only requires the knowledge of the surface geometry, the properties of the fluid and the normal velocity field distribution.

4 PROBLEM STATEMENT

A laminated hybrid sandwich plate is considered with a viscoelastic core described by a fractional derivative constitutive law. The plate is a 300 mm \times 200 mm laminated sandwich with all edges clamped and made of carbon fibre plies and a central isotropic viscoelastic damping material core. The stacking sequence for carbon fibre laminates is $[0^\circ/90^\circ/+45^\circ]$ for (e_1) and $[+45^\circ/90^\circ/0^\circ]$ for (e_2) . The thickness of each carbon fibre ply is 0.5 mm, and the viscoelastic core is 2.5 mm thick.

Material properties for the isotropic viscoelastic damping polymer are described by a five parameter fractional derivative constitutive model [18], where $\nu = 0.49$ and $\rho = 1300 \text{ kg/m}^3$, have been assumed here. The expression for the complex shear modulus is as follows:

$$G(j\omega) = G_0 + G_0(d-1) \frac{(j\omega\tau)^\alpha}{1 + (j\omega\tau)^\beta} \quad (14)$$

where $G_0 = 0.8$ MPa is the static shear modulus, $d = 1$, $\alpha = 0.566$, $\beta = 0.558$, and $\tau = 7.23 \times 10^{-10}$ s is the relaxation time.

For the carbon fiber plies, material properties are $E_1 = 130.8$ GPa, $E_2 = 10.6$ GPa, $G_{12} = 5.6$ GPa, $G_{13} = 4.2$ GPa, $G_{23} = 3.0$ GPa, $\nu_{12} = 0.36$, and $\rho = 1543$ kg/m³.

Surface electroded 0.9 mm thick piezoelectric patches are also bonded to the upper surface of the plate. Material properties for these piezoelectric patches are $E_1 = 50.9$ GPa, $E_2 = 46.1$ GPa, $G_{12} = 14.3$ GPa, $G_{13} = 8.0$ GPa, $G_{23} = 20.6$ GPa, $\nu_{12} = 0.29$, $\rho = 7800$ kg/m³, $e_{31}^* = -17.0$ N/Vm, $e_{32}^* = -12.2$ N/Vm, and $\epsilon_{33}^{*e} = 1.549 \times 10^{-8}$ F/m.

A 100 Pa incident pressure wave is applied at $t = 0$ to the bottom surface of the plate.

The optimization problem is defined in terms of five objectives. The first objective is to minimize the added mass of the patches $f_1 = \sum_i m_i$, where m_i is the mass associated to the patch of element i . The second objective is to minimize the number of equipotential zones f_2 at the surface of the plate. This allows for the minimization of the total number of individual RL circuits needed for each equipotential zone. In this work we also minimize simultaneously the amplitude of the response of the first three modes of vibration in the radiated sound power response curve. Thus, objectives f_3 , f_4 and f_5 correspond to the largest 3 peaks of the radiated sound power curve defined through Eq. (12).

$$\begin{aligned} \min \quad & F(x) \equiv (f_1(x), f_2(x), f_3(x), f_4(x), f_5(x))^T \\ \text{s. t.} \quad & x_i \in [x_i^l, x_i^u] \end{aligned} \quad (15)$$

Two types of design variables are defined: the patch position design variables and the design variables associated to the values of each resistance and inductor of the RL circuits. The position design variables take values of 0 or 1, where the zero value means that there is no patch and a one represents a patch at that particular element. Since DMS uses real valued design variables and our problem has discrete variables, we consider a vector of real variables in the interval $[0,1]$ with length equal to the number of elements in the mesh. If a design variable value is greater or equal to 0.5, we consider that the patch exists, otherwise the patch is not present at that particular element. Regarding the values of the resistances and inductors for each RL circuit, the resistance varies from zero to 1 M Ω in intervals of 100 Ω and the inductors vary between 0 and 1 H in intervals of 10 mH.

For the application described in this paper, symmetry conditions on the distribution of the piezoelectric patches is considered. The finite element mesh will be a 6×6 mesh with a total of 36 elements. Hence we are considering only 9 position design variables, corresponding to a quarter of symmetry.

The optimization problem is solved using Direct MultiSearch (DMS) [10] which is a solver for multiobjective optimization problems, without the use of derivatives and does not aggregate any components of the objective function. It essentially generalizes all direct-search methods of directional type from single to multiobjective optimization. DMS maintains a list of feasible non-dominated points (from which the new iterates or poll centers are chosen). The search step is optional and when included it aims at improving numerical performance. DMS tries, however, to capture the whole Pareto front from the polling procedure itself. At each iteration, the new feasible evaluated points are added to this list and the dominated ones are removed. Successful iterations correspond then to changes in the iterate list, meaning that a new feasible non-dominated point was found. Otherwise, the iteration is declared as unsuccessful.

When a point is infeasible, the components of the objective function F are not evaluated, and the values of F_Ω are set to $+\infty$. This approach allows to deal with black-box type constraints, where only

Figure 2: The problem of optimal distribution of piezoelectric patches on the sandwich laminated plate

a yes/no type of answer is returned. A number of details of the algorithm are omitted and the reader is referred to [10] for a complete description. The authors in [10] prove under the common assumptions used in direct search for single objective optimization that at least one limit point of the sequence of iterates generated by DMS lies in (a stationary form of) the Pareto front.

5 RESULTS

We present in this section some of the results obtained for the multiobjective optimization described in the previous section. There are a total of 155 nondominated solutions, from which we have retained solutions number 43, 34, 9 and 118, represented in Figure 3. Solutions 43, 34 and 9 correspond to the best possible values of objectives f_3 , f_4 and f_5 , respectively, and solution 118 is the best for the sum of f_3 , f_4 and f_5 . It should be noted that in Figure 3 the values of f_1 correspond to the number of added piezoelectric elements, which are directly proportional to the added mass and objectives f_3 to f_5 are scaled by a factor of 10^6 .

Figure 4 displays the radiated sound power curves for the three selected solutions, where the baseline curve corresponds to the sandwich plate with no added piezoelectric patches. The effect of the noise reduction can be clearly noticed from these response curves. The optimal values of the resistors and inductors for each solution can be found in Table 1.

It is worthwhile mentioning that these are preliminary results, in the sense that convergence has not yet been obtained. Further iterations of the optimization algorithm are necessary to guarantee that these solution in fact represent optimal configurations. Fully converged results will be presented at the conference.

6 CONCLUSIONS

A vibroacoustic optimization of laminated sandwich panels with surface bonded piezoelectric patches has been addressed in this paper. The radiated sound power has been calculated for a sandwich panel with a viscoelastic core and RL circuits have been used to implement the additional damping using the piezoelectric patches. The optimal location of the piezoelectric patches has been obtained for five objectives: minimum added mass, minimum number of RL circuits and minimum radiated sound power response amplitudes for the first three modes of vibration. This methodology proved to be efficient in maximizing damping over this frequency range.

Abstract. This article investigates the Liquid Resin Infusion (LRI) manufacturing of glass fiber/polyester composite plates embedding a thin piezoelectric (PZT) disk. The real-time in-situ Process Monitoring (PM) of this technique is performed using the electrical capacitance signature of the embedded PZT transducer. To help with the understanding of capacitance variations, an internal/external multi-instrumentation (Infrared Thermography, thermocouples, Acoustic Emission, Z-displacement sensing, pressure sensing) was set on the infusion systems, so that it was possible to make couplings between the various obtained measurements and the PZT capacitance curves. Rheological tests were also performed on resin samples to find correlations between the matrix chemo-physical transitions during curing and PZT capacitance inflections during its final decrease. It was shown that the PZT capacitance is sensitive to several key moments of the infusion process, such as the end of preform impregnation, the isolation of the system at the end of resin injection, and the different resin curing stages such as gelation and vitrification. It is therefore a cheap and quite powerful in-situ Non-Destructive Testing device for the PM of the LRI manufacturing.

1 INTRODUCTION

In the Polymer-Matrix Composite (PMC) materials industry, the parameters of Liquid Composite Moulding (LCM) manufacturing processes such as mould filling rate, fiber impregnation quality, resin curing kinetics or internal temperature gradients are relatively difficult to evaluate, especially in real time. Knowledge of these parameters can be of great help in order to optimize these processes and thus obtain parts having better mechanical properties and good dimensional tolerances. Various research teams have already undertaken the study and control of these parameters, called “Process Monitoring” (PM), ([1] - [5]). However, there

is still little work on PM using Non Destructive Testing (NDT) techniques, the latter being mainly used for monitoring the life in service of composite structures already manufactured ([6] - [8]). Current contributions to the PM of PMC by NDT use a variety of techniques, both internal and external. External (or ex-situ) techniques, which are more common, may involve the use of pressure sensors [9], thermocouples [10], electrical measurements ([11] - [13]) or ultrasound ([14] - [17]). In-situ techniques, on the other hand, allow the measurement to take place at the heart of the part being manufactured, by inserting the NDT system inside the composite. It is thus possible to integrate them with optical fibers ([18], [19]), piezoresistive systems ([20], [21]) or also dielectric analysis sensors (DEA) ([18], [22]).

In the continuity of the works related to in-situ PM of PMC, this paper focuses on the insertion of a thin piezoceramic disk (PZT) inside a fiberglass / polyester matrix composite plate realized by infusion, with the objective of real-time follow-up of this process thanks to the PZT electrical capacitance information. To understand the evolution of this capacitance during manufacturing, a multi-instrumentation with both internal (2 thermocouples) and external (1 infrared camera, 4 acoustic emission sensors, 1 pressure sensor and 2 vertical displacement sensors) NDT systems is set around the infusion system, allowing to highlight the potential multi-physical couplings existing between these data and those provided by the PZT. The sensitivity of the PZT to the state transitions of the resin during its curing was also investigated using oscillatory rheology tests performed aside on the polyester resin alone. The details of the experiments are explained in the next section.

2 MATERIAL AND METHODS

PZT discs (Wealthland - China) of 25mm diameter and 0.135mm thickness were used for this study. Their static capacitance was measured and compared to the manufacturer's information before integration into the fibrous preform consisting of 6 fiberglass (twill weave 2/2) plies of dimensions 150 * 150mm², as shown in Figure 1. The wiring of the PZT is made using tinned copper wires with a diameter of 210µm.

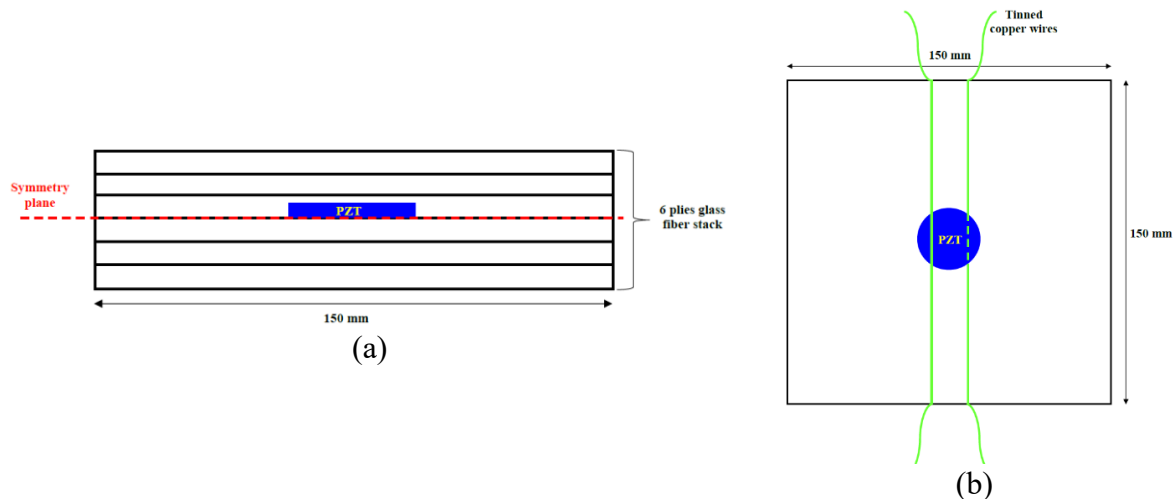

Figure 1: (a) PZT location inside the fiber stack, (b) Wiring of the PZT

The infusion is then performed at room temperature using an unsaturated polyester resin mixed at fixed concentration (1% wt) with a Methyl Ethyl Ketone Peroxide (MEKP) type hardener. During infusion, both internal and external multi-instrumentation is used to retrieve real-time information on the manufacturing process. This multi-instrumentation composed of 1 infrared thermography (IRT) camera, 4 acoustic emission (AE) sensors, 1 pressure sensor, 2 vertical displacement sensors (LVDT) and 2 thermocouples (1 at the heart of the preform, 1 on its surface) is shown schematically in Figure 2 a. A digital multimeter is used to measure the electrical capacitance of the in-situ PZT. The injection of the resin conditions the simultaneous triggering of all the instrumentations, to be able to work on the same time base. The stop of the acquisitions and the demolding of the plate are carried out 6 hours after the injection, to have the certainty of the quasi-complete curing of the resin. The complete experimental setup is presented in Figure 2 b. Three plates were made to ensure the repeatability of the experiment.

Figure 2: (a) Sketch of the multi-instrumentation system, (b) Complete setup before resin injection

The oscillatory rheology tests (3 repeatability) were carried out at room temperature on resin samples mixed with the same MEKP hardener with a concentration identical to the one used for the infused composite plates. The test consists of a dynamic shear of the mixture between two parallel planar plates held at a constant distance (1mm) from each other, at a constant shear strain $\gamma = 1\%$ and at a constant oscillation frequency $f = 1\text{Hz}$. The test is conducted until the complex viscosity modulus $|\eta^*|$ is stabilized. To be able to plot the rheology and infusion curves together and detect the potential couplings, a constant Δt was maintained between the resin + hardener mixing and the start of the test for both types of experiments.

3 RESULTS AND DISCUSSIONS

3.1 Multi-instrumented infusion: couplings between in and ex-situ signatures

Typical results obtained for the multi-instrumented infusion are shown in Figure 3 a.

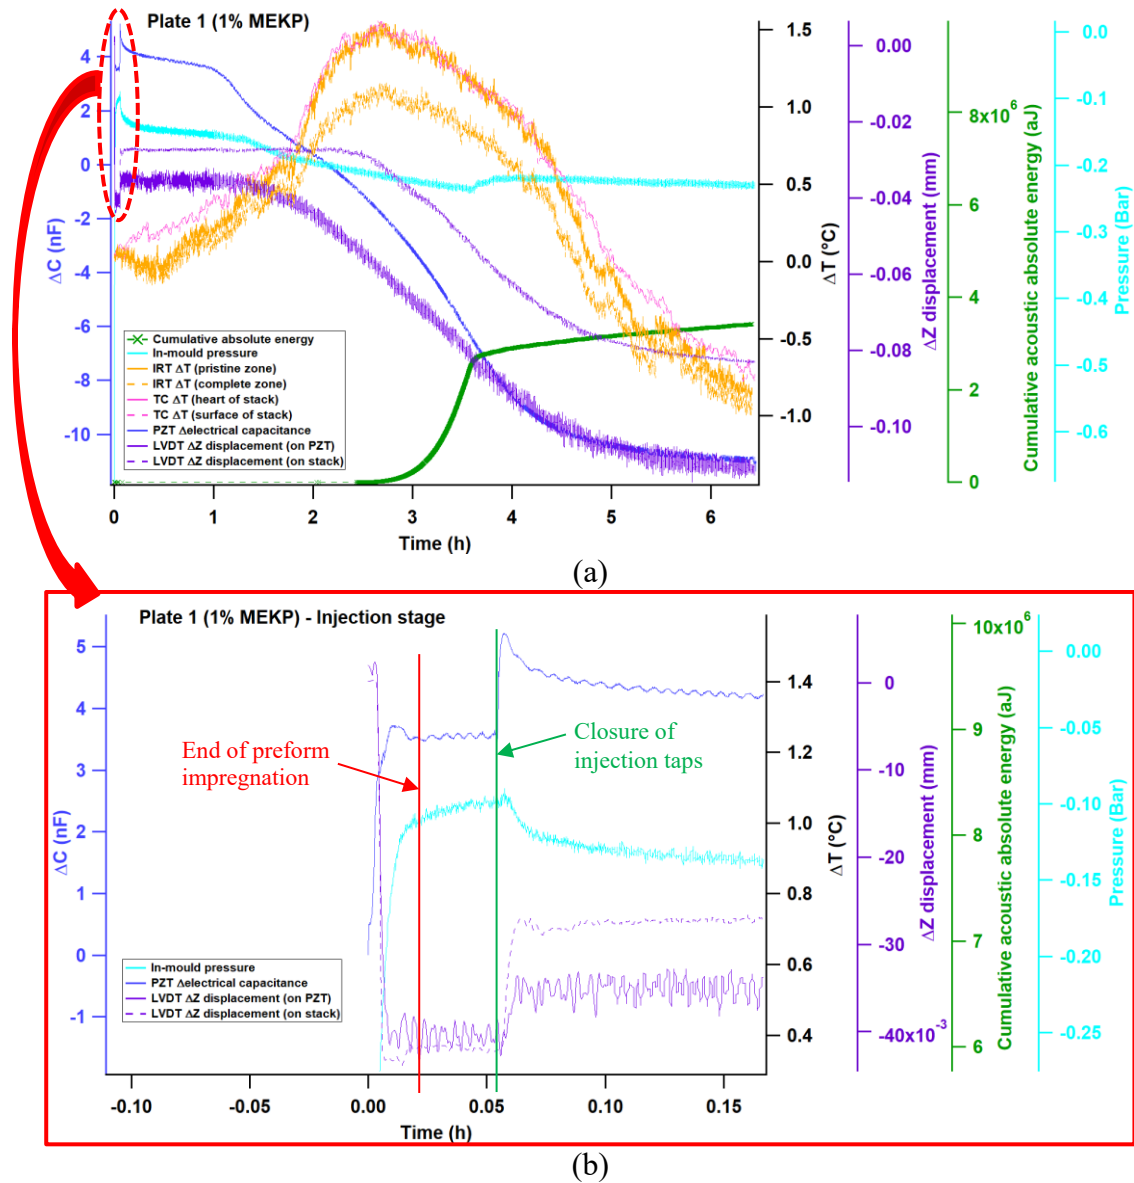

Figure 3: Results of the multi-instrumented infusion: (a) full experiment, (b) resin injection step (plate 1)

It is easy to see on Fig. 3. a) that the signatures of the TC placed at the heart of the preform and the IRT ones taken in the virgin zone of the plate are similar. It is therefore justified to trust IRT to measure thermal phenomena inside the plate, and this will be the case for the rest of this work. However, it is necessary to perform IRT measurements on a virgin zone (no instrumentation placed on it), not to disturb the camera with parasitic reflections and differences in thermal emissivity, which results in underestimated temperature measurement when it is taken on the full plate. Several couplings are observable between the various in and ex-situ signatures. The beginning of each curve appears chaotic, which corresponds to the step of resin injection into the infusion system. Figure 3 b allows highlighting the various phenomena occurring during this stage. The arrival of the resin in the preform causes a fall in the vacuum created by the vacuum pump, associated with an increase in the electrical capacitance (ΔC) of

the PZT and a descent of the LVDTs. The behavior of the capacity is explained by the progressive release of the pressure applied on the PZT by the vacuum during the impregnation of the preform [23], whereas the fall of the LVDT is due to their sliding in one of the cavities of the draining fabric positioned under the vacuum bag. A stabilization of these signatures is then observed, corresponding to the end of the impregnation of the fibrous stack (red demarcation on the Figure 3 b): a steady state begins then, during which the resin continues to flow through the preform to eliminate potential air bubbles as much as possible. The end of the injection is associated with the closing of the two resin inlet and outlet taps, which isolates the preform from the vacuum pump (green demarcation on the Figure 3 b). This results in an immediate response of the 3 signals, related to a gradual stabilization of the pressure in the isolated system: the PZT reacts to the closure (peak) and is then gradually compressed again, this reasoning going hand in hand with the reaction of the LVDTs. The rest of the manufacturing (Figure 3 a) shows new behaviors and couplings. The IRT (virgin zone) shows a progressive exothermal behavior associated with the curing of the resin, which decreases thereafter once the reaction on its end. After a plateau, the capacitance drops continuously until the end of the experiment. The beginning of this fall being associated with the rise in temperature, it is clear that the PZT is sensitive to the start of the curing of the polyester matrix. Indeed, the more a PZT is constrained in its environment (here the progressive contraction of the curing resin), the more its electrical capacitance drops [23]. The signature of the LVDTs provides information on the vertical displacement of the vacuum bag on which they are positioned: it is notable that when the resin contracts during curing, the associated shrinkage causes a negative Z-displacement of the plate, and therefore a reaction of LVDTs. However, it should be noted that LVDTs are less sensitive to the start of the crosslinking than the PZT, their fall occurring later in time than the one of ΔC . This is due to the fact that the PZT is directly surrounded by the resin, which makes its measurement much more local and sensitive than those of the LVDTs. The capacitance and LVDTs signatures appear to stabilize after the end of the exothermal peak, which means that the curing is not complete yet at the temperature peak. The AE signals are also rich in information: after some signals initially sensed corresponding to the passage of the resin front during the injection step, no signal is noticed until the exothermal peak, from which the acoustic activity reappears in the form of an increase in the cumulative absolute energy (CAE) of detected AE bursts. This behavior is associated with the variation of the physical properties of the resin during manufacturing: before the exothermal peak, the resin attenuates the acoustic signals too much so that they can be detected by the 4 AE sensors on the surface. It is necessary to wait for a sufficient degree of cure for the signals to be transmitted through the plate, which suggests that the exothermal peak / CAE rise coupling corresponds to a major state transition of the resin. The acoustic activity related to the rise of the CAE is mainly due to the vibration of the PZT, this being confirmed by the location of the corresponding AE bursts in the integration zone of the PZT (Figure 4). Two slopes are observable in the CAE curve, the transition from one to the other occurring at the beginning of the temperature decrease. Given the quasi-constancy of the second CAE regime, it is clear that at this stage the properties of the resin are stabilized, thus providing information on the end of the curing matrix curing.

Figure 4: Location of AE events on a plate being cured (AEwin software)

The pressure variation can finally be combined with the other measurements: it follows the trend of the capacitance and LVDTs signals, thus linking the curing of the resin to a progressive depression in the infusion system. A point of interest corresponds to a not negligible increase in pressure at the end of the test, correlated with the previously described temperature drop and second EAC regime, thus confirming the existence at this stage of another transition in the resin curing.

The multi-instrumentation has shown the reaction of the PZT to the resin curing and the existence of state transitions inside it, the next part focuses on the sensitivity of the PZT to detect these transitions.

3.2 Sensitivity of the PZT to the state transitions of the curing resin

The capacitance decrease being related to the crosslinking of the polyester matrix, the study focused on the analysis of this decrease. The observation of Figure 5 reveals three regimes, separated by inflections (regime changes). The existence and the temporal appearance of these regimes and inflections being repeatable for each manufactured plate, the hypothesis was emitted that these inflections corresponded to state transitions of the resin during its curing, and that they therefore framed different chemo physical states (stable or unstable) of the resin.

Figure 5: Methodology for the measurement of regime changes (inflections) of the PZT electrical capacitance

These inflections were subsequently correlated with the signatures coming from the multi-instrumentation for each of the manufactured plates. The first inflection had already been attributed to the start of resin curing in § 3.1. The second inflection appears just before the exothermal peak and the increase in the CAE, which confirms the hypothesis emitted earlier that a major state transition of the resin occurs at this time. The third capacity inflection occurs after the exothermal peak, following the start of the second (almost constant) growth regime of the CAE associated with the final pressure re-increase described above: it therefore corresponds to another transition state, this one leading to the near-final state of the resin (chemical reaction substantially completed). At this time, the resin is almost completely cured, which is also confirmed by the progressive stabilization of the plate retraction measured by the LVDTs.

Since strong hypotheses have been put forward on the sensitivity of the PZT to the resin curing and to the various transitions that compose it, it remains to characterize these transitions and to confirm their direct link with the inflections and regimes detected on the decay of PZT electrical capacitance. Consequently, chemo physical characterization tests of the resin alone by oscillatory rheology were undertaken. A thermoset such as the polyester resin passes through different states during its curing, the two main ones being gelation and vitrification [24]. Gelation allows the resin to change from a liquid state to a gel state, then this gel gradually hardens until it becomes a glass (vitrification stage). After the vitrification stage, the chemical reaction slows down (even stops), even if the system temperature is increased [24]. Other events, such as devitrification or phase separation may occur during curing, but these do not occur in this study. The objective is to characterize these two main states, to be able to correlate them with the signatures obtained during infusion. Since the chemo physical characterization of the infused plates is not possible in real time, several pure resin samples (with MEKP) were tested in oscillatory rheology as detailed in section 2. The tests were carried out under conditions as close as possible from those used during infusion manufacturing, namely at room temperature and shear and oscillations as low as possible to reproduce the stable state of the resin when it cures in the plate. These dynamic tests, highlighting the viscoelastic behavior of the resin, make it possible to reveal the gelation by the crossing of the storage modulus (G')

and loss modulus (G'') curves if the test is conducted at constant oscillation frequency ([25] - [27]); this crossing goes hand in hand with an increase in the viscosity complex modulus $|\eta^*|$. The vitrification is determined by the maximum of G'' [28], and each result is normalized with respect to its own mass. The tests are conducted until the appearance of a plateau of $|\eta^*|$, associated with a significant slowing of the curing reaction. This plateau is considered as the end of the vitrification, knowing that it is associated with a drop of G'' meaning that the resin (reticulated) no longer has viscous properties (elastic solid with a maximized G'). The obtained results being repeatable, only those of sample 1 are presented below. These results were then correlated with those obtained in infusion, as shown in Figure 6. Analysis of the latter makes it possible to associate the first inflection of electrical capacitance with the G' / G'' crossing, that is to say gelation. This confirms that when the resin goes from the liquid state to the gel state, it begins to compress the PZT transducer, effectively lowering its capacitance. In the gel state, the resin is a medium in which the acoustic waves are strongly attenuated (and thus not transmitted to the external AE sensors), which is why the CAE signal is flat during this period. The pressure is decreasing at the first inflection because the resin is gradually curing (increased exothermal behavior), consequently the depression of the infusion system is increased. At the beginning of the vitrification (maximum of G''), the second inflection of capacitance appears. This coupling is coherent because the vitrification makes the resin go from a gel state to a much more rigid glass state, which increases the compression seen by the PZT and thus induces a change in the decrease of its capacitance. This second inflection also sees the temperature coming close to its peak, while the CAE prepares to enter its first rise. These other couplings are also consistent: since the chemical curing reaction generates heat throughout its duration, the associated temperature will be close to its maximum when the appearance of the final state change (vitrification) of the resin will occur. Moreover, since the resin gradually transforms into a glass state, its physical properties become more and more similar to those of a sufficiently continuous propagation medium able to transmit the acoustic waves generated by the vibration of the PZT, explaining the rise of CAE to come. However, the resin still being cured at this stage, the depression continues its decline. The third capacitance inflection occurs more than three hours after the resin injection step: at this point, the G' has already converged to a final plateau, and the G'' has returned to zero. It should be noted, however, that this last inflection always happens at a time never reached in rheology, due to the risk of breakage of the rheometer when a very rigid sample is tested too long. The behavior of G' and G'' indicates that the resin is almost completely cured at this stage because as a purely vitreous solid, it has only an elastic behavior and no more viscous properties. This third inflection of electrical capacitance is associated with the change in slope of the CAE (previously mentioned) towards a quasi-linear behavior until the end of the infusion manufacturing, which confirms the hypothesis that at this stage the resin possesses its final properties and therefore always transmits acoustic waves in the same way. A correlation with the temperature drop following the exothermal peak as well as with the final rise in pressure is also observable. This means that since the resin is almost completely cured, the almost complete chemical reaction releases practically no more heat (hence the gradual decrease in temperature), and that the opening made in the vacuum bag to perform the pressure measurement has partially obstructed by the vitrified resin. An important point is the continuity of the decay (albeit much slower than before) of the electrical capacitance after this last inflection, a sign that the curing, although practically complete, is still active. There are still some residual percentages of resin to be cured at this stage.

It is henceforth possible to associate each of the three inflections of the in-situ PZT electrical capacitance with the start of a chemo physical transformation of the polyester resin in crosslinking: gelation, vitrification and finally the slow transformation of a small amount of residual resin still uncured after the end of vitrification.

Figure 6: Comparison of the infusion and rheological measurements

4 CONCLUSION AND OUTLOOK

This article studies the interest of inserting a thin piezoelectric ceramic disc (PZT) inside a PMC preform in order to carry out an in-situ and real-time monitoring of its infusion manufacturing. Several in and ex-situ NDT instrumentations are used in addition to the PZT to obtain correlations between the different signatures. Multiple couplings are observed, providing information both on the impregnation of the preform during the injection stage and on the curing of the resin. The electrical capacitance signal of the PZT has three different inflections during its final decay phase, and these have been studied thanks to the multi-instrumentation data associated with oscillatory rheology measurements made on resin samples alone. These last tests made it possible to associate the first capacitance inflection with the beginning of gelation of the resin, the second with the beginning of its vitrification and the last with the curing of the last resin percentages still not transformed at the end of vitrification. The in-situ PZT giving repeatable and relatively accurate information about the various major transitions (chemo physical or not) occurring during the infusion process, its potential is obvious. The end of vitrification (third capacitance inflection) is particularly interesting because it can be used in industrially to determine when to unmold composite parts without risk of damaging them, and thus increase production rates. These information on transitions can also be very useful for processes using closed molds, such as Resin transfer Molding (RTM), where it is impossible to visualize the progress of manufacturing. This work has also demonstrated the interest of using a multi-instrumentation to monitor this process in real time, and in particular the use of the PZT (transducer) - AE (sensors) couple to detect the presence of the vitrification phase by the

acousto-ultrasonic method. The ultimate interest of this study lies in obtaining a "smart" composite material with an embedded and functional PZT transducer after manufacturing. The PZT can then be used for health monitoring applications of composite structures in use, when the latter are subjected to various physical loads. Finding thresholds to know when to stop the structure to control it more accurately or replace it completely, all without having to use the external and cumbersome NDT techniques available on the market, would be a major breakthrough in the composite materials industry.

Key words: Polymeric composite material, stress-strain state, fiber-optic sensor, numerical simulation, monitoring system.

Abstract. The paper presents a prototype of a system for monitoring the deformed state of a typical part of an aircraft engine – an outlet guide vane (OGV) made of composite materials. The system includes: fiber optic sensors (FOS) based on Bragg gratings, an ASTRO X327 interrogator, and software interrogating and recording data from the FOS. In addition, the system includes a module for calculating the stress-strain state and comparing the calculated strains with the readings of the FOS. The results of approbation of the system for the control of stress-strain state in laboratory tests of OGV are presented. The results of mathematical modeling of the mechanical behavior of the OGV in the software package ANSYS are given. A comparison of experimental data and numerical simulation results was made.

1 INTRODUCTION

Polymer composite materials (PCM) are increasingly used in the manufacture of elements of aircraft propulsion systems. Previously PCM were used for the manufacture of lightly loaded body parts, such as, fairings, casings, engine nacelle shells. Currently, PCM are used in the manufacture of power parts, working in conditions of complex stress state, for example, the outlet guide vanes and fan blades [1-4]. Periodic monitoring, evaluation of the performance and residual strength of such parts during long-term operation is an important task, which causes interest in developing systems for monitoring the state of such parts.

In the civilian sector, there are many examples of existing monitoring systems. The Austrian group of companies belonging to the association NBG Holding GmbH developed systems for monitoring the condition of various structures and infrastructure, such as bridges, tunnels, roads and railways [5]. The monitoring systems described in the literature include the long-term monitoring system of a historic building of the 16th century [6], the stinger condition monitoring system when laying deep-water pipes [7], the monitoring and assessing system for the condition of the wind generator, which makes it possible to make a decision on extending the service life or replacing blades. [eight].

A number of systems have been developed for monitoring composite structures. In [9, 10], the types of damage to composite structural elements arising from the operation of aircraft and the options for building monitoring systems for these structures are considered. In these monitoring systems, it is proposed to use various types of sensors: piezoelectric, acoustic emission, fiber-optic, as well as a non-contact method of monitoring the infrared field emitted by the object. The papers propose the use of these systems for monitoring the condition of airframe elements. The described systems make it possible to record deformations, accumulation of damage, or destruction of controlled elements during the entire life cycle.

Recently, fiber-optic sensors (FOS), which allow to measure temperature and deformation, are increasingly being used as sensitive elements of condition monitoring systems. FOS,

possessing dimensions of the order of 0.15 mm, are capable of withstanding deformations comparable to those of a composite, they are immune to electrical interference, are highly sensitive and can be installed on the surface of a controlled object or embedded in the structure of a composite material to control the structure during the entire life cycle [11,12]. Interrogators, which are part of such systems, depending on the maximum sampling frequency of the sensors, can be used to monitor the state of the object in the quasi-static or dynamic loading mode.

2 Conceptual diagram of the developed monitoring system prototype

Traditionally, systems for monitoring the state of aircraft engines estimate integral indicators such as temperature, pressure, exhaust gas velocity, turbine speed, etc. [13]. Modern systems are aimed at assessing structural damage to structural elements using various sensors. This approach is used along with traditional methods of non-destructive testing and allows you to quickly assess the state of integrity of composite structures. Early detection of defects increases safety and allows for less capital and costly repairs, and also minimizes the problem of human factors in the process of flaw detection [14].

Since 2006, for example, Sandia National Laboratories has been actively working in this direction in collaboration with the Structural Monitoring System, Sykorsky, Boeing, AEM, Acellent, and others [15]. The main line of research is related to automated data analysis for the detection of delaminations and cracks in composite structures using piezoelectric and vacuum sensors. The main task of the prototype system for monitoring structures made of PCM considered in this paper is to monitor the stress-strain state of aircraft engine parts during bench or flight tests. The various elements of such a monitoring system have their own requirements. In particular, sensitive elements placed on the surface or in the structure of the monitoring object should remain operable under complex dynamic and static loading. The sensors must withstand temperatures from -55 to +150 C, and in the case of sensors embedded in the structure of the composite material, and the maximum temperature of technological processing of the material, for example, +160 within 4 hours. The interrogator and information processing modules should be located on board the aircraft, therefore, mass and dimensional restrictions are imposed on them.

The composition of the monitoring system developed in this article includes: a monitoring facility, fiber-optic sensors, peripheral measuring equipment, a computer with software. Fiber-optic sensors can be located on the surface of the monitoring object or be embedded in its structure. The introduction of FOS into the structure of a controlled object is preferable, therefore, in previous studies [16], the technology of introducing FOS into the structure of PCM, obtained by hot pressing and autoclave molding, was developed. Figure 1 shows an outlet guide vane manufactured using autoclave molding technology and the corresponding layout of glued and embedded fiber-optic sensors. The layout of the FOS on the OGV surface (Figure 1, b) was chosen to test the operation of the prototype system based on the results of numerical simulation. Sensors S001-203 are located in areas of large deformations and deformation gradients, and sensors S301-302 are located in the zone of the most probable primary delamination of the OGV structure under quasistatic loading. In the case of placing FOS into the structure of the material (Figure 1, d), the scheme is more convenient from a technological point of view. This scheme allows you to embed 3 lines of four sensors FOS with the formation of 4 groups of FOS with different orientations ($0, \pm 45$) relative to the longitudinal axis, in order to calculate the total deformations based on the readings of these groups in different sections.

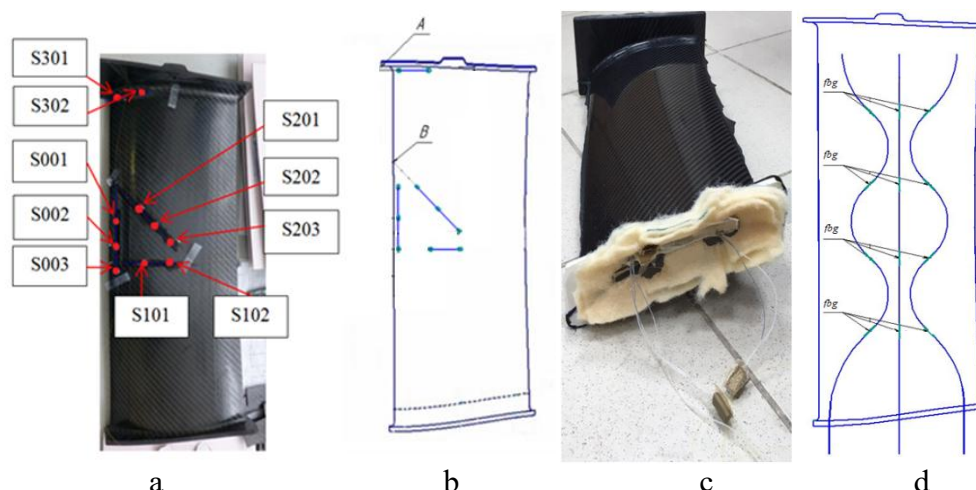

Figure 1. OGV with the FOS lines pasted on the surface (a) and embedded (c). Layout of FOS on the surface (b) and in the construction of the OGV (d).

The peripheral measuring equipment (interrogator) receives information about the resonant wavelengths of Bragg gratings and transmits it to the software module for further processing. The frequency of his work determines the dynamic range of effects that the system can measure.

The system contains two levels of software. The lower level software includes modules that perform primary data processing. In the case of the introduction of FOS into the structure of the PCM, technological factors cause the initial deformation of the fibers, which leads to the birefringence effect and the appearance of noise in the spectrum of the signal of FOS. The lower level software filters noise by a specially developed algorithm, calculates the deviation of the resonant wavelength from the base for each grating, calculates the deformations and transfers these values to the upper level software for further processing.

The upper level software consists of modules with mathematical models of controlled objects for calculating stress-strain state. These programs allow you to compare the deformations recorded by the sensors at specific points in the structure with the calculated values and, in case of compliance, determine stresses and deformations at all points of the object. Indirectly, the simulation results allow us to assess the nature and level of loads acting on the object. It is intended to develop an information analysis module for assessing the safety margin of a structure under a given stress-strain state and a module for detecting the occurrence of defects such as cracks, delaminations or break of layers in a structure during long-term operation or abnormal effects. In addition, it is planned to develop a wrapper program that provides output of various information to the operator interface. The block structure of the monitoring system being developed is shown in Figure 2.

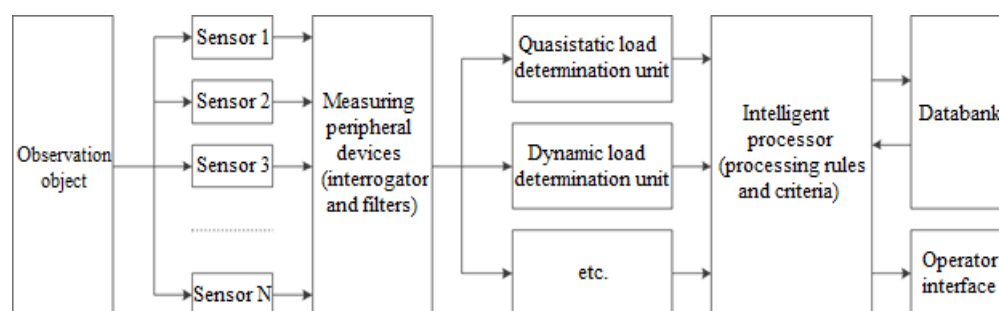

Figure 2. Block structure of the system for monitoring the state of structures

The use of the system implies monitoring both in real time of the structure operation (in flight) and in the post-analysis mode (on the ground) based on the data collected in flight. The

structure of the system implies the possible inclusion of other blocks, for example, by determining the stress-strain state at shock loads or artificial (post-flight) loads, to analyze its deformed state in order to search for possible defects.

3 PCM OGV monitoring system prototype

The object of control in the monitoring system being developed is the outlet guide vane (OGV) of an aircraft engine (Figure 1). The blade is made of carbon-fiber plastic according to pre-peg technology with autoclave molding at a temperature of 160 C. In the design of the blade, can be seen feather and shelves, by means of which the blade is fixed, both in the propulsion system and in the rigging equipment.

As sensitive elements of the monitoring system prototype, fiber-optic sensors with resonant wavelengths were used for:

S001=1565.069nm, S002=1535.032nm, S003=1505.020nm, S101=1564.929nm,
S102=1535.032nm, S201=1565.040nm, S202=1534.985nm, S203=1504.986nm,
S301=1534.990nm, S302=1505.043nm.

Below are considered the results of testing the OGV sample with sensors pasted on the surface (Fig. 1, b). The gluing scheme of the sensors is shown in figure 1, c, where A is the base of longitudinal dimensions, B is the point for the orientation of the inclined line.

The sensors were polled by the ASTRO X327 interrogator. The interrogator generates and transmits a broadband optical signal $\psi(\lambda)$ through an optical fiber (λ is the wavelength). On the Bragg grating part of this signal is reflected. The main part of the reflected optical signal occurs at the resonant wavelength λ , the value of which is directly proportional to the effective refractive index n and the Bragg grating period L . The polling of the sensors can determine the difference of the resonant wavelengths of the reflected spectrum $\Delta\lambda = \lambda - \lambda^*$ in the current λ and initial λ^* time. The relative difference of the resonance wavelength of the reflected spectrum $\Delta\lambda / \lambda$ will be proportional to the relative change in the period $\Delta L / L$ of the Bragg grating, which makes it possible to evaluate its relative mechanical deformations ε and temperature change ΔT [17]:

$$\Delta\lambda/\lambda = K_\varepsilon \varepsilon + K_T \Delta T, \quad (1)$$

where K_ε , K_T are the deformation and temperature coefficients, respectively. These coefficients depend on the optical and mechanical properties of the optical fiber and are known constants.

In the developed monitoring system, information on the change in the resonant wavelength was transmitted to the software module of the lower level. When placing the FOS on the surface of the monitoring object, changes in the spectrum were not observed in the FOS signal. This made it possible not to perform additional signal processing and filtering. The constant temperature during the tests allows not to take into account the influence of the second term of the formula (1) on the signal of the ESP. The software of the lower level received information about the resonant wavelengths of each WATER, carried out the calculation of the deviations of the wavelengths, the calculation of deformations for each sensor using the formula (1). In the upper level software, the monitoring object's stress-strain state was calculated under laboratory loads, the calculated and experimental deformations were compared, and under the condition of satisfactory agreement, the structure's safety margin was estimated from the calculated stress values.

4 Testing a monitoring system prototype

The tests of the developed system were intended to check the operation of all its components under quasi-static loading and to compare the deformations recorded by FOS with the results of the numerical calculation of the stress-strain state of the OGV under study. The OGV was loaded in a specially designed metal tooling through a rubber gasket 20 mm

thick onto the surface of the vane blade. The sensors were attached to another surface of the feather free of load. The tests were carried out on a Zwick Z100 servo-hydraulic machine with a cylinder of 90mm diameter (complex of equipment of the “Unique Scientific and Technological Complex of Automated Layout” PNRPU) at a constant temperature. During the tests, load monitoring and registration of fiber-optic sensors with a sampling frequency of 100 Hz were carried out. The general scheme of the tests is presented in figure 3.

To process the sensor signal and calculate the strain, the software described above was used. Tests have shown that the chosen technology of gluing sensors ensures their reliable fixation on the surface of the object, this, in turn, ensures the registration of the signal with minimal distortion.

Deformations obtained according to the indications of the FOS, depending on the applied load, are shown in figure 4. The analysis of these dependences shows the non-linear nature of the deformation, which is especially pronounced with the S201-S203 sensors oriented at an angle to the OGV axis. Further, the readings of the sensors are compared with the results of the OGV numerical simulation.

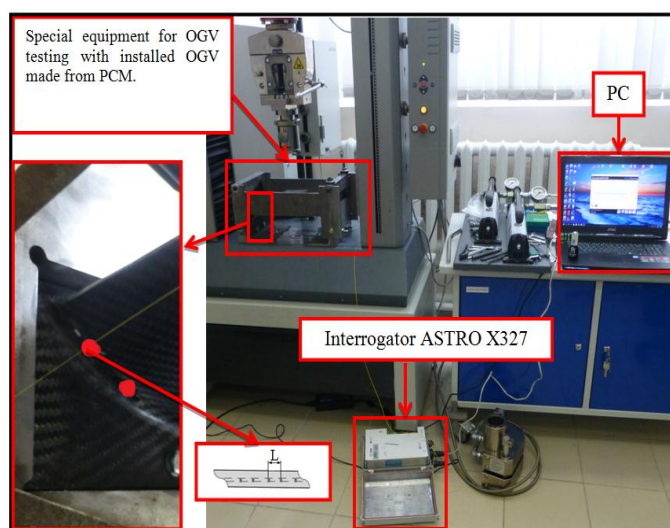

Figure 3. Test scheme of the OGV monitoring system.

Figure 4. Dependence of the strain on the applied load, obtained from FOS, placed on the free surface of the OGV, the sensor numbers are shown in Figure 1a.

5 Numerical modeling and comparison of results

For the numerical simulation of mechanical deformation of the OGV, a three-dimensional computer model was developed. The model explicitly describes the vane reinforcement scheme in the form of a set of anisotropic CFRP layers with different geometries. The loading scheme corresponded to the laboratory test conditions. On the top shelf of the vane, rigid fastening was set on the bolt joint holes, on the bottom shelf the absence of movements in two directions UX, UY was set. A proportionally increasing distributed load was applied to the vane tip through the rubber plate (Figure 5). The rubber plate was deformed nonlinearly, the deformation of carbon fiber was considered linear, the elastic properties of the material of the layers in the coordinate system of the OX1X2X3 layer are given in (Table 1).

Figure 5. The design scheme of OGV 1 is rigid attachment, 2 is the prohibition of UX, UY movements, 3 is the load.

Table 1. Elastic properties of composite material.

Material	E11, GPa	E22, GPa	E33, GPa	G12, GPa	G13, GPa	G23, GPa	v21	v13	v32
Equal Strength Carbon Fiber	63,9	63,9	5,0	19,5	2,7	2,7	0,04	0,3	0,3

The solution of the nonlinear three-dimensional problem of mechanics of inhomogeneous media for the vane under consideration with an explicit description of the reinforcement scheme requires large computational resources. Therefore, in the present work, the simulation of mechanical deformation of a vane was carried out for a homogeneous anisotropic material with effective elastic properties of a layers package. The effective elastic properties of a layers package were calculated separately on the basis of the reinforcement scheme and the properties of the layers (Table 1). The problem was solved in the ANSYS Workbench software package using the spatial finite elements SOLID 86. The load was set from the initial total load of 100 N to the load of 1500 N with a step of 100 N.

Figure 6 shows deformation fields of the free of loading vane surface obtained as a result of the calculation for a load of 1500 N. It also shows the values of deformations in the vicinity of the location of the FOS in directions that coincide with the axis of sensitivity of the FOS. Calculations show that the deformation fields are non-uniform, and there are areas of compressive and tensile deformations on the surface of the blade. It should be noted that FOSs were installed in the most dangerous zones of compressive deformations.

Table 2 for load values of 500, 1000, and 1500 N presents a comparison of the deformations determined from the FOS readings and the calculated values of the deformations at the sensor locations.

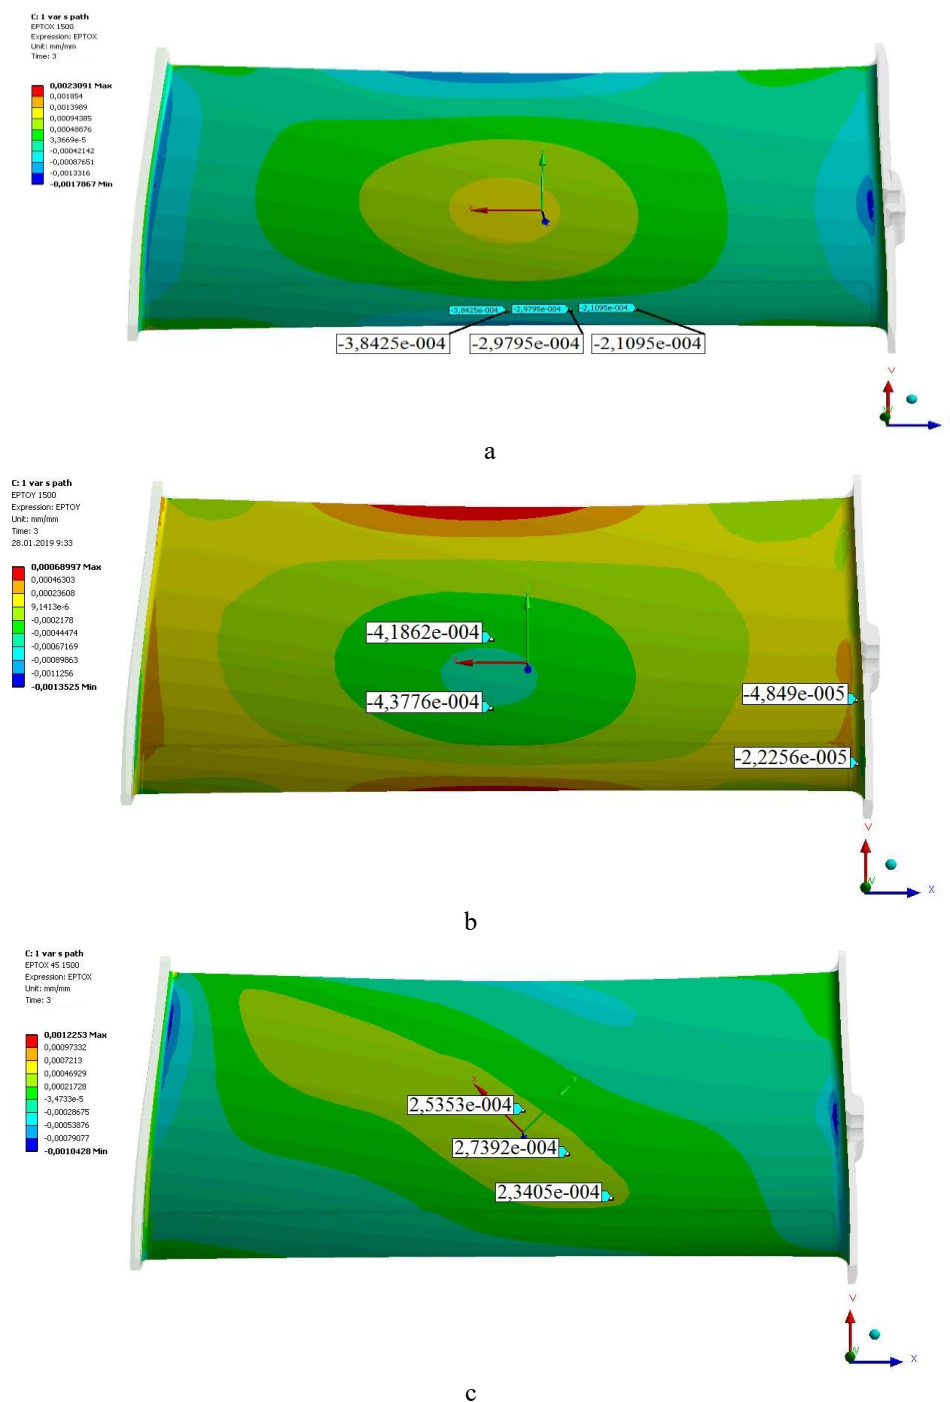

Figure 6. The field of axial deformations on the free surface of the OGV feather in the area of mounting the FOS at 1500H in the local layer coordinate system in the directions a) ϵ_x b) ϵ_y c) ϵ_{x45°

TABLE 2. Comparison of deformations determined by the FOS indications, and calculated values of deformations at the sensor locations under loads of 500, 1000 and 1500 N

Parameter		Longitudinal direction			Cross direction				At 45° angle		
	Load , N	S001	S002	S003	S101	S102	S301	S302	S201	S202	S203
Deformations FOS*, 10 ⁻⁴ .	500	-0,88	-1,38	-1,52	-2,23	-1,26	-0,07	-0,09	-0,42	-0,35	-0,21
	1000	-1,56	-2,34	-2,64	-3,85	-2,24	-0,16	-0,27	-0,18	-0,03	-0,04
	1500	-2,27	-3,31	-3,77	-5,21	-3,41	-0,23	-0,48	0,45	0,69	0,64
Calculated deformations · 10 ⁻⁴ .	500	-0,86	-1,10	-1,26	-1,13	-1,42	-0,08	-0,09	0,78	0,94	0,90
	1000	-1,51	-2,13	-2,41	-2,91	-2,76	-0,16	-0,22	1,55	1,85	1,73
	1500	-2,11	-2,98	-3,84	-4,19	-4,38	-0,22	-0,48	2,34	2,74	2,54
Deviation, %	500	2,12	25,04	20,30	98,55	11,66	9,22	8,77	154,6	137,3	123,0
	1000	3,63	9,53	9,80	32,55	12,58	5,74	21,27	111,8	101,3	97,65
	1500	7,69	11,18	1,94	24,41	22,13	4,89	-0,23	80,75	74,62	74,79
	$\bar{\Delta}$	4,48	15,25	9,39	51,83	15,46	0,47	9,94	115,7	104,4	98,51

$\bar{\Delta}$ Mean deviation

Table 2 data analysis shows that the deformations in the longitudinal and cross directions detected by the sensors S001, S002, S003, S102, S301, S302 are close to the calculated values. The difference in strain at a point is from 2 to 25%, the average difference in strain in the three measurement options (calculations) is from 4.5 to 15.5%.

The lateral deformations detected by the S101 sensor differ from the calculated deformations by 24.5-98.5%. Deformations at an angle of 45 °, recorded by the sensors S201, S 202, S203, differ from the calculated deformations by 74.6-154.6%. It should be noted that the sensors S201, S202, S203, S301 and S302 record the strain values that are included in the equipment error zone (0.5 10-4). In this case, the readings of the sensors S301 and S302 are in satisfactory agreement with the calculation, and the readings of the sensors S201, S202, S203, differ significantly.

The difference between the calculated and experimentally obtained values of deformations using FOS is apparently due to the error in the simulation of the deformation of the vane using the effective material properties and the error in determining the Poisson coefficients for the material layer.

In further studies, it is planned to obtain an updated solution to the problem of mechanical deformation of the vane with a complete description of its reinforcement scheme and an updated value of the Poisson's ratio of the layers material. After a satisfactory coincidence of the calculated and experimental values of deformations, it is planned to obtain a calculated estimate of the strength margin of the vane under laboratory load and to experimentally verify the accuracy of this estimate.

6 Conclusion

A technology has been developed for introducing and gluing fiber optic sensors into a composite material structure, manufactured using prepreg technology of hot pressing. A prototype of a system for monitoring the stress-strain state of outlet guide vane made of composite materials using fiber-optic sensors on Bragg gratings and a mathematical model of the structure has been developed. The prototype of the monitoring system was checked in laboratory tests of the vane. A satisfactory coincidence (calculated on average to 15.5%) was obtained for the calculated and experimental FOS registered deformation values at six control points of ten. The significant (over 100%) difference in deformations at four control points is explained by the error of calculations due to the use of a simplified mathematical model of the structure and the error in determining the Poisson's ratio of the layers material. In further

studies, it is planned to obtain an updated solution of the problem of mechanical deformation of the vane for a satisfactory agreement between the calculated and experimental values of the deformations at all control points. Next, it is planned to obtain a calculated estimate of the safety margin of the vane under laboratory load and to experimentally test the accuracy of this estimate. This will test the possibility of using a monitoring system prototype for assessing the safety margin of a structure during testing.

Key words: Nonlinear plates and shells, Direct approach, Electrostrictive polymers

Abstract. In this paper we discuss modeling of electrostrictive polymer plates and shells as electro-elastic material surfaces. A complete direct approach is developed without the need to involve the three-dimensional formulation. Electrostatic forces as well as constitutive coupling by means of electrostriction are accounted for. We propose a rational formulation for the augmented free energy of electro-elastic material surfaces incorporating electrostriction by a multiplicative decomposition of the surface stretch tensor and an additive decomposition of the surface curvature tensor into elastic and electrical parts. Results computed within the framework of this complete direct approach are compared to results computed with a method that requires the numerical integration of the three-dimensional constitutive relations through the thickness of the plate or shell.

1 INTRODUCTION

Elastic dielectrics, such as piezoelectric materials and electro-active polymers, belong to the class of electro-active materials, which are materials with an inherent electromechanical coupling due to electrostatic forces as well as constitutive coupling resulting from e.g. ferroelectricity, piezoelectricity and electrostriction. Electro-active polymers are divided into two types, ionic and field-activated electro-active polymers, of which we are solely interested in field-activated electro-active polymers in this paper. The latter can further be sub-divided into dielectric elastomers, electrostrictive polymers and ferroelectric polymers; see Pelrine et.al. [1] or Bar-Cohen [2]. Dielectric elastomers are actuated through electrostatic and ponderomotive forces only, ferroelectric polymers exhibit an electrostrictive effect in a non-poled virgin state, but show piezoelectric behavior in the poled state, and electrostrictive polymers are actuated by both, electrostatic and ponderomotive forces as well as through a molecular alignment resulting into electrostriction; see e.g. Zäh and Miehe [3]. Constitutive modeling in field-activated electro-active polymers is based on a proper specification of the Helmholtz free energy, see Dorfmann and Ogden [4] and

Vu et.al. [5]. When it comes to ferroelectric polymers and electrostrictive polymers, coupling by means of electrostriction becomes involved. In such a case a multiplicative decomposition of the deformation gradient tensor for finite strains is typically applied, in which the electrostrictive and the piezoelectric part of the deformation is accounted for by means of a purely electric part of the deformation gradient tensor. In the context of electro-active polymers we refer to Skatulla [6] and Zäh and Miehe [3] and our own previous work, Staudigl et.al. [7], and for reversible piezoelectric materials see Humer and Krommer [8].

In many cases structures with integrated electro-active materials can be assumed as thin plates and shells, such that the theories of structural mechanics come into play. A common approach in nonlinear structural mechanics - often denoted as direct approach - is to consider these structures as two-dimensional material surfaces with specific mechanical degrees of freedom for each material point of the surface - typically translations and rotations. Dealing with plates and shells with integrated electro-active materials electrical degrees of freedom must be introduced for the material surface as well and the modeling must be completed by consistently incorporating electrostatic and ponderomotive forces as well as the appropriate two-dimensional form of the Helmholtz free energy on the structural level of the material surface. In contrast to the direct approach, various other approaches to the modeling and analysis for electro-elastic plates and shells are reported in the literature in the context of piezoelectric materials; see Vetyukov et.al. [9] and the literature cited there. Concerning electro-elastic plates and shells made of field-activated electro-active polymers the literature is by no means exhaustive. Typically, such plates and shells are either modeled based on the implementation of three-dimensional solid plate or shell elements (e.g. Klinkel et al. [10] and Bishara and Jabareen [11] for dielectric elastomer plates) or on the full three-dimensional formulation (e.g. Vu et.al. [5], Skatulla [6] and Zäh and Miehe [3]). So far, a direct approach to the modeling of the nonlinear behavior of electro-elastic plates and shells was applied to piezoelectric shells by Vetyukov et.al. [9] and to dielectric elastomer plates by Staudigl et.al. [12]. In this latter reference the direct approach was only concerned with the geometry of deformation and forces; yet, the specific form of the structural two-dimensional augmented free energy was not discussed, but rather the three-dimensional form was numerically integrated through the thickness by making a-priori assumptions on the thickness distribution of the deformation. A first account for a complete direct approach for dielectric elastomer plates was presented by Krommer and Staudigl in [13].

In the present paper we summarize the material independent equations for electro-elastic material surfaces. Then, we focus on proposing a rational formulation for the augmented free energy of such surfaces for the case the underlying plates and shells are made of an electrostrictive polymer. Electrostriction will be accounted for by a multiplicative decomposition of the surface stretch tensor and an additive decomposition of the surface curvature tensor into elastic and electrical parts. Finally, the proposed theory is validated.

2 ELECTRO-ELASTIC PLATES AS MATERIAL SURFACES

In this section we discuss the governing equations of thin plates modeled as a two-dimensional electro-elastic material surface with mechanical and electrical degrees of freedom. In particular, we consider the plate as a two-dimensional continuum with five mechanical degrees of freedom, three translations and two rotations. Concerning the electrical degrees of freedom, we use only the dominant one, i.e., the electric potential difference V .

2.1 Strain measures

The material surface is plane in the reference configuration, and it is denoted as reference surface. In the deformed or actual configuration the material surface is denoted as actual surface. The first metric tensor of the plane reference surface $\mathbf{A} = \mathbf{I}$ is the two-dimensional identity tensor and the second metric tensor is zero, $\mathbf{B} = \mathbf{0}$. For the actual surface the first and second metric tensors are \mathbf{a} and \mathbf{b} . The reference configuration and the actual configuration of the material surface are related to each other by means of a deformation gradient tensor $\mathbf{F} = (\nabla_0 \mathbf{r})^T$ with the differential operator ∇_0 of the reference surface and the position vector \mathbf{r} of points of the material surface in the actual configuration. Also note that the second metric tensor of the actual surface is $\mathbf{b} = \mathbf{b}^T = -\nabla \mathbf{n}$ with the unit normal vector \mathbf{n} of the actual surface, and $\mathbf{a} = \nabla \mathbf{r} = \mathbf{I}_3 - \mathbf{n}\mathbf{n}$ with the three-dimensional identity tensor \mathbf{I}_3 holds for the first metric tensor. The differential operators ∇_0 and ∇ with $\nabla_0 = \mathbf{F}^T \cdot \nabla$ refer to either the reference surface or the actual surface. We introduce two tensor valued Green strain measures for the material surface, which are defined as the difference between the two metric tensors in the two configurations, with the proper transformation by means of \mathbf{F} ,

$$\boldsymbol{\varepsilon} = \frac{1}{2} (\mathbf{F}^T \cdot \mathbf{F} - \mathbf{I}) , \quad \boldsymbol{\kappa} = -\mathbf{F}^T \cdot \mathbf{b} \cdot \mathbf{F}. \quad (1)$$

Both strain measures remain constant if and only if the motion of the material surface is a rigid body motion, see [14] for a discussion. A theory with these strain measures is denoted as Kirchhoff-Love theory.

2.2 Material independent equations

A variational principle is introduced for the electro-elastic material surface as

$$\int_{A_0} (\delta\Omega - (\mathbf{p} \cdot \delta\mathbf{r} - \mathbf{m} \times \mathbf{n} \cdot \delta\mathbf{n} + \sigma\delta V)) dA_0 - \delta A^{e,b} = 0, \quad (2)$$

with the area A_0 of the reference surface, the external electric charge σ per unit area of the reference surface and the voltage V . \mathbf{p} and \mathbf{m} are purely mechanical external forces and moments per unit area of the reference surface and Ω is the plate augmented free energy. External forces and moments acting at the boundary, which involve both, mechanical and electrical contributions, are accounted for by means of the virtual work $\delta A^{e,b}$. Due to the fact that external forces and moments \mathbf{p} and \mathbf{m} are assumed purely mechanical, ponderomotive forces must be accounted for by means of Ω . With ease one can show that the plate augmented free energy per unit reference area of the plate has the form $\Omega = \Omega(\boldsymbol{\varepsilon}, \boldsymbol{\kappa}, V)$. Formally computing the variation of this energy to

$$\delta\Omega = \frac{\partial\Omega}{\partial\boldsymbol{\varepsilon}} \cdot \cdot \delta\boldsymbol{\varepsilon} + \frac{\partial\Omega}{\partial\boldsymbol{\kappa}} \cdot \cdot \delta\boldsymbol{\kappa} + \frac{\partial\Omega}{\partial V} \delta V, \quad (3)$$

and noting the general relation $\delta\Omega = \boldsymbol{\tau} \cdot \cdot \delta\boldsymbol{\varepsilon} + \boldsymbol{\mu} \cdot \cdot \delta\boldsymbol{\kappa} - q\delta V$ finds the constitutive relations of the electro-elastic material surface to

$$\boldsymbol{\tau} = \frac{\partial\Omega}{\partial\boldsymbol{\varepsilon}} , \quad \boldsymbol{\mu} = \frac{\partial\Omega}{\partial\boldsymbol{\kappa}} , \quad q = -\frac{\partial\Omega}{\partial V}. \quad (4)$$

Here, $\boldsymbol{\tau}$ and $\boldsymbol{\mu}$ are two second Piola-Kirchhoff type stress tensors and q is the internal charge per unit area of the reference surface.

2.3 Constitutive modeling for isotropic dielectric elastomer plates

The present approach to modeling of plates as electro-elastic material surfaces involves two strain measures, $\boldsymbol{\varepsilon}$ and $\boldsymbol{\kappa}$. Talking about hyperelastic plates, we rather work with the right Cauchy-Green tensor \mathbf{C} than with $\boldsymbol{\varepsilon}$; hence, we recall the definitions

$$\mathbf{C} = \mathbf{F}^T \cdot \mathbf{F}, \quad \boldsymbol{\kappa} = -\mathbf{F}^T \cdot \mathbf{b} \cdot \mathbf{F}. \quad (5)$$

Next, we introduce the polar decomposition of the deformation gradient tensor as $\mathbf{F} = \mathbf{R} \cdot \mathbf{U}$, in which \mathbf{R} is an orthogonal tensor with $\mathbf{n} = \mathbf{R} \cdot \mathbf{N}$ and $\mathbf{U} = \mathbf{U}^T$ is the symmetric stretch tensor of the material surface. Then, the two strain measures may as well be written in the form

$$\mathbf{C} = \mathbf{U}^2, \quad \boldsymbol{\kappa} = -\mathbf{U} \cdot \mathbf{R}^T \cdot \mathbf{b} \cdot \mathbf{R} \cdot \mathbf{U}. \quad (6)$$

For the purpose of constitutive modeling, we involve the alternative second strain measure

$$\mathbf{K} = \mathbf{U}^{-1} \cdot \boldsymbol{\kappa} \cdot \mathbf{U}^{-1} = -\mathbf{R}^T \cdot \mathbf{b} \cdot \mathbf{R}, \quad (7)$$

which we denote as curvature tensor. Then, $\Omega = \Omega(\mathbf{C}, \mathbf{K}, V)$ holds.

2.3.1 Augmented free energy

The bottleneck in our formulation is the specific form of the augmented free energy $\Omega = \Omega(\mathbf{C}, \mathbf{K}, V)$; in particular, when it involves hyperelastic material laws. In this paper, we will only concern ourselves with thin plates with thickness h made of isotropic and incompressible hyperelastic materials, for which the material is assumed homogenous through the thickness and obeys a neo-Hookean law. In order to introduce the specific form of the plate augmented free energy we start with an additive decomposition of $\Omega = \Omega(\mathbf{C}, \mathbf{K}, V)$ into a mechanical part and a total electrical part,

$$\Omega = \eta_0 \Psi_{me}(\mathbf{C}, \mathbf{K}) + \eta_0 \Psi_{el,tot}(\mathbf{C}, \mathbf{K}, V). \quad (8)$$

Strain energy We start with a discussion of the mechanical part, i.e., the strain energy, for which the polar decomposition $\mathbf{F} = \mathbf{R} \cdot \mathbf{U}$ enables an additive decomposition into a membrane and a bending part, $\eta_0 \Psi_{me}(\mathbf{C}, \mathbf{K}) = W_m(\mathbf{C}) + W_b(\mathbf{C}, \mathbf{K})$. The membrane part is taken in analogy to a plane stress incompressible neo-Hookean strain energy as

$$W_m = \eta_0 w_m = \frac{1}{2} \frac{A}{4} (\text{tr} \mathbf{C} + (\det \mathbf{C})^{-1} - 3). \quad (9)$$

Here, $A = Yh(1 - \nu^2)^{-1}$ is the membrane stiffness well known from linear plate theory. With $\nu = 0.5$ we have Young's modulus as $Y = 3\mu$ and $A = 4\mu h$ holds. η_0 is the mass per unit reference area and w_m the membrane energy per unit mass. In order to introduce the bending energy, we recall the polar decomposition $\mathbf{F} = \mathbf{R} \cdot \mathbf{U}$, by means of which the deformation gradient tensor is multiplicatively decomposed into a plane part \mathbf{U} and an orthogonal part \mathbf{R} . As the first part does not contribute to the bending deformation, the bending energy must not directly depend on the stretch tensor \mathbf{U} , and the corresponding intermediate configuration must be free of bending stresses. Therefore, the bending energy should be formulated in terms of the curvature tensor only, and be referred to the mass η per unit area in the intermediate configuration with a plate

stiffness \tilde{D} accounting for the thickness of the plate in the intermediate configuration. Hence, we write the bending energy per unit area in the intermediate configuration in analogy to the one of an isotropic incompressible Kirchhoff plate as

$$\eta w_b = \frac{1}{2} \tilde{D} ((\text{tr} \mathbf{K})^2 - \det \mathbf{K}). \quad (10)$$

Here, we have taken the standpoint that the curvature tensor is of an order of smallness that justifies the use of an incompressible Saint-Venant Kirchhoff strain energy. With the area change from the reference configuration to the intermediate configuration $J = \det \mathbf{U} = \det \mathbf{F}$, $\eta = J^{-1} \eta_0$ holds; obviously, η also represents the mass per unit actual area. Noting in addition the three-dimensional incompressibility condition $J_3 = 1 = J F_{33}$ with the thickness stretch $U_{33} \equiv F_{33} = \lambda_3$, the plate stiffness in the intermediate configuration is $\tilde{D} = J^{-3} D$, in which $D = Y h^3 / 12 (1 - \nu^2)^{-1}$ is the classical plate stiffness, which is $D = \mu h^3 / 3$ for $\nu = 0.5$. Therefore, we have

$$W_b = \eta_0 w_b = \frac{1}{2} (\det \mathbf{C})^{-1} D ((\text{tr} \mathbf{K})^2 - \det \mathbf{K}). \quad (11)$$

Total electrical energy In a homogenous plate with a homogenous electric field through the thickness, the contribution from the total electrical free energy is written in analogy to a capacitor as $2\eta\psi_{el,tot} = -\tilde{c}V^2$, with the voltage V and the capacity \tilde{c} and mass η per unit actual area; the latter is identical to the mass per unit area in the intermediate configuration emerging by means of \mathbf{U} . \tilde{c} is related to the capacity per unit reference area c by $\tilde{c} = Jc$. Therefore, we have

$$\Omega_{el,tot} = \eta_0 \psi_{el,tot} = -\frac{1}{2} c V^2 (\det \mathbf{C}) \quad (12)$$

for the electrically homogenous case. In such a case, the total electrical free energy only contributes to the membrane part of the augmented free energy, which only depends on \mathbf{C} . In the more general scenario of a non-homogenous electric field through the thickness of the plate, the total electrical free energy must also contribute to the bending part of the augmented free energy; therefore, it must depend also on \mathbf{K} . In order to introduce this contribution, we propose the overall bending part of the augmented free energy in the form

$$\eta \omega_b = \frac{1}{2} \left(\tilde{D} ((\text{tr} \mathbf{K})^2 - \det \mathbf{K}) - 2\tilde{m}^* \text{tr} \mathbf{K} \right), \quad (13)$$

which formally constitutes the classical bending energy of an isotropic Kirchhoff plate with a so-called *Eigenspannungsquelle* \tilde{m}^* ; the second term represents the bending part of the total electrical free energy. Here, we have naturally extended our previous standpoint, that the curvature tensor is of an order of smallness that justifies the use of an incompressible Saint Venant–Kirchhoff strain energy to the electrical energy. Keeping in mind that \tilde{m}^* is an *Eigenspannungsquelle* per unit area in the intermediate configuration, it relates to the *Eigenspannungsquelle* per unit area in the reference configuration m^* by virtue of $\tilde{m}^* = Jm^*$. Therefore,

$$\eta_0 \omega_b = \frac{1}{2} ((\det \mathbf{C})^{-1} D ((\text{tr} \mathbf{K})^2 - \det \mathbf{K}) - 2(\det \mathbf{C}) m^* \text{tr} \mathbf{K}) \quad (14)$$

holds. The first part is the bending energy from above, whereas the second part can be combined with the electrical energy introduced for a homogenous electric field to

$$\Omega_{el,tot}(\mathbf{C}, \mathbf{K}, V) = \eta_0 \psi_{el,tot} = -\frac{1}{2}cV^2 \det \mathbf{C} - \frac{1}{2}2(\det \mathbf{C})m^* \text{tr} \mathbf{K}. \quad (15)$$

As m^* must be proportional to V^2 and the capacity per unit reference area c is a constant, we write $m^* = c\alpha V^2$ and obtain the final form of the total electrical contribution to the augmented free energy as

$$\Omega_{el,tot}(\mathbf{C}, \mathbf{K}, V) = \eta_0 \psi_{el,tot} = -\frac{1}{2}cV^2 \det \mathbf{C} (1 + 2\alpha \text{tr} \mathbf{K}), \quad (16)$$

in which α is a parameter characterizing the non-homogeneity of the electric field through the thickness.

Summarizing our result, the augmented free energy of an isotropic, elastically homogenous and incompressible hyperelastic neo-Hookean electro-elastic plate is proposed as

$$\begin{aligned} \Omega(\mathbf{C}, \mathbf{K}, V) &= \frac{1}{2} \frac{A}{4} (\text{tr} \mathbf{C} + (\det \mathbf{C})^{-1} - 3) + \frac{1}{2} (\det \mathbf{C})^{-1} D((\text{tr} \mathbf{K})^2 - \det \mathbf{K}) \\ &\quad - \frac{1}{2} cV^2 \det \mathbf{C} (1 + 2\alpha \text{tr} \mathbf{K}). \end{aligned} \quad (17)$$

Finally, we note that the relations $\text{tr} \mathbf{K} = \text{tr}(\mathbf{U}^{-1} \cdot \boldsymbol{\kappa} \cdot \mathbf{U}^{-1}) = \text{tr}(\mathbf{C}^{-1} \cdot \boldsymbol{\kappa})$, $\det \mathbf{K} = \det(\mathbf{U}^{-1} \cdot \boldsymbol{\kappa} \cdot \mathbf{U}^{-1}) = \det(\mathbf{C}^{-1} \cdot \boldsymbol{\kappa})$ and $\mathbf{C} = \mathbf{I} + 2\boldsymbol{\varepsilon}$ enable us to write the augmented free energy as $\Omega = \Omega(\boldsymbol{\varepsilon}, \boldsymbol{\kappa}, V)$, which closes the theory of electro-elastic material surfaces for the case of plates and in the absence of constitutive coupling by means of electrostriction.

2.3.2 Electrostrictive coupling

The augmented free energy as proposed in the previous section accounts for electrostatic forces, but not for constitutive coupling by means of electrostriction. A straightforward extension is obtained by replacing the strain measures \mathbf{C} and \mathbf{K} by their elastic counterparts \mathbf{C}_e and \mathbf{K}_e in the strain energy part of the augmented free energy. Hence, we write

$$\begin{aligned} \Omega(\mathbf{C}_e, \mathbf{K}_e, \mathbf{C}, \mathbf{K}, V) &= \frac{1}{2} \frac{A}{4} (\text{tr} \mathbf{C}_e + (\det \mathbf{C}_e)^{-1} - 3) + \frac{1}{2} (\det \mathbf{C}_e)^{-1} D((\text{tr} \mathbf{K}_e)^2 - \det \mathbf{K}_e) \\ &\quad - \frac{1}{2} cV^2 \det \mathbf{C} (1 + 2\alpha \text{tr} \mathbf{K}). \end{aligned} \quad (18)$$

It remains to define the elastic strain measures. For this sake we introduce a multiplicative decomposition of the total stretch tensor and an additive decomposition of the total curvature tensor in the following.

First, we use a multiplicative decomposition $\mathbf{U} = \mathbf{U}_e \cdot \mathbf{U}_{el}$ for the symmetric stretch tensor \mathbf{U} of the material surface into an electrical part $\mathbf{U}_{el} = \mathbf{U}_{el}(V)$ and an elastic part \mathbf{U}_e . Analogous multiplicative decompositions have been introduced by different authors for electro-active polymers but also piezoelectric materials in a three-dimensional framework, see [6], [3] and [8]. Introducing the multiplicative decomposition for the stretch tensor rather than for the deformation gradient tensor restricts the electrical part to be symmetric, which in the present paper is fully justified. Moreover, due to isotropy we consider the electrical part as spherical, $\mathbf{U}_{el} = \lambda_{el} \mathbf{I}$

with $\lambda_{el} = \lambda_{el}(V)$. With the decomposition at hand, the right Cauchy-Green tensor of the material surface is

$$\mathbf{C} = \mathbf{U}_{el} \cdot \mathbf{C}_e \cdot \mathbf{U}_{el} = \lambda_{el}^2 \mathbf{C}_e. \quad (19)$$

Here, $\mathbf{C}_e = \mathbf{U}_e^2$ is the elastic right Cauchy-Green tensor, which can also be written as

$$\mathbf{C}_e = \lambda_{el}^{-2} \mathbf{C}. \quad (20)$$

Concerning the curvature tensor we use an additive decomposition $\mathbf{K} = \mathbf{K}_e + \mathbf{K}_{el}$, from which the elastic curvature tensor follows to

$$\mathbf{K}_e = \mathbf{K} - \mathbf{K}_{el} = \mathbf{U}^{-1} \cdot (\boldsymbol{\kappa} - \boldsymbol{\kappa}_{el}(V)) \cdot \mathbf{U}^{-1}. \quad (21)$$

Eventually, $\lambda_{el}(V)$ and $\boldsymbol{\kappa}_{el}(V)$ must be properly specified. With \mathbf{C}_e and \mathbf{K}_e at hand, the augmented free energy is $\Omega = \Omega(\mathbf{C}_e, \mathbf{K}_e, \mathbf{C}, \mathbf{K}, V)$, in which $\mathbf{C}_e = \lambda_{el}^{-2}(V) \mathbf{C}$ and $\mathbf{K}_e = \mathbf{K} - \mathbf{K}_{el} = \mathbf{U}^{-1} \cdot (\boldsymbol{\kappa} - \boldsymbol{\kappa}_{el}(V)) \cdot \mathbf{U}^{-1} = \mathbf{U}^{-1} \cdot \boldsymbol{\kappa}_e \cdot \mathbf{U}^{-1}$ hold.

2.3.3 Electrical part of the stretch tensor and the curvature tensor

To complete the constitutive modeling for plates, we must introduce the electrical stretch tensor $\mathbf{U}_{el}(V)$ as well as the electrical part of the curvature tensor $\mathbf{K}_{el}(V)$. Concerning the latter we note the relation $\mathbf{K}_{el} = \mathbf{U}^{-1} \cdot \boldsymbol{\kappa}_{el} \cdot \mathbf{U}^{-1}$ and rather introduce $\boldsymbol{\kappa}_{el} = \boldsymbol{\kappa}_{el}(V)$. Due to the specific material structure, we have

$$\mathbf{U}_{el} = \lambda_{el} \mathbf{I}, \quad \boldsymbol{\kappa}_{el} = \kappa_{el} \mathbf{I}. \quad (22)$$

The electrical stretch and the material electrical curvature are taken as functions of the square of the voltage, $\lambda_{el} = \lambda_{el}(V^2)$ and $\kappa_{el} = \kappa_{el}(V^2)$. In general, one must identify these functions from experiments. In the present paper, we will discuss the specific form of λ_{el} and κ_{el} only for the example presented in the final section.

3 EXTENSION TO SHELLS

In contrast to plates the reference surface of a shell is not plane; hence, the two metric tensors of the reference surface are $\mathbf{A} = \mathbf{I}_3 - \mathbf{N}\mathbf{N}$ and $\mathbf{B} = \mathbf{B}^T = -\nabla_0 \mathbf{N}$. In this case the total strain measures become

$$\boldsymbol{\varepsilon} = \frac{1}{2} (\mathbf{F}^T \cdot \mathbf{F} - \mathbf{A}), \quad \boldsymbol{\kappa} = -(\mathbf{F}^T \cdot \mathbf{b} \cdot \mathbf{F} - \mathbf{B}). \quad (23)$$

As in the plate theory we introduce the curvature tensor \mathbf{K} as

$$\mathbf{K} = -(\mathbf{R}^T \cdot \mathbf{b} \cdot \mathbf{R} - \bar{\mathbf{B}}) \quad (24)$$

with $\bar{\mathbf{B}} = \mathbf{U}^{-1} \cdot \mathbf{B} \cdot \mathbf{U}^{-1}$. Using again the additive decomposition of the curvature tensor $\mathbf{K} = \mathbf{K}_e + \mathbf{K}_{el}$, we obtain the elastic part of the curvature tensor to

$$\mathbf{K}_e = -(\mathbf{R}^T \cdot \mathbf{b} \cdot \mathbf{R} - \bar{\mathbf{B}}) - \mathbf{K}_{el} = -(\mathbf{R}^T \cdot \mathbf{b} \cdot \mathbf{R} - \mathbf{B}_{el}), \quad (25)$$

in which we have introduced an effective second metric tensor \mathbf{B}_{el} of the intermediate configuration, which evolves through the total stretch tensor \mathbf{U} from the reference configuration; note

that \mathbf{B}_{el} is not an actual metric tensor, as it is not necessarily the negative gradient of some unit normal vector. This effective second metric tensor \mathbf{B}_{el} with

$$\mathbf{B}_{el} = \bar{\mathbf{B}} - \mathbf{K}_{el} = \mathbf{U}^{-1} \cdot (\mathbf{B} - \boldsymbol{\kappa}_{el}) \cdot \mathbf{U}^{-1} \quad (26)$$

takes the role of $\bar{\mathbf{B}}$, which is present in the total curvature tensor, in the definition of the elastic curvature tensor. Therefore, we can write the augmented free energy for a shell as

$$\begin{aligned} \Omega(\mathbf{C}_e, \mathbf{K}_e, \mathbf{C}, \mathbf{K}, V) = & \frac{1}{2} \frac{A}{4} (\text{tr} \mathbf{C}_e + (\det \mathbf{C}_e)^{-1} - 3) + \frac{1}{2} (\det \mathbf{C}_e)^{-1} D((\text{tr} \mathbf{K}_e)^2 - \det \mathbf{K}_e) \\ & - \frac{1}{2} c V^2 \det \mathbf{C} (1 + 2\alpha \text{tr} \mathbf{K}), \end{aligned} \quad (27)$$

with $\mathbf{C}_e = \lambda_{el}^{-2} \mathbf{C}$ and $\mathbf{K}_e = \mathbf{U}^{-1} \cdot (\boldsymbol{\kappa} - \kappa_{el} \mathbf{I}) \cdot \mathbf{U}^{-1}$, which is formally identical to the plate formulation, with the only difference being the presence of \mathbf{B} in the definition of the strain measure $\boldsymbol{\kappa}$.

4 VALIDATION

Having proposed a novel form for the augmented free energy of electro-elastic thin plates and shells made of incompressible isotropic electrostrictive polymers, we proceed with a first validation of the theory. We validate the theory against an alternative approach, for which numerical solution computed with Finite elements are available. This formulation is based on the three-dimensional augmented free energy for an incompressible neo-Hookean electro-elastic material, which is

$$\Omega_3 = \frac{\mu}{2} (\text{tr} \mathbf{C}_{3,e} - 3) - \frac{1}{2} \varepsilon \boldsymbol{\mathcal{E}} \cdot (\mathbf{C}_3^{-1} \cdot \boldsymbol{\mathcal{E}}). \quad (28)$$

The three-dimensional elastic right Cauchy-Green tensor

$$\mathbf{C}_{3,e} = \mathbf{F}_{el,3}^{-T} \cdot \mathbf{C}_3 \cdot \mathbf{F}_{el,3}^{-1} \quad (29)$$

follows from a multiplicative decomposition of the deformation gradient tensor at the three-dimensional level with $\mathbf{F}_3 = \mathbf{F}_{e,3} \cdot \mathbf{F}_{el,3}$; here $\mathbf{F}_{el,3}$ is the electrical part of the deformation gradient tensor, which already accounts for incompressibility. Hence, we write

$$\mathbf{F}_{el,3} = \lambda_{el,3} (\mathbf{I}_3 - \mathbf{M} \mathbf{M}) + \lambda_{el,3}^{-2} \mathbf{M} \mathbf{M}, \quad (30)$$

in which $\lambda_{el,3} = \lambda_{el,3}(\mathcal{E}^2)$ is the stretch in any direction perpendicular to the direction \mathbf{M} of the material electric field vector $\boldsymbol{\mathcal{E}} = \mathcal{E} \mathbf{M}$. Specific forms for $\lambda_{el,3}$ have been proposed in the literature as

$$\lambda_{el,3} = (1 + \frac{3k}{2} \mathcal{E}^2)^{1/3}, \quad \lambda_{el,3} = e^{\frac{k}{2} \mathcal{E}^2}, \quad (31)$$

in which the first law was suggested by Zäh and Miehe [3] and the second one by Skatulla et al. [6]. Identifying the direction of the electric field with the thickness direction, $\mathbf{M} = \mathbf{N}$, and assuming a plane stress condition for the total second Piola-Kirchhoff stress tensor together with the incompressibility condition $\det \mathbf{C}_3 = 1$, the plane stress augmented free energy becomes

$$\Omega_2 = \frac{\mu}{2} \left(\lambda_{el,3}^{-2} \text{tr} \mathbf{C}_2 + \lambda_{el,3}^4 (\det \mathbf{C}_2)^{-1} - 3 \right) - \frac{1}{2} \varepsilon \det \mathbf{C}_2 \mathcal{E}^2. \quad (32)$$

\mathbf{C}_2 is the plane part of \mathbf{C}_3 . Eventually, \mathbf{C}_2 is approximated with $\mathbf{C}_2 = 2(\boldsymbol{\varepsilon} + Z\boldsymbol{\kappa}) + \mathbf{I} = \mathbf{C} + Z\boldsymbol{\kappa}$. A numerical integration through the thickness then finds the plate augmented free energy, see e.g. [7] or [15]. For the case of problems without constitutive coupling by means of electrostriction, this type of modeling is already well tested against results from the literature in [12] using Finite Elements within the geometrically exact formulation.

4.1 Bi-morph bending actuator

As a numerical example, we study a bi-morph rectangular homogenous plate with dimensions $L \times b \times h = 100\text{mm} \times 50\text{mm} \times 1\text{mm}$ with two identical layers made of polyurethane with the material parameters $\varepsilon_r = 8.8$, $k = 6.86 \times 10^{-16} \text{m}^2 \text{V}^{-2}$ and $\mu = 1.2 \times 10^6 \text{Pa}$, which are taken from [16]. However, only the bottom layer is used for actuation and the top layer is short-circuited. Accordingly, a bending actuator is obtained. Before we proceed to the results, we must first discuss the electrical stretch λ_{el} and the electrical curvature κ_{el} , the capacity c and the geometry parameter α in the augmented free energy. As a starting point, we note that the material electric field $\mathcal{E} = V(h/2)^{-1}$ acts only in the bottom layer, such that the electric field is not homogenous through the thickness. Then, $\lambda_{el,3} = 1$ holds in the top layer, whereas

$$\lambda_{el,3} = e^{\frac{k}{2}\mathcal{E}^2} \quad (33)$$

is true in the bottom layer. We compute the plate electrical stretch as the mean value and the electrical curvature as the first moment of the stretch $\lambda_{el,3}$ to

$$\lambda_{el} = \frac{1}{h} \int_h \lambda_{el,3} dZ, \quad \kappa_{el} = \frac{12}{h^3} \int_h \lambda_{el,3} Z dZ. \quad (34)$$

The capacity per unit reference area of the bottom layer is $c = \varepsilon(h/2)^{-1}$ and the geometry parameter α is taken as $\alpha = h/4$, which is the thickness center of the bottom layer. The plate is clamped at $x = 0$ and free on the other three edges and a voltage V is applied between the electrodes of the bottom layer. In this problem, the augmented free energy of the plate is

$$\begin{aligned} \Omega = & \frac{1}{2} \frac{A}{4} (\lambda_{el}^{-2} \text{tr} \mathbf{C} + \lambda_{el}^4 (\det \mathbf{C})^{-1} - 3) \\ & + \frac{1}{2} \lambda_{el}^4 (\det \mathbf{C})^{-1} D ((\text{tr} (\mathbf{C}^{-1} \cdot (\boldsymbol{\kappa} - \kappa_{el} \mathbf{I})))^2 - \det (\mathbf{C}^{-1} \cdot (\boldsymbol{\kappa} - \kappa_{el} \mathbf{I}))) \\ & - \frac{1}{2} c V^2 \det \mathbf{C} (1 + 2\alpha \text{tr} (\mathbf{C}^{-1} \cdot \boldsymbol{\kappa})), \end{aligned} \quad (35)$$

because $\text{tr} \mathbf{K} = \text{tr} (\mathbf{C}^{-1} \cdot \boldsymbol{\kappa})$, $\text{tr} \mathbf{K}_e = \text{tr} (\mathbf{C}^{-1} \cdot \boldsymbol{\kappa}_e)$ and $\det \mathbf{K}_e = \det (\mathbf{C}^{-1} \cdot \boldsymbol{\kappa}_e)$ hold. Hence, with $\mathbf{C} = 2\boldsymbol{\varepsilon} + \mathbf{I}$ we have $\Omega = \Omega(\boldsymbol{\varepsilon}, \boldsymbol{\kappa}, V)$. In this conservative problem with a prescribed voltage, the principle of virtual work reduces to a stationarity principle,

$$\delta \Sigma = 0 \quad \text{with} \quad \Sigma = \int_{A_0} \Omega(\boldsymbol{\varepsilon}, \boldsymbol{\kappa}, V) dA. \quad (36)$$

As we are mainly interested in verifying the proposed form of the augmented free energy, we compute solutions with a simple Ritz approximation within the framework of the Novozhilov nonlinear plate theory (see Amabili [17]) rather than for the fully geometrically nonlinear theory. Therefore, the strain measures $\boldsymbol{\varepsilon}$ and $\boldsymbol{\kappa}$ are approximated as

$$\boldsymbol{\varepsilon} = \frac{1}{2} (\nabla_0 \mathbf{u}^S + (\nabla_0 u \nabla_0 u + \nabla_0 v \nabla_0 v + \nabla_0 w \nabla_0 w)) , \quad \boldsymbol{\kappa} = -\nabla_0 \nabla_0 w, \quad (37)$$

in which w is the deflection of the plate, $\mathbf{u} = [u \ v \ 0]^T$ is the in-plane displacement vector and $\nabla_0 \mathbf{u}^S$ denotes the symmetric part of the plane displacement gradient tensor. For the Ritz-Ansatz we set

$$u(x, y) = \sum_{i=1}^3 \sum_{j=0}^1 x^i y^{2j} u_{ij}, \quad v(x, y) = \sum_{i=1}^2 \sum_{j=0}^1 x^i y^{2j+1} v_{ij}, \quad w(x, y) = \sum_{i=1}^4 \sum_{j=0}^1 x^{i+1} y^{2j} w_{ij}. \quad (38)$$

We use this Ansatz and the Novozhilov kinematics for the present theory as well as the one based on the three-dimensional augmented free energy; results computed with the latter approach will be denoted with *Gauss* in the figures.

We increase the voltage in the bottom layer starting with $V = 0\text{V}$ up to $V = 2000\text{V}$ and show results for the non-dimensional end point deflection wh^{-1} and the non-dimensional end point axial position xh^{-1} in the center of the free end in Fig. 1. Clearly, our complete direct

Figure 1: Non-dimensional end point deflection wh^{-1} and non-dimensional end point axial position xh^{-1} for the bending actuator.

approach results into a solution, which is hardly to be distinguished from the approach based on the three-dimensional augmented free energy.

Finally, we use the three-dimensional approach to compute numerical solutions of the fully geometrically nonlinear plate formulation using plate Finite elements. A comparison between the present theory and the Finite element solution for the non-dimensional end point deflection wh^{-1} and the non-dimensional end point axial position $xh^{-1}h$ in the center of the free end is shown Fig. 2. The solid line corresponds to the Finite elements and the circular markers to the present theory. A reasonable agreement is found up to the voltage $V = 2000\text{V}$. Finally the end point position is presented in Fig. 3.

5 Conclusions

In the present paper we have proposed a complete direct approach to modeling of thin plates and shells made of electrostrictive polymers. In particular, an electro-elastic Kirchhoff-Love theory as a special case of a Cosserat surface was developed, in which the augmented free energy was directly introduced for the material surface. Electrostriction was incorporated by means of a multiplicative decomposition of the surface stretch tensor and an additive decomposition of the surface curvature tensor. The resulting formulation was tested against a theory derived from the

three-dimensional formulation based on a plane stress assumption and an a-priori assumption concerning the distribution of the strain through the thickness. An excellent agreement was observed.

Key words: Shape Memory Alloy, Matrix Composite, Multiscale Analysis, Scale Adaptive Method

Abstract. Shape memory alloys (SMA) are used for smart devices due to their mechanical-thermal coupling properties. Because of the high costs, SMAs are currently employed only in special applications. One possibility is to use them in combination with a low-cost matrix material. From a numerical point of view, such composite materials require a considerable additional effort in the simulation. Especially with regard to the nonlinear behaviour of SMA, and with respect to thermal and mechanical coupling, the computational effort increases considerably. A multi-scale simulation offers a possibility to consider the deformation and thermal dependent material properties of SMA composites. The macroscopic material properties are determined with an accompanying homogenization on the micro level. Commonly, the accompanying homogenization is performed at each Gaussian point of the macroscale. In the frame of FE^2 method the accompanying homogenization results in an exponential growth of the equations depending on the macroscopic/microscopic discretization. This contribution is concerned with a method to reduce the computational cost of the nested homogenization within an FE^2 formulation. The SMA, however, shows constant material properties within a certain range of deformation, therefore the material properties of the macroscopic material parameters do not change. Here, an indicator on the macroscale is introduced, which indicates if an accompanying homogenization is necessary or not. The indicator is a function of the the strain and in addition of the temperature state of the material point. It detects whether the material behaves linearly on the microscale or not. In case the microstructure behaves linear, no accompanying homogenization is necessary. The computational savings are discussed in several numerical simulations of SMA composite structures.

1 INTRODUCTION

Shape memory alloys are materials which are able to restore the current permanent deformations to their original state when heated. These properties follow from the different crystal lattice structures at different temperatures, see e.g. [1]. This paper deals with Ni-Ti alloys and a large number of other alloys such as ceramics or polymers. The rearrangement of atoms are induced by variable temperature and electric fields. The structural phases of SMAs depend on the material temperature and are known as martensitic (low temperature) and austenitic (high temperature) phase. In addition to the shape memory effect, superelasticity is also a remarkable property of the material. SMA are expensive, hence there-

fore they are often embedded in a composite material. The result is a new material, from which the material properties can be determined either from cost-intensive experiments or alternatively with numerical methods such as homogenization. The micro-scale, which represents the heterogeneous material structure, is modeled by a representative volume element (RVE) to calculate the effective macroscopic material properties. The definition of the RVE is a crucial task, for further details the reader is referred to e.g. [2]. One possibility is to model the RVE by the finite element method, which leads to a numerical homogenization. Since the macro-structure is also modeled by finite elements, an accompanying nested finite element analysis is observed. The advantage of a nested finite element method is remarkable in the in situations of non-linear material behavior, where a homogenization is provided for the current deformation state and load step, respectively. The so-called FE^2 or multilevel finite element method is discussed in e.g. [3]. Since the iterations are nested, an extremely high computational capacity is needed. In the present contribution, an indicator for an adaptive FE^2 method is developed by considering a SMA-matrix composite, where the matrix material is assumed to be linear elastic. It is remarked that an accompanying homogenization is only necessary for non-linear material behavior. Hence, the indicator on the macroscopic scale needs to predict the non-linear behavior, which depends on the stress and temperature field on the microscopic scale. A limit strain state associated with the phase-transition stress of the SMA is employed. In case the indicator is reached, an accompanying numerical homogenization is performed.

2 Macro and Micro Boundary Value Problem

Let $\bar{\Omega}$ be an arbitrary macroscopic body with the two mechanical boundaries $\partial\Omega_{\sigma}$ for the tractions $\bar{\mathbf{t}}$ (Neumann) and the displacements $\partial\Omega_{\mathbf{u}}$ (Dirichlet) in the mechanical BVP, the whole boundary is defined as $\partial\Omega = \partial\Omega_{\sigma} \cup \partial\Omega_{\mathbf{u}}$, the thermal BVP is given with the two thermal boundaries $\partial\Omega_q$ for the heat flux $\bar{\mathbf{q}}$ and the temperature θ as the Dirichlet boundary condition $\partial\Omega_{\theta}$. The description of the kinematics is in the context of small strains and described by the gradient of the macroscopic displacement $\bar{\mathbf{u}}$, resulting in the macroscopic strain

$$\bar{\boldsymbol{\varepsilon}} = \bar{\nabla}^{sym} \bar{\mathbf{u}}(\bar{\mathbf{X}}), \quad (1)$$

where $\bar{\nabla}^{sym} = \frac{1}{2}(\bar{\nabla} + \bar{\nabla}^T)$.

The governing equations for the mechanical macro-problem are the balance of linear and angular momentum. The balance of linear momentum yields

$$\text{div } \bar{\boldsymbol{\sigma}} + \bar{\mathbf{b}} = \mathbf{0} \quad \text{in } \bar{\Omega}_0 \quad \text{and} \quad \mathbf{t}_0 = \bar{\boldsymbol{\sigma}} \mathbf{N}, \quad (2)$$

with $\bar{\mathbf{b}}$ denoting the body force density and $\bar{\boldsymbol{\sigma}}$ the macroscopic stress. The symmetry of the stress $\bar{\boldsymbol{\sigma}} = \bar{\boldsymbol{\sigma}}^T$ follows from the balance of angular momentum. The thermal field in the body $\bar{\Omega}$ can be defined as

$$\bar{\boldsymbol{\gamma}} = \nabla \bar{\theta}(\bar{\mathbf{X}}), \quad (3)$$

where $\bar{\nabla}$ denotes the gradient operator and $\bar{\theta}$ the temperature at point $\bar{\mathbf{X}}$. The governing balance law for the thermal sub-problem excluding heat sources appear with Fourier's law as

$$\bar{\rho} \bar{c}_V \dot{\bar{\theta}} + \text{div } \bar{\mathbf{q}} = 0, \quad (4)$$

where $\bar{\rho}$ is the macroscopic density and \bar{c}_V the volumetric heat capacity of the macroscopic body. For the microscopic body, due to the ansatz of scale separation the volume forces can be neglected and the linear balance of momentum on the micro-scale reads

$$\text{div } \boldsymbol{\sigma} = \mathbf{0} \quad \text{with} \quad \boldsymbol{\sigma} = \boldsymbol{\sigma}_M + \boldsymbol{\sigma}_F. \quad (5)$$

Hereby, the stress $\boldsymbol{\sigma}$ refers to the matrix or to the fiber, denoted as $\boldsymbol{\sigma}_M$ and $\boldsymbol{\sigma}_F$, respectively. Fourier's law in the microscopic body is given as

$$\rho c_V \dot{\theta} + \operatorname{div} \mathbf{q} = 0. \quad (6)$$

2.1 Boundary conditions of the micro-scale

When solving the BVP at the micro-scale, the definition of the boundary condition is needed. In the classical strain-driven-homogenization process, the conditions are a direct consequence of the Hill-Mandel condition [4]. To incorporate the thermal part, we introduce a generalized macro-homogeneity condition based on the work of [5] and [6] as

$$\begin{aligned} \bar{\Psi} &= \langle \Psi \rangle_{RVE}, \\ \bar{\boldsymbol{\sigma}} : \bar{\boldsymbol{\varepsilon}} - \bar{\mathbf{q}} \cdot \bar{\boldsymbol{\gamma}} &= \langle \boldsymbol{\sigma} : \boldsymbol{\varepsilon} \rangle_{RVE} - \langle \mathbf{q} \cdot \boldsymbol{\gamma} \rangle_{RVE}, \end{aligned} \quad (7)$$

where $\langle \bullet \rangle_{RVE} := \frac{1}{V} \int_V (\bullet) dV$ denotes the average over the RVE. The solution of the BVP on the lower scale must satisfy the generalized macro-homogeneity condition. The two parts, the mechanical and the thermal one, have to hold independently. Thus,

$$\underbrace{\bar{\boldsymbol{\sigma}} : \bar{\boldsymbol{\varepsilon}}}_{\bar{\Psi}_{mech}} = \underbrace{\langle \boldsymbol{\sigma} : \boldsymbol{\varepsilon} \rangle_{RVE}}_{\Psi_{mech}}, \quad \underbrace{\bar{\mathbf{q}} \cdot \bar{\boldsymbol{\gamma}}}_{\bar{\Psi}_{therm}} = \underbrace{\langle \mathbf{q} \cdot \boldsymbol{\gamma} \rangle_{RVE}}_{\Psi_{therm}}. \quad (8)$$

Hill's lemma transforms the right side in terms of a surface integral over the boundary of the RVE and leads to the following equations.

$$\bar{\boldsymbol{\sigma}} : \bar{\boldsymbol{\varepsilon}} - \langle \boldsymbol{\sigma} : \boldsymbol{\varepsilon} \rangle_{RVE} = \int_{\partial\Omega} [\mathbf{t} - \bar{\boldsymbol{\sigma}} \mathbf{n}] [\mathbf{u} - \bar{\boldsymbol{\varepsilon}} \mathbf{x}] da, \quad \bar{\mathbf{q}} \cdot \bar{\boldsymbol{\gamma}} - \langle \mathbf{q} \cdot \boldsymbol{\gamma} \rangle_{RVE} = \int_{\partial\Omega} [\boldsymbol{\theta} - \bar{\boldsymbol{\gamma}} \cdot \mathbf{x}] [Q - \bar{\mathbf{q}} \cdot \mathbf{n}] da. \quad (9)$$

In equation (9), the right-side should identically clear out to fulfill the Hill-Mandel condition. The following conditions satisfy the Hill-Mandel condition.

$$\begin{aligned} \mathbf{t} &= \bar{\boldsymbol{\sigma}} \cdot \mathbf{n}, & \mathbf{u} &= \bar{\boldsymbol{\varepsilon}} \cdot \mathbf{x}, \\ Q &= \bar{\mathbf{q}} \cdot \mathbf{n}, & \boldsymbol{\theta} &= \bar{\boldsymbol{\gamma}} \cdot \mathbf{x}, \end{aligned} \quad (10)$$

where Q is the thermal surface flux density. For the sake of completeness there is also the possibility of periodic Dirichlet boundary conditions and antiperiodic Neumann conditions for the RVE. Due to the considered random micro-structure, this approach cannot be used and it is not further discussed.

3 Material Model of the SMA

The model for the fiber is described as one-dimensional. For the assumption of small deformations the geometric field equation reduces to linear strains $\boldsymbol{\varepsilon} = \frac{\partial \mathbf{u}}{\partial \mathbf{x}} = \mathbf{u}'$. Due to the fact that for applications in civil engineering, e.g. shape memory fiber reinforced concrete, only small deformations occur small strains with an additive decomposition $\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^e + \boldsymbol{\varepsilon}^i$, into an elastic and plastic part are assumed.

3.1 Free energy equation

The material model is derived on the basis of a free Helmholtz energy function. A certain form for this energy function

$$\Psi = z \cdot \Psi^M + (1 - z) \cdot \Psi^A \quad (11)$$

is proposed in [7]. Here, the overall free energy is additively decomposed in a free energy part for the martensitic and the austenitic fraction. The proportion of each phase is controlled via the martensite volume fraction z . Due to the balance of mass the latter one is of scalar type and takes values between zero and one ($0 \leq z \leq 1$). The martensitic ratio is spilt into $z = z_{//} + z_{\gg}$ whereby the oriented martensite $z_{//}$ is stress-induced and the twinned martensite z_{\gg} depends on the change of temperature. The martensitic and the austenitic energy part are given as

$$\begin{aligned} \psi^{A/M} = & \frac{1}{2} \epsilon^e E^{A/M} \epsilon^e + \frac{1}{2} \alpha K^{A/M} \alpha \\ & + c_d^{A/M} (\theta - \theta_0) + u_0^{A/M} - \theta \left[c_d^{A/M} \ln \frac{\theta}{\theta_0} + \eta_0^{A/M} \right] \end{aligned} \quad (12)$$

and have the same form. It consists of an elastic, a plastic and a calorian energy part. The last term can be interpreted as an additional term to classic plasticity models. Assuming the same material parameters for each phase and inserting equation (12) into equation (11) yields the simplified free energy function

$$\begin{aligned} \psi = & \frac{1}{2} \epsilon^e E \epsilon^e + \frac{1}{2} \alpha K \alpha + z_{//} \cdot (\Delta u_0 - \theta \Delta \eta_0) \\ & + z_{\gg} \cdot (\Delta u_0 - \theta \Delta \eta_0) - \theta \cdot \left[c_d \ln \frac{\theta}{\theta_0} + \eta_0^A - c_d \right] - c_d \theta_0 + u_0^A. \end{aligned} \quad (13)$$

In this equation the elastic energy part can be recognized by the use of Young's modulus E and the elastic strain ϵ^e . Further, the plastic energy part incorporates the hardening modulus K with the inelastic, inner variable α and the energy difference $(\Delta u_0 - \theta \Delta \eta_0)$ with the oriented martensite fraction $z_{//}$. The last term to be found in equation (13) is a calorian function. In addition to the martensite volume fraction z the temperature θ and the effective heat capacity c_d occur. The variable u_0 stands for the inner energy and η_0 for the entropy in unloaded conditions. Δ indicates the difference of the inner energy u and respectively the entropy η between the austenitic and the martensitic phase.

3.2 Constitutive equations

The constitutive equations are derived by taking the partial derivative of the free energy function with respect to the inner variables ϵ^e , α and $\Delta \psi$. The cauchy stress σ is defined as

$$\sigma = \frac{\partial \psi}{\partial \epsilon^e} = E \cdot \epsilon^e = E \cdot (\epsilon - \epsilon^i) . \quad (14)$$

In the same way, a quantity p is derived by

$$p = -\frac{\partial \psi}{\partial \alpha} = -K \cdot \alpha . \quad (15)$$

This quantity is also of stress type. In comparison to classical plasticity, p is similar to a "backstress", well known from the kinematic hardening rheological model. At least, the derivation with respect to the martensitic volume fraction z reads

$$\Delta \psi = \Delta \psi(\theta) = \frac{\partial \psi}{\partial z} = \Delta u_0 - \theta \Delta \eta_0 . \quad (16)$$

$\Delta \psi$ is very important for the phase transition of the presented model. In literature it is referred to as *driving force* or *thermodynamic force*.

3.3 Phase transition conditions

Classical plasticity theory uses one yield condition to differentiate between the elastic and plastic range. The elastic range defines the set of the admissible stresses. Shape memory alloys provide a more complex stress-strain-behavior due to the temperature dependency. The "yield condition" for the SMA arises from the phase transition condition. Here, only the loading case is regarded, which leads to the following phase transition condition, where the loading is bonded by

$$\vec{\Phi}(\sigma, p, \Delta\psi) = \left| \sigma - p - \frac{\langle \Delta\psi \rangle}{\beta} \cdot \text{sign}(\sigma - p) \right| - \sigma_y \leq 0. \quad (17)$$

The Macaulay-bracket $\langle \dots \rangle$ is defined as $\langle x \rangle = (|x| + x)/2$. The description of phase transitions in the case of loading necessitates a stress criterion which is given as

$$\sigma \stackrel{!}{\geq} \sigma_{\text{ctrl}} = |\sigma - p| - \frac{\langle \Delta\psi \rangle}{\beta}. \quad (18)$$

In comparison to classical plasticity the yield condition has the additional term $\Delta\psi$ which is like an offset, scaled by the material parameter of maximum hysteresis width β . It always refers to the center of each hysteresis. The driving force $\Delta\psi$ is the most important quantity for the transformation of the material from pseudoplasticity at low temperature to pseudoelasticity at the high temperature range, see Fig. 1.

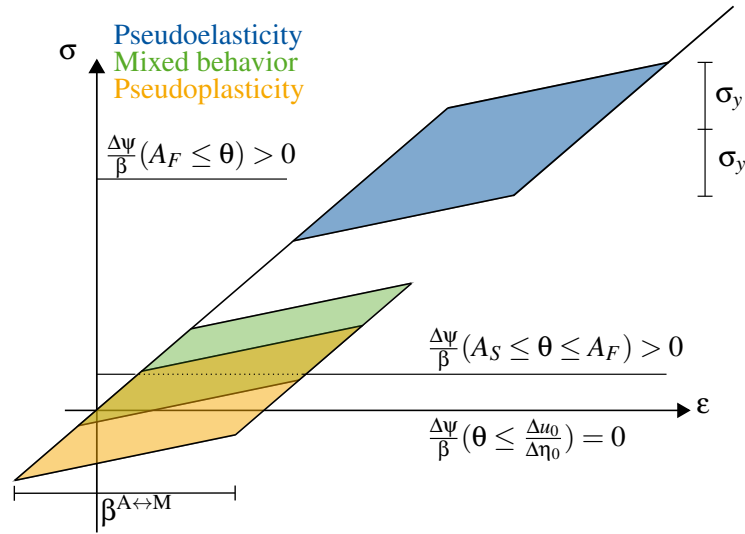

Figure 1: Off-set properties of $\Delta\psi$ and other material parameters

4 Adaptive FE² method

4.1 Nested mechanical finite element formulation

The nested finite element formulation is only needed for the mechanical part of the coupled problem. This results from the non-temperature-dependent thermal properties of the composite, which only requires initial homogenization, see section 4.3. A strain-driven homogenization is used for the accompanying homogenization, see e.g. [8], [9] and the references therein. In the strain-driven homogenization the Dirichlet boundary condition (DBC) results directly from the Hill-Condition. Here, every single

node on the surface of the RVE is constrained for both degrees of freedom. The displacements $\hat{\mathbf{u}}$ of the boundary nodes of the RVE are prescribed. They are defined via the macroscopic strain state as

$$\hat{\mathbf{u}} = \mathbf{D} \bar{\boldsymbol{\epsilon}}_i = \begin{bmatrix} \hat{u}_x \\ \hat{u}_y \end{bmatrix} = \begin{bmatrix} x & 0 & y \\ 0 & y & x \end{bmatrix} \begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ 2\epsilon_{12} \end{bmatrix}, \quad (19)$$

where x and y are the coordinates of the RVE boundary. Equation (19) transforms the macro-strain to the micro-deflection on the surface of the RVE. An explanation of the governing macro and microscopic equations is presented in Section 2.1 and 2.2. In the following, the static field equations for the global and local BVP are summarized with the neglect of volume forces for the sake of simplicity.

$$\text{Div } \bar{\boldsymbol{\sigma}} = 0 \quad \text{in } \bar{\Omega}, \quad (20)$$

$$\text{Div } \boldsymbol{\sigma}_m + \text{Div } \boldsymbol{\sigma}_{sf} - \text{Div } \boldsymbol{\sigma}_{mf} + \mathbf{b} = 0 \quad \text{in } \Omega_i. \quad (21)$$

For the sake of brevity, the derivation of the linear system is omitted. For further details, the reader is referred to e.g. [8], [10].

$$\mathbf{L}[g(\bar{\mathbf{v}}^h, \delta \bar{\mathbf{v}}^h), \Delta \bar{\mathbf{v}}^h] = \sum_{e=1}^{numel} \begin{bmatrix} \delta \bar{\mathbf{v}} & \delta \boldsymbol{\epsilon}_1 & \dots & \delta \boldsymbol{\epsilon}_i & \dots & \delta \boldsymbol{\epsilon}_{NGP} \end{bmatrix}_e \cdot \left\{ \begin{bmatrix} \bar{\mathbf{k}}(\bar{\mathbb{C}}_i) & \mathbf{0} & \vdots & \mathbf{0} & \vdots & \mathbf{0} \\ \mathbf{0} & \mathbb{C}_1 & \vdots & \mathbf{0} & \vdots & \mathbf{0} \\ \dots & \dots & \ddots & \mathbf{0} & \dots & \dots \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbb{C}_i & \mathbf{0} & \mathbf{0} \\ \dots & \dots & \dots & \mathbf{0} & \ddots & \dots \\ \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \dots & \mathbb{C}_{NGP} \end{bmatrix} \begin{bmatrix} \Delta \bar{\mathbf{v}} \\ \Delta \boldsymbol{\epsilon}_1 \\ \vdots \\ \Delta \boldsymbol{\epsilon}_i \\ \vdots \\ \Delta \boldsymbol{\epsilon}_{NGP} \end{bmatrix} + \begin{bmatrix} \bar{\mathbf{f}}(\bar{\boldsymbol{\sigma}}_i) \\ \boldsymbol{\sigma}_1 \\ \dots \\ \boldsymbol{\sigma}_i \\ \dots \\ \boldsymbol{\sigma}_{NGP} \end{bmatrix} \right\}_e \quad (22)$$

It turns out that the two scales are coupled in $\bar{\boldsymbol{\sigma}}_i$, $\bar{\mathbb{C}}_i$ and the strains $\boldsymbol{\epsilon}_i$. The non-linear system of equations is then solved with a Newton-Raphson-scheme simultaneously. Equilibrium in a load-step is achieved when each micro-problem in each Gauss point and the macro problem have attained equilibrium, see Fig. 2.

4.2 The adaptive FE² approach

The previous Section describes the standard FE² deformation-driven method. One of the main disadvantages is the high computational effort due to the accompanying homogenization in every Gauss-point on the macro scale. The adaptive approach arises from the idea, that a accompanying homogenization is only needed in the case of non-linear behavior on the lower scale. The macroscopic material answer remains linear-elastic until the first fiber reaches the phase-transition condition, see equation (17). Afterward, the homogenization of the micro-scale results in a different macro-stress $\bar{\boldsymbol{\sigma}}$ and material tangent $\bar{\mathbb{C}}$. The aim of the adaptive approach is to predict the non-linear material behavior of the fibers in the RVE. From [11] or [12] it is well known, that a traction boundary condition (Neumann) for the mechanical problem and a heat flux condition for the thermal one [6] (NBC) of the lower scale leads to a softer material stiffness prediction than the displacement or temperature boundary condition (Dirichlet). Considering the Voigt and the Reuss bound it follows, for the Eigenvalues of the different material tangents or the overall heat conductivity tensor,

$$\bar{\mathbb{C}}_{Neu.} \leq \bar{\mathbb{C}} \leq \bar{\mathbb{C}}_{Dir.} \quad \bar{\mathbf{H}}_{Neu.} \leq \bar{\mathbf{H}} \leq \bar{\mathbf{H}}_{Dir.}, \quad (23)$$

Figure 2: FE² scheme for strain driven RVEs. Every Gauss points of the macro-structure is associated to a RVE. The macroscopic strain $\bar{\mathbf{e}}_i$ is applied as the displacement boundary condition on the micro-scale BVP. Solving the BVP on the micro-scale leads to the macro-stress $\bar{\mathbf{\sigma}}$ and material tangent $\bar{\mathbb{C}}_i$

see e.g. [11]. This relation is used for the adaptive approach. Instead of the classic strain-driven formulation, the initial homogenization is realized by traction boundary conditions in a stress free reference configuration. The resulting material tangent \mathbb{C}_{Neu} underestimates the stiffness and is employed for the macroscopic constitutive equation of the macro problem,

$$\bar{\boldsymbol{\sigma}} = \bar{\mathbb{C}}_{New.} : \bar{\boldsymbol{\varepsilon}}. \quad (24)$$

The finite element analysis by Neumann boundary conditions leads to an overestimation of the displacement and thus the strain rate. The accompanying homogenization is not needed in the linear elastic regime. An indicator for an accompanying homogenization is introduced by utilizing the phase transition condition of the fiber model. The prediction of the nonlinear behavior is done via the reformulation of the phase transition condition, see equation (17) in the so called "phase transition strain" $\epsilon_{sf,pt}$

$$\epsilon_{sf,pt} = \frac{\sigma_{F,y} + \frac{\Delta\psi}{\beta}}{E_{sf}}. \quad (25)$$

Equation (25) shows the temperature dependence of the strain-based indicator for the macro-scale. The relation of the actual macroscopic strain $\bar{\epsilon}$ and the fiber strain in the RVE needs to be defined. Here a randomly distributed fiber contribution is given. In this case, the principal strains are calculated via the Eigenvalue problem,

$$(\bar{\mathbf{e}} - \lambda \mathbf{I}) \mathbf{n} = \mathbf{0}. \quad (26)$$

The principal strains are assumed to coincide with the direction of the fibers which will yield first. The indicator for the accompanying homogenization, in case of randomly distributed fibers, reads

$$\max(\epsilon_1, \epsilon_2) \geq \epsilon_{sf,pt}. \quad (27)$$

Accordingly, the algorithm frame for the adaptive FE² scheme can be described by the flowchart depicted in Fig.3.

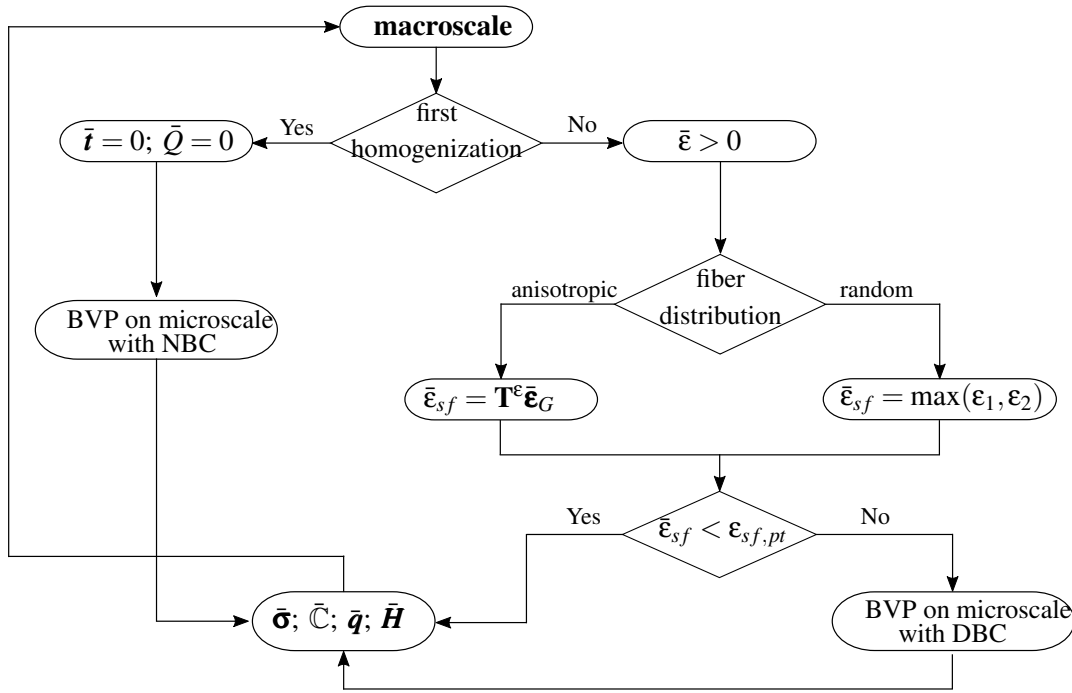

Figure 3: Flowchart of the adaptive FE² approach

4.3 Initial homogenization for the mechanical and thermal problem

As described in Section 4.2, the adaptive FE² needs an initial homogenization with Neumann boundary conditions for the mechanical and the thermal problem. Therefore the first homogenization is performed by the application of traction and heat flux boundary conditions, see e.g. [13], [14], [15]. The algorithm in the present approach is based on the variational formulation. The advantage of this method is given by the possibility to incorporate the macro-strains $\bar{\boldsymbol{\epsilon}}$ or rather of the macro temperature gradient $\bar{\boldsymbol{\gamma}}$ as the input quantity for the traction and heat flux boundary condition. The discretized boundary value problem needs the definition of the nodal area vector \mathbf{a}_i , see [12]. This nodal area vector is defined for the 2D case as

$$\mathbf{a}_i = \frac{1}{2} [\mathbf{x}_{i+1} - \mathbf{x}_{i-1}] \times \mathbf{e}_3. \quad (28)$$

The effective macroscopic material tangent and the heat conduction tensor are determined by eliminating the interior degrees of freedom by a static condensation as

$$\begin{aligned} \bar{\mathbf{C}}_{NBC} &= [\mathbf{\Xi} \tilde{\mathbf{K}}_{bb}^{-1} \mathbf{\Xi}^T]^{-1} \quad \text{with} \quad \tilde{\mathbf{K}}_{bb} = \mathbf{K}_{bb} - \mathbf{K}_{ba} \mathbf{K}_{aa}^{-1} \mathbf{K}_{ab}, \\ \bar{\mathbf{H}}_{NBC} &= [\mathbf{\Xi}_{th} (\tilde{\mathbf{K}}_{bb,th})^{-1} \mathbf{\Xi}_{th}^T]^{-1} \quad \text{with} \quad \tilde{\mathbf{K}}_{bb,th} = \mathbf{K}_{bb,th} - \mathbf{K}_{ba,th} \mathbf{K}_{aa,th}^{-1} \mathbf{K}_{ab,th}. \end{aligned} \quad (29)$$

In equation (29) $\bar{\mathbf{C}}_{NBC}$ denoting the overall material tangent with traction boundary conditions, $\mathbf{\Xi}$ is the assembled nodal vector components area matrix, $\tilde{\mathbf{K}}_{bb}$ is the static condensed stiffness matrix. The subscripts a stand for the inner nodes and b for the boundary nodes of the RVE. The resulting macroscopic heat conduction tensor with zero heat flux is $\bar{\mathbf{H}}_{NBC}$, in the equation the introduced subscript th denotes the thermal subproblem with the thermal assembled nodal vector components area matrix $\mathbf{\Xi}_{th}$ and stiffness matrix \mathbf{K}_{th} .

5 Numerical Example

In the following example the ability of the presented approach is demonstrated. The example employs a random fiber orientation on the microscale. On the macroscale a variation of different temperature load cases are considered. For the matrix and the fiber, the set of material parameters is given in Tab.1.

Table 1: material parameters for the SMA-Matrix composite

Material parameter	Notation	Unit	Value
Young's modulus (SMA)	E_{sf}	MPa	60000
Hardening modulus (SMA)	K_{sf}	MPa	2000
Half hysteresis height	σ_y	MPa	120
Max. hysteresis width	β		0.05
Diff. of inner energy	Δe_0	MPa	-204.00
Diff. of inner entropy	$\Delta \eta_0$	MPa/°K	-0.8
Martensite-finish	M_F	°K	241.25
Martensite-start	M_S	°K	247.50
Austenite-start	A_S	°K	256.25
Austenite-finish	A_F	°K	262.50
fiber proportion	ρ_f	%	10
fiber diameter	d_{sf}	m	10^{-3}
Young's modulus (matrix)	E_m	MPa	100
Poisson ratio (matrix)	ν_m		0.0

5.1 Cook's membrane with random fiber distribution

The Cook's membrane with an uniformly distributed load, with a magnitude of $F = 0.25 \cdot \lambda$ is analyzed, see Fig. 4. The thermal boundary conditions for the cook's membrane are given as follows. The bottom and upper side has a zero heat flux, while we distinguish between different Dirichlet boundary conditions on the left and right side, see Tab. 2. The micro-structure of the composite is defined by a

Table 2: Thermal boundary conditions for Cook's Membrane

Localisation	case I	case II	case III
Left side	255°K	270°K	255°K
Right side	255°K	270°K	270°K

unit cell with a length of 2. The RVE is generated by 1000 randomly distributed fibers under the constraint of an orientation distribution which approximates isotropic material behavior. The macro-domain is discretized by 400 elements and the RVE by 400 elements. To show the adaptivity for the random fiber distribution, the stationary temperature field in the membrane is given. A comparison between the standard and the adaptive FE² method is performed for the three cases. Within the standard FE² the accompanying homogenization is performed at each integration point. The deviation in the displacement response is displayed on the left side in Fig. 5. The maximum deviation of 5% for a very small load step is observed in all three cases. It occurs due to the different boundary conditions for the RVE. The standard FE² method employs Dirichlet boundary conditions whereas the adaptive FE² approach utilizes Neumann boundary conditions for the initial homogenization. The colored lines shows the deviation,

Figure 4: Cook's membrane with a uniform distributed load λ at the free end tip of the structure. The micro-structure consists of a random fiber distribution.

which is getting smaller with the increasing load factor. The decrease of the deviation is getting smaller due to the higher temperatures which arises from a longer simulation with the softer material tangent from the initial homogenization. The number of elements which reach the indicator and therefore re-

Figure 5: Left: The deviation of point A for the displacement in y-direction. Right: The representation of multiscale elements (green) which are triggered by the FE^2 indicator in dependency of the temperature boundary conditions and λ .

quire an accompanying homogenization are represented as columns in Fig. 5 on the right side. In order to compare the different cases with regard to the numerical effort and to demonstrate the development of the multiscale elements, Fig. 6 shows the multiscale elements for the load factors $\lambda = 10$ and $\lambda = 20$. The color of the tetragon indicates if the indicator for FE^2 is fulfilled and an accompanying homogenization is necessary. In case of an accompanying homogenization, the tetragons are denoted as multiscale elements and are marked with green color. Otherwise, the points are denoted as single scale element and marked with blue color. Like in the previous example, one can see the temperature dependency with respect to the number of multiscale elements. The computational saving at load factor $\lambda = 10$ for the adaptive

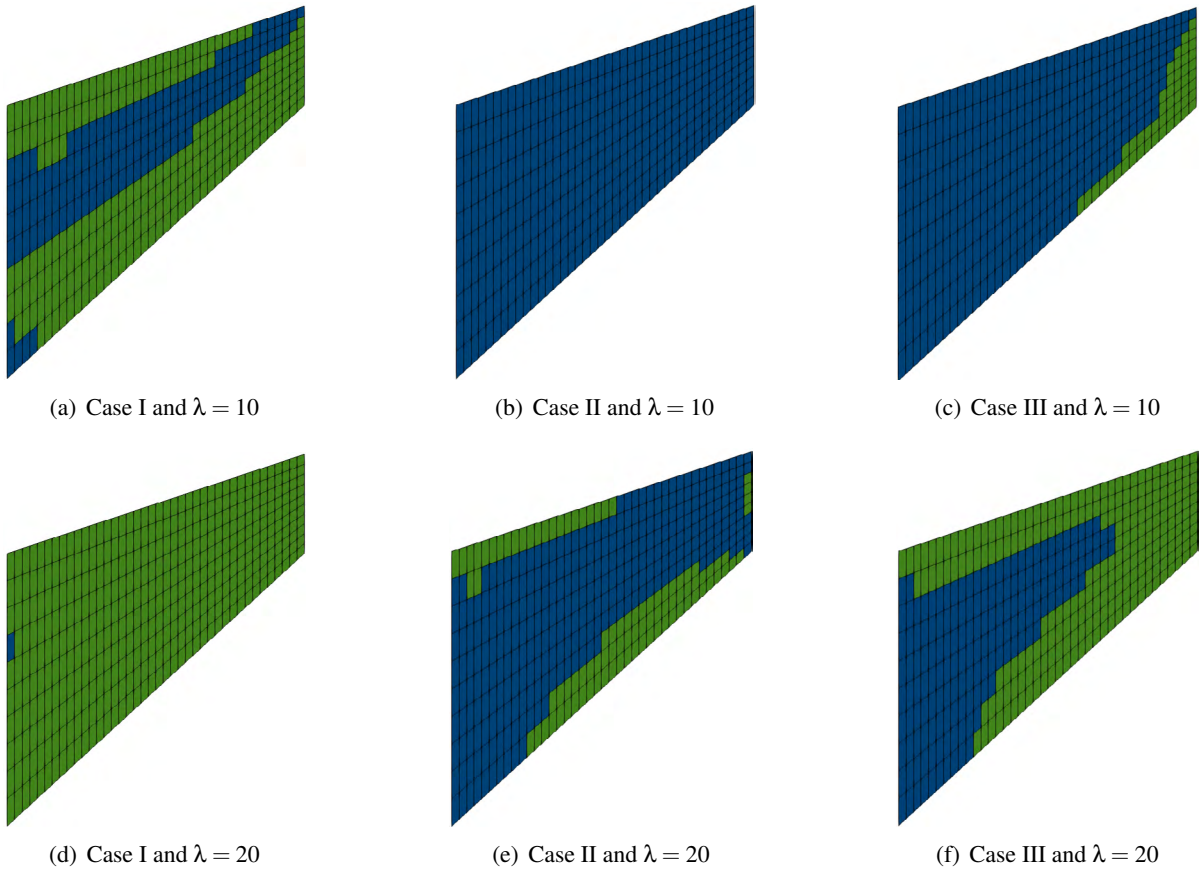

Figure 6: Representation of multi-scale elements (green) which are triggered by the FE^2 indicator in dependency of the fiber orientation and λ .

approach is hereby for case I: $cs_I = 36.96\%$, for case II: $cs_{II} = 99.89\%$ and for case III: $cs_{III} = 87.40\%$, respectively.

6 CONCLUSIONS

The adaptive approach shows a significant reduction of the computational effort without loss of accuracy with respect to the standard FE^2 approach and the method has the potential to be applied to many other applications in the context of heterogeneous micro-structures.

Key words: ferroelectricity, polarization, variational inequality, mixed finite elements

Abstract. We are concerned with the mathematical modeling of the polarization process in ferroelectric media. We assume that this dissipative process is governed by two constitutive functions, which are the free energy function and the dissipation function. The dissipation function, which is closely connected to the dissipated energy, is usually non-differentiable. Thus, a minimization condition for the overall energy includes the subdifferential of the dissipation function. This condition can also be formulated by way of a variational inequality in the unknown fields strain (or displacement), dielectric displacement, polarization and, for remanent straining models, remanent strain. We are concerned with analyzing the mathematical well-posedness of this problem, and try to give an existence result for a solution of the time-dependent incremental variational inequality. We propose to solve the update equation in a single Newton iteration for all unknowns at once. We propose to use mixed finite elements, where displacement, dielectric displacement and polarization are unknowns. Gauss' law of zero free charges is satisfied exactly. We present numerical examples gained in the open source software package Netgen/NGSolve.

1 INTRODUCTION

A thermodynamical framework for the description of ferroelectric materials based on the Helmholtz free energy was originally provided in the series of papers [1, 2, 3, 4] by Bassiouny, Ghaleb and Maugin. Their theory allows to describe multiaxial electromechanical loading procedures. The introduced notions are similar to elasto-plasticity, including internal variables, yield (or switching) criteria and hardening moduli. Explicit choices of energy and switching criteria were provided by Cocks and McMeeking [8] for the one-dimensional case. The multi-dimensional case follows in [14, 13]. In the former reference, the remanent polarization vector is the only internal unknown, and the polarization stress is linked directly to the remanent polarization. Contrarily, in the latter work remanent polarization and strain are independent of each other, but are determined by a common switching condition. With these theories, not only hysteresis loops can be tracked, but also butterfly hysteresis loops are predicted correctly. The models were validated against measurements provided by Huber and Fleck [10] for non-proportional loading procedures.

Miehe, Rosato and Kiefer [15] introduced an incremental variational principle for the even more general case of coupled electro-magneto-mechanics. They distinguish between *energy*-based and *enthalpy*-based models. For the latter, the independent unknowns are strain and electric field, whereas for

the former, strain and dielectric displacement are independent. While most finite element formulations use enthalpy-based models discretizing the electric potential, we provide theory for an energy-based setting with an independent dielectric displacement.

Semenov et al. [16] present an energy-based formulation using a vector potential for the dielectric displacement. Then, the dielectric displacement vector satisfies Gauss' law of zero divergence automatically. Contrarily, we propose to use $H(\text{div})$ conforming finite elements as can be found in the context of mixed methods [5]. Gauss' law is then introduced as a constraint enforced exactly by a Lagrangian multiplier. This way accuracy of the electric unknowns is improved, as no derivatives have to be taken. In some sense, the approach by Klinkel [12] may be seen as diametrically opposed, where an irreversible electric field is introduced instead of the remanent polarization vector.

In the current paper, we aim at proving existence and uniqueness of a solution to the problem of finding an update solution in the polarization process of ferroelectric media. To this end, we describe the polarization of ferroelectric media as a dissipative process in the mathematical framework of variational inequalities. We start from an energy-based model of the problem, from which we derive time-dependent variational equations and inequalities. The independent unknowns are then strain (or displacement), dielectric displacement, remanent polarization, and, if included in the model, remanent polarization strain. We provide an abstract mathematical framework for this problem. We see that, under the standard assumption of convexity of the free energy function, existence and uniqueness of a solution can be shown. These results fit well with the findings in [17, 6], where stability issues are discussed.

2 ENERGY-BASED CONSTITUTIVE MODELING

In the following, we present a variational inequality that describes the problem of polarization of ferroelectric media. We postpone mathematical exactness concerning solution spaces, (weak) differentiability and other issues to Section 3, in order not to complicate matter too much. Let $\Omega \subset \mathbb{R}^d$, $d = 2, 3$ denote the body of interest. Concerning the mechanical quantities, we use \mathbf{u} for the displacement field and \mathbf{T} for the total stress. We assume small deformations, thus we identify deformed and undeformed configuration, and use the linear strain $\mathbf{S} = \frac{1}{2}(\nabla \mathbf{u} + \nabla \mathbf{u}^T)$. Additionally, we assume to be in the quasistatic regime. The electric part of the problem is then characterized by the electric potential ϕ , while $\mathbf{E} = -\nabla \phi$ is the electric field. The dielectric displacement vector shall be denoted as \mathbf{D} . We are interested in finding the remanent polarization \mathbf{P}^i and the remanent strain \mathbf{S}^i .

We assume the material is characterized by a Helmholtz free energy function

$$\Psi = \Psi^r(\mathbf{D}, \mathbf{P}^i, \mathbf{S}, \mathbf{S}^i) + \Psi^i(\mathbf{P}^i, \mathbf{S}^i), \quad (1)$$

which consists of a *reversible* or *stored* part Ψ^r , and a part Ψ^i that is associated only to the internal variables of remanent polarization and strain. This part may tend to infinity as the polarization approaches saturation. For a similar characterization we refer to [13].

The independent reversible unknowns are strain and dielectric displacement, where the latter additionally has to satisfy Gauss' law, $\text{div } \mathbf{D} = 0$. Electric field and mechanic stress are dependent quantities, and defined as derivatives of the free energy with respect to dielectric displacement and strain,

$$\mathbf{E} = \frac{\partial \Psi}{\partial \mathbf{D}}, \quad \mathbf{T} = \frac{\partial \Psi}{\partial \mathbf{S}}. \quad (2)$$

As strain and dielectric displacement are not constrained, or constrained to the linear subspace of divergence-free functions in the latter case, there holds the following variational equality,

$$\mathbf{E} \cdot \delta \mathbf{D} + \mathbf{T} \cdot \delta \mathbf{S} = \delta W_{ext} \quad \text{for all } \delta \mathbf{D}, \text{div } \delta \mathbf{D} = 0 \text{ and } \delta \mathbf{S} = \mathbf{S}(\delta \mathbf{u}). \quad (3)$$

In (3), all virtual strains and divergence-free virtual dielectric displacements are considered, where $\delta \mathbf{D}$ and $\delta \mathbf{u}$ have to satisfy the respective boundary conditions. On the right hand side, all virtual work by external forces is summarized as δW_{ext} . This formula is well-known as *principle of virtual works*.

Polarization of ferroelectric materials is a dissipative process. The *dissipative driving forces* are

$$\hat{\mathbf{E}} = -\frac{\partial \Psi}{\partial \mathbf{P}^i}, \quad \hat{\mathbf{T}} = -\frac{\partial \Psi}{\partial \mathbf{S}^i}. \quad (4)$$

The dissipation is then given by the inner product of these driving forces and the *dissipative fluxes* $\dot{\mathbf{P}}^i$ and $\dot{\mathbf{S}}^i$,

$$\mathcal{D} = \hat{\mathbf{E}} \cdot \dot{\mathbf{P}}^i + \hat{\mathbf{T}} : \dot{\mathbf{S}}^i. \quad (5)$$

The dissipation function Φ relates the driving forces $\hat{\mathbf{E}}$, $\hat{\mathbf{T}}$ to the driving rates $\dot{\mathbf{P}}^i$, $\dot{\mathbf{S}}^i$. Typically, the dissipation function is not smooth, but weakly lower semicontinuous and allows for a *subdifferential*¹. The driving forces are contained in the respective subdifferentials, i.e.

$$\hat{\mathbf{E}} \in \partial_{\dot{\mathbf{P}}^i} \Phi(\dot{\mathbf{P}}^i, \dot{\mathbf{S}}^i) \quad \text{and} \quad \hat{\mathbf{T}} \in \partial_{\dot{\mathbf{S}}^i} \Phi(\dot{\mathbf{P}}^i, \dot{\mathbf{S}}^i). \quad (7)$$

By definition of the subdifferential, eq. (7) is equivalent to the variational inequality

$$-\hat{\mathbf{E}} \cdot (\tilde{\mathbf{P}}^i - \dot{\mathbf{P}}^i) - \hat{\mathbf{T}} : (\tilde{\mathbf{S}}^i - \dot{\mathbf{S}}^i) + \Phi(\tilde{\mathbf{P}}^i, \tilde{\mathbf{S}}^i) - \Phi(\dot{\mathbf{P}}^i, \dot{\mathbf{S}}^i) \geq 0 \quad \forall \tilde{\mathbf{P}}^i, \tilde{\mathbf{S}}^i. \quad (8)$$

To arrive at one single variational inequality, we add up (3) and (8). In (3), we use the admissible virtual dielectric displacement $\delta \mathbf{D} = \tilde{\mathbf{D}} - \dot{\mathbf{D}}$, where $\text{div } \tilde{\mathbf{D}} = \text{div } \dot{\mathbf{D}} = 0$. The virtual strain is defined from the admissible displacement update $\tilde{\mathbf{u}}$ and $\dot{\mathbf{u}}$ by $\delta \mathbf{S} = \mathbf{S}(\tilde{\mathbf{u}}) - \mathbf{S}(\dot{\mathbf{u}})$. With these choices, we deduce for all $\tilde{\mathbf{u}}$, $\tilde{\mathbf{D}}$, $\tilde{\mathbf{P}}^i$ and $\tilde{\mathbf{S}}^i$,

$$\mathbf{E} \cdot (\tilde{\mathbf{D}} - \dot{\mathbf{D}}) + \mathbf{T} : (\mathbf{S}(\tilde{\mathbf{u}}) - \dot{\mathbf{S}}) - \hat{\mathbf{E}} \cdot (\tilde{\mathbf{P}}^i - \dot{\mathbf{P}}^i) - \hat{\mathbf{T}} : (\tilde{\mathbf{S}}^i - \dot{\mathbf{S}}^i) + \Phi(\tilde{\mathbf{P}}^i, \tilde{\mathbf{S}}^i) - \Phi(\dot{\mathbf{P}}^i, \dot{\mathbf{S}}^i) \geq \delta W^{ext}. \quad (9)$$

3 A MATHEMATICAL FRAMEWORK

We define the variational inequality that describes the polarization process in a mathematical framework. Therefore, we introduce compact notation, which is compatible with the literature on variational inequalities, especially the monograph [9]. We use

$$\mathbf{w} = [\mathbf{S}(\mathbf{u}), \mathbf{D}, \mathbf{S}^i, \mathbf{P}^i]^T \quad \text{for the reactions} \quad (10)$$

$$\mathbf{z} = [\mathbf{S}(\tilde{\mathbf{u}}), \tilde{\mathbf{D}}, \tilde{\mathbf{S}}^i, \tilde{\mathbf{P}}^i]^T \quad \text{for admissible rates.} \quad (11)$$

A priori, we assume the different quantities to live in the following Sobolev spaces, and use compound spaces for compact notation,

$$\mathbf{u} \in \mathbb{U} := \{\mathbf{u} \in [H^1(\Omega)]^d : \mathbf{u} = 0 \text{ on } \Gamma_{fix}\}, \quad (12)$$

$$\mathbf{D} \in \mathbb{D}_0 := \{\mathbf{D} \in \mathbb{D} : \text{div } \mathbf{D} = 0\} \quad \text{with} \quad \mathbb{D} := \{\mathbf{D} \in H(\text{div}) : \mathbf{D} \cdot \mathbf{n} = 0 \text{ on } \Gamma_{ins}\}, \quad (13)$$

$$\mathbf{S}^i \in \mathbb{S} := [L^2(\Omega)]_{sym}^{d \times d}, \quad (14)$$

$$\mathbf{P}^i \in \mathbb{P} := [L^2(\Omega)]^d, \quad (15)$$

$$\mathbb{H} := \mathbb{U} \times \mathbb{D} \times \mathbb{S} \times \mathbb{P}, \quad \text{and} \quad \mathbb{H}_0 := \mathbb{U} \times \mathbb{D}_0 \times \mathbb{S} \times \mathbb{P}. \quad (16)$$

¹The subdifferential of some function j with respect to u is denoted by $\partial_u j$ and represents a set, namely

$$z \in \partial_u j(u) \quad \Longleftrightarrow \quad j(v) - j(u) \geq z \cdot (v - u) \quad \text{for all } v. \quad (6)$$

Depending on the definition of the irreversible energy Ψ^i , the free energy Ψ may tend to infinity as \mathbf{P}^i approaches saturation. We introduce the *effective domain* of Ψ by (cf. [9, p 73])

$$\mathbb{X} := \{\mathbf{z} \in \mathbb{H} : \Psi(\mathbf{z}) < \infty\}, \quad \mathbb{X}_0 := \mathbb{X} \cap \mathbb{H}_0. \quad (17)$$

We define the nonlinear operator $A : \mathbb{X} \rightarrow \mathbb{H}^*$ mapping reaction to forces,

$$\langle A(\mathbf{w}), \mathbf{z} \rangle := \left\langle \frac{\partial \Psi}{\partial \mathbf{w}}(\mathbf{w}), \mathbf{z} \right\rangle, \quad A(\mathbf{w}) = A(\mathbf{S}(\mathbf{u}), \mathbf{D}, \mathbf{S}^i, \mathbf{P}^i) = [\mathbf{S}(\mathbf{u}), \mathbf{D}, -\mathbf{S}^i, -\mathbf{P}^i]^T. \quad (18)$$

The work of external forces δW^{ext} shall be represented by the linear functional $\ell \in \mathbb{H}^*$. Note that, for the present choice of independent unknowns \mathbf{u} and \mathbf{D} , the external work also contains boundary conditions on the electric potential. In the exemplary case of a body under mechanical volume load \mathbf{f} , surface tractions \mathbf{t} on the boundary part Γ_{trac} , and a prescribed potential ϕ_0 on the electrodes Γ_{el} , this functional is defined as

$$\langle \ell, \mathbf{z} \rangle := \int_{\Omega} \mathbf{f} \cdot \tilde{\mathbf{u}} \, dx + \int_{\Gamma_{trac}} \mathbf{t} \cdot \tilde{\mathbf{u}} \, ds - \int_{\Gamma_{el}} \phi_0 \tilde{\mathbf{D}}_n \, ds. \quad (19)$$

Thus, the variational inequality (9) translates to the abstract variational inequality of the form: Find $\mathbf{w} : [0, T] \rightarrow \mathbb{X}_0$ such that

$$\langle A(\mathbf{w}), \mathbf{z} - \dot{\mathbf{w}} \rangle + \Phi(\mathbf{z}) - \Phi(\dot{\mathbf{w}}) \geq \langle \ell, \mathbf{z} - \dot{\mathbf{w}} \rangle \quad \text{for all } \mathbf{z} \in \mathbb{H}_0. \quad (20)$$

The variational inequality can be extended to hold for all $\mathbf{z} \in \mathbb{H}$, i.e. also for dielectric displacement updates with non-zero divergence. To this end, the dissipation function needs to be augmented by this restriction, see [9]. Indeed, the augmented dissipation maps all dielectric displacements with non-zero divergence to infinity. In the following, it shall be denoted by $j : \mathbb{H} \rightarrow \bar{\mathbb{R}}^+ := \mathbb{R} \cup \{+\infty\}$ and is defined as

$$j(\mathbf{z}) := \Phi(\mathbf{z}) + \sup_{\phi \in L^2(\Omega)} \int_{\Omega} \operatorname{div} \tilde{\mathbf{D}} \phi \, dx. \quad (21)$$

Note that, when restricted to \mathbb{H}_0 , $j(\cdot)$ and $\Phi(\cdot)$ are equivalent. Therefore, we will use $j(\cdot)$ in the following, and consider the variational inequality (equivalent to (20)),

$$\langle A(\mathbf{w}), \mathbf{z} - \dot{\mathbf{w}} \rangle + j(\mathbf{z}) - j(\dot{\mathbf{w}}) \geq \langle \ell, \mathbf{z} - \dot{\mathbf{w}} \rangle \quad \text{for all } \mathbf{z} \in \mathbb{H}. \quad (22)$$

3.1 Assumptions

We collect assumptions on the various functionals, that we need to proof existence and uniqueness of the update in a time-discrete scheme. In Section 4, we show whether these assumptions are satisfied for some standard material models. The following definitions are taken from Brezis [7].

Definition 1. Let E be a Hilbert space. A functional $\phi : E \rightarrow \bar{\mathbb{R}}^+$ is called *convex* iff for all $\rho \in [0, 1]$, $u_1, u_2 \in E$,

$$\phi(\rho u_1 + (1 - \rho)u_2) \leq \rho \phi(u_1) + (1 - \rho)\phi(u_2). \quad (23)$$

The functional ϕ is called *lower semicontinuous* iff for all $u \in E$, and all sequences $u_n \rightarrow u$,

$$\liminf \phi(u_n) \geq \phi(u). \quad (24)$$

It is weakly lower semicontinuous if (24) holds for all weakly convergent sequences $u_n \rightharpoonup u$.

An operator $A : X \rightarrow E$ is called *hemicontinuous* on a convex subset $X \subset E$ if for all $x, y \in X$ the mapping

$$[0, 1] \rightarrow \mathbb{R}, \quad t \mapsto \langle A((1-t)x + ty), x - y \rangle \quad (25)$$

is continuous.

As a minimal assumption on the Helmholtz free energy we demand it to be lower semicontinuous and convex. Its Frechet (or full) derivative shall exist and define the operator A ,

$$\Psi : \mathbb{X} \rightarrow \mathbb{R} \text{ is convex, lower semicontinuous and Frechet differentiable.} \quad (26)$$

To get convergence estimates and stability bounds, we need further that $A : \mathbb{X}_0 \rightarrow \mathbb{H}^*$ is strongly monotone, i.e. there exist $m > 0$ such that for all $\mathbf{w}_1, \mathbf{w}_2 \in \mathbb{X}_0$,

$$\langle A(\mathbf{w}_1) - A(\mathbf{w}_2), \mathbf{w}_1 - \mathbf{w}_2 \rangle \geq m \|\mathbf{w}_1 - \mathbf{w}_2\|_{\mathbb{H}}^2. \quad (27)$$

The dissipation function $\Phi : \mathbb{H} \rightarrow \mathbb{R}$ as well as its augmented counterpart $j : \mathbb{H} \rightarrow \overline{\mathbb{R}}^+$ need not be differentiable, but non-negative, proper, and positively homogeneous,

$$\begin{aligned} j(\mathbf{w}) &\geq 0 \text{ for all } \mathbf{w}, \mathbf{z} \in \mathbb{H}, \text{ and it exists at least one } \mathbf{w} \in \mathbb{H} \text{ with } j(\mathbf{w}) < \infty, \text{ and} \\ j(\alpha \mathbf{z}) &= \alpha j(\mathbf{z}) \text{ for all } \alpha > 0, \mathbf{z} \in \mathbb{H}. \end{aligned} \quad (28)$$

Additionally, we assume

$$j : \mathbb{H} \rightarrow \overline{\mathbb{R}}^+ \text{ is convex and lower semicontinuous.} \quad (29)$$

3.2 Time discrete update equation

We use a uniform partitioning of the time interval $[0, T]$ into N sub-intervals,

$$0 = t_0 < t_1 < \dots < t_{N-1} < t_N = T \quad \text{with} \quad t_n - t_{n-1} = \Delta T = T/N. \quad (30)$$

For N fixed, we will define a sequence $\{\mathbf{w}_n\}_{n=0}^N \in [\mathbb{H}_0]^{N+1}$ as consecutive solutions to (spatial but time-independent) variational inequalities. We use the backward difference $\Delta \mathbf{w}_n = \mathbf{w}_n - \mathbf{w}_{n-1}$ and $\ell_n = \ell(t_n)$. We show that this sequence is defined uniquely, and that stability estimates are satisfied. We use the following existence result by Brezis:

Theorem 1 (Corollaire 30 in [7]). *Let E be a reflexible Banach space, and let $X \subset E$ be closed and convex with $0 \in X$. Let $A : X \rightarrow E^*$ be weakly pseudo-monotone and $\phi : X \rightarrow]-\infty, +\infty]$ be convex lower semicontinuous with $\phi(0) < \infty$. If*

$$\lim_{\|x\| \rightarrow \infty} \frac{\langle A(x), x \rangle + \phi(x)}{\|x\|} = \infty, \quad (31)$$

then for $\ell \in E^*$ there exists a solution $u \in X$ to

$$\langle A(u), v - u \rangle + \phi(v) - \phi(u) \geq \langle \ell, v - u \rangle \quad \forall v \in X. \quad (32)$$

If A is additionally strongly monotone, the solution is unique.

The main result of this section is the following:

Theorem 2. *Let $\Psi : \mathbb{X} \rightarrow \mathbb{R}$ be convex, lower semicontinuous and Frechet differentiable as in (26), and let $A : \mathbb{X} \rightarrow \mathbb{H}^*$ be its derivative. Let $j : \mathbb{H} \rightarrow \overline{\mathbb{R}}^+$ be non-negative, proper, convex, positively homogeneous and lower semicontinuous as in (28) and (29). Let moreover $A : \mathbb{X}_0 \rightarrow \mathbb{H}^*$ be strongly monotone on \mathbb{X}_0 as in (27).*

Then, for N fixed and any given $\{\ell_n\}_{n=0}^N$ with $\ell_n \in \mathbb{H}^$ and $\ell_0 = 0$, there exists a unique sequence $\{\mathbf{w}_n\}_{n=0}^N$ such that $\mathbf{w}_n \in \mathbb{X}_0$ and $\Delta \mathbf{w}_n \in \mathbb{H}_0$ and*

$$\langle A(\mathbf{w}_n), \mathbf{z} - \Delta \mathbf{w}_n \rangle + j(\mathbf{z}) - j(\Delta \mathbf{w}_n) \geq \langle \ell_n, \mathbf{z} - \Delta \mathbf{w}_n \rangle \quad \forall \mathbf{z} \in \mathbb{H}. \quad (33)$$

The set of test functions can be equivalently restricted to $\mathbf{z} \in \mathbb{H}_0$. For m the constant of monotonicity in (27), the solution satisfies the stability estimate

$$\|\Delta \mathbf{w}_n\|_{\mathbb{H}} \leq 1/m \|\Delta \ell_n\|_{\mathbb{H}^*}. \quad (34)$$

Proof. We use Theorem 1 from convex analysis to show existence and uniqueness of the solutions. For the stability estimates, we progress along the lines of proof of [9] and see that some of their assumptions can be weakened. To show existence and uniqueness of the sequence $\{\mathbf{w}_n\}_{n=0}^N$, we proceed inductively from $\mathbf{w}_0 = \mathbf{0}$, assuming \mathbf{w}_{n-1} known. We rewrite the variational inequality (33) in terms of the unknown $\Delta \mathbf{w}_n$ and \mathbf{w}_{n-1} ,

$$\langle A(\Delta \mathbf{w}_n + \mathbf{w}_{n-1}), \mathbf{z} - \Delta \mathbf{w}_n \rangle + j(\mathbf{z}) - j(\Delta \mathbf{w}_n) \geq \langle \ell_n, \mathbf{z} - \Delta \mathbf{w}_n \rangle \quad \forall \mathbf{z} \in \mathbb{H}_0. \quad (35)$$

We show that we can apply Theorem 1 to obtain existence of a solution $\Delta \mathbf{w}_n$. As solution space we choose $E = \mathbb{H}_0$. We see that admissible updates are in the set $\mathbb{X}_{0, \mathbf{w}_{n-1}} := \mathbb{X}_0 - \mathbf{w}_{n-1} = \{\mathbf{z} : \mathbf{z} + \mathbf{w}_{n-1} \in \mathbb{X}_0\}$ where saturation is not reached. From [7, Proposition 1] we know that convexity of Ψ implies monotony and hemicontinuity of A on the open set $\mathbb{X}_{0, \mathbf{w}_{n-1}}$, which further implies pseudo-monotony of A . But still we cannot use $\mathbb{X}_{0, \mathbf{w}_{n-1}}$ directly for X in Theorem 1, as this set is not closed. Instead, we use the parameter-dependent closed sub-set

$$\mathbb{X}_{0, \mathbf{w}_{n-1}}(c) := \{\mathbf{z} \in \mathbb{X}_0 : \langle A(\mathbf{w}_{n-1} + \mathbf{z}), \mathbf{z} \rangle - \langle \ell, \mathbf{z} \rangle \leq c \|\mathbf{z}\|\}, \quad (36)$$

with the choice of $c > 0$ still to be determined. We show that this set is closed: Assume a sequence $\mathbf{z}_k \in \mathbb{X}_{0, \mathbf{w}_{n-1}}(c)$ that converges strongly to some $\mathbf{z} \in \mathbb{H}$. To show closedness of $\mathbb{X}_{0, \mathbf{w}_{n-1}}(c)$ we need to prove that $\mathbf{z} \in \mathbb{X}_{0, \mathbf{w}_{n-1}}(c)$. Starting from the defining condition of (36) applied for \mathbf{z}_k ,

$$\langle A(\mathbf{w}_{n-1} + \mathbf{z}_k), \mathbf{z}_k \rangle - \langle \ell, \mathbf{z}_k \rangle \leq c \|\mathbf{z}_k\|, \quad (37)$$

we apply $\liminf_{k \rightarrow \infty}$ on both sides. Proposition 6 in [7] and continuity of ℓ ensure that

$$\langle A(\mathbf{w}_{n-1} + \mathbf{z}), \mathbf{z} \rangle - \langle \ell, \mathbf{z} \rangle \stackrel{[7]}{\leq} \liminf_{k \rightarrow \infty} \langle A(\mathbf{w}_{n-1} + \mathbf{z}_k), \mathbf{z}_k \rangle - \langle \ell, \mathbf{z}_k \rangle \leq c \liminf_{k \rightarrow \infty} \|\mathbf{z}_k\| = c \|\mathbf{z}\|. \quad (38)$$

Thus we have shown $\mathbf{z} \in \mathbb{X}_{0, \mathbf{w}_{n-1}}(c)$ due to (36), and further that $\mathbb{X}_{0, \mathbf{w}_{n-1}}(c)$ is closed for any fixed $c > 0$.

The functional $\phi = j$ satisfies the conditions of Theorem 1. With all assumptions of Theorem 1 satisfied, there exists a solution $\Delta \mathbf{w}_n^c$ to the parameter-dependent variational inequality

$$\langle A(\Delta \mathbf{w}_n^c + \mathbf{w}_{n-1}), \mathbf{z} - \Delta \mathbf{w}_n^c \rangle + j(\mathbf{z}) - j(\Delta \mathbf{w}_n^c) \geq \langle \ell_n, \mathbf{z} - \Delta \mathbf{w}_n^c \rangle \quad \forall \mathbf{z} \in \mathbb{X}_{0, \mathbf{w}_{n-1}}(c). \quad (39)$$

The solution is unique if A is strongly monotone.

It remains to show that the variational inequality holds also for test functions $\mathbf{z} \in \mathbb{H}_0 \setminus \mathbb{X}_{0, \mathbf{w}_{n-1}}(c)$ provided c is larger than some fixed value not depending on the solution. Additionally we have to show that no $\mathbf{w} \in \mathbb{X}_0 \setminus \mathbb{X}_{0, \mathbf{w}_n}(c)$ can be an additional solution to preserve uniqueness.

For the first task, choose $c_{n-1} = c(\mathbf{w}_{n-1})$ depending on the previous iterate such that

$$\langle A(\mathbf{w}_{n-1}), \mathbf{z} \rangle - \langle \ell, \mathbf{z} \rangle \leq c_{n-1} \|\mathbf{z}\| \quad \forall \mathbf{z} \in \mathbb{H}_0. \quad (40)$$

This constant exists since for $\mathbf{w}_{n-1} \in \mathbb{X}_0$ fixed, the derivative $A(\mathbf{w}_{n-1})$ is a continuous linear operator. Now set $c = 2c_{n-1}$, and let $\mathbf{z} \in \mathbb{X}_0 \setminus \mathbb{X}_{0, \mathbf{w}_{n-1}}(2c_{n-1})$, i.e.

$$\langle A(\mathbf{w}_{n-1} + \mathbf{z}), \mathbf{z} \rangle - \langle \ell, \mathbf{z} \rangle > 2c_{n-1} \|\mathbf{z}\|. \quad (41)$$

From the hemicontinuity of A we deduce that there exists some $t_0 > 0$ such that for all $t \in [0, t_0]$

$$\langle A(\mathbf{w}_{n-1} + t\mathbf{z}), t\mathbf{z} \rangle - \langle \ell, t\mathbf{z} \rangle \leq 2c_{n-1} t \|\mathbf{z}\|, \quad (42)$$

i.e. $t\mathbf{z} \in \mathbb{X}_{0, \mathbf{w}_{n-1}}(2c_{n-1})$. But then the variational inequality (39) is satisfied for $t\mathbf{z}$, and due to linearity and positive homogeneity of j , it is thus satisfied also for test function $\mathbf{z} \in \mathbb{H}$.

On the other hand we have to show that there cannot exist any $\Delta \mathbf{w} \in \mathbb{X}_0 \setminus \mathbb{X}_{0, \mathbf{w}_{n-1}}(2c_{n-1})$ that is also solution to (35). But for such a $\Delta \mathbf{w}$ we know

$$-\langle A(\mathbf{w}_n + \Delta \mathbf{w}), \Delta \mathbf{w} \rangle + \langle \ell_n, \Delta \mathbf{w} \rangle < -2c_{n-1} \|\mathbf{w}\| < 0. \quad (43)$$

Together with the positivity of dissipation, one immediately obtains that the variational inequality (35) is not satisfied for $\mathbf{z} = 0$. Thus $\Delta \mathbf{w}_n$ is the only solution to (35).

We proceed to the stability estimates (34). We additionally assume strong monotonicity of A as in (27). Note that in this case, condition (31) is trivially satisfied. In (35), we set $\mathbf{z} = 0$ to obtain

$$\langle A(\Delta \mathbf{w}_n + \mathbf{w}_{n-1}), \Delta \mathbf{w}_n \rangle + j(\Delta \mathbf{w}_n) \leq \langle \ell_{n-1} + \Delta \ell_n, \Delta \mathbf{w}_n \rangle. \quad (44)$$

Next, in (33) at time step $n - 1$, we use $\mathbf{z} = \Delta \mathbf{w}_n + \Delta \mathbf{w}_{n-1} \in \mathbb{H}_0$. By algebraic manipulations, using convexity and positive homogeneity of $j(\cdot)$, we see

$$\langle A(\mathbf{w}_{n-1}), \Delta \mathbf{w}_n \rangle + \underbrace{j(\Delta \mathbf{w}_n + \Delta \mathbf{w}_{n-1}) - j(\Delta \mathbf{w}_{n-1})}_{\leq j(\Delta \mathbf{w}_n)} \geq \langle \ell_{n-1}, \Delta \mathbf{w}_n \rangle. \quad (45)$$

Subtracting (45) from (44) and applying strong monotonicity on the one and continuity of $\Delta \ell_n$ on the other hand we arrive at the desired result (34),

$$m \|\Delta \mathbf{w}_n\|_{\mathbb{H}}^2 \leq \langle A(\Delta \mathbf{w}_n + \mathbf{w}_{n-1}) - A(\mathbf{w}_{n-1}), \Delta \mathbf{w}_n \rangle \leq \langle \Delta \ell_n, \Delta \mathbf{w}_n \rangle \leq \|\Delta \ell_n\|_{\mathbb{H}^*} \|\Delta \mathbf{w}_n\|_{\mathbb{H}}. \quad (46)$$

□

4 APPLICATION TO SPECIAL FERROELECTRIC MATERIAL MODELS

The assumptions from the previous section are reasonable ones. We motivate this for the example of the ferroelectric material model for non-remnant straining as proposed by Landis [13]. We will see that all assumptions of the previous section are satisfied if material parameters are in common ranges. We derive the form of the dissipation function $\Phi(\dot{\mathbf{P}}^i)$ when given the switching surface depending on $\hat{\mathbf{E}}$.

We use the reversible part of the energy as proposed by [13],

$$\Psi^r := \frac{1}{2}(\mathbf{S} - \mathbf{S}^i) : \mathbf{c} : (\mathbf{S} - \mathbf{S}^i) - (\mathbf{S} - \mathbf{S}^i) : \mathbf{h} \cdot (\mathbf{D} - \mathbf{P}^i) + \frac{1}{2}(\mathbf{D} - \mathbf{P}^i) \cdot \boldsymbol{\beta} \cdot (\mathbf{D} - \mathbf{P}^i). \quad (47)$$

For non-remanent straining, one supposes $\mathbf{S}^i = 0$ and \mathbf{c} , \mathbf{h} and $\boldsymbol{\beta}$ depend on the remanent polarization. Quite similarly, one might introduce a kinematic assumption for the remanent strain $\mathbf{S}^i = \mathbf{S}^i(\mathbf{P}^i)$, as done in [14, 15]. For simplicity, we do not consider this case in the analytical deductions below, but in our numerical examples. The irreversible part of the energy is assumed as [13, Section 5]

$$\Psi^i = \frac{H_0 P_0^2}{(m-1)(m-2)} \left(1 - \frac{|\mathbf{P}^i|}{P_0} \right)^{2-m} - \frac{H_0 P_0}{m-1} |\mathbf{P}^i| \quad \text{if } m \neq 2 \text{ and} \quad (48)$$

$$\Psi^i = -H_0 P_0^2 \log \left(1 - \frac{|\mathbf{P}^i|}{P_0} \right) - H_0 P_0 |\mathbf{P}^i| \quad \text{if } m = 2. \quad (49)$$

In [13], it has been shown that the free energy is differentiable, and all differentiations are provided analytically. We assume that the material constants are such that the compound material tensor has positive eigenvalues bounded away from zero independently of \mathbf{P}^i . This issue has been treated in detail by Stark et al. [17], conditions on the material parameters are given there. Considering the special form of Ψ^r , then its derivative $A^r := \partial \Psi^r / \partial \mathbf{w}$ is strictly monotone in the sense that

$$\langle A^r(\mathbf{w}) - A^r(\mathbf{z}), \mathbf{w} - \mathbf{z} \rangle \geq c_1 (\|\mathbf{S} - \tilde{\mathbf{S}}\|_{L^2}^2 + \|\mathbf{D} - \mathbf{P}^i - \tilde{\mathbf{D}} + \tilde{\mathbf{P}}^i\|_{L^2}^2) \quad (50)$$

The irreversible and saturation part $A^i := \partial(\Psi^i + \Psi^s) / \partial \mathbf{w}$ are strictly monotone in the remanent polarization,

$$\langle A^i(\mathbf{w}) - A^i(\mathbf{z}), \mathbf{w} - \mathbf{z} \rangle \geq c_2 \|\mathbf{P}^i - \tilde{\mathbf{P}}^i\|_{L^2}^2. \quad (51)$$

Thus, for the sum $A = A^r + A^i$, one immediately deduces that

$$\langle A(\mathbf{w}) - A(\mathbf{z}), \mathbf{w} - \mathbf{z} \rangle \geq \frac{1}{2} \min(c_1, c_2) (\|\mathbf{S} - \tilde{\mathbf{S}}\|_{L^2}^2 + \|\mathbf{D} - \tilde{\mathbf{D}}\|_{L^2}^2 + \|\mathbf{P}^i - \tilde{\mathbf{P}}^i\|_{L^2}^2). \quad (52)$$

The last, essential ingredient to strict monotonicity is the fact that we restricted the full space of all dielectric displacements \mathbb{D} to those which are divergence-free, $\operatorname{div} \mathbf{D} = 0$, and that this space \mathbb{D}_0 is closed. In this case, the L^2 norm is equivalent to the full $H(\operatorname{div})$ norm on \mathbb{D}_0 , and (52) is sufficient for strict monotonicity of A on \mathbb{H}_0 .

As a second task, we show that the assumptions on the dissipation function are satisfied. To this end, we first characterize the dissipation function in detail. Usually, it is defined by a threshold or switching surface, i.e. a condition on the forces $\hat{\mathbf{E}}$ and $\hat{\mathbf{T}}$. We assume a condition of the form $\varphi(\hat{\mathbf{E}}) = |\hat{\mathbf{E}}|/E_0 - 1 \leq 0$. Then the dissipation function Φ is then given as

$$\Phi(\dot{\mathbf{P}}^i) = \sup \left\{ \int_{\Omega} \dot{\mathbf{P}} \cdot \hat{\mathbf{E}} \, dx : \varphi(\hat{\mathbf{E}}) \leq 0 \right\} = \int_{\Omega} E_0 |\dot{\mathbf{P}}^i| \, dx. \quad (53)$$

In [9] it is shown that dissipation functions of the above format satisfy all assumptions such as convexity, lower semicontinuity and positive homogeneity. Indeed, in case of elasto-plasticity the dissipation function is of the same abstract form, where the coercitive electric field E_0 resembles the yield stress.

5 FINITE ELEMENT IMPLEMENTATION

5.1 Finite element spaces

We propose to use conforming finite element spaces for the discretization of the variational inequality. For a simplicial finite element mesh $\mathcal{T} = \{T\}$, we use the nodal space for the displacements, the Raviart-Thomas space \mathcal{RT}_0 for the divergence-conforming dielectric displacement (see e.g. [5]), and piecewise constant remanent polarizations,

$$\mathbf{u} \in \mathbb{U}_h := \{\mathbf{u} \in [H^1(\Omega)]^d : \mathbf{u}|_T \in [P^1(T)]^d, \mathbf{u} = 0 \text{ on } \Gamma_{fix}\} \subset \mathbb{U}, \quad (54)$$

$$\mathbf{D} \in \mathbb{D}_h := \mathcal{RT}_0 \subset \mathbb{D}, \quad (55)$$

$$\mathbf{P}^i \in \mathbb{P} := \{\mathbf{P} \in [L^2(\Omega)]^d : \mathbf{P}|_T \in [P^0(T)]^d\} \subset \mathbb{P}. \quad (56)$$

Gauss' law of divergence free dielectric displacements is enforced by a Lagrangian multiplier in the sense of (21), which resembles the electric potential ϕ and is discretized also by piecewise constant functions,

$$\phi \in \mathbb{W}_h := \{\phi \in L^2(\Omega) : \phi|_T \in P^0(T)\}. \quad (57)$$

Note that it is essential to choose dielectric displacement and its Lagrangian multiplier in a stable combination of spaces, such that not only

$$\int_{\Omega} \operatorname{div} \mathbf{D} \phi \, dx = 0 \text{ for all } \phi \in \mathbb{W}_h \text{ implies } \operatorname{div} \mathbf{D} = 0, \quad (58)$$

but also the discrete inf-sup condition holds independently of the mesh size,

$$\inf_{\mathbf{D} \in \mathbb{D}_h} \sup_{\phi \in \mathbb{W}_h} \frac{\int_{\Omega} \operatorname{div} \mathbf{D} \phi \, dx}{\|\mathbf{D}\|_{H(\operatorname{div})} \|\phi\|_{L^2}} \geq c. \quad (59)$$

This condition is satisfied for the pair \mathcal{RT}_0 and piecewise constants. For a thorough theoretical background we refer the interested reader to the exhaustive monograph [5] on mixed problems.

5.2 Regularization of the dissipation function

For solving variational inequalities, different numerical algorithms are proposed in the literature. Well-known for dual variational inequalities is the *return-mapping algorithm* in different variants. There, after a predictor step, in the corrector step the generalized stress is projected back to the admissible set in a consistent way. Also for primal variational inequalities, as derived in this work, predictor/corrector iterations have been analyzed e.g. in the application of elasto-plasticity [9, Section 12.2].

In contrast, we propose to regularize the non-differentiable dissipation function, such that the problem can be solved “all at once” in a single Newton iteration. This *regularization technique* has been analyzed for convergence and accuracy in [9, Section 12.4]. Briefly, for some given parameter ε , the non-differentiable dissipation j is replaced by a smooth function j_ε , which differs from j only by ε (see Section 6 for a special choice). If the findings from [9] can be transferred to the ferroelectric polarization problem, one can expect that the solution \mathbf{w}_ε converges to \mathbf{w} in \mathbb{H} , and $\|\mathbf{w} - \mathbf{w}_\varepsilon\|_{\mathbb{H}} \leq c\sqrt{\varepsilon}$. However, we do not aim at proving these convergence estimates for the present problem. In the present manuscript, we used the following regularized version of the dissipation,

$$j_\varepsilon(\dot{\mathbf{P}}^i) := \int_{\Omega} E_0 |\dot{\mathbf{P}}^i|_\varepsilon \, dx \quad \text{with } |\dot{\mathbf{P}}^i|_\varepsilon := \begin{cases} |\dot{\mathbf{P}}^i| - \varepsilon/2 & \text{if } |\dot{\mathbf{P}}^i| \geq \varepsilon, \\ 1/(2\varepsilon) |\dot{\mathbf{P}}^i|^2 & \text{else.} \end{cases} \quad (60)$$

Figure 1: Loadcase electric polarization and depolarization: Hysteresis of dielectric displacement (left) and strain (right).

6 NUMERICAL RESULTS

We provide a patch test example, where we reproduce known hysteresis effects and mechanical depolarization on a ferroelectric cube. In the second example, a ferroelectric cantilever is polarized by an applied electric field, and partially depolarized in bending. In both examples, we use the energies Ψ^r and Ψ^i as described in (47), (48) and (49). We assumed the permittivity at constant strain $\beta = \epsilon^{-1}\mathbf{I}$ to be independent of \mathbf{P}^i . The piezoelectric tensor \mathbf{d} depends on \mathbf{P}^i in the standard way as given in [13, eq. (4.3)]. Then the coupling tensor \mathbf{h} and the stiffness at constant dielectric displacement can be computed algebraically by β , \mathbf{d} and the (assumed constant) stiffness at constant electric field, cmp. [13].

We use the open source all-purpose finite element code Netgen/NGSolve², where high-order hierarchical finite elements for all element types (segments, triangles, quadrilaterals, tetrahedra, hexahedra, prisms, ...) and many different spaces (continuous or discontinuous, curl or div conforming, ...) are implemented. Via a python interface, variational equations or even energies can be entered symbolically. In a nonlinear problem, the (symbolic) equations are differentiated automatically, and a Newton iteration can be realized in a straightforward manner, without need to implement tedious tangent stiffnesses etc. by hand for each formulation.

6.1 Patch test

Consider a cube of side length 2 mm whose normal displacement is fixed at the three coordinate planes. The cube is electroded on top and bottom, the other faces are electrically insulated. We use material constants derived from the dimensionless constants proposed by [14]. We set $E_0 = 1$ MV/m, $P_0 = 0.3$ C/m², $S_0 = 0.002$, $m = 2$, $\epsilon = 12$ nC/(V m), $E_Y = 30$ GPa, $\nu = 0.3$, $d_{31} = -2.1 \times 10^{-10}$ N/(V m), $d_{33} = 4.2 \times 10^{-10}$ N/(V m), $H_0 = \frac{1}{3}$ MV m/C. The regularization parameter from Section 5.2 is set to $\varepsilon = 10^{-6} P_0$.

We provide hysteresis curves for the standard load case of electric polarization and depolarization by an electric field of $1.5E_0$ in Figure 1. Moreover, Figure 2 shows the effect of mechanical depolarization by a compressive load of 200 N/mm² applied to the top surface of the cube.

6.2 Ferroelectric cantilever

The second example is that of a ferroelectric cantilever beam of length 10 mm and cross section 2×2 mm, which was proposed by [18]. The clamped end as well as the tip of the beam are electroded.

²available at <https://ngsolve.org>

Figure 2: Loadcase mechanic depolarization: Remanent polarization as a function of the applied electric field (left), stress evolution over dielectric displacement (center) and over strain (right).

Figure 3: Mechanical depolarization of a polarized cantilever beam under a vertical tip force – absolute value of remanent polarization $|P_i|$ (left) and stress distribution T_{xx} .

First, the beam is polarized applying an electric potential to the beam tip while keeping the other electrode grounded. The electric field is raised in 12 load steps amounting to $3E_0$, then lowered back to zero. Afterwards, a vertical tip force of 16 N is applied to the tip surface. Due to the compression in the upper part of the beam, the material depolarizes mechanically in this section.

The obtained values cannot be compared directly to the original work of [18], as in this reference a different material model based on Kamlah's work [11] is used. We chose material constants close to their values, using $E_0 = 1 \text{ MV/m}$, $P_0 = 0.3 \text{ C/m}^2$, $S_0 = 0.002$, $m = 1.1$, $\epsilon = 15 \text{ nC/(V m)}$, $E_Y = 10 \text{ GPa}$, $\nu = 0.3$, $d_{31} = -2.74 \times 10^{-10} \text{ N/(V m)}$, $d_{33} = 5.93 \times 10^{-10} \text{ N/(V m)}$, $H_0 = 1 \text{ MV m/C}$. The d_{15} effect was neglected in the current implementation, the regularization parameter is $\varepsilon = 10^{-6} P_0$.

The absolute value of the remanent polarization $|P^i|$ after bending, and the corresponding stress distribution T_{xx} , are depicted in Figure 3. As observed in [18], the cantilever depolarizes in the region close to the clamped end where compressive stresses arise. This depolarization reduces the stress level there to a maximum of -123.771 N/mm^2 , which compares well to the values listed in the original reference. However, due to the different description of the ferroelectric material, the region of depolarization is much larger.

Key words: Shape Memory Alloys, Bending, Boundary-Value Problem, Modeling.

Abstract. This work presents a numerical simulation of a TiNi shape memory alloy (SMA) beam performance in the mode of pure bending with the use of Bernoulli-Euler hypotheses. The beam is subjected to an action of a bending torque, an axial force and temperature variations. Thickness distributions of the stress and strain as well as the beam deflection for various stages of thermomechanical loading are obtained. The formulation of the boundary-value problem includes the equations describing the mechanical equilibrium and the constitutive behavior of an SMA representative volume, for which two models - a microstructural and a macroscopic ones are used. They account for the deformations due to elasticity, thermal expansion and phase transformation. It is noted that since the microstructural model automatically accounts for the tension-compression asymmetry of TiNi the use of this model for the description of the SMA behavior predicts that the neutral line of the bent beam does not pass through its center and the beam performance in the mode of bending differs from that in the mode of tension.

1 INTRODUCTION

In many applications shape memory alloy (SMA) parts are used as working bodies of actuators, force elements [1,2], medical staples [3], endovascular stents [4], etc., in which they experience strain accumulation and recovery in the mode of bending. This mode of deformation is distinguished by an inhomogeneous stress and strain fields. Moreover the tensile stress has different signs on the inner and outer surfaces of the bent beam. Keeping in mind that some SMA, such as the widely used TiNi-based alloys, demonstrate the tension-compression asymmetry [5, 6], one can conclude that the functional properties of a bent SMA beam cannot be the same as the properties of a rod, subjected only to tension or only to compression.

To find the dependences of the beam curvature and deflection under the action of the bending torque as well as the martensite phase and stress distributions over the beam cross-section one must solve a boundary-value problem. Such an attempt is made in this work.

2 CONSTITUTIVE RELATIONS: MICROSTRUCTURAL MODEL

Microstructural models have significant advantages, since they can account for the structure of SMA and the specific features of their mechanical behavior. Most well developed models are [7,8]. In this work an earlier developed microstructural model [9-11] was used to describe the deformation of the SMA. The equations are formulated for the physical processes, producing micro-strain in the micro-regions and the macroscopic strain of a representative volume is calculated by averaging of strains of micro-regions constituting this volume. The primary structural elements of martensite are considered to be Bain's variants (domains) originated from the parent phase in each grain by different but crystallographically equivalent variants of Bain's deformation. Therefore, the internal variables in this model are the volume fractions of the Bain's variants. Note that another choice of these elements used in [12] and leading to similar results is the martensitic plates bearing the martensitic shift on a habit plane.

The representative volume V of a SMA (fig.1) consists of a set of grains, each characterized by the orientation ω of its crystallographic axes.

Fig.1. Scheme of the representative volume of SMA

The A. Reuss' hypothesis is accepted according to which the macroscopic strain can be calculated as the average of all micro-strains. In this model the spatial averaging of the micro-strains, is substituted by the orientation averaging, thus expressing the macroscopic strain ε and the volume fraction Φ^M of martensite by the formulae:

$$\varepsilon = \sum_{\omega} f(\omega) \varepsilon^{\text{gr}}(\omega), \quad \Phi_M = \sum_{\omega} f(\omega) \Phi^{\text{gr}}(\omega)$$

where the sum is taken over all grains, $f(\omega)$ is the volume fraction of the grains with orientation ω (a discrete analogue of the orientation distribution function), $\varepsilon^{\text{gr}}(\omega)$ and $\Phi^{\text{gr}}(\omega)$

are the strain tensor and the volume fraction of martensite in a grain with orientation ω (in this article small deformation tensors are used).

In each grain there exist N orientational variants of martensite obtained from austenite by different but crystallographically equivalent Bain's deformations D_n ($n = 1, \dots, N$). For the transformation of cubic phase into monoclinic one $N=12$ (shuffles are not considered since they do not change the homogeneous part of the Bain's strain). Thus, martensite is characterized by the internal variables Φ_n ($n = 1, \dots, N$), such that $(1/N)\Phi_n$ is the volume fraction of the domain occupied by the n -th orientational variant of martensite. For the phase deformation of this grain one has:

$$\varepsilon^{\text{gr}} = (1 - \Phi^{\text{gr}})\varepsilon^{\text{A}} + \frac{1}{N} \sum_{n=1}^N \Phi_n \varepsilon_n^{\text{M}}$$

The superscripts A and M denote austenite and martensite, ε^{A} and ε^{M} are the deformations of the austenitic and martensitic phases. In general, each of the strains ε^{A} and ε^{M} can be expressed as the sum of the elastic strain ε^{e} , thermal expansion strain ε^{T} , dislocation slip plastic strain ε^{P} , phase strain ε^{Ph} (strain due to the phase transformation) and the micro-plastic strain ε^{MP} , which is the strain occurring by the localized dislocation slip under the action of the inter-phase stresses. In the present work we consider the case when $\varepsilon^{\text{MP}} = \varepsilon^{\text{P}} = 0$. Elastic and thermal strains are calculated by commonly known formulae, which we do not write down here. Since the phase strain is the strain, which occurs as the result of the transformation of austenite to martensite we put that for the austenite $\varepsilon^{\text{PhA}} = 0$ and for the n -th variant of martensite $\varepsilon_n^{\text{PhM}} = D_n$. So, the total phase strain of a grain is

$$\varepsilon^{\text{Ph gr}} = \frac{1}{N} \sum_{n=1}^N \Phi_n D_n.$$

The evolution equations for Φ_n is formulated in terms of the generalized thermodynamic forces, which are derived from the Gibbs' potential. G . For a unit volume:

$$G = G^{\text{eig}} + G^{\text{mix}}, \quad G^{\text{eig}} = (1 - \Phi^{\text{gr}})G^{\text{A}} + \frac{1}{N} \sum_{n=1}^N \Phi_n G_n^{\text{M}}, \quad G_n^{\text{mix}} = \frac{\mu}{2} \sum_{m,n=1}^N A_{mn} \Phi_m \Phi_n$$

where G^{A} , G_n^{M} , G^{eig} are the potentials of non-interacting austenite and martensite and their average value; G^{mix} is the potential of the interaction equal to the elastic energy of the internal stresses. In the work [13] this potential is referred to as the "phase interaction energy function" (PIEF). The eigenpotentials G^{A} and G_n^{M} at temperature T and stress σ can be expressed by the formula:

$$G^{\text{a}} = G_0^{\text{a}} - S_0^{\text{a}}(T - T_0) - \frac{c_{\sigma}^{\text{a}}(T - T_0)^2}{2T_0} - \varepsilon^{\text{0a}}(T) : \sigma - \frac{1}{2} \sigma : Q^{\text{a}} : \sigma, \quad \text{a} = \text{A, M}$$

where T_0 is the temperature of the thermodynamic equilibrium of austenite and martensite at zero stress, G_0^{a} and S_0^{a} are the values of the Gibbs' potential and of the entropy at $T=T_0$ and $\sigma=0$, c_{σ}^{a} is the specific heat (per unit volume), $\varepsilon^{\text{0a}}(T)$ is the strain at $\sigma=0$, Q^{a} is the tensor of elastic compliances, symbol ":" denotes double scalar product of tensors.

Potential G^{mix} is estimated by a quadratic form of the internal parameters describing the phase deformation. The matrix A_{mn} of this quadratic form accounts for the interactions between the different variants of martensite. The matrix A_{mn} of this quadratic form accounts for the interactions between the different variants of martensite. In TiNi the transformation is from cubic B2 phase into monoclinic B19' phase. For this transformation there exists 12 different Bain's deformations. These variants group into pairs called the Corresponding Variants Pairs (CVP) [14-16]. This martensite structure allows lowering the elastic energy of the interphase stresses. The tendency of the Bain's variants for grouping is taken into account by the matrix A_{mn} . Enumerating the Bain's variants in a proper order the following structure of the matrix A_{mn} was suggested:

$$A = \begin{pmatrix} A_1 & 0 & 0 \\ 0 & A_1 & 0 \\ 0 & 0 & A_1 \end{pmatrix}, \quad A_1 = \begin{pmatrix} 1 & -\alpha & -\alpha & 0 \\ -\alpha & 1 & 0 & -\alpha \\ -\alpha & 0 & 1 & -\alpha \\ 0 & -\alpha & -\alpha & 1 \end{pmatrix}$$

where α is a material constant ($0 \leq \alpha < 1/2$) measuring the degree of the interaction between the Bain's variants forming one CVP.

The evolution equation for the internal variables is deduced from the condition of equilibrium of the thermodynamic forces, which are obtained as the derivatives of the Gibbs' potential.

$$F_n = -\frac{\partial G}{\partial \Phi_n} \approx \frac{q_0(T-T_0)}{T_0} + \sigma: D_n - \mu \sum_{m=1}^N A_{nm} \Phi_m,$$

Here q_0 is the latent heat of the transformation ($q_0 < 0$); T_0 is the phase equilibrium temperature, for which the approximation $T_0 = (M_s + A_f)/2$ suggested in [17] is used; μ is a material constant. The transformation does not occur at the equilibrium state, i.e. at $F_n = 0$, but rather at a state apart from equilibrium, when there is an excess of the driving force. So, the condition of the transformation can be formulated in the form:

$$F_n = \pm F^{\text{tr}},$$

Sign “+” must be taken for the direct and “-” for the reverse transformation; material constant F^{tr} determines the extent of the deviation from equilibrium and it is responsible for the temperature – phase hysteresis of the transformation.

To describe the reorientation (twinning) of martensite three hypotheses are accepted: (1) any variant of martensite can be transformed in any other variant; (2) reorientation occurs along the direction in the space Φ_1, \dots, Φ_N , which corresponds to the fastest decrease of the Gibbs' potential; (3) reorientation starts when the thermodynamic force reaches some critical

value. To find the direction of the reorientation we use vector $F_n = \left\{ -\frac{\partial G}{\partial \Phi_1}, \dots, -\frac{\partial G}{\partial \Phi_N} \right\}$ and

take its projection L onto plane $\Phi_1 + \dots + \Phi_N = \text{const}$. Then if for some n it holds that $\Phi_n = 0$ and $L_n < 0$ we substitute L for its projection L' onto intersection of planes $\Phi_n = 0$ and

$\Phi_1 + \dots + \Phi_N = \text{const}$, repeating this procedure for other components of L_n if necessary. Finally we obtain the direction l , which does not lead to a violation of conditions $\Phi_1 + \dots + \Phi_N < 1$, $\Phi_n > 0$, $n=1, \dots, N$. For this direction we postulate the condition of reorientation:

$$F^{\text{tw}}(l) = F^{\text{fr tw}},$$

where $F^{\text{tw}}(l) = -\frac{\partial G}{\partial l} = -\sum_{n=1}^N l_n \frac{\partial G}{\partial \Phi_n} = \sum_{n=1}^N l_n F_n$, $F^{\text{fr tw}}$ is a material constant, characterizing the critical driving force for reorientation. From hypotheses 1 and 2 it follows that the increments $d\Phi_n$ are proportional to l_n : $d\Phi_n = l_n d\phi$, where $d\phi$ is the proportionality factor.

There are rather few material constants in the model for the deformation of a SMA accounting only for the elastic thermal and phase deformation. The values for most of the constants are found from independent experiments: the Bain's strain is determined from the X-ray diffraction data and the scheme of the crystal lattice deformation; values for F^{fr} and μ are derived from the values of the characteristic temperatures M_f , M_s , A_s , A_f , and the latent heat q_0 (all of them can be measured on the differential scanning calorimeter). The adjustable parameters are $F^{\text{fr tw}}$ and α . The first of them is related to the phase yield limit of martensite and is easily found from the tensile test. The second controls the value of the reversible phase strain accumulated on cooling of the specimen under a constant stress: with the growth of α the tendency of the Bain's variants to form self-accommodated configurations becomes more pronounced and the macroscopic phase strain decreases. The number of grains N is the model parameter, which affects the anisotropy of a simulated SMA. For a single crystal ($N=1$) the material is anisotropic, becoming almost isotropic when N exceed 300. So, this parameter must correlate to the ratio of the grain diameter to the characteristic dimension of the specimen. For TiNi the values of the constants were determined in the previous works [9-11].

This microstructural approach proved to be efficient for simulating the deformation of a specimen in different states (martensitic, two-phase and austenitic) as well as strain accumulation on cooling and heating under a constant or varying load.

3 BOUNDARY-VALUE PROBLEM FOR BENDING OF AN SMA BEAM

Consider the boundary problem of bending of an SMA beam (fig.2). We assume that loading is made in isothermal conditions, which means that the rod is in contact with the thermostat over its entire surface and, besides, the cross-sectional shape is such that heat transfer processes occur fast, so that the temperature is distributed over the section uniformly.

Fig.2. Scheme of pure bending.

For simplicity, we consider a beam with a rectangular cross-section with width b and a small thickness h , loaded by a bending torque M and thus, experiencing pure bending, in which the plane of the bending moment coincides with the plane of the curvature of the beam. For pure bending, the Bernoulli plane-sections hypothesis and the hypothesis of non-compression of layers are valid. In this case, the distribution of relative deformations over the cross section of the rod can be calculated by the formula

$$\varepsilon_{zz}(y) = \kappa y + \bar{\varepsilon}, \quad (1)$$

where κ is the curvature of the central layer of the beam and $\bar{\varepsilon}$ is the relative elongation of this layer. The only non-vanishing stress is σ_{zz} . Further, for simplicity notations ε and σ are used for ε_{zz} and σ_{zz} . The Hook's law gives:

$$\sigma = E(\varepsilon - \varepsilon^{ne}) \quad (2)$$

where E is the Young's modulus and ε^{ne} is the non-elastic strain.

For a given distribution $\sigma(z)$ the equilibrium conditions are valid:

$$\int_{-h/2}^{h/2} b\sigma(y)dy = 0, \quad \int_{-h/2}^{h/2} b\sigma(y)ydy = M. \quad (3)$$

In this work we do not consider thermal expansion, thus, the non-elastic strain consists only of the phase strain, the increment of which as well of the increments of the internal parameters as well as the increments of the internal variables are given by the microstructural model described in section 2, and which can be schematically expressed as

$$\Delta\varepsilon^{ne}(y) = F_1(\Delta T, \Delta\sigma(y), X(y)), \quad \Delta X(y) = F_2(\Delta T, \Delta\sigma(y), X(y)) \quad (4)$$

where the functions F_1 and F_2 are defined by microstructural model and by X is denoted the set of internal variables $\Phi_n(\omega)$, that is the volume fractions of martensite for each variant n in each grain ω .

To solve the problem specified by equations (1) – (4) we use the discrete scheme, dividing the interval $[-h/2, h/2]$ into K equal segments and search for the values $\sigma_j = \sigma(y_j)$, $\varepsilon_j = \varepsilon(y_j)$,

where $y_j = (jh/K), j = 0, \dots, K$.

Then we split the whole problem into two parts. The first problem is the problem of the mechanical equilibrium and it is to find the “vector” $\{\sigma_j\}$ for given torque M and “vector” $\{\varepsilon_j^{ne}\}$ using formulae (1) – (3). Denoting the operator solving this problem by Mech, we write

$$\{\sigma_j\} = \text{Mech}(M, \{\varepsilon_j^{ne}\}) \quad (5)$$

The second (“rheological”) problem is to find the increments of the non-elastic strains $\{\Delta\varepsilon_j^{ne}\}$ for known increments ΔT and $\{\Delta\sigma_j\}$ using the microstructural model (4). Denoting this operator by Rheo, we write:

$$\{\Delta\varepsilon_j^{ne}\} = \text{Rheo}(\Delta T, \{\Delta\sigma_j\}) \quad (6)$$

Now it is possible to formulate the scheme of passing from the “vector” $\{\varepsilon_j^{ne}(t)\}$ corresponding to the time instant t to the “vector” $\{\varepsilon_j^{ne}(t+\Delta t)\}$, where the time increment Δt corresponds to the increments ΔT and ΔM of the temperature and of the bending torque. This scheme is as follows.

1. Choose the 0-th approximation $\{\varepsilon_j^{ne}\}^{(0)} = 0$ for “vector” $\{\varepsilon_j^{ne}\}$.
2. Find $\{\sigma_j\}^{(1)} = \text{Mech}(M + \Delta M, \{\varepsilon_j^{ne}\}^{(0)})$.
3. Find the 1-st approximation $\{\varepsilon_j^{ne}\}^{(1)} = \lambda \{\varepsilon_j^{ne}\}^{(0)} + (1-\lambda) \text{Rheo}(\Delta T, \{\Delta\sigma_j\}^{(1)})$.
4. Repeat steps 1 – 3 until $\max_j (\{\varepsilon_j^{ne}\}^{(i+1)} - \{\varepsilon_j^{ne}\}^{(i)}) < e$,

where λ is the iteration parameter ($0 < \lambda \leq 1$) and e denotes the admissible error.

Thus, for given regime of the thermomechanical loading specified by the values of temperature T_i and bending torque M_i corresponding to time instants t_i , one can find the values $\{\varepsilon_j^{ne}(t_i)\}$ and $\{\sigma_j(t_i)\}$ as well as the values κ_i of the curvature.

4 SIMULATION RESULTS

For simulation the following beam dimensions were chosen: length $l = 50$ mm, width $b = 10$ mm, thickness $h = 2.8$ mm. The characteristic temperatures M_f , M_s , A_s , A_f , were 300, 315, 350 365 K, and the latent heat $q_0 = -150.0$ J/cm³. The diagram of bending is presented on Fig.3 (the deflection measured at the center of the bent arc) and the height distributions of the stress and phase are presented on fig.4.

Fig.3. The dependence of the bending torque on the deflection of the beam during its deformation at 375 K.

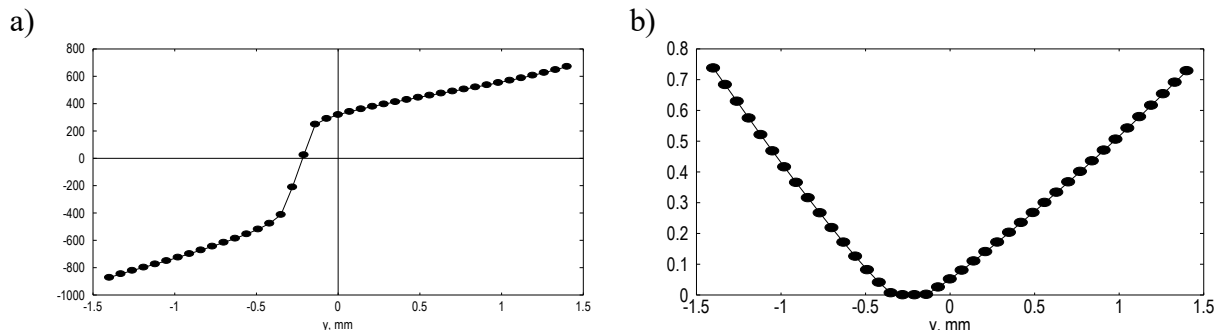

Fig.4. Distribution of the normal stress (a) and of the volume fraction of martensite (b) along the height of the pseudoelastic beam loaded at 375 K by a bending torque 12 N · m

Since the microstructural model automatically takes into account the asymmetry of TiNi properties with respect to tension – compression, the simulation using this model predicts that the neutral line of the bent beam does not pass through its center, but rather is shifted towards the compressed beam layers. The maximum absolute value of the compressive stress is bigger than the tensile stress. This circumstance should be taken into account when assessing the functional properties of the SMA tested in bending mode.

Analogous dependences of the maximum deflection on the bending moment are obtained during isothermal bending of the beam in the pseudoplastic (martensitic) state.

Fig.5. The dependence of the bending torque on the deflection of the beam during its deformation at 295 K

Fig.6. Distribution of the normal stress along the height of the beam loaded at 295 K by a bending torque 12 N · m (a) and after unloading (b).

Again one can see that distribution of the stress is not symmetric and the compressive stress is much higher than the tensile one. The asymmetry of the distribution of stress is present also after unloading of the beam.

11 CONCLUSIONS

- Microstructural modeling allows solving simple boundary-value problems for thermomechanical loading of SMA in the pure bending mode, revealing the inhomogeneity of the distributions of the stress.
- The tension – compression asymmetry of SMA leads to the asymmetric distribution of the stress, at which the compressed side of the bent beam is under a higher stress than the stretched side.

Key words: Laminated Piezoelectric Shell, Nonlinear Exact Geometry Solid-Shell Element, Hybrid-Mixed Method, Sampling Surfaces Formulation.

Abstract. The paper presents a robust nonlinear exact geometry or geometrically exact (GeX) laminated piezoelectric four-node solid-shell element using the method of sampling surfaces (SaS). The term GeX reflects the fact that the parametrization of the middle surface is known and, therefore, the coefficients of the first and second fundamental forms and Christoffel symbols are taken exactly at element nodes. The SaS method is based on choosing inside the n th layer I_n SaS parallel to the middle surface in order to introduce the displacements and electric potentials of these surfaces as basic shell unknowns. Such choice of unknowns with the consequent use of Lagrange polynomials of degree $I_n - 1$ in assumed approximations of displacements, strains, electric potential and electric field through the layer thickness yields the efficient higher-order piezoelectric shell formulation. The inner SaS are located inside each layer at Chebyshev polynomial nodes that makes it possible to minimize uniformly the error due to Lagrange interpolation. The nonlinear GeX solid-shell element formulation utilizes the Green-Lagrange strain tensor that exactly represents the arbitrarily large rigid-body motions of a shell in any curvilinear coordinate system. This permits one to calculate the transverse components of the second Piola-Kirchhoff stress tensor with a high accuracy. The developed solid-shell element is based on the hybrid-mixed method and allows the use of load steps, which are much larger than possible with existing displacement-based solid-shell elements. The tangent stiffness matrix is evaluated by efficient 3D analytical integration. As a result, the GeX/SaS solid-shell element exhibits a superior performance in the case of coarse meshes. It can be useful for the 3D stress analysis of thick and thin doubly-curved laminated piezoelectric shells undergoing finite rotations.

1 INTRODUCTION

In recent years, a considerable progress has been achieved on the development of continuum-based finite elements that can handle the geometrically nonlinear analysis of laminated piezoelectric shells satisfactorily [1-5]. These elements are typically defined by two layers of nodes on the bottom and top surfaces of the shell with three displacement degrees of freedom (DOFs) and one electric potential DOF per node and known as isoparametric 6-parameter piezoelectric solid-shell elements taking into account the number of only displacement DOFs. However, the 6-parameter piezoelectric solid-shell element formulation based on the complete constitutive equations of piezoelectricity is deficient because thickness locking occurs. This is due to the fact that the linear displacement field in the thickness direction results in a constant transverse normal strain, which in turn causes artificial stiffening of the shell element in the case of non-vanishing Poisson's ratios. It should be mentioned that the errors caused by thickness locking do not decrease with the mesh refinement because the reason of stiffening lies in the shell theory itself rather than the finite element discretization. To prevent thickness locking, the transverse normal strain is enriched in the thickness direction by a linear term [6].

In a more general 9-parameter piezoelectric solid-shell element formulation, three layers of nodes located on the bottom, middle and top surfaces with three displacement DOFs and one electric potential DOF per node are introduced [7, 8]. Such choice of sampling surfaces (SaS) with the use of Lagrange polynomials of the second degree in the through-thickness approximations of displacements, strains, electric potential and electric field leads to a very compact form of the 9-parameter piezoelectric solid-shell element formulation. Moreover, this model allows one to derive the Green-Lagrange strain tensor, which exactly represents arbitrarily large rigid-body motions of the shell in convected curvilinear coordinates. Considering that the displacement vectors of SaS are resolved in the middle surface basis, the higher-order shell formulation with nine displacement DOFs is very suitable to develop the exact geometry or geometrically exact (GeX) piezoelectric solid-shell elements. The term GeX means that the parametrization of the middle surface is known a priori and, therefore, the coefficients of the first and second fundamental forms and the Christoffel symbols are taken exactly at element nodes.

It should be noted that the 6- and 9-parameter solid-shell elements do not describe correctly the transverse components of the second Piola-Kirchhoff stress tensor and electric displacement vector in laminated piezoelectric shells. To evaluate them, the advanced computational techniques should be invoked. The present paper is intended to overcome this gap in the finite element literature and develop the four-node solid-shell element for calculating the second Piola-Kirchhoff stresses in laminated piezoelectric shells. For this purpose, the GeX nonlinear solid-shell element in the framework of the SaS formulation [9] is proposed. The SaS laminated shell formulation is based on choosing inside each layer I_n SaS parallel to the middle surface in order to introduce the displacements and electric potentials of these surfaces as fundamental shell unknowns. Such choice of unknowns with the consequent use of Lagrange polynomials of degree $I_n - 1$ in the through-thickness approximations of displacements, strains, electric potential and electric field of the n th layer yields a robust higher-order layerwise shell formulation, in which all basic variables including strains, stresses, electric field and electric displacement are related to SaS. Recently, the SaS

formulation has been employed to analyze analytically and numerically the electroelastic and thermoelectroelastic response of laminated and functionally graded piezoelectric shells [10–14]. However, the nonlinear solid-shell elements for the analysis of laminated piezoelectric shells through the SaS formulation have not been developed yet.

Figure 1: Geometry of the laminated piezoelectric shell

2 HU-WASHIZU VARIATIONAL SAS FORMULATION

Consider a laminated piezoelectric shell of the thickness h . Let the middle surface Ω be described by orthogonal curvilinear coordinates θ_1 and θ_2 , which are referred to the lines of principal curvatures of its surface. The coordinate θ_3 is oriented along the unit vector $\mathbf{e}_3(\theta_1, \theta_2)$ normal to the middle surface. Introduce the following notations: $\mathbf{e}_\alpha(\theta_1, \theta_2)$ are the orthonormal base vectors of the middle surface; $A_\alpha(\theta_1, \theta_2)$ are the coefficients of the first fundamental form; $k_\alpha(\theta_1, \theta_2)$ are the principal curvatures of the middle surface; $c_\alpha = 1 + k_\alpha \theta_3$ are the components of the shifter tensor; $c_\alpha^{(n)i_n}(\theta_1, \theta_2) = 1 + k_\alpha \theta_3^{(n)i_n}$ are the components of the shifter tensor at SaS; $\theta_3^{(n)i_n}$ are the transverse coordinates of SaS of the n th layer $\Omega^{(n)i_n}$ given by

$$\theta_3^{(n)1} = \theta_3^{[n-1]}, \quad \theta_3^{(n)I_n} = \theta_3^{[n]}, \quad (1)$$

$$\theta_3^{(n)m_n} = \frac{1}{2}(\theta_3^{[n-1]} + \theta_3^{[n]}) - \frac{1}{2}h_n \cos\left(\pi \frac{2m_n - 3}{2(I_n - 2)}\right), \quad (2)$$

where $h_n = \theta_3^{[n]} - \theta_3^{[n-1]}$ is the thickness of the n th layer; $\theta_3^{[m]}$ are the coordinates of interfaces $\Omega^{[m]}$ depicted in Figure 1; the index n identifies the belonging of any quantity to the n th layer and runs from 1 to N , whereas the index m identifies the belonging of any quantity to the interface and runs from 1 to $N-1$; N is the number of layers; the indices m_n running from 2 to $I_n - 1$ describe the inner SaS of the n th layer, whereas the indices i_n, j_n, k_n running from 1 to I_n describe all SaS of the n th layer; I_n is the total number of SaS of the n th layer; Latin indices i, j, k, l range from 1 to 3, whereas Greek indices α, β range from 1 to 2.

It is seen from equation (2) that the transverse coordinates of inner SaS $\theta_3^{(n)m_n}$ coincide with Chebyshev polynomial nodes (roots of the Chebyshev polynomial of degree $I_n - 2$). This fact has a great meaning for a convergence of the SaS method [9-12].

The SaS approximations through the thickness [9] can be written as

$$[u_i^{(n)} \ \varepsilon_{ij}^{(n)} \ S_{ij}^{(n)} \ \varphi^{(n)} \ E_i^{(n)}] = \sum_{i_n} L^{(n)i_n} [u_i^{(n)i_n} \ \varepsilon_{ij}^{(n)i_n} \ S_{ij}^{(n)i_n} \ \varphi^{(n)i_n} \ E_i^{(n)i_n}], \quad (3)$$

where $u_i^{(n)}, \varepsilon_{ij}^{(n)}, S_{ij}^{(n)}, \varphi^{(n)}, E_i^{(n)}$ are the displacements, Green-Lagrange strains, second Piola-Kirchhoff stresses, electric potential and electric field of the n th layer; $u_i^{(n)i_n}, \varepsilon_{ij}^{(n)i_n}, S_{ij}^{(n)i_n}, \varphi^{(n)i_n}, E_i^{(n)i_n}$ are the displacements, Green-Lagrange strains, second Piola-Kirchhoff stresses, electric potential and electric field of SaS of the n th layer; $L^{(n)i_n}(\theta_3)$ are the Lagrange basis polynomials of degree $I_n - 1$ related to the n th layer:

$$L^{(n)i_n} = \prod_{j_n \neq i_n} \frac{\theta_3 - \theta_3^{(n)j_n}}{\theta_3^{(n)i_n} - \theta_3^{(n)j_n}}. \quad (4)$$

In the orthonormal basis \mathbf{e}_i , the relations between strains and displacements of SaS of the n th layer are written as

$$\begin{aligned} 2\varepsilon_{\alpha\beta}^{(n)i_n} &= \frac{1}{c_{\beta}^{(n)i_n}} \lambda_{\alpha\beta}^{(n)i_n} + \frac{1}{c_{\alpha}^{(n)i_n}} \lambda_{\beta\alpha}^{(n)i_n} + \frac{1}{c_{\alpha}^{(n)i_n} c_{\beta}^{(n)i_n}} \lambda_{i\alpha}^{(n)i_n} \lambda_{i\beta}^{(n)i_n}, \\ 2\varepsilon_{\alpha 3}^{(n)i_n} &= \frac{1}{c_{\alpha}^{(n)i_n}} \lambda_{3\alpha}^{(n)i_n} + \beta_{\alpha}^{(n)i_n} + \frac{1}{c_{\alpha}^{(n)i_n}} \lambda_{i\alpha}^{(n)i_n} \beta_i^{(n)i_n}, \\ 2\varepsilon_{33}^{(n)i_n} &= 2\beta_3^{(n)i_n} + \beta_i^{(n)i_n} \beta_i^{(n)i_n}, \end{aligned} \quad (5)$$

where $\lambda_{i\alpha}^{(n)i_n}$ are the strain parameters of SaS of the n th layer; $\beta_i^{(n)i_n}$ are the values of the derivative of displacements with respect to thickness coordinate on SaS defined as

$$\begin{aligned} \lambda_{\alpha\alpha}^{(n)i_n} &= \frac{1}{A_{\alpha}} u_{\alpha,\alpha}^{(n)i_n} + B_{\alpha} u_{\beta}^{(n)i_n} + k_{\alpha} u_3^{(n)i_n}, \quad \lambda_{\beta\alpha}^{(n)i_n} = \frac{1}{A_{\alpha}} u_{\beta,\alpha}^{(n)i_n} - B_{\alpha} u_{\alpha}^{(n)i_n} \text{ for } \beta \neq \alpha, \\ \lambda_{3\alpha}^{(n)i_n} &= \frac{1}{A_{\alpha}} u_{3,\alpha}^{(n)i_n} - k_{\alpha} u_{\alpha}^{(n)i_n}, \quad B_{\alpha} = \frac{1}{A_{\alpha} A_{\beta}} A_{\alpha,\beta} \text{ for } \beta \neq \alpha, \\ \beta_i^{(n)i_n} &= \sum_{j_n} M^{(n)j_n}(\theta_3^{(n)i_n}) u_i^{(n)j_n}, \end{aligned} \quad (6)$$

where $M^{(n)j_n} = L_{,3}^{(n)j_n}$ are the polynomials of degree $I_n - 2$; their values on SaS are

$$\begin{aligned} M^{(n)j_n}(\theta_3^{(n)i_n}) &= \frac{1}{\theta_3^{(n)j_n} - \theta_3^{(n)i_n}} \prod_{k_n \neq i_n, j_n} \frac{\theta_3^{(n)i_n} - \theta_3^{(n)k_n}}{\theta_3^{(n)j_n} - \theta_3^{(n)k_n}} \text{ for } j_n \neq i_n, \\ M^{(n)i_n}(\theta_3^{(n)i_n}) &= - \sum_{j_n \neq i_n} M^{(n)j_n}(\theta_3^{(n)i_n}). \end{aligned} \quad (7)$$

In equation (5) and below, the summation on repeated Latin indices is implied.

In the orthonormal basis \mathbf{e}_i , the relations between the electric field and electric potentials of SaS of the n th layer [9] are expressed as

$$\begin{aligned} E_\alpha^{(n)i_n} &= -\frac{1}{A_\alpha c_\alpha^{(n)i_n}} \varphi_{,\alpha}^{(n)i_n}, \\ E_3^{(n)i_n} &= -\sum_{j_n} M^{(n)j_n} (\theta_3^{(n)i_n}) \varphi^{(n)j_n}. \end{aligned} \quad (8)$$

The proposed hybrid-mixed piezoelectric solid-shell element is based on the Hu-Washizu variational equation of electroelasticity in which displacements, strains, stresses and electric potential are utilized as independent variables [7, 8]:

$$\delta \iint \sum_n \int_{\theta_3^{[n-1]}}^{\theta_3^{[n]}} \left[\frac{1}{2} \eta_{ij}^{(n)} C_{ijkl}^{(n)} \eta_{kl}^{(n)} - E_k^{(n)} e_{kij}^{(n)} \eta_{ij}^{(n)} - \frac{1}{2} E_i^{(n)} \epsilon_{ij}^{(n)} E_j^{(n)} - \sigma_{ij}^{(n)} (\eta_{ij}^{(n)} - \epsilon_{ij}^{(n)}) \right] dV = \delta W, \quad (9)$$

where $\eta_{ij}^{(n)}$ are the displacement-independent strains of the n th layer; $C_{ijkl}^{(n)}$, $e_{kij}^{(n)}$ and $\epsilon_{ij}^{(n)}$ are the elastic, piezoelectric and dielectric constants of the n th layer; $dV = A_1 A_2 c_1 c_2 d\theta_1 d\theta_2 d\theta_3$ is the infinitesimal volume element; W is the work done by external electromechanical loads.

According to the SaS technique, we introduce the through-thickness approximation of displacement-independent strains choosing them similar to the displacement-dependent strain approximation (3):

$$\eta_{ij}^{(n)} = \sum_{i_n} L^{(n)i_n} \eta_{ij}^{(n)i_n}. \quad (10)$$

Substituting the through-thickness distributions (3) and (10) in variational equation (9) and introducing

$$\Lambda^{(n)i_n j_n} = \int_{\theta_3^{[n-1]}}^{\theta_3^{[n]}} L^{(n)i_n} L^{(n)j_n} c_1 c_2 d\theta_3, \quad (11)$$

one can write the Hu-Washizu variational equation in terms of only SaS variables as

$$\begin{aligned} \delta \iint \sum_n \sum_{i_n} \sum_{j_n} \Lambda^{(n)i_n j_n} \left[\frac{1}{2} (\boldsymbol{\eta}^{(n)i_n})^T \mathbf{C}^{(n)} \boldsymbol{\eta}^{(n)j_n} - (\mathbf{E}^{(n)i_n})^T \mathbf{e}^{(n)} \boldsymbol{\eta}^{(n)j_n} \right. \\ \left. - \frac{1}{2} (\mathbf{E}^{(n)i_n})^T \boldsymbol{\epsilon}^{(n)} \mathbf{E}^{(n)j_n} - (\mathbf{S}^{(n)i_n})^T (\boldsymbol{\eta}^{(n)j_n} - \boldsymbol{\epsilon}^{(n)j_n}) \right] A_1 A_2 d\theta_1 d\theta_2 = \delta W, \end{aligned} \quad (12)$$

where

$$\begin{aligned} \boldsymbol{\epsilon}^{(n)i_n} &= [\epsilon_{11}^{(n)i_n} \quad \epsilon_{22}^{(n)i_n} \quad \epsilon_{33}^{(n)i_n} \quad 2\epsilon_{12}^{(n)i_n} \quad 2\epsilon_{13}^{(n)i_n} \quad 2\epsilon_{23}^{(n)i_n}]^T, \\ \boldsymbol{\eta}^{(n)i_n} &= [\eta_{11}^{(n)i_n} \quad \eta_{22}^{(n)i_n} \quad \eta_{33}^{(n)i_n} \quad 2\eta_{12}^{(n)i_n} \quad 2\eta_{13}^{(n)i_n} \quad 2\eta_{23}^{(n)i_n}]^T, \\ \mathbf{S}^{(n)i_n} &= [S_{11}^{(n)i_n} \quad S_{22}^{(n)i_n} \quad S_{33}^{(n)i_n} \quad S_{12}^{(n)i_n} \quad S_{13}^{(n)i_n} \quad S_{23}^{(n)i_n}]^T, \\ \mathbf{E}^{(n)i_n} &= [E_1^{(n)i_n} \quad E_2^{(n)i_n} \quad E_3^{(n)i_n}]^T, \end{aligned} \quad (13)$$

$$\mathbf{C}^{(n)} = \begin{bmatrix} C_{1111}^{(n)} & C_{1122}^{(n)} & C_{1133}^{(n)} & C_{1112}^{(n)} & 0 & 0 \\ C_{2211}^{(n)} & C_{2222}^{(n)} & C_{2233}^{(n)} & C_{2212}^{(n)} & 0 & 0 \\ C_{3311}^{(n)} & C_{3322}^{(n)} & C_{3333}^{(n)} & C_{3312}^{(n)} & 0 & 0 \\ C_{1211}^{(n)} & C_{1222}^{(n)} & C_{1233}^{(n)} & C_{1212}^{(n)} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{1313}^{(n)} & C_{1323}^{(n)} \\ 0 & 0 & 0 & 0 & C_{2313}^{(n)} & C_{2323}^{(n)} \end{bmatrix}, \quad (14)$$

$$\mathbf{e}^{(n)} = \begin{bmatrix} 0 & 0 & 0 & 0 & e_{113}^{(n)} & e_{123}^{(n)} \\ 0 & 0 & 0 & 0 & e_{213}^{(n)} & e_{223}^{(n)} \\ e_{311}^{(n)} & e_{322}^{(n)} & e_{333}^{(n)} & e_{312}^{(n)} & 0 & 0 \end{bmatrix}, \quad \mathbf{\epsilon}^{(n)} = \begin{bmatrix} \epsilon_{11}^{(n)} & \epsilon_{12}^{(n)} & 0 \\ \epsilon_{21}^{(n)} & \epsilon_{22}^{(n)} & 0 \\ 0 & 0 & \epsilon_{33}^{(n)} \end{bmatrix}.$$

3 HYBRID-MIXED FOUR-NODE SOLID-SHELL ELEMENT FORMULATION

The finite element formulation is based on a simple interpolation of the shell via GeX four-node piezoelectric solid-shell elements

$$u_i^{(n)i_n} = \sum_r N_r u_{ir}^{(n)i_n}, \quad \varphi^{(n)i_n} = \sum_r N_r \varphi_r^{(n)i_n}, \quad (15)$$

where $N_r(\xi_1, \xi_2)$ are the bilinear shape functions of the element; $u_{ir}^{(n)i_n}$ and $\varphi_r^{(n)i_n}$ are the displacements and electric potentials of SaS of the n th layer at element nodes; ξ_1, ξ_2 are the normalized curvilinear coordinates θ_1, θ_2 (Figure 2); the nodal index r runs from 1 to 4.

Figure 2: Biunit square in (ξ_1, ξ_2) -space mapped into the middle surface of the GeX piezoelectric solid-shell element in (x_1, x_2, x_3) -space

To implement the efficient analytical integration throughout the element, the extended ANS method is employed:

$$\varepsilon_{ij}^{(n)i_n} = \sum_r N_r \varepsilon_{ijr}^{(n)i_n}, \quad E_i^{(n)i_n} = \sum_r N_r E_{ir}^{(n)i_n}, \quad (16)$$

where $\varepsilon_{ijr}^{(n)i_n}$ and $E_{ir}^{(n)i_n}$ are the displacement-dependent strains and electric field of SaS of the n th layer at element nodes. The main idea of such approach can be traced back to the ANS method developed by many scientists [1-6] for the isoparametric solid-shell element formulation. In contrast with above formulation, we treat the term ANS in a broader sense. In the proposed GeX four-node solid-shell element formulation, all components of the displacement-dependent strain tensor and electric field vector are assumed to vary bilinearly throughout the biunit square in (ξ_1, ξ_2) -space.

Further, it is convenient to rewrite the ANS interpolation (16) in the following form:

$$\varepsilon^{(n)i_n} = \sum_{r_1, r_2} (\xi_1)^{r_1} (\xi_2)^{r_2} \varepsilon_{r_1 r_2}^{(n)i_n}, \quad \mathbf{E}^{(n)i_n} = \sum_{r_1, r_2} (\xi_1)^{r_1} (\xi_2)^{r_2} \mathbf{E}_{r_1 r_2}^{(n)i_n}, \quad (17)$$

$$\varepsilon_{r_1 r_2}^{(n)i_n} = [\varepsilon_{11r_1 r_2}^{(n)i_n} \quad \varepsilon_{22r_1 r_2}^{(n)i_n} \quad \varepsilon_{33r_1 r_2}^{(n)i_n} \quad 2\varepsilon_{12r_1 r_2}^{(n)i_n} \quad 2\varepsilon_{13r_1 r_2}^{(n)i_n} \quad 2\varepsilon_{23r_1 r_2}^{(n)i_n}]^T, \quad \mathbf{E}_{r_1 r_2}^{(n)i_n} = [E_{1r_1 r_2}^{(n)i_n} \quad E_{2r_1 r_2}^{(n)i_n} \quad E_{3r_1 r_2}^{(n)i_n}]^T, \quad (18)$$

where the indices r_1 and r_2 run from 0 to 1.

Using equations (5), (6), (8) and (18), one obtains

$$\varepsilon_{r_1 r_2}^{(n)i_n} = (\mathbf{B}_{r_1 r_2}^{(n)i_n} + \mathbf{A}_{r_1 r_2}^{(n)i_n}(\mathbf{q})) \mathbf{q}, \quad \mathbf{E}_{r_1 r_2}^{(n)i_n} = -\mathbf{B}_{\varphi r_1 r_2}^{(n)i_n} \Phi, \quad (19)$$

where $\mathbf{B}_{r_1 r_2}^{(n)i_n}$ and $\mathbf{A}_{r_1 r_2}^{(n)i_n}(\mathbf{q})$ are the nodal matrices [15] of order $6 \times 12N_{\text{SaS}}$ corresponding to linear and non-linear strain-displacement transformations; $\mathbf{B}_{\varphi r_1 r_2}^{(n)i_n}$ are the nodal piezoelectric matrices [13, 14] of order $3 \times 4N_{\text{SaS}}$; \mathbf{q} and Φ are the displacement and electric potential vectors of the shell element defined as

$$\mathbf{q} = [\mathbf{q}_1^T \quad \mathbf{q}_2^T \quad \mathbf{q}_3^T \quad \mathbf{q}_4^T]^T, \quad \Phi = [\Phi_1^T \quad \Phi_2^T \quad \Phi_3^T \quad \Phi_4^T]^T, \quad (20)$$

$$\mathbf{q}_r = \left[(\mathbf{u}_r^{[0]})^T (\mathbf{u}_r^{(1)2})^T \dots (\mathbf{u}_r^{(1)I_1-1})^T (\mathbf{u}_r^{[1]})^T (\mathbf{u}_r^{(2)2})^T \dots (\mathbf{u}_r^{(N-1)I_{N-1}-1})^T (\mathbf{u}_r^{[N-1]})^T (\mathbf{u}_r^{(N)2})^T \dots (\mathbf{u}_r^{(N)I_N-1})^T (\mathbf{u}_r^{[N]})^T \right]^T,$$

$$\mathbf{u}_r^{[m]} = [u_{1r}^{[m]} \quad u_{2r}^{[m]} \quad u_{3r}^{[m]}]^T, \quad \mathbf{u}_r^{(n)m_n} = [u_{1r}^{(n)m_n} \quad u_{2r}^{(n)m_n} \quad u_{3r}^{(n)m_n}]^T,$$

$$\Phi_r = \left[(\varphi_r^{[0]})^T (\varphi_r^{(1)2})^T \dots (\varphi_r^{(1)I_1-1})^T (\varphi_r^{[1]})^T (\varphi_r^{(2)2})^T \dots (\varphi_r^{(N-1)I_{N-1}-1})^T (\varphi_r^{[N-1]})^T (\varphi_r^{(N)2})^T \dots (\varphi_r^{(N)I_N-1})^T (\varphi_r^{[N]})^T \right]^T,$$

where $u_{ir}^{[0]}$ and $u_{ir}^{[N]}$ are the nodal displacements of bottom and top surfaces; $u_{ir}^{[m]}$ are the nodal displacements of interfaces $\Omega^{[m]}$; $N_{\text{SaS}} = \sum_n I_n - N + 1$ is the total number of SaS.

To circumvent shear and membrane locking and have no spurious zero energy modes, the robust stress interpolation [15] is utilized

$$\mathbf{S}^{(n)i_n} = \sum_{r_1+r_2 < 2} (\xi_1)^{r_1} (\xi_2)^{r_2} \mathbf{Q}_{r_1 r_2} \mathbf{S}_{r_1 r_2}^{(n)i_n}, \quad (21)$$

$$\mathbf{S}_{00}^{(n)i_n} = [\chi_1^{(n)i_n} \chi_2^{(n)i_n} \chi_3^{(n)i_n} \chi_4^{(n)i_n} \chi_5^{(n)i_n} \chi_6^{(n)i_n}]^T,$$

$$\mathbf{S}_{01}^{(n)i_n} = [\chi_7^{(n)i_n} \chi_9^{(n)i_n} \chi_{11}^{(n)i_n}]^T, \quad \mathbf{S}_{10}^{(n)i_n} = [\chi_8^{(n)i_n} \chi_{10}^{(n)i_n} \chi_{12}^{(n)i_n}]^T,$$

where $\mathbf{Q}_{r_1 r_2}$ are the projective matrices given by

$$\mathbf{Q}_{00} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}, \quad \mathbf{Q}_{01} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \quad \mathbf{Q}_{10} = \begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}. \quad (22)$$

The similar interpolation [15] can be used for the displacement-independent strains, that is,

$$\boldsymbol{\eta}^{(n)i_n} = \sum_{r_1+r_2 < 2} (\xi_1^{r_1} \xi_2^{r_2} \mathbf{Q}_{r_1 r_2} \boldsymbol{\eta}_{r_1 r_2}^{(n)i_n}), \quad (23)$$

$$\boldsymbol{\eta}_{00}^{(n)i_n} = [\psi_1^{(n)i_n} \psi_2^{(n)i_n} \psi_3^{(n)i_n} \psi_4^{(n)i_n} \psi_5^{(n)i_n} \psi_6^{(n)i_n}]^T,$$

$$\boldsymbol{\eta}_{01}^{(n)i_n} = [\psi_7^{(n)i_n} \psi_9^{(n)i_n} \psi_{11}^{(n)i_n}]^T, \quad \boldsymbol{\eta}_{10}^{(n)i_n} = [\psi_8^{(n)i_n} \psi_{10}^{(n)i_n} \psi_{12}^{(n)i_n}]^T.$$

Substituting finite element approximations (15), (17), (21) and (23) into the Hu-Washizu variational equation (12), one can integrate analytically throughout the finite element. As a result, the following equilibrium equations of the GeX hybrid-mixed solid-shell element are obtained:

$$\boldsymbol{\eta}_{r_1 r_2}^{(n)i_n} = \mathbf{Q}_{r_1 r_2}^T (\mathbf{B}_{r_1 r_2}^{(n)i_n} + \mathbf{A}_{r_1 r_2}^{(n)i_n}(\mathbf{q})) \mathbf{q} \quad \text{for } r_1 + r_2 < 2, \quad (24)$$

$$\mathbf{S}_{r_1 r_2}^{(n)i_n} = \mathbf{Q}_{r_1 r_2}^T (\mathbf{C}^{(n)} \mathbf{Q}_{r_1 r_2} \boldsymbol{\eta}_{r_1 r_2}^{(n)i_n} + (\mathbf{e}^{(n)})^T \mathbf{B}_{\varphi r_1 r_2}^{(n)i_n} \boldsymbol{\Phi}) \quad \text{for } r_1 + r_2 < 2, \quad (25)$$

$$\sum_n \sum_{i_n} \sum_{j_n} \Lambda^{(n)i_n j_n} \sum_{r_1+r_2 < 2} \frac{1}{3^{r_1+r_2}} (\mathbf{B}_{r_1 r_2}^{(n)i_n} + 2\mathbf{A}_{r_1 r_2}^{(n)i_n}(\mathbf{q}))^T \mathbf{Q}_{r_1 r_2} \mathbf{S}_{r_1 r_2}^{(n)j_n} = \mathbf{F}_u, \quad (26)$$

$$\sum_n \sum_{i_n} \sum_{j_n} \Lambda^{(n)i_n j_n} \sum_{r_1+r_2 < 2} \frac{1}{3^{r_1+r_2}} (\mathbf{B}_{\varphi r_1 r_2}^{(n)i_n})^T (\mathbf{e}^{(n)} \mathbf{Q}_{r_1 r_2} \boldsymbol{\eta}_{r_1 r_2}^{(n)j_n} - \mathbf{e}^{(n)} \mathbf{B}_{\varphi r_1 r_2}^{(n)j_n} \boldsymbol{\Phi}) = \mathbf{F}_\varphi, \quad (27)$$

where \mathbf{F}_u and \mathbf{F}_φ are the element-wise mechanical and electric surface vectors.

Because of equilibrium equations (24)-(26) are nonlinear, the Newton-Raphson method is employed to linearize them

$$\mathbf{q}^{[k+1]} = \mathbf{q}^{[k]} + \Delta \mathbf{q}^{[k]}, \quad \boldsymbol{\Phi}^{[k+1]} = \boldsymbol{\Phi}^{[k]} + \Delta \boldsymbol{\Phi}^{[k]},$$

$$\mathbf{S}_{r_1 r_2}^{(n)i_n[k+1]} = \mathbf{S}_{r_1 r_2}^{(n)i_n[k]} + \Delta \mathbf{S}_{r_1 r_2}^{(n)i_n[k]}, \quad \boldsymbol{\eta}_{r_1 r_2}^{(n)i_n[k+1]} = \boldsymbol{\eta}_{r_1 r_2}^{(n)i_n[k]} + \Delta \boldsymbol{\eta}_{r_1 r_2}^{(n)i_n[k]}, \quad (28)$$

where $k = 0, 1, \dots, \text{NIter}$; NIter is the total number of iterations.

By using a standard technique, we arrive at the linearized equilibrium equations. Eliminating then stresses $\Delta \mathbf{S}_{r_1 r_2}^{(n) i_n [k]}$ and displacement-dependent strains $\Delta \boldsymbol{\eta}_{r_1 r_2}^{(n) i_n [k]}$ on the element level, the following system of equations are obtained:

$$\begin{bmatrix} \mathbf{K}_{uu} & \mathbf{K}_{u\varphi} \\ \mathbf{K}_{\varphi u} & \mathbf{K}_{\varphi\varphi} \end{bmatrix} \begin{bmatrix} \Delta \mathbf{q}^{[k]} \\ \Delta \Phi^{[k]} \end{bmatrix} = \begin{bmatrix} \mathbf{F}_u^{[k]} \\ \mathbf{F}_\varphi^{[k]} \end{bmatrix}, \quad (29)$$

where \mathbf{K}_{uu} , $\mathbf{K}_{u\varphi}$, $\mathbf{K}_{\varphi u} = (\mathbf{K}_{u\varphi})^T$, $\mathbf{K}_{\varphi\varphi}$ are the displacement, piezoelectric and dielectric stiffness matrices of the element.

The equilibrium equations (29) for each element are assembled to form the global equilibrium equations. These equations should be performed until the required accuracy of the solution is reached employing the displacement-based convergence criteria as follows:

$$\|\Delta \mathbf{U}^{[k+1]} - \Delta \mathbf{U}^{[k]}\| < \varepsilon \|\Delta \mathbf{U}^{[k]}\|, \quad (30)$$

where $\|\cdot\|$ stands for the Euclidean norm; $\Delta \mathbf{U}$ is the global vector of nodal displacements and electric potentials; ε is the prescribed tolerance.

4 NUMERICAL EXAMPLE

The performance of the developed GeX/SaS laminated piezoelectric four-node solid-shell element, called the GeXSaS4 element, is evaluated with the help of the nonlinear isoparametric 5-parameter piezoelectric shell element [16] and 20-node SOLID226 element from the software package ANSYS [17].

Consider a cantilever square plate composed of the T300/976 graphite/epoxy composite with the PZT G1195 actuators attached to its bottom and the top surfaces. The direction of fibers coincides with the y -axis. The actuators are polarized in opposite directions parallel to the thickness direction and subjected to opposite electric potentials $-\hat{\varphi}$ and $\hat{\varphi}$, as shown in Figure 3, to induce the bending actuation. The electrodes on the interfaces are assumed to be grounded. The mechanical properties of materials are

$$\begin{aligned} \text{G1195 [1]: } E = 63 \text{ GPa, } G = 24.23 \text{ GPa, } \nu = 0.3, e_{311} = e_{322} = 44.37 \text{ C/m}^2, e_{333} = 50.18 \text{ C/m}^2, \\ e_{113} = e_{223} = 14.15 \text{ C/m}^2, \epsilon_{11} = \epsilon_{22} = 1.53 \cdot 10^{-8} \text{ F/m, } \epsilon_{33} = 1.5 \cdot 10^{-8} \text{ F/m;} \end{aligned} \quad (31)$$

$$\begin{aligned} \text{T300/976 [16]: } E_L = 150 \text{ GPa, } E_T = 9 \text{ GPa, } G_{LT} = 7.1 \text{ GPa, } G_{TT} = 2.5 \text{ GPa, } \nu_{LT} = \nu_{TT} = 0.3, \\ \epsilon_{11} = \epsilon_{22} = \epsilon_{33} = 2.7 \cdot 10^{-11} \text{ F/m.} \end{aligned} \quad (32)$$

To compare the results with the finite element solution [16], the geometrical parameters are taken to be $a = b = 40 \text{ mm}$, $h_1 = h_3 = 0.15 \text{ mm}$ and $h_2 = 0.2 \text{ mm}$.

Due to symmetry of the problem, only one half of the plate is modeled by regular meshes. Table 1 lists results of the convergence study via longitudinal and transverse displacements of the middle surface \bar{u}_1 and \bar{u}_3 at point A($a, 0$) choosing three and four SaS for each layer. A comparison with the SOLID226 element [17] is also given. It is seen that only one load step

and five Newton iterations are needed to find the converged solution with the chosen criterion and tolerance, where NStep denotes a number of load steps employed to equally divide the maximum load. Note that the GeXSaS4 element allows the use of coarse meshes.

Figure 4 shows the displacements of the middle surface at point A of the three-layer plate versus the applied voltage using three SaS for each layer compared to those obtained by the 5-parameter isoparametric piezoelectric shell element [16] and SOLID226 element [17]. As can be seen, all results agree closely but the developed GeXSaS4 element is less expensive due to 3D analytical integration that leads to the economical computation of its tangent stiffness matrix. Figure 5 presents the through-thickness distributions of second Piola-Kirchhoff stresses, electric potential and electric displacement at points B($a/2, b/2$) and C($a/2, b/4$) for the three-layer plate under applied voltage $\hat{\phi} = 2000 \text{ V}$ employing four SaS for layers and a fine 64×32 mesh compared to those obtained by the SOLID226 element [17] using $64 \times 32 \times 2$ mesh for each layer. One can see that the SOLID226 element leads to a worse prediction for the transverse stresses. It should be noted that it is impossible for this solid element to satisfy the boundary conditions on outer surfaces and the continuity conditions at interfaces choosing a more number of elements in the thickness direction.

Abstract. This study aims to predict the nonlinear dynamics of elastic structures equipped with piezoelectric devices, for application such as reduction vibration, energy harvesting or design of nonlinear resonant M/NEMS such as ultra-sensitive sensors. In this context, reduced-order model (ROM) based on a modal expansion are used to compute the response of the structures, including both geometrical nonlinearities and the electromechanical (EM) coupling. This approach results to a system of coupled oscillators, in which geometrically nonlinear and electromechanical terms appear separately, along with less classical terms stemming from both effects. This system is solved in the frequency domain with the Harmonic Balance Method associated with an Asymptotic Numerical Method. The parameters of the ROM are computed thanks to a non-intrusive method and a finite element commercial code. This study focuses first on the computation of these coefficients, which is separately performed in the EM and non-linear cases. The EM coefficients are validated by comparison with the effective and modal EM coupling factors (EEMCF, MEMCF). A validation of the procedure is proposed by studying the nonlinear dynamics of an elastic circular plate equipped with eight piezoelectric patches equally spaced and placed along an inner circumference. This configuration enables to excite and measure several vibration modes, either axisymmetric or asymmetric. Curved frequency responses are obtained, both in free nonlinear vibrations (backbone curves) and under voltage forcing. In the case of asymmetric modes, 1:1 internal resonances are obtained, showing the coupling between both companion modes. Experimental validations are also proposed.

1 INTRODUCTION

The prediction of the geometrically nonlinear mechanical behavior of electrically driven structures is an issue of great interest in the context of Micro- or Nano-ElectroMechanical Systems (M/NEMS) developments [1, 2, 3, 4] or energy harvesting [5]. The geometrical nonlinearities are due to the large

amplitude of the displacements of the structures. In this framework, the investigated structures present often complex geometries, such that multilayered thin systems, for which a finite element approach offer great flexibility in modelling. To solve the nonlinear dynamical system, the model must be reduced in size. The modal basis is used to identify the reduced-order models because of its efficiency to capture the relevant displacement components of the structures, particularly when the targeted application focuses on resonant phenomena. An original approach to estimate efficient reduced-order models (ROM) and validate them by comparison with experimental results is proposed in this study. The approach to identify the ROM parameters is based on non-intrusive methods, which suppose to compute the nonlinear components of the proposed problem without modifying the source of a finite element code. The present paper proposes first a generalization of the use of non-intrusive methods - initially devoted to study only geometrical nonlinearities of dynamical systems [6] - to electromechanical systems. Secondly, the article presents in detail an experimental procedure to identify the geometrically nonlinear parameters of a vibrating structure with an electric actuation and detection, by taking into account the electromechanical coupling.

2 MODEL REDUCTION

2.1 General formulation of the problem and modal expansion

Here is considered an elastic structure equipped with P piezoelectric patches denoted with indice (p) . The governing equations of the free, undamped, piezoelectric and nonlinear problem is written as :

$$\mathbf{M}_m \ddot{\mathbf{u}} + \mathbf{K}_m \mathbf{u} + \mathbf{f}_{nl} + \sum_{p=1}^P [\mathbf{f}_c^{(p)} + \mathbf{P}_c^{(p)} \mathbf{u}] V^{(p)} = \mathbf{0}, \quad (1a)$$

$$\mathbf{C}^{(p)} V^{(p)} - [\mathbf{f}_c^{(p)} + \frac{1}{2} \mathbf{P}_c^{(p)} \mathbf{u}]^T \mathbf{u} = \mathcal{Q}^{(p)}. \quad (1b)$$

where \mathbf{K}_m , \mathbf{M}_m , \mathbf{u} and \mathbf{f}_{nl} denote respectively the mechanical stiffness and mass matrices, and the mechanical displacements and the geometrically nonlinear internal force vectors. $V^{(p)}$, $\mathbf{C}^{(p)}$ and $\mathcal{Q}^{(p)}$ are the voltage, the electrical capacitance and the electrical charge contained in one of the electrodes of the p^{th} patch. Finally, $\mathbf{f}_c^{(p)}$ and $\mathbf{P}_c^{(p)}$ denote the electromechanical forcing vector and the electromechanical coupling matrix related to geometric nonlinearities.

The expansion basis consists of N_m mechanical linear eigenmodes Φ_k :

$$\mathbf{u}(t) = \sum_{k=1}^K \Phi_k q_k(t). \quad (2)$$

where $q_k(t)$ is the k -th. unknown modal coordinate. The eigenmodes are solutions of:

$$(\mathbf{K} - \omega_k^2 \mathbf{M}) \Phi_k = \mathbf{0}. \quad (3)$$

Multiplying Eq.(1) by a linear mode Φ_k^T yields the following system of coupled oscillators :

$$\ddot{q}_k(t) + \omega_k^2 q_k(t) + \sum_{i=1}^K \sum_{j=1}^K a_{ij}^k q_i q_j + \sum_{i=1}^K \sum_{j=1}^K \sum_{l=1}^K b_{ijl}^k q_i q_j q_l + \sum_{p=1}^P \chi_k^{(p)} V^{(p)} + \sum_{p=1}^P \sum_{i=1}^K \Theta_{ik}^{(p)} q_i V^{(p)} = 0, \quad (4a)$$

$$\mathbf{C}^{(p)} V^{(p)} - \sum_{k=1}^K \chi_k^{(p)} q_k + \sum_{i=1}^K \sum_{j=1}^K \frac{1}{2} \Theta_{ij}^{(p)} q_i q_j = \mathcal{Q}^{(p)}, \quad (4b)$$

The nonlinear stiffnesses a_{ij}^k , b_{ijl}^k , and electromechanical linear and nonlinear coupling coefficients $\chi_k^{(p)}$ and $\Theta_{ij}^{(p)}$ characterize the nonlinear system. In order to compute nonlinear responses with this reduced order model, these coefficients must be estimated at an initial stage. In the next paragraph, they constitute the unknowns of the problem.

2.2 Estimation of the ROM coefficients

2.2.1 Presentation of the non-intrusive approach

The system of equations (4) gives the possibility to study separately the purely mechanical geometrically nonlinear (NL) effects, the linear electromechanical (EM) coupling and finally the electromechanical nonlinear coupling (EM-NL).

Following this partition of the different effects, an original approach proposes to compute these coefficients in three successive steps :

(i) the identification of the nonlinear stiffness coefficients by solving a set of geometrically nonlinear problems. In this case, there is no electrical equation and the expanded system writes

$$\ddot{q}_k + \omega_k^2 q_k + \sum_{i=1}^K \sum_{j=i}^K a_{ij}^k q_i q_j + \sum_{i=1}^K \sum_{j=i}^K \sum_{l=j}^K b_{ijl}^k q_i q_j q_l = F_k. \quad (5)$$

A family of non-intrusive methods initially proposed in [7] enables to estimate the nonlinear coefficients a_{ij}^k and b_{ijl}^k by prescribing static displacement fields as linear combination of eigenmodes, and computing the resulting internal forces.

(ii) the estimation of the linear coefficients $\chi_k^{(p)}$. The new approach proposed here consists in imposing the static displacement fields with short-circuited piezoelectric patches, as combinations of eigenmodes, and computing the resulting electric charge on the electrodes of the piezoelectric patches. In the linear case, the linear terms of the electrical equation (6) are computed :

$$-\sum_{k=1}^K \chi_k^{(p)} q_k = Q^{(p)}. \quad (6)$$

This method allows to estimate the linear coefficients $\chi_k^{(p)}$ of all patches p of a given vibration mode k .

(iii) Finally, the previous procedure generalized to a geometrically nonlinear problem leads to :

$$-\sum_{k=1}^K \chi_k^{(p)} q_k + \sum_{i=1}^K \sum_{j=1}^K \frac{1}{2} \Theta_{ij}^{(p)} q_i q_j = Q^{(p)}. \quad (7)$$

Just as in the case of the coefficients a_{ij}^k and b_{ijl}^k , the coefficients $\Theta_{ij}^{(p)}$ can be computed by prescribing as many static loads than coefficients $\Theta_{ij}^{(p)}$ contained in the ROM.

When the ROM has been built, the resulting nonlinear system can be solved thanks to a asymptotic numerical method associated with a harmonic balance method, which allows to equally compute the forced as well as the free response of the plane structures [9]. The interested reader can refer to [8] for a detailed procedure and a validation of the computation of the mechanical nonlinear coefficients a_{ij}^k and b_{ijl}^k , which includes also the computations of the nonlinear free and forced response computed from

the ROMs of mechanical structures. Note that in order to estimate all the coefficients of the ROM with this non-intrusive approach, the finite element code used for the computations must possess for a same computation electromechanical and geometrically nonlinear abilities. In our case the 3D finite element formulation of Abaqus is used. The validation stage of only the electromechanical linear coefficients is presented in detail in this article. The validation stage of the computation of the EM-NL coefficients $\Theta_{ij}^{(p)}$ is still under progress at the present time.

2.2.2 Case study: estimation of the linear electro-mechanical coefficients $\chi_k^{(p)}$

The validation of the linear EM coefficients is performed on a bi-layered beam shown on the figure 1, and made on an elastic material and a piezoelectric material. The validation step founds on a comparison with an analytical model with an Euler-Bernoulli kinematics, presented in [10]. The dimensions and material properties used for the numerical model are presented in the Tab. 1: the isotropic elastic material is characterized with a Young Modulus Y_e and a Poisson's ratio ν_e , whereas the transversely isotropic piezoelectric material requires more coefficients, the values assigned here are deduced from a piezoelectric constitutive law and values of the provider PI Ceramic available in the public domain [11]. The finite element model consists of 30 elements in the length of the beam, 4 elements in the width, and 3 and 2 elements in the thicknesses, respectively of the elastic and piezoelectric layers. 20-noded cubic elements are used in this model.

Table 1: Set of the parameters of the beam test case. In order of appearance: elastic constants and densities of the elastic (e) and piezoelectric (p) layers, dimensions, piezoelectric and dielectric coefficients.

To validate the coefficients, the EM coupling factor is written on an dimensionless form defined by:

$$k_{\text{mod},k} = \frac{\chi_k}{\omega_{k,\text{sc}}\sqrt{C}}, \quad (8)$$

known as the Modal ElectroMechanical Coupling Factor (MEMCF) [12]. In this equation, $\omega_{k,\text{sc}}$ denotes the k^{th} eigenpulsation of the short-circuited system, and C refers to the capacitance of the patch. The physical interpretation of the MEMCF is that it measures the energy that can be exchanged between the coupled electrical circuit and the mechanical structure in a given modal motion. It is often considered as equal to Efficient ElectroMechanical Coupling Factor (EEMCF), which is computed from the following expression [12, 13]:

$$k_{\text{eff},k} = \sqrt{\frac{\omega_{k,\text{oc}}^2 - \omega_{k,\text{sc}}^2}{\omega_{k,\text{sc}}^2}} \quad (9)$$

where $\omega_{k,\text{oc}}^2$ is the eigenpulsation of the open-circuited system. The comparison between numerical and analytical values of the MEMCF and the computed values of the EEMCC obtained with the finite element modesl are plot in the Tab. 2. The values of the numerical MEMCF are validated by comparison with

Table 2: Comparison of the numerical and analytic computations of short-circuited pulsations and modal electro-mechanical coupling factor. The Effective EMCF is also presented.

analytical ones. The EEMCF slightly overestimates the coupling. It can be explained by the assumption of modal truncation, which is necessary to compute the EEMCF [12]. More details on the models and computations are needed to explain the small difference between analytical and numerical MEMCF: it can be due to the numerical approximation, or because of the assumptions on the kinematics or the electric field in the analytic model.

3 EXPERIMENTAL INVESTIGATION

An elastic circular plate made of brass and equipped with eight piezoelectric patches, has been considered for these experiments. The piezoelectric material is the PIC151, the patches are equally spaced and placed along an inner circonference, following the configuration presented on the figure 2. Three holes of small radius are equally spaced near the outer edge of the structure to hang up the plate with nylon threads and thus to set up experimental free boundary conditions. This plate has been built by gluing the piezoelectric patches to the elastic plate: preliminary capacitance measurements verified that the layer of glue is sufficiently thin in order that the electric potential at the lower electrode of all patches equals to the potential of the plate. Consequently, the voltage applied to the patches is imposed by connecting the electric ground to the lower electrode of only one patch, and imposing the potential at the upper electrodes of the other patches. An experimental continuation procedure detailed in [14] is performed, which

Figure 2: Characteristics of the piezoelectric circular plate: overview, shape of the first eigenmode computed from a finite element model and dimensions of the plate and piezoelectric patches.

enables to measure the equivalent of the free response as well as the forced responses of the system. The principle is founded on the adjustment of the excitation frequency of the forcing signal, in order to control the phase lag between the forcing and the output response, which can be controlled in real-time. This procedure consists of three blocks: first a phase detector estimates the phase lag between the forcing and the response signals thanks to a synchronous demodulation. Secondly, a controller corrects the frequency excitation compared with the initial one. Finally, the adjusted frequency is used as the input of a Voltage Control Oscillator which generates the excitation signal. These three main steps are computed in a Simulink scheme and performed in real-time via a MicroLabBox dSPACE, with a frequency step fixed at 50 kHz. High values of the integral and proportional gains are used for the experimental continuation, in order to avoid the instability regions of the control system in closed-loop case. It has been shown that for mechanical systems the equivalent of free undamped responses - called also *backbone curves* or nonlinear modes - can be measured by locking the phase at $\phi = \pi/2$ between the displacement and the excitation, and by increasing the forcing. Moreover the forced responses are measured by imposing a phase variation from $\phi = 0$ to $\phi = \pi$ between the excitation and the displacement signals, and by keeping the excitation amplitude constant.

3.1 Experimental set-up

The figure 3 shows the experimental set-up to investigate the dynamical and nonlinear behavior of the free circular plate with piezoelectric actuation and detection. The vibrating circular plate (a) and the PLL performed via the dSpace MicroLabBox (c) are the main blocks of the set-up. By electromechanical coupling, the piezoelectric patches can generate a voltage with potentially high amplitude values. Since the dSpace can not support input voltage bigger than 10 V, the input signals are attenuated thanks to two resistances connected in serie (b): in these experiments the values of the two resistances are chosen at $R_1 = 680 \text{ k}\Omega$ and $R_2 = 10 \text{ k}\Omega$, thus the input signals $V_m = \frac{R_2}{R_1 + R_2} V_{in}$ are attenuated with a gain close to 69. Since the dSpace changes the excitation signals V_{exc} with potential discontinuities in amplitude and frequency, a low-pass filter (d) is applied to these signals in output of the dSpace. This filter consists in a RC-circuit with a resistance value fixed at $R_{lp} = 750 \text{ }\Omega$ and a capacitor $C_{lp} = 69 \text{ nF}$, such that the cut-off frequency $f_{lp} = \frac{1}{2\pi R_{lp} C_{lp}} \approx 3 \text{ kHz}$ of the filter is larger than the frequency of interest.

Figure 3: Experimental set-up: the upper part shows the main steps of the global loop, with (a) the circular plate, (b) the attenuators of input signals V_{in} measured at piezoelectric patches, (c) the Phase-Locking Loop (PLL), (d) the low-pass filter of the excitation signal V_{exc} and (e) the amplification.

Finally, a power amplifier (e) PZD700A-M/S dedicated to piezoelectric actuation enables to amplify the filtered excitation signal V_{lp} to inject in the piezoelectric patches a voltage V_p with a maximum amplitude value at 700 V. A preliminary modal analysis has been performed from velocity measurements measured and processed thanks to a scanning laser vibrometer and its software environment.

3.2 Case of an axisymmetric mode

Figure 4: Operational shapes of the plate at frequencies of the (0,1) mode and connection of the patches for the excitation (e) and measurements (m).

The configuration around the first axisymmetric mode of the circular plate is studied: the modal analysis identified the frequency of this mode at $f_{01} = 212.2 \text{ Hz}$. The notation (01) means that the mode shape presents no nodal diameter and one nodal circle, as shown on the operational shape of the figure 4. The application of the procedure described in section verifies that the linear EM coupling coefficients of the eight patches are theoretically equal. Thus this configuration can equally be studied by forcing and measuring with any configuration of patches.

Figure 5: Amplitudes and phases of the measured voltage V_m during an amplitude sweep (Backbone) and phase sweeps (Forced) at different electric excitation levels V_p .

In the present case, the patch 1 is used for the excitation whereas patch 8 is connected for the measurements. The curves in amplitude (on the Fig. 4 - left) presented on the figure 5 show that the forced responses at different excitation levels lie around the backbone curve (undamped free response, in black), with a main hardening effect, indeed the frequency increases with the amplitude. A very slight softening effect is noticeable at the low amplitudes of the free response, which could be explained by the effects of material nonlinearities. The phase differences (on the Fig. 4 - right) are increasing from 0 to π , which is consistent with the command applied to the system.

3.3 Case of a pair of asymmetric modes: 1:1 internal resonance

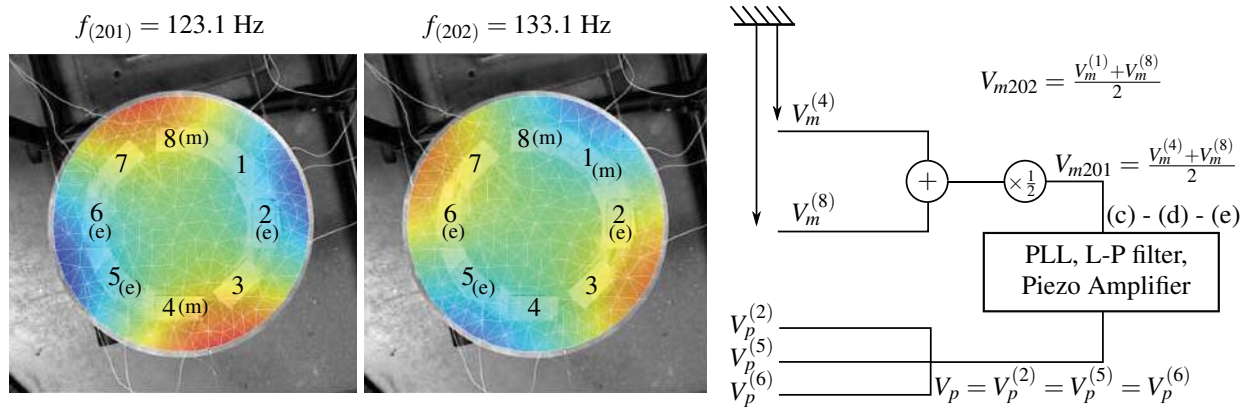

Figure 6: Operational shapes of the plate at frequencies of the (0,1) mode and connection of the patches for the excitation (e) and measurements (m).

The two first mode of the circular plate are companion modes of similar shapes: they have both two nodal diameters and no nodal circle. The two configurations present a spatial dephasing with their nodal diameters, in accordance with the Fig. 6 -. They theoretically have the same frequencies, which differ in experimental conditions because of unavoidable imperfections of the structure. They are referred to as (2,0,1) and (2,0,2) modes where the last indice denotes the lower (indice 1) and upper (indice 2) frequency. In order to observe energy exchange between two preferential configurations, magnets are placed as additional lests on the anti-nodes of the (2,0,2) mode to reduce its frequency and bring it nearer from the frequency of the (2,0,1) mode: in this case the frequency has been reduced from 133.1 Hz to $f_{202} = 125.9$ Hz. With the present disposition of the mode shapes, the nodal diameter are placed between the patch. Thus linear EM coupling coefficients are either quasi-equal, or quasi-opposed for each of the two companion modes. To capture the modal components of the two configurations, the averages between two pairs of patches are computed in real-time, one for each of the configuration: the voltage at patch 4 and 8 are added for the (2,0,1) mode, whereas the sum of the voltage at the patch 1 and 8 is computed for the (2,0,2) mode. The gains of the input voltage of the PLL are adjusted at low amplitudes such that the signals are perfectly either equal, or perfectly opposed. Three patches are connected in parallel for the excitation - at patches 2, 5 and 6 - to force effeciently the (2,0,1) configuration.

The figure 7 shows the amplitude responses of the average voltage V_{m201} : as for the (0,1) mode, the forced responses lie around the backbone curve, with a hardening behavior, and a slight softening behavior at low amplitudes which could be due to material nonlinearities. At the right hand side of the resonances, some forced responses make appear a discontinuity or a secondary resonance curve which could be explained by the influence of a possible interaction with the (2,0,2) mode.

Figure 7: Amplitudes of the measured output voltage V_{m1} during an amplitude sweep (Backbone) and phase sweeps at different electric excitation levels V_p .

To ensure this point, the amplitude and phase of only one forced response at the V_{m201} and V_{m202} measurement signals are presented on the figure 8: the amplitude responses highlights the emergence of a second resonance in the V_{m202} which was not noticeable on the voltage V_{m201} . When the amplitude of this last one continues to increase, with a slight change of curvature when the resonance in the V_{m202} was activated. Moreover, this resonance curve lies around the free response measured at the V_{m202} signal. The activation of the second resonance is partially confirmed on the phase response curves (Fig. 8 - left),

Figure 8: Amplitudes and phases of the measured voltage V_{m1} and V_{m2} corresponding to the modes $(2,0,1)$ and $(2,0,2)$ during an amplitude sweep (Backbone) and a phase sweep (Forced) at constant excitation level $V_p = 240$ V.

indeed the phase follows a path which decreases with a detuning with the phase of the V_{m201} signal, and reaches a maximum in frequency when the signal is in phase with the excitation.

4 CONCLUSIONS

This paper presented an original procedure to compute the nonlinear dynamical responses of systems with an electromechanical coupling and a piezoelectric device for the actuation and detection. Different approaches are proposed to validate the numerical computations : analytical models are used to validate the finite element ROMs at the coefficient's level, and an experimental procedure to measure the nonlinear free and forced responses on a laminated piezoelectric structure has been set up. To complete the validation process, the perspectives include the computation of the last family of coefficients of the ROM and the comparison of the computed responses with the experimental results. The approach could then be applied to a large range of application.

Key words: Ferroelectric Materials, Polarization, Finite Deformation, Smart Structures

Abstract. Smart materials respond to external stimuli as, e.g., electric fields, which enables their usage as actuators and, possibly, also as sensors. The electromechanical coupling of the direct and converse piezoelectric effects, for instance, is used for both actuation and sensing in diverse engineering applications. The response of ferroelectric materials depends on their state of remanent polarization and the presence of an external electric field. To extend the operational range of sensors and actuators, an accurate understanding of the evolution of the material's state of polarization is required, which requires both physical and geometrical non-linearities to be taken into account. Moreover, polymeric materials as PVDF allow significantly larger deformation as compared to conventional piezoelectric ceramics. The electro-mechanical coupling in piezoelectric materials manifests in ferroelectric and ferroelastic hystereses, which are related to both reversible and irreversible processes. Focusing on the latter, we transfer phenomenological models for domain switching in ferroelectric materials to the geometrically non-linear regime. For this purpose, we follow related concepts of geometrically non-linear elastoplasticity, where the concept of a multiplicative decomposition of the deformation gradient plays a key role. Accordingly, an additional deformation path that describes the evolution of the poled state from the unpoled referential configuration is introduced. The constitutive response of the material to mechanical and electrical loads is discussed and dissipative internal forces that drive the evolution of the remanent polarization are derived within a thermodynamical framework and the principle of maximum dissipation.

1 INTRODUCTION

Ferroelectric materials have been adopted as sensors and actuators in diverse fields of applications, which range from microelectromechanical systems (MEMS) for high-precision positioning to vibrational and structural noise control. Typically, ferroelectric ceramics as, e.g., PZT, are used due to their comparatively high coupling coefficients. These polycrystalline ceramics are characterized by a relatively

high brittleness, which is why they do not admit large strains. For this reason, their constitutive models are usually formulated within the range of small (linearized) strains, which gives Voigt's linearized theory of piezoelectricity for the reversible response, see, e.g., [1, 13]. The response of ferroelectric materials is intrinsically related to their state of remanent polarization, which is assumed to be constant for most applications. Electro-mechanical loadings beyond so-called coercive electric fields or coercive stresses, however, induce an irreversible re-orientation of dipoles in the material and therefore a change of the remanent polarization [3]. These mechanisms are referred to as "switching" and result in ferroelectric and ferroelastic hystereses. The mathematical modeling and the computational approximation of switching phenomena in ferroelectric materials shares many aspects with well-established approaches in elasto-plasticity, see, e.g., [4].

Unlike ceramic materials, ferroelectric polymers as, e.g., PVDF, can be subjected to comparatively large strains well beyond the linear range. Based on the modeling of the reversible electro-mechanically coupled response presented in [2], we propose a first attempt towards the continuum modeling of the ferroelectric hysteresis in the geometrically non-linear range of deformation. For this purpose, we repeatedly adopt the concept of a multiplicative decomposition of the deformation gradient, which has successfully been applied to the modeling of inelastic processes, see [6] for an overview. The idea of multiple multiplicative decompositions is discussed in [8]. In the present approach, the deformation gradient is decomposed into three parts: the irreversible part governs the evolution of a poled (intermediate) configuration from the unpoled reference configuration. The second part describes the reversible local response of a poled volume element subjected to an electric field, which deforms into a second intermediate configuration, which can be regarded as de-stressed, i.e., the current configuration is relieved from stresses. Third part accounts for the mechanical stress response of the material. The modeling of the dissipative response follows the concepts of finite strain elasto-plasticity [10, 11, 12], where ideas of damage modeling are included to incorporate changes of the material parameters due to poling [5]. The evolution equation for the dissipative internal forces follow as an associative flow rule from the constrained optimization problem that is obtained from the principle of maximum dissipation [10, 9]. In our first approach, we want to restrict ourselves to the ferroelectric hysteresis, i.e., the mechanisms of mechanical depolarization are not accounted for.

2 BALANCE EQUATIONS OF NON-LINEAR ELECTRO-MECHANICS

We start our considerations recalling fundamental ideas of reversible electro-mechanics, in which no changes of the state of remanent polarization takes place. In the quasi-static case, the local balance of linear momentum gives the spatial representation of the equilibrium relation as

$$\operatorname{div} \boldsymbol{\sigma} + \mathbf{f} + \mathbf{f}^E = \mathbf{0}, \quad \mathbf{f}^E = (\operatorname{grad} \mathbf{e}) \cdot \mathbf{p} = \operatorname{div} \boldsymbol{\sigma}^E. \quad (1)$$

The Cauchy stress tensor is denoted by $\boldsymbol{\sigma}$, and \mathbf{f} are mechanical body forces; \mathbf{e} and \mathbf{p} denote the electric field and the polarization vector, respectively. A dielectric material body that is subjected to an electric field experiences additional body forces \mathbf{f}^E , which can be represented by means of the divergence of the electrostatic stress tensor $\boldsymbol{\sigma}^E$. The balance of angular momentum yields the symmetry of the sum of the Cauchy stresses and the polarization stresses $\boldsymbol{\sigma}^P$

$$\boldsymbol{\sigma} + \boldsymbol{\sigma}^P = (\boldsymbol{\sigma} + \boldsymbol{\sigma}^P)^T, \quad \boldsymbol{\sigma}^P = \mathbf{e} \mathbf{p}. \quad (2)$$

We obtain the total (Cauchy) stress tensor as the sum of the (mechanical) Cauchy stress and the (non-symmetric) electrostatic stress tensor,

$$\boldsymbol{\sigma}^{\text{tot}} = \boldsymbol{\sigma} + \boldsymbol{\sigma}^E, \quad \boldsymbol{\sigma}^E = \mathbf{e} \mathbf{d} - \frac{1}{2} \epsilon_0 (\mathbf{e} \cdot \mathbf{e}) \mathbf{I}, \quad (3)$$

where \mathbf{d} denotes the dielectric displacement. The dielectric displacement is related to the electric field and the polarization \mathbf{p} through

$$\mathbf{d} = \epsilon_0 \mathbf{e} + \mathbf{p}. \quad (4)$$

We note that the (mechanical) Cauchy stress tensor is not symmetric due to electrostatic couples induced in a dielectric body. We further observe that the definition of the electrostatic stress tensor is not unique since any divergence-free tensor can be added without changing the electrostatic body forces \mathbf{f}^E . The electrostatic stress tensor, in turn, can be represented as the sum of polarization stress σ^P and the Maxwell stress tensor σ^M

$$\sigma^M = \sigma^E - \sigma^P = \mathbf{e}\mathbf{e} - \frac{1}{2} \epsilon_0 (\mathbf{e} \cdot \mathbf{e}) \mathbf{I}. \quad (5)$$

From Maxwell's equations, we have Gauss' law of conservation of charge, which reduces to

$$\operatorname{div} \mathbf{d} = 0, \quad (6)$$

for the case of dielectric materials, for which the free charge density vanishes. The quasi-static form of Faraday's law of induction yields

$$\operatorname{curl} \mathbf{e} = \mathbf{0} \quad \Leftrightarrow \quad \mathbf{e} = -\operatorname{grad} \phi, \quad (7)$$

where ϕ denotes the electric potential. The electro-mechanical power density (per unit volume in the current configuration) p is immediately related to the rate of the specific free energy ψ , for which the local form of the balance equation reads

$$p = \rho \dot{\psi} = \sigma : \operatorname{grad} \mathbf{v} - \mathbf{p} \cdot \dot{\mathbf{e}}. \quad (8)$$

The velocity field is denoted by \mathbf{v} ; ρ is the mass density per unit (current) volume. The spatial velocity gradient can be expressed in terms of the (material) deformation gradient tensor \mathbf{F} as $\operatorname{grad} \mathbf{v} = \dot{\mathbf{F}} \cdot \mathbf{F}^{-1}$.

Note that the current configuration is the natural configuration in problems of electrostatics, in which a deformation of the material is neglected. On the other hand, we often prefer to relate mechanical quantities to the known referential state of the body rather than the unknown current configuration which may significantly deviate from the referential state in general. Material quantities associated with the reference configuration and their spatial counterparts associated with the current configuration are related by push-back and pull-forward operations, see, e.g., [7]. We can introduce material fields corresponding to the electric quantities. The respective pull-back operations are defined by the nature of the global balance equations, see, e.g., [13], which preserves the structure of the local balance laws. The Piola transformation is used for the dielectric displacement and the polarization. The electric field is pulled back using the deformation gradient, which relates and material gradients. In what follows, we stick with the spatial formulation for the sake of brevity.

To determine the constitutive equations for the total stresses and the dielectric displacement, the free energy is augmented by the vacuum contribution

$$\psi^{\text{tot}} = \psi + \psi^{\text{aug}}, \quad \psi^{\text{aug}} = -\frac{\epsilon_0}{\rho} \mathbf{e} \cdot \mathbf{e}. \quad (9)$$

By direct computation, we can show that the total electro-mechanical power follows to

$$p^{\text{tot}} = \rho \dot{\psi}^{\text{aug}} = \sigma^{\text{tot}} : \mathbf{d} - \mathbf{d} \cdot \dot{\mathbf{e}}, \quad (10)$$

where \mathbf{d} denotes the symmetric part of the spatial velocity gradient, i.e., $\text{grad } \mathbf{v} = \mathbf{d} + \mathbf{w}$, with

$$\mathbf{d} = (\dot{\mathbf{F}} \cdot \mathbf{F}^{-1})_s = \frac{1}{2} \left(\dot{\mathbf{F}} \cdot \mathbf{F}^{-1} + \mathbf{F}^{-T} \cdot \dot{\mathbf{F}}^T \right), \quad \mathbf{w} = (\dot{\mathbf{F}} \cdot \mathbf{F}^{-1})_a = \frac{1}{2} \left(\dot{\mathbf{F}} \cdot \mathbf{F}^{-1} - \mathbf{F}^{-T} \cdot \dot{\mathbf{F}}^T \right). \quad (11)$$

Comparing the balance law (10) with the rate of the augmented free energy $\dot{\psi}^{\text{tot}} = \dot{\psi}^{\text{tot}}(\mathbf{F}, \mathbf{e})$,

$$\dot{\psi}^{\text{tot}} = \frac{\partial \psi^{\text{tot}}}{\partial \mathbf{F}} : \dot{\mathbf{F}} + \frac{\partial \psi^{\text{tot}}}{\partial \mathbf{e}} \cdot \dot{\mathbf{e}}, \quad (12)$$

we can identify the constitutive relations as

$$\boldsymbol{\sigma}^{\text{tot}} = \rho \frac{\partial \psi^{\text{tot}}}{\partial \mathbf{F}} \cdot \mathbf{F}^T, \quad \mathbf{d} = -\rho \frac{\partial \psi^{\text{tot}}}{\partial \mathbf{e}}. \quad (13)$$

Well aware of the abuse of notation, we omit all superscripts “tot” in what follows, since we only use total stresses and the dielectric displacement as primary dependent variables subsequently.

Next, we consider the constitutive equation for the case of a dissipative response that occurs once we admit the state of remanent polarization to change. We adopt the concept of internal variables to describe the dissipative response of the material. In the simplest case, the remanent polarization itself plays the role of an internal variable. We then assume the free energy to additionally depend on the remanent polarization, i.e.,

$$\psi = \psi(\mathbf{F}, \mathbf{e}, \mathbf{p}_i), \quad \dot{\psi} = \frac{\partial \psi}{\partial \mathbf{F}} : \dot{\mathbf{F}} + \frac{\partial \psi}{\partial \mathbf{e}} \cdot \dot{\mathbf{e}} + \frac{\partial \psi}{\partial \mathbf{p}_i} \cdot \dot{\mathbf{p}}_i. \quad (14)$$

The dissipation density d (per unit current volume) is introduced in (10),

$$p = \rho \dot{\psi} + d. \quad (15)$$

The second law of thermodynamics requires the energy that is dissipated into heat to be positive, i.e.,

$$d = p - \rho \dot{\psi} \geq 0. \quad (16)$$

For a given electro-mechanical power $p = \boldsymbol{\sigma} : \mathbf{d} - \mathbf{d} \cdot \dot{\mathbf{e}}$, we obtain the relation

$$d = \left(\boldsymbol{\sigma} - \rho \frac{\partial \psi}{\partial \mathbf{F}} \cdot \mathbf{F}^T \right) : \mathbf{d} - \left(\mathbf{d} - \rho \frac{\partial \psi}{\partial \mathbf{e}} \right) \cdot \dot{\mathbf{e}} - \rho \frac{\partial \psi}{\partial \mathbf{p}_i} \cdot \dot{\mathbf{p}}_i \geq 0. \quad (17)$$

With the stresses and the dielectric displacement being defined as in the reversible case (13), the dissipation follows to

$$d = \mathbf{f}_i \cdot \dot{\mathbf{p}}_i \geq 0, \quad \mathbf{f}_i = -\rho \frac{\partial \psi}{\partial \mathbf{p}_i}, \quad (18)$$

where \mathbf{f}_i denotes the internal forces conjugate to the remanent polarization \mathbf{p}_i , which can be regarded as dissipative driving forces.

3 MULTIPLICATIVE DECOMPOSITION

To begin with, we briefly recall the underlying physical processes and the phenomena observed when a ferroelectric material is irreversibly polarized. A polarizable material is characterized by the presence of microscopic structures (unit cells) that possess a spontaneous polarization, i.e., the centers of positive and negative charges do not coincide and an electric dipole is formed. The unit cells may form so-called domains in which the spontaneous polarization of the unit cells is oriented in the same direction. Due to

the random orientation of dipoles/unit cells, the net polarization on the macroscopic level vanishes in the unpoled state. Ferroelectric materials can be polarized by exposing them to a sufficiently strong electric field. Beyond the so-called coercive field, the dipoles of the unit cells re-orient (“switching”) themselves along the applied field and maintain that orientation once the field is removed again, i.e., the process is irreversible and a hysteretic behavior is observed (ferroelectric hysteresis). From a mechanical point of view, we note the following phenomena that need to be accounted for by appropriate phenomenological models:

- A change of remanent polarization is accompanied by (irreversible) deformation due to the rotation of the dipoles. The poling induced deformation is isochoric.
- Both the electrical and the mechanical response depend on the state of polarization. In fact, the piezoelectric effect is only present if a material is polarized. The poling process induces a principal direction along the poling direction in ferroelectric materials. Initially isotropic materials therefore exhibit a transversally isotropic behavior once they have been poled.
- A poled specimen can be irreversibly de-poled by sufficiently strong mechanical loadings that exceed the so-called coercive stress (ferroelastic hysteresis). In this case, the dipoles switch into the plane perpendicular to the applied force vector. Note that the mechanical de-polarization is not addressed in the present approach.

From a mechanical point of view, the polarization process bears a close resemblance to phenomenological models of elasto-plasticity, which is reflected in both the structure of the constitutive models and numerical methods used for the construction of approximate solutions. This observation is the starting point for our attempt to translate constitutive models from finite-strain plasticity to non-linear electro-elasticity.

If we leave the range of infinitesimal deformations, the conventional additive decomposition of stresses and strain measures into reversible and irreversible parts lacks a physical underpinning. For this purpose, we begin our considerations by multiplicatively splitting the deformation gradient \mathbf{F} into an irreversible part \mathbf{F}_i and a reversible part \mathbf{F}_r ,

$$\mathbf{F} = \mathbf{F}_r \cdot \mathbf{F}_i. \quad (19)$$

Such multiplicative decomposition introduces the notion of an intermediate configuration that enters the deformation path. The irreversible part of the deformation gradient \mathbf{F}_i describes the evolution of the poled intermediate configuration from the unpoled state of the material due to changes of the state of remanent polarization, whereas \mathbf{F}_r describes the response due to reversible processes induced by mechanical or electric loadings. Owing to the electro-mechanical coupling, the reversible response involves an inelastic electric part and an elastic mechanical part, for which we want to adopt a second multiplicative decomposition, i.e.,

$$\mathbf{F}_r = \mathbf{F}_{r,m} \cdot \mathbf{F}_{r,e}. \quad (20)$$

The electrical part \mathbf{F}_e governs the local response of a poled material due to the presence of an electric field. The current state of stress, in turn, is determined from the mechanical part \mathbf{F}_m . In the proposed model, the total deformation \mathbf{F} is consequently composed from three parts,

$$\mathbf{F} = \mathbf{F}_{r,m} \cdot \mathbf{F}_{r,e} \cdot \mathbf{F}_i, \quad (21)$$

hence, a second intermediate configuration is introduced into the deformation path.

In the constitutive modeling, we assume that the free energy is split into three parts that are associated with the individual paths related to three components of the deformation gradient:

$$\psi = \psi_e + \psi_{r,m} = \psi_i + \psi_r, \quad \psi_e = \psi_i + \psi_{r,e}, \quad \psi_r = \psi_{r,e} + \psi_{r,m}. \quad (22)$$

The stress response is governed by the (reversible) mechanical part of the free energy $\psi_{r,m}$, which is associated with the deformation path from the second intermediate configuration to current configuration. The (second) intermediate configuration can be regarded as a configuration that is obtained from the current configuration upon de-stressing at a constant electric field. Note that de-stressing does not imply that the total stresses vanish in the intermediate configuration, see [2] for a discussion.

We can choose any suitable strain energy function of non-linear elasticity, as, e.g., a Neo-Hookean material or the physically linearized St. Venant-Kirchhoff law, where the right Cauchy-Green strain in the (second) intermediate configuration serves as Lagrangian deformation measure. As the material properties generally change in the course of poling, we also need to include a dependence on the remanent polarization \mathbf{p}_i . Following concepts proposed for the modeling of damage in large-strain plasticity [5], we can adopt the notion of a second-order structural tensor $\mathbf{a}(\mathbf{p}_i)$ to describe anisotropy induced by the poling process. Relating the structural tensor to the remanent polarization in the current configuration, we may define it as

$$\mathbf{a} = \frac{\|\mathbf{p}_i\|}{p_{\text{sat}}} \mathbf{n} \mathbf{n}, \quad \mathbf{n} = \frac{\mathbf{p}_i}{\|\mathbf{p}_i\|}, \quad (23)$$

where p_{sat} denotes the saturation polarization. Transversal isotropy can be described by augmenting the integrity basis by invariants of the structural tensor and mixed invariants of the structural tensor and the respective strain measure. The free energy of the mechanical part of the deformation gradient therefore can be introduced as a function of the corresponding right Cauchy-Green tensor \mathbf{C}_m and the structural tensor $\bar{\mathbf{a}}$, which is pulled back from the current configuration,

$$\psi_{r,m} = \psi_{r,m}(\mathbf{C}_m, \bar{\mathbf{a}}), \quad \bar{\mathbf{a}} = J_m^2 \mathbf{F}_{r,m}^{-1} \cdot \mathbf{a} \cdot \mathbf{F}_{r,m}^{-T}, \quad J_m = \det \mathbf{F}_{r,m}. \quad (24)$$

The (total) Cauchy stresses are obtained from the derivative of the mechanical pure energy with respect to \mathbf{C}_m upon a push-forward to the current configuration,

$$\boldsymbol{\sigma} = \rho \mathbf{F}_{r,m} \cdot \frac{\partial \psi_{r,m}}{\partial \mathbf{C}_m} \cdot \mathbf{F}_{r,m}^T + \rho \frac{\partial \psi_e}{\partial \mathbf{F}} \cdot \mathbf{F}^T, \quad (25)$$

where the dependence of the electrical parts on the deformation gradient is also regarded. We have introduced double over-bars to distinguish quantities that are related to the second intermediate configuration. We will use a single bar if quantities are related to the first intermediate configuration.

The reversible part of the electric deformation gradient $\mathbf{F}_{r,e}$ describes the evolution of the poled (first) intermediate configuration into the de-stressed (second) intermediate configuration in the presence of an electric field. For this reason, it is constitutively defined as a function of the electric field in the poled intermediate configuration, $\bar{\mathbf{e}} = \mathbf{e} \cdot \mathbf{F}_r = \boldsymbol{\mathcal{E}} \cdot \mathbf{F}_i^{-1}$, e.g., a series expansion of the form

$$\mathbf{F}_{r,e}(\bar{\mathbf{e}}, \bar{\mathbf{a}}) = \mathbf{I} + \bar{\mathbf{e}} \cdot {}^3\bar{\mathbf{d}}(\bar{\mathbf{a}}) + \bar{\mathbf{e}}\bar{\mathbf{e}} : {}^4\bar{\mathbf{b}}(\bar{\mathbf{a}}) + \dots, \quad (26)$$

where ${}^3\bar{\mathbf{d}}$ and ${}^4\bar{\mathbf{b}}$ represent coefficients describing piezoelectric and electrostrictive coupling, respectively. The reversible part of the electric free energy is related to the permittivity, which includes the vacuum contribution (9) and a term governed by the susceptibility χ of the material. For the present

choice of dependent variables, we have an additional term that couples the electric field and the remanent polarization,

$$\psi_{r,e} = \psi_{r,e}(\mathbf{e}, \mathbf{a}) = -\frac{1}{2} \rho^{-1} \mathbf{e} \cdot (\chi(\mathbf{a}) + \epsilon_0 \mathbf{I}) \cdot \mathbf{e} - \rho^{-1} \mathbf{e} \cdot \mathbf{p}_i. \quad (27)$$

If the irreversible part of the electric free energy ψ_i depends on the remanent polarization \mathbf{p}_i only, the constitutive relation for (spatial) dielectric displacement follows as

$$\mathbf{d} = -\rho \frac{\partial \psi_{r,e}}{\partial \mathbf{e}} + \rho \frac{\partial \psi_{r,m}}{\partial \mathbf{F}_{r,e}} : \frac{\partial \mathbf{F}_{r,e}}{\partial \mathbf{e}}, \quad (28)$$

where the mechanical part of the free energy generally depends on the electric field through the (reversible) electric part of the deformation gradient $\mathbf{F}_{r,e}$.

The evolution of the poled state from the unpoled, undeformed reference configuration is governed by the irreversible part of the deformation gradient \mathbf{F}_i , for which we have to provide a constitutive definition. As the deformation induced by the poling is typically isochoric, we may use a stretching type deformation with a saturation strain S_{sat} as proposed in [14]:

$$\mathbf{F}_i(\mathbf{p}_i) = \left(1 - \frac{3}{2} S_{\text{sat}} \frac{\|\mathbf{p}_i\|}{p_{\text{sat}}}\right)^{-2/3} \left\{ \left(1 - \frac{3}{2} S_{\text{sat}} \frac{\|\mathbf{p}_i\|}{p_{\text{sat}}}\right) \mathbf{I} + \frac{3}{2} S_{\text{sat}} \frac{\|\mathbf{p}_i\|}{p_{\text{sat}}} \mathbf{N} \mathbf{N} \right\}, \quad \mathbf{N} = \frac{\mathcal{P}_i}{\|\mathcal{P}_i\|}. \quad (29)$$

where the material polarization is defined as

$$\mathcal{P}_i = J \mathbf{p}_i \cdot \mathbf{F}^{-T}, \quad J = \det \mathbf{F}. \quad (30)$$

The poled (first) intermediate configuration can be regarded as a configuration that is stress-free and in which no (external) electric field is present. Due to the deformation induced by the poling, the intermediate configuration is incompatible in general. The corresponding part of the free energy ψ_i related to the poling process can exemplarily be assumed as quadratic function in the remanent polarization,

$$\psi_i = \psi_i(\mathbf{p}_i) = \frac{1}{2} (\rho J)^{-1} c \mathbf{p}_i \cdot \mathbf{p}_i, \quad (31)$$

where c denotes a kinematic hardening parameter. By introducing the (constant) density in the reference configuration $\rho_0 = \rho J$, we avoid a dependence on the deformation gradient \mathbf{F} , i.e., $\partial \psi_i / \partial \mathbf{F} = \mathbf{0}$. The dissipative internal forces conjugate to the remanent polarization are obtained from the individual parts of the free energy as

$$\mathbf{f}_i = -\rho \frac{\partial \psi_i}{\partial \mathbf{p}_i} - \rho \frac{\partial \psi_{r,e}}{\partial \mathbf{p}_i} - \rho \frac{\partial \psi_{r,m}}{\partial \mathbf{p}_i}. \quad (32)$$

Analogously to a rate-independent elasto-plastic response, we use the principle of maximum dissipation to derive the evolution equations of the remanent polarization. We expect the dissipation to assume a maximum, i.e., the dissipative forces \mathbf{f}_i are determined such such that

$$d = \sup_{\mathbf{f}_i \in \mathbb{E}} \mathbf{f}_i \cdot \dot{\mathbf{p}}_i, \quad (33)$$

where \mathbb{E} denotes the reversible domain, which is defined by a threshold (switching) function f ,

$$\mathbb{E} = \{ \mathbf{f}_i \in \mathbb{R}^3 \mid f(\mathbf{f}_i) \leq 0 \}. \quad (34)$$

For example, if we require the norm of the dissipative forces to be constrained from above by a so-called coercive field e_c , we can use the threshold function

$$f = \|\mathbf{f}_i\| - e_c \leq 0. \quad (35)$$

The constrained maximization problem can be solved using a Lagrange multiplier λ , i.e.,

$$d = \sup_{\mathbf{f}_i, \lambda \geq 0} (\mathbf{f}_i \cdot \mathbf{p}_i + \lambda f(\mathbf{f}_i)), \quad (36)$$

from which we obtain an “associative flow rule” that governs the evolution of the remanent polarization as the necessary condition

$$\dot{\mathbf{p}}_i = \lambda \frac{\partial f(\mathbf{f}_i)}{\partial \mathbf{f}_i}, \quad (37)$$

as well as the classical Kuhn-Tucker conditions for loading/unloading:

$$\lambda \geq 0, \quad f \leq 0, \quad \lambda f = 0. \quad (38)$$

Unlike plasticity, in which plastic strains can accumulate until a material eventually breaks, the remanent polarization saturates as the reservoir of switchable dipoles/domains is finite. Saturation can be accounted for, e.g., by means of a hardening parameter that depends on the (norm of the) remanent polarization, i.e., $c = c(\|\mathbf{p}_i\|/p_{\text{sat}})$.

4 CONCLUSION

In the present paper, we have discussed a constitutive framework for the modeling of both the reversible and the irreversible response of ferroelectric materials in the geometrically non-linear domain. Our approach is based on the concept of the multiplicative decomposition of the deformation gradient into three parts that are associated with the irreversible poling, the (local) electric response and the elastic stress response. The individual parts of the free energy are related to the respective configuration in the deformation path. The constitutive equations for the stresses, the dielectric displacement and the dissipative forces follow from standard arguments of thermodynamics. The evolution equation for the remanent polarization is obtained from the principle of maximum dissipation.

Abstract. In this paper a theoretical and computational framework are presented for analyzing the nonlinear electromechanical response of shallow doubly curved laminated shells with attached piezopolymer film sensors, undergoing elastic snap through instability and eventually a transition between at least two stable equilibrium paths. The computational framework is based on nonlinear mechanics, incorporating full coupling between mechanical and electric fields and encompassing geometric nonlinearity effects due to large displacements and rotations. The governing equations are formulated explicitly in orthogonal curvilinear coordinates and are combined with the kinematic assumptions of a multi-field shear-layerwise shell laminate theory. A finite element methodology is adopted to yield the discrete coupled nonlinear equations which are linearized and iteratively solved, using the Cylindrical Arc Length Method in combination with the Newton-Raphson iterative technique. Numerical results demonstrate the capability of the method to predict the complex sensory electromechanical response of shallow cylindrical shells that transit between two stable equilibrium states. At the same time the generated sensory electric potential, electric charge and the stored electric energy in the piezoelectric films during the nonlinear bistable loading and unloading paths is predicted. The feasibility to detect and monitor the onset of snap-through instability, and to enhance the electromechanical energy conversion efficiency of the system for improved energy dissipation/harvesting systems, is also investigated. The influence of shell thickness, curvature and laminate configuration on the electromechanical conversion is finally investigated

1 INTRODUCTION

Shallow shell structures under external transverse loads (mechanical pressure, point load) exhibit a complex nonlinear multi-stable behavior, manifested as instantaneous snap through

instability, which transits the shell between two stable equilibrium configurations, via an unstable equilibrium state, that is associated with large deflections and shape changes. Various mostly experimental studies have explored the active multi-stability of shell for developing morphing structures [1-8]. On the other hand, it is highly desirable to detect the onset of snap through instability, through the sensor signals that describe the local response of piezoelectric sensor patch and eventually the global structural response. Additionally, the nonlinear electromechanical conversion of the attached piezoelectric elements prior and during to the snap through instability associated with electric charge generation and stored electric energy for improving energy harvesting/dissipation systems must be thoroughly modelled and understood. The current work represents an extension of the previous authors work [6] for analyzing the snap through buckling instability of smart shell structures, with emphasis on the equation of electric charge conservation and electromechanical coupling. Building upon the nonlinear multifield mechanics an eight-node shell finite element is developed to yield the coupled nonlinear equations of motion in discrete form, which are subsequently linearized and solved, using the Cylindrical Arc Length Method in combination with the Newton-Raphson iterative method. Numerical results illustrate the capability of the present model to predict the complex sensory electromechanical response (electric potential, electric charge, electric energy) of multi-stable cylindrical smart shells, during the bistable loading and unloading paths. The feasibility of smart shells to detect the onset of snap through instability, via the monitoring of sensory voltages, as well as to enhance the electromechanical energy conversion efficiency is also investigated. The influence of geometric parameters (thickness, curvature) on the electromechanical conversion efficiency is finally quantified.

2 PIEZOELECTRIC LAMINATED SHALLOW SHELL

All governing equations for doubly curved piezoelectric laminated shells are described and derived on an orthogonal curvilinear coordinate system $O\xi\eta\zeta$ with ξ, η axes lying on reference mid-surface A_o , while ζ axis remains straight and perpendicular on A_o . The material of each ply of the piezoelectric laminate is assumed to remain within the range of linear piezoelectricity:

$$\begin{aligned}\sigma_i &= C_{ij}^E S_j - e_{ik} E_k & i, j &= 1, \dots, 6 \\ D_l &= e_{lj} S_j + \varepsilon_{lk}^S E_k & k, l &= 1, \dots, 3\end{aligned}\tag{1}$$

σ_i, S_i are the mechanical stresses and Green's engineering strains in extended vectorial notation, C_{ij} is the elastic stiffness tensor in structural coordinates, e_{ik} is the piezoelectric tensor, E_k is the electric field vector, D_l is the electric displacement vector and ε_{lk} is the electric permittivity tensor of the material. Superscripts E and S indicate constant electric field and strain conditions, respectively.

The theory combines linear displacement field with a linear layer-wise electric potential field consisting of $N-1$ discrete segments, thus representing all state variables through the piezo-laminate thickness. According to the previous kinematic assumptions, the mechanical strain and generalized electric field approximations through the laminate thickness are given below:

$$\begin{aligned}
S_1^o &= \left[\frac{1}{g_{11}^o} (u_{,\xi}^o + \frac{g_{11,\eta}^o}{g_{22}^o} v^o) + \frac{w^o}{R_1} \right] + \frac{\zeta}{g_{11}^o} [\beta_{\xi,\xi}^o + \frac{g_{11,\eta}^o}{g_{22}^o} \beta_\eta^o] + \frac{1}{2} \left[\frac{w^{o^2}}{R_1^2} + \frac{u^{o^2}}{R_1^2} + \frac{w_{,\xi}^{o^2}}{g_{11}^o} - 2 \frac{u^o w_{,\xi}^o}{R_1 g_{11}^o} \right] \\
S_2^o &= \left[\frac{1}{g_{22}^o} (v_{,\eta}^o + \frac{g_{22,\xi}^o}{g_{11}^o} u^o) + \frac{w^o}{R_2} \right] + \frac{\zeta}{g_{22}^o} [\beta_{\eta,\eta}^o + \frac{g_{22,\xi}^o}{g_{11}^o} \beta_\xi^o] + \frac{1}{2} \left[\frac{w^{o^2}}{R_2^2} + \frac{v^{o^2}}{R_2^2} + \frac{w_{,\eta}^{o^2}}{g_{22}^o} - 2 \frac{v^o w_{,\eta}^o}{R_2 g_{22}^o} \right] \\
S_3^o &= 0 \\
S_6^o &= \left[\frac{1}{g_{11}^o} (v_{,\xi}^o - \frac{g_{11,\eta}^o}{g_{22}^o} u^o) + \frac{1}{g_{22}^o} (u_{,\eta}^o - \frac{g_{22,\xi}^o}{g_{11}^o} v^o) \right] + \\
&\quad \left[\frac{\zeta}{g_{11}^o} (\beta_{\eta,\xi}^o - \frac{g_{11,\eta}^o}{g_{22}^o} \beta_\xi^o) + \frac{\zeta}{g_{22}^o} (\beta_{\xi,\eta}^o - \frac{g_{22,\xi}^o}{g_{11}^o} \beta_\eta^o) \right] + \left[\frac{w_{,\xi}^o w_{,\eta}^o}{g_{11}^o g_{22}^o} + \frac{u^o v^o}{R_1 R_2} - \frac{u^o w_{,\eta}^o}{R_1 g_{22}^o} - \frac{v^o w_{,\xi}^o}{R_2 g_{11}^o} \right] \\
S_4^o &= \beta_\eta^o + \frac{w_{,\eta}^o}{g_{22}^o} - \frac{v^o}{R_2} \\
S_5^o &= \beta_\xi^o + \frac{w_{,\xi}^o}{g_{11}^o} - \frac{u^o}{R_1}
\end{aligned}$$

$$\begin{aligned}
E_1(\xi, \eta, \zeta, t) &= \sum_{m=1}^N -\frac{1}{g_{11}^o} (\Phi_{,\xi}^{m+1}(\xi, \eta) \Psi^{m+1}(\zeta) + \Phi_{,\xi}^m(\xi, \eta) \Psi^m(\zeta)) \\
E_2(\xi, \eta, \zeta, t) &= \sum_{m=1}^N -\frac{1}{g_{22}^o} (\Phi_{,\eta}^{m+1}(\xi, \eta) \Psi^{m+1}(\zeta) + \Phi_{,\eta}^m(\xi, \eta) \Psi^m(\zeta)) \\
E_3(\xi, \eta, \zeta, t) &= \sum_{m=1}^N -(\Phi^{m+1}(\xi, \eta) - \Phi^m(\xi, \eta)) / h_m
\end{aligned} \tag{2}$$

where in Eqs. (2) the in-plane strains consist of both linear and nonlinear strains while the out of plane strains consist only of linear terms; $h_m = \zeta_{m+1} - \zeta_m$ is the thickness of the layer within a piezoelectric layer, Φ^{m+1} and Φ^m denote the electric potentials at the corresponding thickness points, respectively. Using the divergence theorem, neglecting both the inertia effects and the free body charge density, and integrating through the piezolaminate thickness, the stress equilibrium and electric charge conservation can be obtained over the whole piezolaminated medium by the following variational form:

$$\begin{aligned}
\delta \mathbf{u}^T \Psi_u &= - \int_V \delta \mathbf{S}^T \boldsymbol{\sigma} dV + \int_V \delta \mathbf{u}^T \mathbf{b} dV + \int_{\Gamma_r} \delta \mathbf{u}^T \bar{\boldsymbol{\tau}} d\Gamma \quad \rightarrow = 0 \quad \text{at equilibrium} \\
\delta \boldsymbol{\phi}^T \Psi_e &= - \int_V \delta \mathbf{E}^T \mathbf{D} dV + \int_{\Gamma_q} \delta \boldsymbol{\phi}^T \bar{q} d\Gamma \quad \rightarrow = 0 \quad \text{at equilibrium}
\end{aligned} \tag{3}$$

The focus in this work is placed on the second equation of Eqs. (3), which describes the balance of electric charge in the piezoelectric elements. The vectors Ψ_u , Ψ_e represent generalized

imbalances between internal and external multifield forces and electric charges, respectively, which both vanish at equilibrium; $\bar{\tau}, \bar{q}$ are the applied surface tractions and electric charges on the bounding surfaces Γ_τ and Γ_q , respectively; b are the body forces over the volume V . Substituting Eqs. (1)-(2) into Eqs. (3) and making substantial calculations the individual electromechanical terms of the coupled system are derived [6].

3 COUPLED NONLINEAR SHELL FINITE ELEMENT

3.1 Discrete Generalized Equations of Motion

An eight-node coupled shell finite element, encompassing the previous generalized coupled mechanics was developed, in order to yield the discrete coupled nonlinear equations. The electromechanical state variables are approximated by the nodal values on the reference surface A_o with local interpolation functions:

$$\begin{aligned} \{u^o, v^o, w^o, \beta_\xi^o, \beta_\eta^o\}(\xi, \eta, t) &= \sum_{i=1}^W \{u^{oi}, v^{oi}, w^{oi}, \beta_\xi^{oi}, \beta_\eta^{oi}\}(t) P^i(\xi, \eta) \\ \{\varphi^m\}(\xi, \eta, t) &= \sum_{i=1}^W \{\varphi^{mi}\}(t) P^i(\xi, \eta), \quad m = 1, \dots, N \end{aligned} \quad (4)$$

where W is the number of element nodes; P denotes C_o continuous shape functions. Combining Eqs. (1)-(2) with Eq. (4) and substituting into Eqs. (3), after collecting the common elastic and electric nodal terms, the coupled system of nonlinear equations is finally derived:

$$\begin{aligned} \Psi_u(u, \varphi) &= [K_{uu}(u)]\mathbf{u} + [K_{ue}(u)]\boldsymbol{\varphi}^A + [K_{ue}(u)]\boldsymbol{\varphi}^S - \mathbf{F} \rightarrow = 0 \quad \text{at equilibrium} \\ \Psi_e(u, \varphi) &= [K_{eu}(u)]\mathbf{u} + [K_{ee}(u)]\boldsymbol{\varphi}^A + [K_{ee}(u)]\boldsymbol{\varphi}^S - \mathbf{Q} \rightarrow = 0 \quad \text{at equilibrium} \end{aligned} \quad (5)$$

where $\mathbf{u}(u, v, w, \beta_\xi, \beta_\eta)$ is the nodal displacement vector; $\boldsymbol{\varphi}^A$ is the applied nodal electric potential at actuators and $\boldsymbol{\varphi}^S$ is the free nodal electric potential at sensors. K_{uu} is the actual stiffness matrix including linear and nonlinear (dependence on \mathbf{u}) terms, K_{ue} , K_{eu} are the actual piezoelectric matrices including linear and nonlinear (dependence on \mathbf{u}) terms; K_{ee} is the actual electric permittivity matrix including only linear terms:

$$\begin{aligned} [K_{uu}(u)] &= [K_{uu}^o] + [K_{uu}^L] = [K_{uu}^o] + [P_1(u)]/2 + [P_2(u^2)]/3 \\ [K_{ue}(u)] &= [K_{ue}^o] + [K_{ue}^L] = [K_{ue}^o] + [P_3(u)] \\ [K_{eu}(u)] &= [K_{eu}^o] + [K_{eu}^L] = [K_{eu}^o] + [P_4(u)]/2 \\ [K_{ee}] &= [K_{ee}^o] \end{aligned} \quad (6)$$

In the first of Eqs. (5), the piezoelectric matrix $K_{ue}(u)$ multiplying by the electric potential vector $\boldsymbol{\varphi}^A$ represents the piezoelectric force (consisting of both linear and nonlinear terms) imposed on the laminate additionally to external mechanical forces \mathbf{F} ; in the second of Eqs. (5) the piezoelectric matrix $K_{eu}(u)$ multiplying by the displacement vector \mathbf{u} represents the electric

charge (consisting both of linear and nonlinear terms) generated at piezoelectric electrodes, additionally to external applied electric charge \mathbf{Q} , given by the following form:

$$\mathbf{Q}_{Gen} = [\mathbf{K}_{eu}] \mathbf{u} \quad (7)$$

Combining Eqs. (5)-(6), the following expressions for the elastic strain energy (ES), piezoelectric energy (PE), for both mechanical force equilibrium and electrical charge conservation, and stored electric energy (EE), over the whole volume of the piezoelectric laminate, are derived:

$$\begin{aligned} H_{ES} &= \frac{1}{2} \left\{ \mathbf{u}^T \right\} [\mathbf{K}_{uu}^o] \left\{ \mathbf{u} \right\} + \left(\frac{1}{2} \left\{ \mathbf{u}^T \right\} ([P_1(u)]/2 + [P_2(u^2)]/3) \left\{ \mathbf{u} \right\} \right) \\ H_{PE}^{mechanical_equilibrium} &= \frac{1}{2} \left\{ \mathbf{u}^T \right\} [\mathbf{K}_{ue}^o] \left\{ \boldsymbol{\varphi}^A \right\} + \frac{1}{2} \left\{ \mathbf{u}^T \right\} [P_3(u)] \left\{ \boldsymbol{\varphi}^A \right\} \\ H_{PE}^{electrical_equilibrium} &= \frac{1}{2} \left\{ \boldsymbol{\varphi}^{S^T} \right\} [\mathbf{K}_{eu}^o] \left\{ \mathbf{u} \right\} + \frac{1}{2} \left\{ \boldsymbol{\varphi}^{S^T} \right\} ([P_4(u)]/2) \left\{ \mathbf{u} \right\} \\ H_{EE} &= \frac{1}{2} \left\{ \boldsymbol{\varphi}^{S^T} \right\} [\mathbf{K}_{ee}^o] \left\{ \boldsymbol{\varphi}^S \right\} \end{aligned} \quad (8)$$

where in the above energy expressions the first and second RHS terms denote linear and nonlinear energy components, respectively. It must be also noticed that in case of open electric circuit conditions all the generated piezoelectric energy is converted and stored as electric energy into the piezoelectric sensor films.

3.2 Solution Scheme for Coupled Nonlinear Equations

In order to solve the coupled nonlinear Eqs. (5), the Cylindrical Arc Length method (CAL) is extended to enable the simultaneous solution for the mechanical force and electric charge imbalance equations, capturing eventually both the stable and unstable trajectory paths. The applied external loads may include combinations of mechanical loads (concentrated force or pressure) and applied electric potentials at actuators. The Newton-Raphson iterative technique is also adopted and combined with the CAL method such that the coupled nonlinear equations linearized and iteratively solved, until the electromechanical equilibrium $\boldsymbol{\Psi}_u = \boldsymbol{\Psi}_e = 0$. The coupled nonlinear system for the i^{th} iteration can be described more analytically below:

$$\begin{aligned} \boldsymbol{\Psi}_u^i(u^i, \boldsymbol{\varphi}^i, \lambda^i) &= [\mathbf{K}_{uu}(u^i)] \mathbf{u}^i + [\mathbf{K}_{ue}(u^i)] \boldsymbol{\varphi}^{S^i} + [\mathbf{K}_{ue}(u^i)] \boldsymbol{\varphi}^{A^i} - \lambda^i \mathbf{F}^i \\ \boldsymbol{\Psi}_e^i(u^i, \boldsymbol{\varphi}^i, \lambda^i) &= [\mathbf{K}_{eu}(u^i)] \mathbf{u}^i + [\mathbf{K}_{ee}] \boldsymbol{\varphi}^{S^i} - \mathbf{Q}^i \end{aligned} \quad (9)$$

where, λ is the mechanical (force or pressure) loading multiplier. In effort to achieve the convergent solution point ($\boldsymbol{\Psi}_u = \boldsymbol{\Psi}_e = 0$) the imbalance force and charge vectors are written for the next iteration ($i+1$) using the Taylor series expansion (considering only sensory voltage variation i.e $\delta \boldsymbol{\varphi} = \delta \boldsymbol{\varphi}^S$ and $\delta \boldsymbol{\varphi}^A = 0$ and keeping only the first derivative:

$$\begin{aligned}\Psi_u^{i+1}(u^{i+1}, \varphi^{i+1}, \lambda^{i+1}) &= \Psi_u^i(u^i, \varphi^i, \lambda^i) + \frac{\partial \Psi_u^i}{\partial u^i} \delta u^{i+1} + \frac{\partial \Psi_u^i}{\partial \varphi^{S^i}} \delta \varphi^{S^{i+1}} + \frac{\partial \Psi_u^i}{\partial \lambda^i} \delta \lambda^{i+1} = 0 \\ \Psi_e^{i+1}(u^{i+1}, \varphi^{i+1}, \lambda^{i+1}) &= \Psi_e^i(u^i, \varphi^i, \lambda^i) + \frac{\partial \Psi_e^i}{\partial u^i} \delta u^{i+1} + \frac{\partial \Psi_e^i}{\partial \varphi^{S^i}} \delta \varphi^{S^{i+1}} + \frac{\partial \Psi_e^i}{\partial \lambda^i} \delta \lambda^{i+1} = 0\end{aligned}\quad (10)$$

Substituting Eqs. (9) into Eqs. (10) and making the extended derivatives, substantial calculations and collecting the common elastic and electric nodal terms the coupled linearized system of equations is derived:

$$\begin{aligned}[\bar{K}_{uu}(u^i)]\delta u^{i+1} + [\bar{K}_{ue}(u^i)]\delta \varphi^{S^{i+1}} &= -\Psi_u(u^i, \varphi^i, \lambda^i) - \delta \lambda^{i+1} F \\ [\bar{K}_{eu}(u^i)]\delta u^{i+1} + [\bar{K}_{ee}] \delta \varphi^{S^{i+1}} &= -\Psi_e(u^i, \varphi^i, \lambda^i)\end{aligned}\quad (11)$$

where $\bar{K}_{uu}, \bar{K}_{ue}, \bar{K}_{eu}, \bar{K}_{ee}$ are the tangential stiffness, piezoelectric, piezoelectric and electric permittivity matrices respectively, associated directly with the actual matrices [6]. The Eqs. (11) includes three unknown variables $\delta u^{i+1}, \delta \varphi^{S^{i+1}}, \delta \lambda^{i+1}$ and are combined with a third additional equation known as *Cylindrical Arc-Length equation* described as:

$$\Delta u^{i+1T} \Delta u^{i+1} = \Delta u^{iT} \Delta u^i = \Delta l^2 \quad (12)$$

where the quantity Δu express incremental displacement vector; Δl is the radius of the specified norm, which is calculated from an initial incremental load value $\Delta \lambda^0$ [9]. The cumulative (u, λ) and incremental $(\Delta u, \Delta \lambda)$ quantities are updated at each iteration by the following expressions:

$$\begin{aligned}\lambda^{i+1} &= \lambda^i + \delta \lambda^{i+1} \quad , \quad \Delta \lambda^{i+1} = \Delta \lambda^i + \delta \lambda^{i+1} \\ u^{i+1} &= u^i + \delta u^{i+1} \quad , \quad \Delta u^{i+1} = \Delta u^i + \delta u^{i+1}\end{aligned}\quad (13)$$

The sensory electric potential is updated at each iteration by the following form:

$$\varphi^{S^{i+1}} = \varphi^{S^i} + \delta \varphi^{S^{i+1}} \quad (14)$$

4 NUMERICAL RESULTS

4.1 Electromechanical Response of Low-Curvature Cylindrical Aluminum [p/Al/p] Strip

The nonlinear electromechanical response of a hinged-hinged cylindrical ($\theta=5^\circ$) Aluminum [PVDF/Al/PVDF] strip, centrally covered with a pair of piezopolymer film sensors, each attached on the upper and lower surface was analyzed. The hoop length of the core and the piezopolymer film were $L_\xi=400\text{mm}$ and $L_{p\xi}=50\text{mm}$ respectively, while the widths were equal to $L_\eta=L_{p\eta}=20\text{mm}$. The Aluminum and piezopolymer layer thicknesses were $h_{Al}=3\text{mm}$ and $h_p=0.1\text{mm}$, respectively. An increasing lateral uniform mechanical pressure was applied at the outer surface of the strip, with direction towards the center of curvature. The inner terminals of each film were assumed to be grounded while the outer remained free. Fig. 1 shows the predicted radial center deflection of the strip versus the applied pressure. Initially, mechanical

compressive membrane stresses are induced on the strip resulting in a reduction on the flexural stiffness, due to membrane- flexural stiffness coupling, until the limit point A is reached where the tangential stiffness vanishes. Beyond the point A the strip enters into an unstable path AB

which is accompanied by a “negative” tangential stiffness, and finally reaches a second equilibrium stable state starting at inflection point B. After this point, the radial deflection has been increased enough such as to activate the membrane stiffening effects and transition of the shell to second stable path. Fig. 2 shows the predicted electric potential in the bottom and top piezofilms versus the center deflection. Initially, the two signals are increased until the point A receiving opposite polarity due to induced compressive membrane stresses, while beyond A the

two signals behave highly nonlinearly and tend to converge in the same value due to dominant bending stresses as the strip enters into the new stable path BC. Finally, the two electric signals are distinguished again beyond the point C due to large membrane stiffening effects. Fig. 3 shows the predicted electric charge generated in both of films versus the deflection, which is initially increased until a maximum value and following an opposite path is reduced until point

C, where beyond that point is increased again accompanied by a conversion of polarity. The predicted electric energy stored in both of piezofilms is shown in Fig. 4, where is monotonically increased passing from an inflection point B, due to redistribution of stresses during the stable-unstable-stable trajectory paths. Fig.5 illustrates the elastic strain energy stored in the whole piezolaminated strip which follows a similar trajectory path with the pressure-deflection curve

The switching from positive to-negative and again to positive values is due both to the redistribution of stresses and the electromechanical energy conversion takes place during the snap through instability.

Effect of piezopolymer film coverage on electromechanical response. Figs. (6)-(7) show the predicted electric charge and energy, respectively, for various piezofilm coverages, where both of two electric quantities are increased for piezofilm coverage enhancement, due to higher electromechanical conversion of distributed mechanical strains to electric potential along the shell circumferential. Both the predicted electric charge and stored electric energy are efficiently increased with the higher electromechanical conversion rate occurred during the unstable path.

Figure 7: Predicted electric energy, for various piezopolymer film coverages, of a hinged-hinged cylindrical Aluminum [PVDF/Al/PVDF] strip ($\theta=5^\circ$)

Effect of core thickness on electromechanical response. Figs. (8)-(9) illustrate the predicted electric charge and energy, respectively, for various core thicknesses. The thicker shell snaps under higher pressure values (following the trajectory path ABC for both of two graphs) due to higher membrane-flexural stiffness coupling and eventually higher amount of potential energy

Figure 8: Predicted electric charge, for various core thicknesses, of a hinged-hinged cylindrical piezopolymer Aluminum [PVDF/Al/PVDF] strip ($\theta=5^\circ$)

is converted both to stored electric and strain energy. Instead of the above, the electric charge is weakly depended on the thickness enhancement.

Effect of skin lamination on electromechanical response. The predicted electric charge and energy, for various skin laminates, are shown in Figs. (10)-(11), respectively. The higher

electromechanical conversion efficiency is corresponding to composite laminates due to their higher membrane-flexural stiffness coupling with the cross ply laminate being more proper, as

it snaps under larger pressure values. are converted to electric than elastic energy.

5 CONCLUSIONS

A computational framework based on coupled nonlinear mechanics was presented to predict the nonlinear electromechanical response of shallow cylindrical shells with attached piezopolymer films, undergoing to snap through instability under mechanical loads. The results illustrated the highly nonlinear sensor signal prediction in both of stable and unstable regions.

- The feasibility of smart shells to detect the onset of snap through instability, via the monitoring of sensory voltages is represented.
- The electromechanical energy conversion efficiency through the snap through buckling instability is quantified and the influence of thickness, laminate configuration and piezofilm coverage is finally investigated.

Abstract. In this study, we present an approach for the optimum material-orientation design of a laminated composite shell structure using the parameter-free optimization method. It is assumed that the fiber in a structure consisting of orthotropic materials can be arbitrarily oriented layer by layer, and the each optimum free-orientation is determined. We introduce the square displacement error norm between the thermal displacements on specified points and their target values as an objective functional, and minimize it under the equilibrium equation constraint. This makes it possible to tailor the deformation of a composite shell. The optimum design problem is formulated as a distributed-parameter optimization problem, and the sensitivity function is derived based on the variational method. The optimum orientation variation is determined by the H^1 gradient method with Poisson's equation, a parameter-free optimization method. This approach makes it simultaneously possible both to reduce the objective functional and to maintain the smooth material orientation of this large scale optimization problem. The design example shows the effectiveness of the proposed approach for tailoring the deformation of a laminated composite shell structure, or for designing a high-performance laminated composite shell structure with the optimum material orientation.

1 INTRODUCTION

Laminated composite shell structures are used in a variety of industrial products, especially in vehicles for their lightweight design, where the usage of carbon-fiber-reinforced plastics (CFRP) in shell structures has been increasing, since they have higher specific mechanical performances compared to metals. Moreover, "Automated fiber placement (AFP)" has enabled the manufacture of curvilinear-distributed material orientation, which can pulled out their potential and improve the mechanical performances more sufficiently. Most of the proposed optimization methods for the curvilinear-distributed material orientation design consider maximizing the stiffness to an external force as their design objective. In the practical design of laminated shell structures, deformation tailoring, (or controlling the

displacements to the desired values) to external loading is needed to achieve high quality, and to maintain mechanical performances and functions required. We focus on thermal loading in this study, since most of the industrial products are exposed to severe temperature environments. Especially, laminated composite shell structures deform unusually due to the coupling and the cross-elasticity effects. It is extremely important for designers to avoid this problem, or to tailor the thermal deformation of the laminated composite shell structures.

The deformation tailoring was called “homology design” or “compliant mechanism design” in the previous papers. The concept of homology design was presented for the design of large radio telescopes by Hoerner [1], where the deformation of the structure was defined as homologous if a given geometrical relation holds for the deformation. Liu and Shimoda developed an optimization method to solve a shape identification problem of linear elastic free-form shells with the purpose of achieving a desired deformation under external forces [2]. However, studies on the homology design and the compliant mechanism are limited and not reported for laminated shell structures.

Focusing on material orientation optimization, many methods and their application techniques for plates or shells have been reported. The representative optimization methods are a sensitivity based gradient method [3], a direct material optimization method (DMO) [4], a normal distribution fiber optimization method (NDFO) [5] and genetic algorithm (GA) based methods [6]. The sensitivity based gradient approach has the advantage of solving large-scale structure optimization problems mechanically. However, it may cause multiple local minima including the unsmooth distributions, and it is highly dependent on the initial material orientation distribution. On the other hand, DMO and NDFO methods are ameliorations for simple-gradient methods, in which the element-based penalization coefficient is used to force the candidate orientations to only one candidate. These methods are categorized into a parametric method. The design variable parameterization is effective for reducing the design freedom, for reducing the risk of obtaining local minima and results in a lower computational cost; however, the obtained mechanical performance is limited since the optimal solution is highly dependent on the pre-defined parameters. GA is also expected to find some local minima and has the potential to provide the global minimum solution, where sensitivity analysis is unnecessary. On the other hand, the application of GA to practical structural problems is limited since Finite Element analyses of large-scale structures with a large number of design variables, especially with every element in every layer of a laminated shell results in a significant calculation cost problem. In addition, considering a parameter-free orientation design problem, or an enormous design degrees of freedom design problem, it is not easy to control their behaviours. Without a countermeasure, the ill-condition like the checkerboard problem of topology optimization or the jaggging problem of shape optimization may happen.

On the contrary, the authors proposed a parameter-free gradient-based material orientation optimization method, or the H^1 gradient method with Poisson’s equation, for compliance minimization problem [7], in which the optimal material distribution can be obtained without design variable parameterization such as the candidate material orientations or the polynomials to express the material distribution. In other words, the materials are varied freely over the entire region with enormous design degrees of freedom. The proposed method overcame the issues including the ill-condition risk aforementioned. The main advantages of the proposed method are that it can conventionally determine the smooth distribution of the

design variables and decrease the objective function simultaneously without design variable parameterization.

Under these backgrounds, we present an approach for the optimum material-orientation design using the H^1 gradient method with Poisson's equation for tailoring thermal displacements of laminated composite shell structures in this study. The approach is applied to a shell design example to confirm the effectiveness of the proposed approach.

2 FORMULATION OF MATERIAL ORIENTATION OPTIMIZATION PROBLEM

2.1 Governing equation for a laminated shell structure

As shown in Fig. 1, a laminated shell structure consists of N layers, and the i^{th} ply of a laminated shell structure has an initial design domain Ω_i , middle surface A_i with boundary ∂A_i , and thickness t_i . The bounded domain of each layer is composed of a set of infinitesimal flat surfaces dA_i . For simplicity, we assume that a laminated shell structure consists of N layers.

It is assumed that the mapping of the local coordinate system $(x_1, x_2, 0)$, which gives the position of the global mid-surface of the laminated shell structure, to the global coordinate system (X_1, X_2, X_3) is piecewise smooth. The Mindlin-Reissner plate theory is employed for plate bending. Using the sign convention on the small triangle domain $d\Omega_i (= dA_i \times t_i)$ in Fig. 1, the displacements of i^{th} ply expressed by the local coordinates $\mathbf{u}^{(i)} = \{u_k^{(i)}\}_{k=1,2,3}$ are considered by dividing them into the displacements in the in-plane direction $\{u_\alpha^{(i)}\}_{\alpha=1,2}$ and the displacements in the out-of-plane direction $u_3^{(i)}$, shown as

$$u_\alpha^{(i)}(x_1^{(i)}, x_2^{(i)}, x_3^{(i)}) \equiv u_{0\alpha}^{(i)}(x_1^{(i)}, x_2^{(i)}) - x_3^{(i)} \theta_\alpha^{(i)}(x_1^{(i)}, x_2^{(i)}), \quad (1)$$

$$u_3^{(i)}(x_1^{(i)}, x_2^{(i)}, x_3^{(i)}) \equiv w^{(i)}(x_1^{(i)}, x_2^{(i)}), \quad (2)$$

where $\{u_{0\alpha}^{(i)}\}_{\alpha=1,2}$, $w^{(i)}$ and $\{\theta_\alpha^{(i)}\}_{\alpha=1,2}$ express in-plane displacement, out-of-plane displacement and rotational angles of the mid-area of the i^{th} ply of the laminated shell structure,

Figure 1: Laminated shell with N layers as a set of infinitesimal flat surfaces.

respectively. Then, the weak form state equation with respect to $\mathbf{u}^{(i)} = (\mathbf{u}_0^{(i)}, w^{(i)}, \boldsymbol{\theta}^{(i)})$, ($i = 1, \dots, N$) can be expressed as Eq. (3) by substituting Eq. (4) and (5) into the variational equation of the three-dimensional linear elastic body, considering $\sigma_{33}^{(i)} = 0$ and eliminating $\varepsilon_{33}^{(i)}$.

$$a\left((\mathbf{u}^{(1)}, \mathbf{u}^{(2)}, \dots, \mathbf{u}^{(N)}), (\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)})\right) = l(\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}), \forall (\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}) \in \bar{U}, \quad (3)$$

$$\mathbf{u}^{(i)} = (\mathbf{u}_0^{(i)}, w^{(i)}, \boldsymbol{\theta}^{(i)}) \in U \quad (i = 1, \dots, N)$$

where $\mathbf{u}^{(i)} = [\mathbf{u}_0^{(i)}, w^{(i)}, \boldsymbol{\theta}^{(i)}]^T$, and $(\bar{\bullet})$ expresses a variation. In addition, the bilinear form $a(\cdot, \cdot)$ and linear form $l(\cdot)$ for the state variables $(\mathbf{u}_0, w, \boldsymbol{\theta})$ are respectively defined as

$$a\left((\mathbf{u}^{(1)}, \mathbf{u}^{(2)}, \dots, \mathbf{u}^{(N)}), (\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)})\right) \quad (4)$$

$$\begin{aligned} &= \sum_{i=1}^N \int_{A_i} \left\{ \left\{ \boldsymbol{\kappa}^{(i)T}(\boldsymbol{\theta}) - \boldsymbol{\alpha}^T \frac{T_g^{(i)}}{t_i} \right\} \mathbf{E}^{B(i)} \bar{\boldsymbol{\kappa}}^{(i)}(\bar{\boldsymbol{\theta}}) + \left\{ \boldsymbol{\varepsilon}_0^{(i)T}(\mathbf{u}_0) - \boldsymbol{\alpha}^T T_m^{(i)} \right\} (\mathbf{u}_0) \mathbf{E}^{M(i)} \bar{\boldsymbol{\varepsilon}}_0^{(i)}(\bar{\mathbf{u}}_0) \right. \\ &\quad + \left\{ \boldsymbol{\kappa}^{(i)T}(\boldsymbol{\theta}) - \boldsymbol{\alpha}^T \frac{T_g^{(i)}}{t_i} \right\} \mathbf{E}^{C(i)} \bar{\boldsymbol{\varepsilon}}_0^{(i)}(\bar{\mathbf{u}}_0) + \bar{\boldsymbol{\kappa}}^{(i)T}(\bar{\boldsymbol{\theta}}) \mathbf{E}^{C(i)} \left\{ \boldsymbol{\varepsilon}_0^{(i)}(\mathbf{u}_0) - \boldsymbol{\alpha} T_m^{(i)} \right\} \\ &\quad + \left\{ \boldsymbol{\varepsilon}_0^{(i)T}(\mathbf{u}_0) - \boldsymbol{\alpha}^T T_m^{(i)} \right\} \mathbf{E}^{C(i)} \bar{\boldsymbol{\kappa}}^{(i)}(\bar{\boldsymbol{\theta}}) + \bar{\boldsymbol{\varepsilon}}_0^{(i)T}(\bar{\mathbf{u}}_0) \mathbf{E}^{C(i)} \left\{ \boldsymbol{\kappa}^{(i)}(\boldsymbol{\theta}) - \boldsymbol{\alpha} \frac{T_g^{(i)}}{t_i} \right\} \\ &\quad \left. + \boldsymbol{\gamma}^{(i)T}(w, \boldsymbol{\theta}) \mathbf{E}^{S(i)} \bar{\boldsymbol{\gamma}}^{(i)}(\bar{w}, \bar{\boldsymbol{\theta}}) \right\} dA_i, \end{aligned}$$

$$l(\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}) \quad (5)$$

$$= \sum_{i=1}^N \left[\int_{A_i} \left(\mathbf{f}^T \bar{\mathbf{u}}_0^{(i)} - \mathbf{m}^T \bar{\boldsymbol{\theta}}^{(i)} + q \bar{w}^{(i)} \right) dA_i + \int_{\partial A_i} \left(\mathbf{N}^T \bar{\mathbf{u}}_0^{(i)} - \mathbf{M}^T \bar{\boldsymbol{\theta}}^{(i)} + Q \bar{w}^{(i)} \right) ds_i \right].$$

The external loadings with respect to the local coordinate system $(x_1, x_2, 0)$ are defined as \mathbf{f} , \mathbf{m} , q , \mathbf{N} , \mathbf{M} , and Q , which denote in-plane load, out-of-plane moment, out-plane load on the global middle surface, in-plane load, bending moment, and shearing force on the global sub-boundaries, respectively. The notations $\mathbf{E}^{B(i)}$, $\mathbf{E}^{M(i)}$, $\mathbf{E}^{C(i)}$ and $\mathbf{E}^{S(i)}$ express the orthotropic elastic matrices with respect to bending, membrane, coupling and shear component of the i^{th} ply, respectively. $\boldsymbol{\alpha} = \{\delta_{ij} \alpha_{ij}\}_{i,j=1,2}$, $T_m^{(i)}$ and $T_g^{(i)} / t_i$ indicate coefficients of thermal expansion, mean temperature difference and temperature gradient, respectively. Additionally, $\boldsymbol{\varepsilon}^{(i)} = \{\varepsilon_{\alpha\beta}\}_{\alpha,\beta=1,2}^{(i)}$, $\boldsymbol{\kappa}^{(i)} = \{\kappa_{\alpha\beta}\}_{\alpha,\beta=1,2}^{(i)}$, $\boldsymbol{\varepsilon}_0^{(i)} = \{\varepsilon_{0\alpha\beta}\}_{\alpha,\beta=1,2}^{(i)}$ and $\boldsymbol{\gamma}^{(i)} = \{\gamma_{\alpha 3}\}_{\alpha=1,2}^{(i)}$ express strain tensor, curvature tensor, in-plane strain tensor and transverse shear strain vector on the middle surface of the i^{th} ply, respectively; and they are defined by the following equations:

$$\varepsilon_{\alpha\beta}^{(i)} \equiv \frac{1}{2} (u_{\alpha,\beta}^{(i)} + u_{\beta,\alpha}^{(i)}), \quad (6)$$

$$u_{\alpha,\beta}^{(i)} = u_{0\alpha,\beta}^{(i)} - x_3^{(i)} \theta_{\alpha,\beta}^{(i)}, \quad (7)$$

$$\gamma_{\alpha}^{(i)} \equiv w_{,\alpha}^{(i)} - \theta_{\alpha}^{(i)}, \quad (8)$$

$$\kappa_{\alpha\beta}^{(i)} \equiv \frac{1}{2}(\theta_{\alpha,\beta}^{(i)} + \theta_{\beta,\alpha}^{(i)}), \quad (9)$$

$$\varepsilon_{0\alpha\beta}^{(i)} \equiv \frac{1}{2}(u_{0\alpha,\beta}^{(i)} + u_{0\beta,\alpha}^{(i)}). \quad (10)$$

The displacement continuity and the Cauchy stress vector between each layer are satisfied as

$$\mathbf{u}^{(i)bottom} = \mathbf{u}^{(i-1)top}, \quad (11)$$

$$\mathbf{n}^{(i)bottom} = -\mathbf{n}^{(i-1)top}, \quad \boldsymbol{\sigma}^{T(i)bottom} \mathbf{n}^{(i)bottom} = -\boldsymbol{\sigma}^{T(i-1)top} \mathbf{n}^{(i-1)top}, \quad (12)$$

where $(\cdot)^{(i)bottom}$ and $(\cdot)^{(i-1)top}$ indicate the value on the bottom surface of the i^{th} ply and the top surface of the $(i-1)^{th}$ ply, respectively. In addition, \mathbf{n} and $\boldsymbol{\sigma}$ are the unit outward normal vector and the Cauchy stress tensor, respectively. Note that, in this paper, the subscripts of the Greek letters are expressed as $\alpha=1,2$ and the tensor subscript notation uses Einsteins summation convention and a partial differential notation with respect to the spatial coordinates $(\cdot)_{,j} = \partial(\cdot)/\partial x_j$.

It will be also noted that U and \bar{U} in Eq. (3) are the spaces of the kinematically admissible displacements given by the following equations:

$$U = \left\{ \left(u_{01}^{(i)}, u_{02}^{(i)}, w^{(i)}, \theta_1^{(i)}, \theta_2^{(i)} \right) \in \left(H^1(A) \right)^5 \left| \begin{array}{l} \text{satisfying the constraint conditon appropriately on the} \\ \text{Dirichlet boundary} \end{array} \right. \right\}, \quad (13)$$

$$\bar{U} = \left\{ \left(\bar{u}_{01}^{(i)}, \bar{u}_{02}^{(i)}, \bar{w}^{(i)}, \bar{\theta}_1^{(i)}, \bar{\theta}_2^{(i)} \right) \in \left(H^1(A_i) \right)^5, (i=1, \dots, N) \left| \begin{array}{l} \bar{u}_{01}^{(i)} = \bar{u}_{02}^{(i)} = \bar{w}^{(i)} = \bar{\theta}_1^{(i)} = \bar{\theta}_2^{(i)} = 0 \\ \text{on each Dirichlet subboundary} \end{array} \right. \right\}, \quad (14)$$

where $H^1(=W^{1,2})$ is the Sobolev space of square integrable and differentiable of order 1.

2.2 Formulation of controlling problem of thermal or static deformation

We aim at tailoring the thermal displacements of a laminated shell structure to desired target values by optimizing the material orientations of every layer. Using the state equation as the constraint condition, and square displacement error norm between the displacements and the target values as the objective function to be minimized, a distributed-parameter optimization problem for determining the optimal distribution of the material orientation is formulated as

$$\text{Find} \quad \delta\varphi^{(i)}(\mathbf{x}) \quad (15)$$

$$\text{that minimizes} \quad d(\mathbf{u}^{(M)} - \hat{\mathbf{u}}^{(M)}, \mathbf{u}^{(M)} - \hat{\mathbf{u}}^{(M)}) \quad (16)$$

$$\text{subject to} \quad \text{Eq. (3)} \quad (17)$$

where $\delta\varphi^{(i)}(\mathbf{x}), (\mathbf{x} \in A_i)$ is the variation of the material orientation from its original material orientation function $\varphi^{(i)}(\mathbf{x})$ of $E_1^{(i)}$ on the i^{th} ply, and the updated material orientation function $\varphi_s^{(i)}(\mathbf{x})$ is described as $\varphi_s^{(i)}(\mathbf{x}) = \varphi^{(i)}(\mathbf{x}) + \delta\varphi^{(i)}(\mathbf{x})$ (shown in Fig. 2). $\mathbf{u}^{(M)}$ and $\hat{\mathbf{u}}^{(M)}$ indicate the actual displacement and the target displacement at the global mid-surface of laminated shell

structure, respectively. Eq. (16) shows the square displacement error norm between $\mathbf{u}^{(M)}$ and $\hat{\mathbf{u}}^{(M)}$.

Figure 2: Variation of material orientation $E_1^{(i)}$ in orthotropic material of the i^{th} ply.

2.3 Derivation of sensitivity function

The Lagrange multiplier method is used to transform this constrained material orientation optimization problem to a non-constrained material orientation optimization problem. Letting $(\bar{\mathbf{u}}_0^{(i)}, \bar{\mathbf{w}}^{(i)}, \bar{\boldsymbol{\theta}}^{(i)})$ denote the Lagrange multiplier with respect to the strong-formed state equation, the Lagrange functional L associated with this problem is expressed as

$$L\left(\left(\mathbf{u}^{(1)}, \mathbf{u}^{(2)}, \dots, \mathbf{u}^{(N)}\right), \left(\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}\right)\right) = d(\mathbf{u}^{(M)} - \hat{\mathbf{u}}^{(M)}, \mathbf{u}^{(M)} - \hat{\mathbf{u}}^{(M)}) + l\left(\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}\right) - a\left(\left(\mathbf{u}^{(1)}, \mathbf{u}^{(2)}, \dots, \mathbf{u}^{(N)}\right), \left(\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}\right)\right). \quad (18)$$

Using the variation of $\varphi^{(i)}(\mathbf{x})$, i.e. the design variable field $\delta\varphi^{(i)}(\mathbf{x})$ to represent the amount of the material orientation variation, the first variation δL of the Lagrange functional L with respect to the material orientation variation can be expressed as

$$\delta L = l\left(\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}\right) - a\left(\left(\mathbf{u}^{(1)}, \mathbf{u}^{(2)}, \dots, \mathbf{u}^{(N)}\right), \left(\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}\right)\right) - a\left(\left(\mathbf{u}^{(1)}, \mathbf{u}^{(2)}, \dots, \mathbf{u}^{(N)}\right), \left(\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}\right)\right) + 2d\left(\mathbf{u}^{(M)} - \hat{\mathbf{u}}^{(M)}, \mathbf{u}^{(M)} - \hat{\mathbf{u}}^{(M)}\right) + \left\langle G_{\varphi}^{(i)}, \delta\varphi^{(i)} \right\rangle_{\varphi}, \quad (19)$$

$$\text{where, } \left\langle G_{\varphi}^{(i)}, \delta\varphi^{(i)} \right\rangle_{\varphi} = \sum_{i=1}^N \int_{A_i} G_{\varphi}^{(i)} \delta\varphi^{(i)} dA_i \quad (20)$$

$$\begin{aligned} &= \sum_{i=1}^N \int_{A_i} \left[\left\{ \boldsymbol{\kappa}^{(i)T}(\boldsymbol{\theta}) - \boldsymbol{\alpha}^T \frac{T_g^{(i)}}{t_i} \right\} \frac{\partial \mathbf{E}^{B(i)}}{\partial \varphi} \bar{\boldsymbol{\kappa}}^{(i)}(\bar{\boldsymbol{\theta}}) + \left\{ \boldsymbol{\varepsilon}_0^{(i)T}(\mathbf{u}_0) - \boldsymbol{\alpha}^T T_m^{(i)} \right\} \frac{\partial \mathbf{E}^{M(i)}}{\partial \varphi} \bar{\boldsymbol{\varepsilon}}_0^{(i)}(\bar{\mathbf{u}}_0) \right. \\ &\quad + \left\{ \boldsymbol{\kappa}^{(i)T}(\boldsymbol{\theta}) - \boldsymbol{\alpha}^T \frac{T_g^{(i)}}{t_i} \right\} \frac{\partial \mathbf{E}^{C(i)}}{\partial \varphi} \bar{\boldsymbol{\varepsilon}}_0^{(i)}(\bar{\mathbf{u}}_0) + \bar{\boldsymbol{\kappa}}^{(i)T}(\bar{\boldsymbol{\theta}}) \frac{\partial \mathbf{E}^{C(i)}}{\partial \varphi} \left\{ \boldsymbol{\varepsilon}_0^{(i)}(\mathbf{u}_0) - \boldsymbol{\alpha} T_m^{(i)} \right\} \\ &\quad + \left\{ \boldsymbol{\varepsilon}_0^{(i)T}(\mathbf{u}_0) - \boldsymbol{\alpha}^T T_m^{(i)} \right\} \frac{\partial \mathbf{E}^{C(i)}}{\partial \varphi} \bar{\boldsymbol{\kappa}}^{(i)}(\bar{\boldsymbol{\theta}}) + \bar{\boldsymbol{\varepsilon}}_0^{(i)T}(\bar{\mathbf{u}}_0) \frac{\partial \mathbf{E}^{C(i)}}{\partial \varphi} \left\{ \boldsymbol{\kappa}^{(i)}(\boldsymbol{\theta}) - \boldsymbol{\alpha} \frac{T_g^{(i)}}{t_i} \right\} \\ &\quad \left. + \boldsymbol{\gamma}^{(i)T}(\mathbf{w}, \boldsymbol{\theta}) \frac{\partial \mathbf{E}^{S(i)}}{\partial \varphi} \bar{\boldsymbol{\gamma}}^{(i)}(\bar{\mathbf{w}}, \bar{\boldsymbol{\theta}}) \right] \delta\varphi^{(i)} dA_i, \end{aligned}$$

and where $(\cdot)'$ indicates the first variation with respect to the design variable field $\delta\varphi^{(i)}(\mathbf{x})$.

When Eqs. (21) and (22) are satisfied,

$$a\left(\left(\mathbf{u}^{(1)}, \mathbf{u}^{(2)}, \dots, \mathbf{u}^{(N)}\right), \left(\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}\right)\right) = l\left(\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}\right), \quad (21)$$

$$\left(\mathbf{u}^{(1)}, \mathbf{u}^{(2)}, \dots, \mathbf{u}^{(N)}\right) \in U, \quad \forall \left(\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}\right) \in \bar{U},$$

$$a\left(\left(\mathbf{u}'^{(1)}, \mathbf{u}'^{(2)}, \dots, \mathbf{u}'^{(N)}\right), \left(\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}\right)\right) = 2d\left(\mathbf{u}^{(M)} - \hat{\mathbf{u}}^{(M)}, \mathbf{u}^{(M)'}\right), \quad (22)$$

$$\left(\bar{\mathbf{u}}^{(1)}, \bar{\mathbf{u}}^{(2)}, \dots, \bar{\mathbf{u}}^{(N)}\right) \in \bar{U}, \quad \forall \left(\mathbf{u}'^{(1)}, \mathbf{u}'^{(2)}, \dots, \mathbf{u}'^{(N)}\right) \in U,$$

then Eq. (19) becomes

$$\delta L = \left\langle G_{\varphi}^{(i)}, \delta\varphi^{(i)} \right\rangle_{\varphi}. \quad (23)$$

Eq. (21) is the governing equation for the state variable $\mathbf{u}^{(i)} = (\mathbf{u}_0^{(i)}, \mathbf{w}^{(i)}, \boldsymbol{\theta}^{(i)})$, ($i = 1, 2, 3, \dots, N$) and coincides with the state equation (Eq. (3)). Eq. (22) is the adjoint equation for the adjoint variable $\bar{\mathbf{u}}^{(i)} = (\bar{\mathbf{u}}_0^{(i)}, \bar{\mathbf{w}}^{(i)}, \bar{\boldsymbol{\theta}}^{(i)})$, ($i = 1, 2, 3, \dots, N$). Finally, the material orientation sensitivity function $G_{\varphi}^{(i)}$ of this problem is derived as

$$\begin{aligned} G_{\varphi}^{(i)} = & \left\{ \boldsymbol{\kappa}^{(i)T}(\boldsymbol{\theta}) - \boldsymbol{\alpha}^T \frac{T_g^{(i)}}{t_i} \right\} \frac{\partial \mathbf{E}^{B(i)}}{\partial \varphi} \bar{\boldsymbol{\kappa}}^{(i)}(\bar{\boldsymbol{\theta}}) + \left\{ \boldsymbol{\varepsilon}_0^{(i)T}(\mathbf{u}_0) - \boldsymbol{\alpha}^T T_m^{(i)} \right\} \frac{\partial \mathbf{E}^{M(i)}}{\partial \varphi} \bar{\boldsymbol{\varepsilon}}_0^{(i)}(\bar{\mathbf{u}}_0) \\ & + \left\{ \boldsymbol{\kappa}^{(i)T}(\boldsymbol{\theta}) - \boldsymbol{\alpha}^T \frac{T_g^{(i)}}{t_i} \right\} \frac{\partial \mathbf{E}^{C(i)}}{\partial \varphi} \bar{\boldsymbol{\varepsilon}}_0^{(i)}(\bar{\mathbf{u}}_0) + \bar{\boldsymbol{\kappa}}^{(i)T}(\bar{\boldsymbol{\theta}}) \frac{\partial \mathbf{E}^{C(i)}}{\partial \varphi} \left\{ \boldsymbol{\varepsilon}_0^{(i)}(\mathbf{u}_0) - \boldsymbol{\alpha} T_m^{(i)} \right\} \\ & + \left\{ \boldsymbol{\varepsilon}_0^{(i)T}(\mathbf{u}_0) - \boldsymbol{\alpha}^T T_m^{(i)} \right\} \frac{\partial \mathbf{E}^{C(i)}}{\partial \varphi} \bar{\boldsymbol{\kappa}}^{(i)}(\bar{\boldsymbol{\theta}}) + \bar{\boldsymbol{\varepsilon}}_0^{(i)T}(\bar{\mathbf{u}}_0) \frac{\partial \mathbf{E}^{C(i)}}{\partial \varphi} \left\{ \boldsymbol{\kappa}^{(i)}(\boldsymbol{\theta}) - \boldsymbol{\alpha} \frac{T_g^{(i)}}{t_i} \right\} \\ & + \boldsymbol{\gamma}^{(i)T}(\mathbf{w}, \boldsymbol{\theta}) \frac{\partial \mathbf{E}^{S(i)}}{\partial \varphi} \bar{\boldsymbol{\gamma}}^{(i)}(\bar{\mathbf{w}}, \bar{\boldsymbol{\theta}}). \end{aligned} \quad (24)$$

The each term in Eq. (24) is calculated by Eqs. (21) and (22), and the finite element method can be employed to solve those equations. The components of the elastic matrices on the right side of Eq. (24) is introduced in [7, 8]. Note that the material orientation sensitivity function for static deformation can be obtained by neglecting the thermal expansion terms of Eq. (24).

The derived material orientation sensitivity function $G_{\varphi}^{(i)}$ will be applied to the H^1 gradient method with Poisson's equation in Section 3.

3 H^1 GRADIENT METHOD WITH POISSON'S EQUATION FOR FREE-MATERIAL ORIENTATION OPTIMIZATION

The original H^1 gradient method called traction method at first was proposed for shape optimization of a linear elastic structure by Azegami and Wu [9]. and Shimoda and Liu extended it for free-form optimization of shells [10], which is a gradient method in the Hilbert space, and is theoretically possible to treat infinite design degrees of freedom. In these methods, the optimal distribution of the vector design variable can be determined via a linear elastic equation. In addition, the H^1 gradient method is further extended to size optimization

[11]. The extended H^1 gradient methods can determine the optimal distribution of the scalar design variable via Poisson's equation. The authors extended this method moreover for the material-orientation optimization problem [7]. The H^1 gradient method with Poisson's equation proposed for the optimal material-distribution is as follows:

When the state and the adjoint equations are satisfied, the perturbation expansion ΔL of Eq. (23) can be expressed as

$$\Delta L = \langle G_\varphi^{(i)}, \Delta s \delta \varphi^{(i)} \rangle. \quad (25)$$

where Δs is a sufficient small positive value.

In order to obtain the optimal material orientation variation field $\delta \varphi^{(i)}(\mathbf{x})$ of the i^{th} ply, the following weak-formed Poisson's equation for $\delta \varphi^{(i)}(\mathbf{x})$ is introduced.

$$\begin{aligned} b(\delta \varphi^{(1)}, v^{(1)}, \dots, \delta \varphi^{(N)}, v^{(N)}) + \beta_\varphi \langle \delta \varphi^{(i)}, v^{(i)} \rangle &= -\langle G_\varphi^{(i)}, v^{(i)} \rangle, \quad \forall v^{(i)} \in C_v, \delta \varphi^{(i)} \in C_\varphi, \\ b(\delta \varphi^{(1)}, v^{(1)}, \dots, \delta \varphi^{(N)}, v^{(N)}) &= \sum_{i=1}^N \int_{A_i} \delta \varphi_i^{(i)} k_{ij} v_j^{(i)} dA_i, \end{aligned} \quad (26)$$

where $\delta \varphi^{(i)}(\mathbf{x})$ denotes the material orientation field to be determined. The notations $\beta_\varphi (> 0)$ and k_{ij} are equivalent to the heat transfer coefficient and the thermal conductivity matrix in the heat transfer analysis, respectively. C_φ is the function space of the kinematically admissible temperatures that satisfy the Dirichlet conditions for material orientation variation $\delta \varphi^{(i)}(\mathbf{x})$, and C_v is the function space of the kinematically admissible temperatures defined as

$$C_v = \{v^{(i)} \in H^1 \mid v^{(i)} = 0 \text{ on the Dirichlet boundaries}\}. \quad (27)$$

The Dirichlet conditions can be arbitrarily defined by only considering the design requirement for the material orientations. Substituting Eq. (26) into Eq. (25) and considering the arbitrariness of $v^{(i)}$ in Eq. (26), we obtain

$$\Delta L = \langle G_\varphi^{(i)}, \Delta s \delta \varphi^{(i)} \rangle = -\Delta s \left(b(\delta \varphi^{(1)}, \delta \varphi^{(1)}, \dots, \delta \varphi^{(N)}, \delta \varphi^{(N)}) + \beta_\varphi \langle \delta \varphi^{(i)}, \delta \varphi^{(i)} \rangle \right). \quad (28)$$

Furthermore, considering the positive definitiveness of $\beta_\varphi \langle \delta \varphi^{(i)}, \delta \varphi^{(i)} \rangle > 0$ and $b(\delta \varphi^{(1)}, v^{(1)}, \dots, \delta \varphi^{(N)}, v^{(N)}) > 0$ in Eq. (28), we have $\Delta L < 0$. This relationship holds true in a piecewise convex design space. As above-mentioned, the sensitivity function is not applied directly to update the material orientation variation but it is once replaced by a fictitious internal heat generation and applied to the design domain. Then, the material orientation variation is determined as the temperature field obtained by the Poisson's equation. This makes it possible both to reduce the objective functional and to maintain the smoothness of the material orientation distribution, simultaneously. β_φ has a role of smoothing filter for controlling the influence range of the sensitivity function at a point. With larger β_φ , the influence area of the material orientation sensitivity function is smaller. With smaller β_φ , the influence area of the material orientation sensitivity function is larger, and then the material orientation distribution becomes smoother, or the curvature change of the material orientation flow becomes smaller. Generally, there is a trade-off relationship between them.

Fig. 3 shows the schematic flowchart with the concept illustrations of the optimization system developed in this study. The material orientation optimization process is summarized as: (1) Stiffness and adjoint analyses by Eqs. (21) and (22), and evaluation of objective function; (2) Calculation of material orientation sensitivity function by Eq. (24) using Eqs.

(21) and (22); (3) The negative material orientation sensitivity function $-G_\phi^{(i)}$ is applied layer by layer as a distributed internal heat generation to a fictitious elastic shell structure to the design surface of the i^{th} ply. The material orientation variation field $\delta\phi(x)$ is obtained as the temperature field solved by the Poisson's equation; (4) Updating of the material orientation by $\delta\phi(x)$. This process is repeated until the convergence or the given iteration number. A commercial FEM code is used for the processes in orange. The optimization system can be easily constructed in combination with a commercial FEA code because the proposed method does not need to manipulate the stiffness matrix in each process.

4 NUMERICAL EXAMPLE

From a practical point of view, most of the industrial products are exposed in thermal environments, and it is important to maintain the required mechanical performances under thermal stress. Here, consider a 3-layer square shell illustrated in Fig. 4, which is loaded 60 K temperature difference between the top and bottom surfaces. The four corners are simply supported. The design domain, which has 200 mm length in each span and the unit thickness for each layer, has 1600 triangular elements. The initial material orientation of E_1 is parallel to x -axis. Young's moduli of each orthotropic element E_1 and E_2 are 210 GPa and 21 GPa, respectively. Transverse elasticity modulus is $G_{12} = 65$ GPa and Poisson ratio is $\nu_{12} = 0.3$. The thickness of each layer is set as 1 mm, and the ratio of each of coefficients of thermal expansion α_1 and α_2 is set as 1:7.

The objective of this problem is to reduce the overall thermal displacements to 1/10 of the initial displacement at each node. Fig. 5 shows the optimal material orientation of E_1 on each

layer, which has a different optimal material orientation while maintaining its smooth distribution. The iteration history of the square displacement error norm is shown in Fig. 6, and it is confirmed that it is monotonically decreased to 94 %. Fig. 7 shows the comparison of the thermal deformations between the initial and the optimized. It is confirmed that the thermal deformation is globally reduced by the optimization.

5 CONCLUSIONS

In this study, we presented an approach for the optimum material-orientation design of a laminated composite shell structure using the H^1 gradient method with Poisson's equation. It was assumed that the fiber in a structure consisting of orthotropic materials could be arbitrarily oriented layer by layer, and the each optimum free-orientation was determined for tailoring the thermal deformation to the desired values. The square displacements error norm was used as the objective function. The optimization problem was formulated and the sensitivity function for material orientation variation was theoretically derived using the Lagrange multiplier method and the adjoint variable method.

With the proposed approach, the arbitrary and smooth optimal distribution of the material orientation of a laminated anisotropic shell structure could be conventionally created for tailoring the thermal deformation. The proposed approach is especially effective for large-scale material orientation design problems of complicated-shape structures with multi-layer, and will become an effective tool for designing a high-performance laminated composite shell structure.

Key words: Shape-memory alloy, Entropy, Smart material, Constitutive model, Strain-rate

Abstract. Superelastic shape-memory alloys (SMAs) are unique smart materials with a considerable energy dissipation potential for dynamic loadings with varying strain-rates. The energy dissipation arises from a hysteretic phase transformation of the polycrystalline atomic grid structure. In fact, the nucleation from austenite to martensite phase and vice versa exhibits a strong thermomechanical coupling. In particular, the hysteresis depends on the latent heat generated by the austenitic-martensitic transformation and the convection of that heat. High strain-rate interferes with the release of the latent heat to the environment and reduces the hysteresis surface. However, the degree of atomic disorder and accordingly the change in entropy influences the reverse phase transformation from martensite to austenite. In other words, the stability of the martensitic state affects the stress-level of the reverse transformation. Consequently, in phenomenological material models for SMAs, the effects of the rate-dependent entropy change must be considered to describe the energy dissipation behavior.

To incorporate the rate-dependent entropy change, we improved a one-dimensional numerical model by introducing an additional control variable in the free-energy formulation for solid-solid phase transformation in superelastic SMAs. In the present model, the observed effects of the strain-rate on the reverse transformation are taken into account by calculating the rate-dependent entropy change. A comparison of the numerical results with the experimental data shows that the model calculates the dynamic superelastic hysteresis of SMAs more accurate.

1 INTRODUCTION

The application field of polycrystalline shape-memory alloys (SMAs) with initial superelasticity covers aeronautic, automotive and civil engineering as well as biomechanics. Most SMA-based engineering applications experience strain-rate varied and cyclic loadings. Especially in civil engineering both seismic events and wind cause dynamic loading on structures. Hence, researchers have investigated numerous structural control strategies to mitigate structural vibrations. Commonly used damping systems, such as steel-hysteresis-dampers, dissipate structural vibration energy by inelastic deformations. However, inelastic damping devices cannot recover deformations and thus suffer loss of damping effects. This problem motivates research into SMA-damping devices. In fact, superelastic SMA-damping devices can reduce structural vibrations significantly without irreversible deformation due to unique hysteretic behavior. The superelastic hysteretic material behavior of NiTi-SMA is thermomechanically triggered and

includes both martensitic transformation and reverse transformation. The phase transformation depends on strain-rate and loading history. On the macroscopic level the nucleation from austenite to martensite is composed by the formation of martensitic transformation bands.

Knowledge of the strain-rate dependent evolution of macroscopic transformation bands is essential to consider strain-rate effects in constitutive modeling of superelastic SMAs. A primary investigation on the macroscopic formation of phase transformation fronts in NiTi was conducted by Shaw [1]. Another seminal study regarding both the macroscopic and microscopic behavior of NiTi under cyclic loading was operated by Otsuka [2]. Based on these investigations, Feng [3] used electromechanical-opting testing machines and high resolution optical recorders to capture images of the material surface during varying strain-rate loadings. Pieczyska [4], furthermore used differential scanning calorimetry (DSC) to record the thermal evolution of the macroscopic phase transition bands, while additionally using infrared cameras to obtain thermograms. Moreover, Xiao [5] investigated the strain field and the temperature field of NiTi specimen with 3D strain field cameras and infrared cameras. Thus, state-of-the art research offers numerous experimental and numerical investigations on the strain-rate dependency formation of transformation bands in NiTi.

The strain-rate dependent constitutive modeling of superelastic SMA for civil engineering applications is predominantly formulated as macroscopic material models. On the macroscopic level, Brinson [6] and Auricchio [7], among others, investigated fundamental macroscopic models. In the last decades, researchers developed several thermomechanical constitutive models for superelastic SMAs. One such example is Ozbulut's numerical model based on neural networks and fuzzy logic, that covers both the rate- and temperature dependent behavior of SMAs [8]. Moreover, numerically simpler macroscopic and thus computationally more efficient models were developed. Auricchio [9] developed a thermomechanical rate-dependent, one-dimensional model based on his primary research.

Superelastic hysteresis is thermomechanically coupled. Accordingly, the dynamic character of excitations strongly influences the thermal evolution and the hysteretic behavior. However, constitutive models developed so far do not explicitly consider the strain-rate dependent phase stability. In particular, the evolution of martensitic transformation bands is influenced by the strain-rate of the excitation. Simultaneously, martensitic phase stability modifies with the rate-dependent evolution of transition fronts.

This work proposes a one-dimensional numerical model that allows integrating changes in phase stability that depend on strain rate. More specifically, the change in phase stability is calculated with the rate-dependent entropy change in the superelastic SMA. In addition, experimental uniaxial tensile shaking-table tests on trained NiTi SMA wires validate the numerical model.

The following is subdivided into three sections. Section 2 includes both the experimental setup and the dynamic behavior of SMA. Subsequently, Section 3 presents a constitutive model for superelastic SMA. Finally, the validation of numerical calculations with the experimental results is presented in Section 4.

2 PRELIMINARY

2.1 Dynamic material properties

The superelastic behavior of NiTi is thermomechanically coupled. For superelastic NiTi, the austenite grid structure is energetically more effective. Thus, energy such as tensile stress has to be applied to initiate a phase transition. Auricchio [9] defines in detail, the stress-induced phase transformation as indicated by the critical martensitic transformation start and finish points R_s^{AM} and R_f^{AM} and inversely by R_s^{MA} and R_f^{MA} . Superscript AM indicates a transformation from austenite to martensite and MA vice versa. To incorporate the thermomechanical coupling, the critical transition point R depends on the stress level

Figure 1: Schematic martensitic transformation induced band evolution for a quasi-static (a) and a dynamic (b) excitation. Martensite-fraction in the NiTi specimen illustrated as transformation bands.

σ and the thermal level T .

$$R = \sigma - T(\eta) \quad (1)$$

SMAs thermal evolution depends on the latent heat generation during the exothermic process when the atomic grid restructures from a austenitic cubic to a martensitic monoclinic grid. Indeed, both the latent heat generation and the convection of generated heat depend on the transformation-rate. As a result, especially the critical transformation points R_f^{AM} and R_s^{MA} shift upwards for a higher material temperature and consequently the slope of the hysteretic transformation area increases.

The strain-rate and transformation-rate dependent thermal evolution during phase transition has an essential influence on the hysteresis surface. However, the martensitic phase stability influences additionally the reverse transformation. For instance, Figure 1 illustrates the evolution of the martensitic transition fronts for both a quasi-static (a) and a dynamic excitation (b). In a quasi-static load-state, the growth of localized martensite bands determines the phase transition [5]. In general terms, for quasi-static excitation the stress field specifies the position of the transition fronts; hence they are located next to the fixture points [1]. Evolution of quasi-static martensite bands leads to wider bands and comparative phase-stable martensitic modes. In contrast, a higher strain-rate causes a homogeneous distribution of small transformation bands all over the specimen. An increase in the band quantity concurrently implies a decrease in the band width. The martensitic phase stability reduces as a result, even if the amount of martensite-volume in the specimen is comparable to the quasi-static case. In addition, the higher transformation-rate raises the degree of atomic disorder and hence the motion of atoms. Indeed, a more unstable atomic state is concomitant with increasing entropy in the material [10]. As a consequence, the reverse transformation process is initiated on a higher stress level, since the martensitic phase becomes too unstable and the material strives for the energetically more effective and more stable austenite grid structure.

Figure 2: Utilized experimental setup, side-view. (1) shaking table, (2) test rig, (3) NiTi-wire, (4) load cell, (5), uniaxial strain direction, (6) pulley, (7) weights.

2.2 Experimental setup

Figure 2 shows the utilized shaking table for uniaxial cyclic-tensile tests. The uniaxial horizontal shaking table is 0.50 m x 0.50 m in size and can simulate both cyclic and stochastic loadings. The major constituents of the experimental setup are the shaking table (1) and a fixed test rig (2). For the tensile tests, NiTi wires (3) are attached to a vertically installed load cell (4) at the test rig. The distance from load cell to the right side fixture is 150 mm and thus sets the NiTi wire length for the experimental investigations. The uniaxial direction movement (5) causes tensile and pressure stress on the NiTi wire. Indeed, uniaxial tests are representative for SMA-braced structures, where only tensile loads excite the SMA-wires. To avoid buckling, which is owing to pressure, a pulley (6) redirects the SMA wire and ensure centric load application to the load cell. Additionally, weights (7) pre-stress the NiTi wire to induce martensitic transformation in a both faster and controlled manner. Moreover, two T-Type thermocouples (8) are installed 5 mm and 60 mm distanced from the right-side fixture. This position enables local temperature evolution measurement and the identification of local thermal differences. To control the table and to record the measurements data a MATLAB/Simulink environment is used. A CAN-hub connects the MATLAB/Simulink code with the shaking table and introduces the excitation signals. Finally, all sensors are connected with BNC-wires via a National Instruments 'NI USB-6210' A/D converter to a target PC.

3 RATE-DEPENDENT CONSTITUTIVE SMA MODEL

This section introduces briefly the rate-dependent constitutive model of Auricchio [9] and describes further advancements developed in this study. To cover the thermomechanical behavior of superelastic SMAs, the constitutive model is based on thermodynamic potential state laws. In general, the internal variable ξ , representing the martensitic volume fraction in the material, is expressed for martensitic

transformation in term of the following evolutionary equation

$$\dot{\xi} = \beta^{AM} \xi \frac{\dot{F}}{(F - R_f^{AM})^2}, \quad (2)$$

as a function of the external variables; the Temperature T and the uniaxial strain ϵ and can further be controlled with the speed-parameter β^{AM} . This cubic evolutionary depends moreover on the driving force F and the thermo-coupled limit stress level for martensitic transformation R_f^{AM} where both are depend on σ and T according to Auricchio [9]. To take into account the thermomechanical coupling, the constitutive model is based on a free energy for formulation ψ . In particular, the derivation of ψ originates from Raniecki and Bruhns thermo-elastic free energy formulation for single-phase materials [11] and reads

$$\psi = \psi_0(T) + \psi^e(\epsilon^e) - (T - T_0)\eta^e(\epsilon^e, T) + C \left[(T - T_0) - T \ln \frac{T}{T_0} \right]. \quad (3)$$

In this case, ψ_0 states the temperature-dependent free energy connection to the materials internal energy u and entropy η in the reference state and ψ^e states the free energy dependency on elastic strain. Moreover, C is the material heat capacity and T_0 the reference temperature. Based on Eq. 3, Auricchio and Sacco proposed a free energy formulation [7] for solid-solid phase transformation in superelastic SMAs as,

$$\psi = [(u_A - T\eta_A) - \xi(\Delta u - T\Delta\eta)] + C \left[(T - T_0) - T \log \frac{T}{T_0} \right] + \frac{1}{2}E\epsilon^e{}^2 - (T - T_0)\epsilon^e E\alpha, \quad (4)$$

where the subscript $-_A$ defines the austenite, Δ the difference between austenite and martensite values, α the thermal expansion and E the elastic modulus, which follows the Reuss-scheme. Accordingly, the stress σ and the temperature T are defined to the corresponding derivations of the free-energy formulation. Hence, we define the σ and T , which is based on the heat equation as

$$\sigma = \frac{\partial \psi}{\partial \epsilon^e} = E\epsilon^e - E\alpha(T - T_0) \quad (5)$$

and

$$C\dot{T} = T \frac{\partial^2 \psi}{\partial T \partial \epsilon^e} \dot{\epsilon} + T \frac{\partial^2 \psi}{\partial T \partial \xi} \dot{\xi} + \sigma \dot{\epsilon} - \frac{\partial \psi}{\partial \epsilon} \dot{\epsilon} - \frac{\partial \psi}{\partial \xi} \dot{\xi} - \gamma(T - T_{ext}). \quad (6)$$

To incorporate the rate-dependent entropy change, we rewrite the free-energy formulation by way of introducing the initial entropy difference $\Delta\eta_0$ to define ψ as

$$\psi = [(\Delta u_0 - T\Delta\eta_0) - \xi(\Delta\eta)] + C \left[(T - T_0) - T \ln \frac{T}{T_0} \right] + \frac{1}{2}E\epsilon^e{}^2 - (T - T_0)\epsilon^e E\alpha \quad (7)$$

Since we deal with thin wires, we neglect the thermal expansion factor α subsequently. Thus, we introduce

$$\eta = -\frac{\partial \psi}{\partial T} = \Delta\eta_0 + \xi(\Delta\eta) + C \ln \frac{T}{T_0} \quad (8)$$

as an additional control variable. Here, $\Delta\eta$ defines the difference between the current entropy level η and the initial entropy level $\Delta\eta_0$. The rate-dependent entropy change calculation enables to consider

observed strain-rate effects on the reverse transformation. The rate-dependency of the calculation arises directly from ξ , which depends on the phase transformation-rate, and from T . To consider the strain-rate effects both on the initial reverse transition stress level and on the martensitic-austenitic hysteresis slope, we reformulate the thermo-coupled initial stress level for reverse transformation and the speed parameter as

$$R_s^{MA} = \sigma_s^{MA} - T_R \frac{\eta}{\epsilon_L} \quad (9)$$

and

$$\beta^{MA} = \frac{\eta}{\Delta\eta_0} . \quad (10)$$

The thermal-coupled initial stress level R_s^{MA} determines the initial reverse transformation strain $\epsilon_s^{MA}(\eta)$ and thus also the linear-elastic part of the austenitic-martensitic phase transition. In brief, the free-energy reformulation enables a rate-dependent calculation of the entropy change and hence the introduction of both the entropy dependent speed parameter $\beta^{MA}(\eta)$ and the entropy dependent initial reverse transformation strain $\epsilon_s^{MA}(\eta)$.

4 RESULTS AND DISCUSSION

The experimental results in Figure 3 visualize the strain-rate effects during cyclic-tensile excitation with a strain amplitude of 4% on trained 0.2 mm Ni-55.8%-Ti-43.55%-SMA wires, produced by 'SAES Getters S.p.A.' (SAES). While comparing the whole hysteresis surface for frequencies of 0.05, 0.1, 0.5, 1.0 and 2.0 Hz, we also visualize both the linear-elastic and the transformation section of the reverse transition. In fact, we focus on the first loading cycle of each cyclic tensile test. Therefore, the decrease of linear-elastic reverse transformation for increasing strain-rates becomes evident, as marked in the plots. The decreasing linear-elastic section and the resulting reverse transformation on a higher stress level strongly influence the shape of the reverse transition hysteresis. This strain-rate dependent reverse transition shape is triggered by the decreasing martensitic phase-stability. However, state-of-the-art constitutive models do not consider these strain-rate dependent changes in reverse transformation. Subsequently, we present the effect of the entropy-change dependent calculation step by step, both of the initial reverse transformation strain $\epsilon_s^{MA}(\eta)$ and the adjusted speed parameter β^{MA} . More precisely, the results are presented in the following order: no rate-dependent entropy change, entropy change adjustment of $\epsilon_s^{MA}(\eta)$, entropy-change adjustment of $\epsilon_s^{MA}(\eta)$ and $\beta^{MA}(\eta)$.

We selected the material parameters, apart from the thermodynamic parameters, on the basis of quasi-static tensile tests taken both from the SAES data-sheet and self-conducted experimental results. The thermodynamic parameters were not determined experimentally. Accordingly, we chose the following thermodynamic parameters appropriately the behavior of the constitutive model and physically consistent, see Table 1. The material parameter ϵ_L is the maximum residual strain, γ is a heat convection coefficient and T_{ext} and T_R are the external and the reference temperatures, respectively. The chosen values for Δu and $\Delta\eta$ differentiate from Auricchio's parameter sets, but allow for the entropy calculation.

Table 1: Material parameter for constitutive model

Parameter	Value		Parameter	Value	
E_A	32350	MPa	Δu	1320	MPa
E_M	18550	MPa	$\Delta\eta_0 = \Delta\eta$	0.0093	MPaK ⁻¹
ε_L	3.34	%	γ	0.1	-
σ_s^{AM}	85	MPa	C	4.0	MPaK ⁻¹
σ_f^{AM}	305	MPa	T_u	573	K
σ_s^{MA}	225	MPa	$T_{ext} = T_0 = T_R$	293	K
σ_f^{MA}	200	MPa			

To show the influence of the rate-dependent entropy change on $\varepsilon_s^{MA}(\eta)$, we first compare the numerical results, excluding the entropy calculation, with the experimental results, see Figure 4. The linear-elastic part of the calculation is again separately marked. Indeed, the calculation of the martensitic-transformation is highly plausible for the three frequencies of 0.05, 0.1 and 0.5 Hz. Although the calculation of the rate-dependent thermal evolution is only qualitatively correct, the model can represent the thermomechanical coupling for austenitic-martensitic transition. However, the linear-elastic reverse-transformation section does not change and the reverse-transformation shape remains nearly the same. Figure 5, shows the included entropy-change effect on $\varepsilon_s^{MA}(\eta)$. To illustrate the effects of the entropy change on $\varepsilon_s^{MA}(\eta)$, we compare Figure 5 to Figure 4 to conclude that the linear-elastic section decreases for increasing strain-rate when entropy-change effects are included in the numerical model. Nevertheless, the reverse transformation shape remains uniform even though the phase transformation is introduced on a higher stress level. Accordingly, further entropy dependent adjustments are necessary for a more accu-

rate calculation of martensitic phase stability.

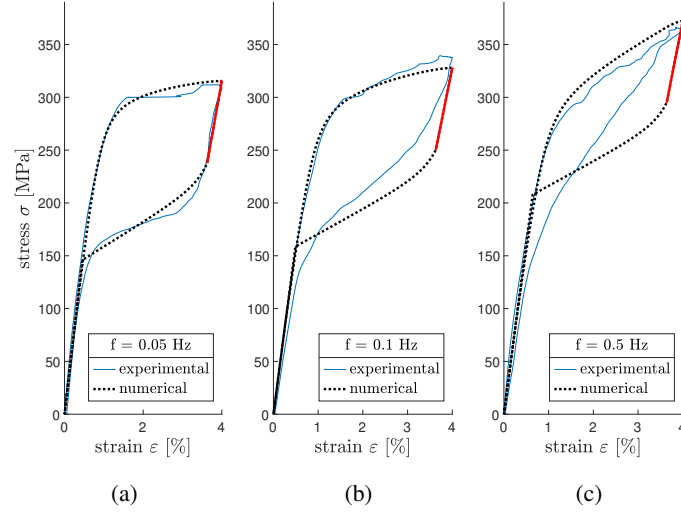

Figure 4: Comparison of experimental data with with numerical results excluding entropy-change effects. Red-marked solid line: martensitic linear-elastic section. $\epsilon = 4\%$. $f = 0.05/0.1/0.5\text{ Hz}$.

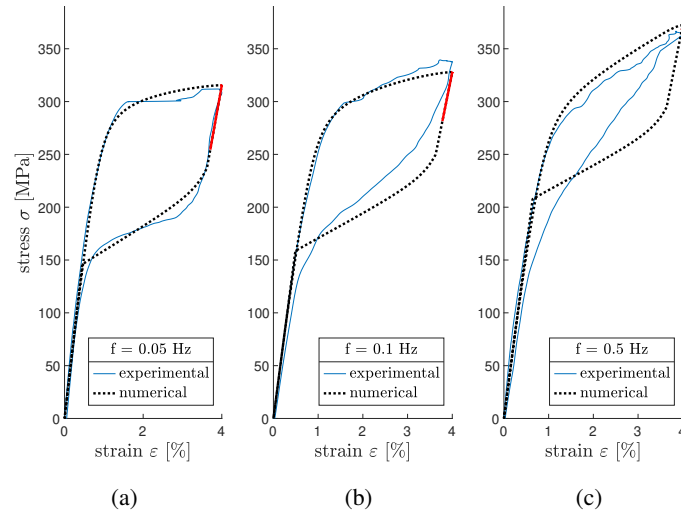

Figure 5: Comparison of experimental data with numerical results including entropy-change effects on $\epsilon_s^{MA}(\eta)$. Red-marked solid line: martensitic linear-elastic section. $\epsilon = 4\%$. $f = 0.05/0.1/0.5\text{ Hz}$.

To incorporate the change in reverse transformation curve, we introduce the rewritten speed parameter β^{MA} as a function of η . In fact, $\beta^{MA}(\eta)$ defines the shape of the cubic evolutionary equation for the reverse transformation and increases with increasing entropy, see Eq. 10. Figure 6 shows the numerical results both including and excluding entropy changes, and further compares the numerical with the exper-

imental results. The inclusion of the rate-dependent entropy change for the reverse transition improves the calculation accuracy. On the one hand, the austenite transformation changes for higher strain-rate from a convex to a slightly concave curve due to the entropy dependent calculation of $\beta^{MA}(\eta)$. On the other, the initial level for reverse transformation rises for increasing strain-rates. Consequently, the advancements on the one-dimensional material model cause – especially for high strain-rates – a more accurate calculation of the hysteresis surface without negative impact on the numerical efficiency of the algorithm.

Figure 6: Comparison of experimental data with numerical results both excluding and including entropy change. Thin solid line (blue): experimental investigation. Width solid line (black): numerical results; including entropy change. Dotted line: numerical results; excluding entropy change. Entropy-change effects on $\epsilon_s^{MA}(\eta)$ and $\beta^{MA}(\eta)$. $\epsilon = 4\%$. $f = 0.05/0.1/0.5/1.0/2.0\text{ Hz}$.

5 CONCLUSION

In this paper, the influence of rate-dependent phase-stability during martensitic transformation of superelastic SMA-wires on the hysteresis surface is investigated. To consider rate-dependent phase-stability in a numerical model, we advanced a one-dimensional constitutive model by way of an adjusted free-energy formulation for phase transition in superelastic SMAs. The rewritten free-energy formulation Eq. 4 enables the rate-dependent entropy change calculation in the material to consider the decreasing martensitic phase-stability for increasing strain-rates. In brief, the entropy change calculation enables a strain-rate dependent calculation of the initial strain level for reverse transformation. The advancement further influences the reverse evolutionary equation and thus the shape of martensitic-austenitic transformation. Hence, the change from a convex to a concave reverse transition shape for increasing strain-rates can be calculated. The significant influence of strain-rate on the reverse transformation was observed by experimental investigations. In particular, we performed cyclic-tensile tests with varying strain-rates on NiTi-wires, using a uniaxial horizontal shaking table. In further process, the dynamic material was analyzed according to state-of-the-art research on the evolution of martensitic transformation bands. Thus, both the relationship between strain-rate and martensitic phase stability and the need for nu-

merical inclusion of this relationship have been noted. Furthermore, the experimental results validate the modified one-dimensional model. In conclusion, the rate-dependent thermomechanical modeling of entropy change in superelastic SMAs enables considering martensitic phase stability effects on the reverse transformation. Hence, we calculate the hysteresis surface more accurately with neither impairment of the numerical models simplicity nor the robustness of the solution algorithm.

Shear behaviour of magnetorheological elastomers: viscoelastic and magnetorheological properties

Alberto Bellelli¹, Andrea Spaggiari^{1*}

¹Department of Sciences and Methods for Engineering, University of Modena and Reggio Emilia, Italy

ABSTRACT

This paper presents the mechanical characterization of several specimens of magnetorheological elastomers (MRE), under shear stress, up to failure. The specimens were designed and manufactured with different ratio of ferromagnetic particles, curing conditions and applied magnetic field. The MRE elastomer is composed by two main ingredients: a base elastomer and carbonyl iron powder, which are mixed in the desired weight ratio, following a structured experiment plan. The PDMS elastomer, is polymerized by mixing the base material with a curing agent and the iron particles at the same time. We decide to characterize the shear behaviour of the bulk MRE in a condition quite close to a typical application such as an isolation mount. This requires the design of a special rig to apply both the load to the cylindrical specimens and the magnetic field at the same time. This method, compared to the use of a traditional rheometer as already present in technical literature, grants the possibility to test the specimen in large deformation and up to failure. The specimens were manufactured and tested according to a Design of Experiment method, in order to obtain a statistically significant influence of the variables considered: particles volume fraction, isotropicity and applied field. Moreover, the MRE was tested both at low shear rate, in order to avoid the viscoelastic effects as well as at high shear rates, in order to evaluate the dynamic effects. An analysis of variance performed on the test results is used to highlight which are the most important variables that affect the output responses and could be exploited to build a simplified phenomenological model of the MRE shear behaviour.

INTRODUCTION

The magnetorheological elastomers (MRE) are a class of smart materials which modifies their

mechanical properties due to an external stimulus, the magnetic field. These materials are gaining increasing popularity nowadays, since the possibility to have free shape MREs could lead to the design of smart components or sensors, which exhibits full integration with the structure. Therefore, the proper design of a MRE system first requires the knowledge of the magneto-mechanical properties of the MRE material. These materials have already gained the attention of the researcher, but still some open questions remain in technical literature. One of the first MRE ever produced was created due to the curiosity towards a toy, the Silly Putty (Cross, 2012; Marc Hartzman, 2013) a viscoelastic material which can be found also in a magnetic sensitive form (Golinelli et al., 2015). Silly Putty is extremely stiff when subjected to high deformation rates, while it is more than soft in case of quasi-static applied stress (Cross, 2012), reaching a quasi-fluid behaviour. This very strong viscoelastic behaviour makes Silly Putty unsuitable for engineering applications: it cannot keep a predefined shape it tends to collapse under its own weight, its behaviour changes dramatically according to the loading rate. More interesting performances are offered by the magnetorheological elastomers (MREs), which are similar to the Silly Putty, but consist of a non-magnetic elastomeric matrix with ferromagnetic micrometric particles in a non colloidal suspension (Davis, 1999; Guan et al., 2008; Ruddy et al., 2008) such that the elastomeric matrix maintains its shape and does not exhibit a fluid-like behaviour. The magnetic interaction between the particles in these composite materials depends on the spatial arrangement of the particle and their volume fraction and this feature leads to an interesting number of magneto-mechanical phenomena (de Vicente et al., 2011; Ginder et al., 2000; Kallio, 2005). The technical literature reports several studies in compressive behaviour, considering both dynamic and quasi static conditions, but scarce information are retrieved in shear and especially regarding the ultimate failure stress (Schubert and Harrison, 2015) since the shear test requires an ad hoc design of the gripper system.

The purpose of this work is to expand the applicability of MREs towards the more industrialized field of magnetorheological fluids (MRFs) which are based on the same concept but exploiting a fluid matrix which makes them suitable for vibration damping and shock absorbers (Carlson and Jolly, 2000; Chen et al., 2007; Shen et al., 2004; Spaggiari et al., 2016; Yang et al., 2015). Compared to MRFs, magnetorheological elastomers show an always solid behaviour, i.e. they do not pass from fluid to quasi-solid state, however their mechanical characteristics in terms of stiffness and damping are a function not

only of the external mechanical loads, but also of the applied external magnetic field. On the one hand the solid matrix prevents the ferromagnetic particles to move and therefore the MR effect is limited, on the other hand the very same solid matrix cancels the problem of confinement and compatibility with standard gaskets damage typical of MRF (Güth et al., 2013; Wiehe and Maas, 2012). Moreover, having the matrix lead to the possibility to make MREs both in isotropic and anisotropic configurations. This feature could be done during the manufacturing of the samples, by applying a magnetic field when the elastomer is still liquid. Figure 1a (Chen et al., 2007) show the or they can be forced to form chain-like column structures, as as shown in Figure 1b with higher magnification.

Figure 1. SEM image with 200 times magnification of MRE prepared in 800 mT (b) SEM image with 1600 times magnification of MRE prepared in 800 mT (Chen et al., 2007)

This paper investigates a custom MRE made by a PDMS elastomeric matrix, which can be cast in various shapes, it undergoes large deformations under shear tests and exhibits a interesting behaviour for a potential use as smart controllable mount.

1. MATERIALS AND METHODS

The manufacture of the specimens was carried out following a Design of Experiment procedure (Montgomery, 2004). We considered as design variables three different volume fractions of ferromagnetic particles, the isotropicity of the specimens and the application of an external magnetic field, which is provide with permanent supermagnets. For each configuration we manufactured 2 samples for a total of 14 specimens. Subsequently, the shear tests, with or without an external magnetic field with cyclic and monotonic loading up to failure are applied.

2.1 Experimental apparatus

The elastomeric matrix is a commercial two-component PDMS (Polydimethylsiloxane) base, Sylgard 184 (Dow Corning Sylgard 184 TDS | Krayden, 2013), which is a material which is widely used in electronic applications, especially for encapsulation of microelectronics circuits. This material shows very interesting properties as an electret (Kachroudi et al., 2017) and it was already described and studied in (Kachroudi et al., 2015), where its viscoelastic, thermal and dielectric properties can be found. Its behaviour as MRE Matrix was already tested in compression in a previous authors' work (Bellelli and Spaggiari, 2019). The aim of this paper is to study and discuss its magnetorheological properties when enriched by various volume fractions of ferromagnetic particles. The elastomeric base was mixed with carbonyl iron particles with an average size of $45\text{ }\mu\text{m}$ - Ferchim RI 63/3.2 by Pometon (Pometon, n.d.). The three ingredients (curing agent, silicone base and iron powder), after being weighted to obtain the desired volume fraction, were deposited and mixed in a 3d printer mold designed to obtain two desired specimens at one time. The mold was made out of nylon reinforced with microparticles of carbon and is shown in Figure 2. All the parts are kept in position and securely tightened through stainless steel screws, which do not disturb the magnetic field, when applied.

Figure 2. – 3d Printed mold.

The specimens are cylindrical with a diameter of 16mm and a height of 31mm. The mold was designed in order to facilitate the extraction of the specimen and to improve the degassing phase. This phase is mandatory to avoid air bubbles inside the specimen, since the manual mixing always introduces air inside the mold. The top cover was thus equipped with a set of holes which allowed gas extraction, obtained by using a vacuum chamber at -0.8 bar. The mold, containing the reagents still in the liquid phase, was left for 15 minutes in the vacuum chamber to ensure a proper elimination of air bubbles and then the curing step started. The mold was placed in rotation through a stepper motor in order to avoid the settling of the iron particles due to the gravity and it was kept for six hours in a climatic chamber at 45°C to ensure the complete polymerization of the elastomeric matrix. Without this procedure the specimens particles are going to settle and the volume fraction in the specimen changes, as shown in Figure 3a. The rotating system and the specimen filling operation need to be carefully done, otherwise inner formation of air bubbles could occur. This issue is particularly difficult to be spotted, since the centripetal acceleration on the air bubbles lead al the porosity to coalesce in one big cavity in the center of the specimens, which can be seen only by halving the specimen as show in Figure 3b.

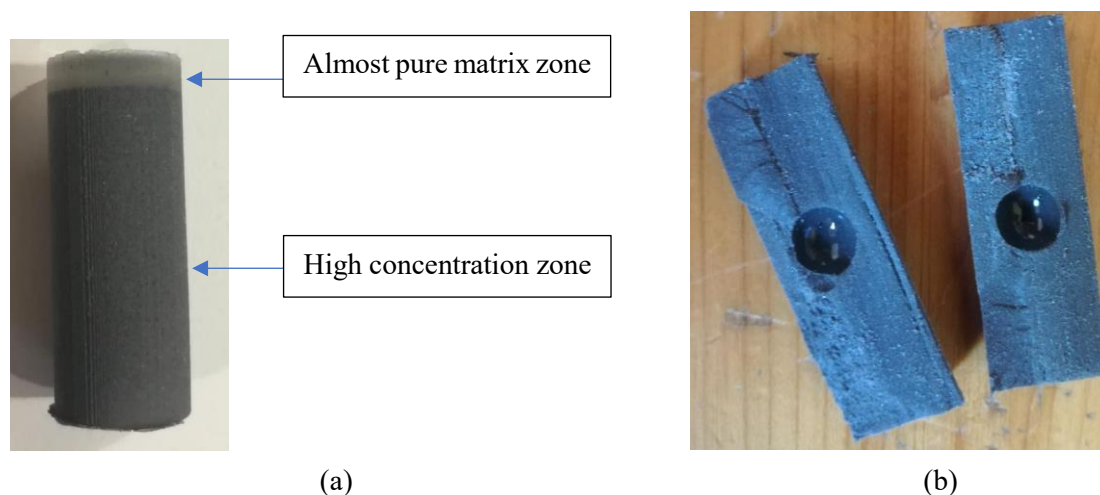

Figure 3. Specimen without the rotating system, effect of gravity (a), specimen with high rotation speed, effect of centripetal acceleration on air.

A total of 14 specimens were manufactured according to the previously described procedure. First, the isotropic specimens were obtained, with different percentages by weight of ferromagnetic material (60%

- 70% -80%), three samples for each volume fraction considered. In order to produce the other 8 anisotropic specimens, a couple of Nd-Fe-Br permanent magnets were placed around the mold when the system was still uncured. The mold was designed to kept the magnet in place while rotating, proving a constant magnetic field inside the specimens. The effect of the magnetic field led to the formation of an aligned arrangement of particles inside the specimens. The magnetic induction field provided by the magnets, measured experimentally through a Gaussmeter (in air), was around 200 mT, enough to obtain particle movement and chain formation. In the end, the last 2 control specimens of pure PDMS, with no ferromagnetic particles, were manufactured to estimate the base material properties under the same test conditions of the magnetorheological samples. The specimens were tested in shear, by means of a classical pin and fork rig, as shown in Figure 4. This configuration allows a quasi pure shear on the MRE without any need of other fixtures or adhesives. The shear stress in the cylinder can be easily determined, according to following equation and to the dimensions in the sketch reported in Figure 4a.

$$\tau = \frac{F}{2\pi d^2/4}$$

The shear strain is, using a small strain approach

$$\gamma = \frac{d}{h}$$

Being h the gap between the two rigid fixtures, which is equal to 0.2mm.

The complete system is reported in Figure 4b. The elastomeric matrix is very soft and the stiffness of the 3D printed system is nearly two times higher, so that the deformation measure is not disturbed by the test rig. The tensile test was not taken into consideration because the gripping of elastomers causes severe stress concentrations, which undermine the test results, and in addition the elastomers do not perform well under tensile stresses. The shear stress test procedure was divided in two parts. The first set of tests were non-destructive since we decided to limit the test to the elastic properties of the material and no plasticization is expected for a hyper elastic material. The desired test conditions were ensured by limiting the maximum force to 100 N and applying a cyclic displacement. This limit values were calibrated after a set of preliminary tests, in order to avoid possible damage of the specimen. The tests have the aim to register the loading/unloading curve in order to estimate the viscoelastic effect. The

experimental plan included the execution of the compression and the three-point bending tests on 18 specimens. Table 1 reports a synthetic representation of the variables considered.

Figure 4. Schematic of the test rig with dimensions (not to scale) and 3d printed test rig with pure elastomeric specimen.

Table 1. Specimens considered in the design plan

Variable	Number of Levels							
% ferromagnetic material	3 levels	0	60		70		80	
Isotropy	Boolean	N/A	YES	NO	YES	NO	YES	NO
Replicates	2	2	2		2		2	
Total specimens	14	2	4		4		4	

The output responses to be computed on the basis of the experimental curves are:

- Tangential stiffness, as the slope of the first elastic part of the stress-strain curves (MPa)
- Specific dissipated energy (mJ/mm³)
- Maximum tangential stress at failure (MPa)
- Maximum tangential strain at failure (%)

2. PRELIMINARY RESULTS

Figure 5 shows the τ - γ curves for the isotropic specimens without the applied field (a) and with the field applied during the compression test (b). The curves in red represents the pure elastomer specimen, which is the same for both the charts, while the three brownish curves in Figure 5a represents the isotropic specimens while the three blue curves in Figure 5b show the anisotropic ones. The other destructive test are under analysis at the moment and will be added to the complete presentation of the results during the Ecomas – Smart Conference.

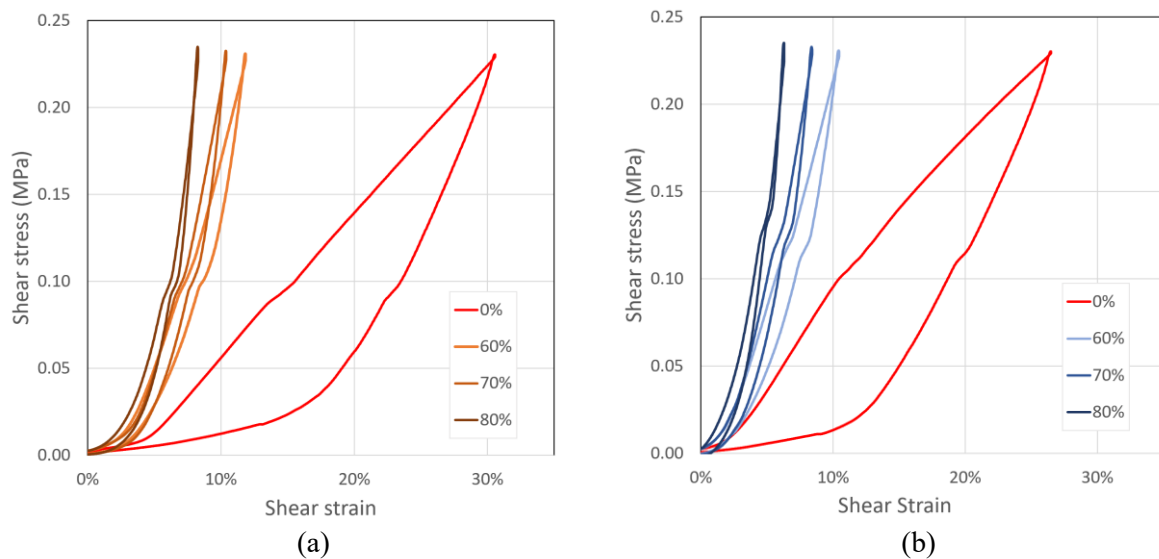

Figure 5. Shear test on isotropic specimens, without (a) and with the field applied (b).

3. DISCUSSION AND CONCLUSION

The discussion and the conclusion of the present work are undermined by several experimental issue occurred during the experimental tests, which drastically stopped the test campaign. The main cause of was an unexpected failure of the control board of the machine needed to carry out the cyclic test, which prevented the experimental campaign to be completed. The selected statistical analysis of the results make little sense with only partial results. The authors believe the test machine will be restored in time to present a proper discussion of the results during the conference.

Key words: ferroelectricity, polarization, variational inequality, mixed finite elements

Abstract. This paper is concerned with modeling the polarization process in ferroelectric media. We propose to use variational inequalities to describe electromechanical hysteresis phenomena as arise in piezoelectric materials. Thermodynamically consistent formulations are based on the free energy, phenomenological models usually comprise a set of switching and saturation conditions for the onset and saturation of the remanent polarization and strains. While thermodynamically consistent models naturally lead to variational formulations, we aim at combining the different phenomenological conditions into one variational inequality. In our formulation we use one Lagrange multiplier for each condition (the onset of domain switching and saturation), each satisfying Karush-Kuhn-Tucker conditions. An update for reversible and remanent quantities is then computed within one, in general nonlinear, iteration.

1 INTRODUCTION

In the current work we aim at describing the process of polarization in ferroelectric media. Polarization has been described as a dissipative process in a thermodynamically consistent framework based on the Helmholtz free energy in a series of papers by Bassiouny, Ghaleb and Maugin [1, 2, 3, 4]. The notions introduced there are close to the theory of elasto-plasticity, including internal variables, yield conditions and hardening moduli. The evolution of the internal variables is based on inequality constraints, such as the so-called switching condition. This condition defines the onset of remanent polarization in ferroelectric media.

McMecking and Landis [12] as well as Landis [11] developed their theory of multi-axial polarization based on those early works. The internal variables are the polarization vector in [12], and an independent polarization strain is added in [11]. They specified non-linear free energy functions that account also for the saturation phenomenon. Once reaching saturation, the polarization cannot grow any further, but may change direction or be reduced by (electric or mechanic) depolarization.

Kamlah and Tsakmakis [8] chose a different set of conditions to describe the polarization process, see also the overview given in [7]. They assume the reversible part of the free energy to be quadratic, and add separate switching and saturation conditions for remanent polarization and remanent polarization strain.

All of these frameworks have been implemented in finite element codes by various authors. Kamlah and Boehle [9] provided the increments for the evolution polarization and polarization strain for the material described in [8]. Klinkel [10] presented a return mapping algorithm realizing Landis-type material properties. Semenov et al. [20] provide such an algorithm for a finite element formulation including the vector (not scalar) potential of the dielectric displacement vector. Elhadrouz and co-workers [5] implemented a material model including different switching functions for polarization and polarization strain, similar as proposed by [8]. Zouari et al. [22] proposed a quadratic element realizing a Kamlah-type constitutive law.

We will follow Kamlah's approach, but formulate the theory in the framework of variational inequalities. These inequalities arise naturally from energy-based constitutive models with dissipation, see [14] for the application to Landis-type and also ferromagnetic materials. In our case, we add both switching and saturation condition for the remanent polarization. In the following derivations, we will see that, in the variational framework, these conditions are not independent as proposed in [7], but that the Lagrangian multiplier enforcing saturation becomes an additional term in the switching criterion. This way, both criteria can be satisfied at once.

Concerning the finite element implementation, we use mixed finite elements for the mechanical unknowns, adding independent stresses. We use non-standard TDNNS elements, where tangential displacements and the normal component of the normal stress are chosen as degrees of freedom [15, 18]. These elements were adapted to linear piezoelectricity in [17, 13].

2 A PHENOMENOLOGICAL MATERIAL LAW

In this section we briefly introduce the phenomenological material model in the spirit of Kamlah [7], before switching to an energy-based model in the next section. We consider a ferroelectric body in the domain $\Omega \in \mathbb{R}^3$ with the boundary $\partial\Omega$. We are concerned with isothermic, rate independent and quasi-static deformation and polarization processes. We are interested in finding the displacement field \mathbf{u} , the electric potential ϕ and the remanent polarization \mathbf{P}_I .

The electric field is introduced as the negative gradient of the electric potential $\mathbf{E} = -\nabla\phi$, whereas we use the linear strain tensor $\boldsymbol{\varepsilon} = \frac{1}{2}(\nabla\mathbf{u} + \nabla\mathbf{u}^T)$. The electrical and mechanical balance equations are

$$-\operatorname{div} \boldsymbol{\sigma} = \mathbf{f} \quad (1)$$

$$-\operatorname{div} \mathbf{D} = 0 \quad (2)$$

for the stress tensor $\boldsymbol{\sigma}$ and the dielectric displacement \mathbf{D} . The mechanical boundary conditions are

$$\mathbf{u} = \mathbf{u}_0 \text{ on } \Gamma_1 \quad \text{and} \quad \boldsymbol{\sigma} \cdot \mathbf{n} = \boldsymbol{\sigma}_0 \text{ on } \Gamma_2 = \partial\Omega \setminus \Gamma_1, \quad (3)$$

and the electrical boundary conditions

$$\phi = \phi_0 \text{ on } \Gamma_3 \quad \text{and} \quad \mathbf{D} \cdot \mathbf{n} = \rho_0 \text{ on } \Gamma_4 = \partial\Omega \setminus \Gamma_3. \quad (4)$$

The constitutive model relates stress $\boldsymbol{\sigma}$ and dielectric displacement \mathbf{D} to strain $\boldsymbol{\varepsilon}$ and electric field \mathbf{E} as well as to the remanent polarization \mathbf{P}_I . A basic assumption is the additive decomposition of dielectric displacement and elastic strain into a reversible and a remanent part. For the reversible parts, constitutive equations analogous to Voigt's linear theory are assumed

$$\boldsymbol{\varepsilon}_R = \boldsymbol{\varepsilon} - \boldsymbol{\varepsilon}_I = \mathbf{S}^E \cdot \boldsymbol{\sigma} + \mathbf{d}^T \cdot \mathbf{E} \quad (5)$$

$$\mathbf{D}_R = \mathbf{D} - \mathbf{P}_I = \mathbf{d} \cdot \boldsymbol{\sigma} + \boldsymbol{\epsilon}^\sigma \cdot \mathbf{E}. \quad (6)$$

The mechanical compliance tensor \mathbf{S}^E as well as the dielectric tensor ϵ^σ are assumed to be isotropic and constant. The components of the dielectric tensor depend on \mathbf{P}_I via

$$d_{kji}(\mathbf{P}_I) = \frac{\mathbf{P}_I}{P_{sat}} \left[d_p e_i^P e_j^P e_k^P + d_n (\delta_{ij} - e_i^P e_j^P) e_k^P + d_t \frac{1}{2} ((\delta_{ki} - e_k^P e_i^P) e_j^P + (\delta_{kj} - e_k^P e_j^P) e_i^P) \right] \quad (7)$$

with unit vector in direction of polarization

$$\mathbf{e}^P = \frac{\mathbf{P}_I}{|\mathbf{P}_I|}, \quad (8)$$

and the Kronecker delta

$$\delta_{ij} = \begin{cases} 1, & \text{if } i = j, \\ 0, & \text{if } i \neq j. \end{cases} \quad (9)$$

The unpolarized material does not show any piezoelectric coupling effects. The dielectric tensor grows (linearly) with the norm of \mathbf{P}_I . The constants d_p , d_n and d_t correspond to the standard parameters d_{33} , d_{31} and d_{15} , respectively, for the fully poled state with polarization in direction of \mathbf{e}_3 . As proposed by McMeeking and Landis [12], the remanent strain is volume-preserving and depends only on the polarization via

$$\epsilon_I = \frac{3}{2} \frac{S_{sat}}{P_{sat}^2} \left(\mathbf{P}_I \otimes \mathbf{P}_I - \frac{1}{3} \mathbf{I} |\mathbf{P}_I|^2 \right), \quad (10)$$

where S_{sat} characterizes the maximum possible remanent strain. The polarization strain ϵ_I is a deviatoric uni-axial strain and does not cause any further remanent strain.

The evolution of the remanent polarization \mathbf{P}_I is determined by switching and saturation conditions. Once the electric field is increased above the coercive field strength E_C , the material will be polarized irreversibly. The switching condition is a condition on the electric driving force $\hat{\mathbf{E}}$ which will be defined in Section 3. In the simplest case, the absolute value of $\hat{\mathbf{E}}$ may not exceed E_C ,

$$f_P = |\hat{\mathbf{E}}| - E_C \leq 0. \quad (11)$$

On the other hand, the saturation condition states that the remanent polarization must not exceed the saturation polarization, which resembles the fully polarized state. The condition reads

$$f_S(\mathbf{P}_I) = |\mathbf{P}_I| - P_{sat} \leq 0 \quad (12)$$

3 ENERGY/ENTHALPY-BASED FORMULATION

We provide energies matching the constitutive equations from the previous section as a basis for all further deductions. According to the literature [11, 7, 21], the free energy decomposes into two parts,

$$\Psi = \Psi^R + \Psi^I, \quad (13)$$

with the reversible or stored part Ψ^R and the (irreversible) additional contribution Ψ^I . The reversible part Ψ^R is given by

$$\Psi^R = \frac{1}{2} \mathbf{E} \cdot (\mathbf{d} : \boldsymbol{\sigma} + \epsilon \cdot \mathbf{E}) + \frac{1}{2} \boldsymbol{\sigma} : (\mathbf{S}^E : \boldsymbol{\sigma} + \mathbf{d} \cdot \mathbf{E}). \quad (14)$$

The additional contribution of the free energy is given by

$$\Psi^I = \frac{1}{2} c \mathbf{P}_I \cdot \mathbf{P}_I, \quad (15)$$

in the simplest case as used by Kamlah [7].

An additional term representing saturation is added in the following. The saturation condition $f_S \leq 0$ (cmp. (12)) is equivalent to an inequality involving the Lagrangian multiplier λ_S ,

$$\lambda_S f_S(\mathbf{P}_I) \leq 0 \quad \text{for all } \lambda_S \geq 0. \quad (16)$$

The updated energy function Ψ^S taking into account saturation is then given by

$$\Psi^S = \Psi^R + \Psi^I + \sup_{\lambda_S \geq 0} \lambda_S f_S(\mathbf{P}_I). \quad (17)$$

As long as $f_S \leq 0$, the supremum in (17) takes zero value, and Ψ^S is equal to the energy function Ψ in (13). If the saturation condition is violated ($f_S > 0$), $\sup_{\lambda_S \geq 0} \lambda_S f_S$ tends to infinity, and with it the energy function Ψ^S .

The enthalpy is introduced as a function of the electric field \mathbf{E} , the mechanical stress $\boldsymbol{\sigma}$, the irreversible polarization \mathbf{P}_I via

$$H = \Psi^R + \Psi^I + \sup_{\lambda_S \geq 0} f_S(\mathbf{P}_I) \lambda_S - \mathbf{E} \cdot \mathbf{D}(\mathbf{E}, \boldsymbol{\sigma}, \mathbf{P}_I) - \boldsymbol{\sigma} : \boldsymbol{\varepsilon}(\mathbf{E}, \boldsymbol{\sigma}, \mathbf{P}_I), \quad (18)$$

with $\mathbf{D}(\mathbf{E}, \boldsymbol{\sigma}, \mathbf{P}_I)$ and $\boldsymbol{\varepsilon}(\mathbf{E}, \boldsymbol{\sigma}, \mathbf{P}_I)$ according to (5) and (6), respectively. From the (total) enthalpy H the driving force $\hat{\mathbf{E}}$ mentioned in Section 2 can be derived. It is defined as the (negative) derivative of the enthalpy by the irreversible quantities, in our case by \mathbf{P}_I . In contrast to the original model by Kamlah, the driving force thus contains λ_S , which is non-zero in case of saturation,

$$\hat{\mathbf{E}} = -\frac{\partial H}{\partial \mathbf{P}_I} = \mathbf{E} + \boldsymbol{\sigma} : \left(\frac{d}{d\mathbf{P}_I} \mathbf{d} \right) \cdot \mathbf{E} + \boldsymbol{\sigma} : \left(\frac{d}{d\mathbf{P}_I} \boldsymbol{\varepsilon}_I \right) - c \mathbf{P}_I - \lambda_S \frac{df_S}{d\mathbf{P}_I} \quad (19)$$

The energy dissipation rate is given by [14]

$$\Phi = \hat{\mathbf{E}} \cdot \dot{\mathbf{P}}_I. \quad (20)$$

3.1 From an Incremental optimization principle to a variational inequality

The (total) free energy and the dissipation can be related to an incremental constitutive minimization principle, which can be found in detail in [14]. As the enthalpy is to be minimized and maximized with respect to different quantities we, in the sequel use the terminus optimization problem. The (total) enthalpy and dissipated energy are to be optimized under side constraints. These are the switching condition (10) and the balance equations (1) - (2).

$$H + \Phi \rightarrow \max_{\mathbf{E}} \max_{\boldsymbol{\sigma}} \min_{\mathbf{P}_I} \text{ subject to } \begin{cases} \operatorname{div} \boldsymbol{\sigma} = 0 \\ f_P(\hat{\mathbf{E}}) \leq 0 \end{cases} \quad (21)$$

Note that, here and in the remainder of Section 3, we neglect the work of external forces. Of course, in finite element implementations, external forces are added in the standard way to the right hand side of the variational equations or inequalities.

The treatment of equilibrium side condition is well known. For the mechanical balance equation the deformation \mathbf{u} can be interpreted as an Lagrangian multiplier, and therefore the product $-\operatorname{div} \boldsymbol{\sigma} \cdot \mathbf{u}$ is added.

In order to consider the inequality side condition for the polarization, another Lagrangian multiplier is introduced, such that the Karush-Kuhn-Tucker conditions (KKT-conditions) are fulfilled,

$$f_P \leq 0, \quad \lambda_P \geq 0, \quad \lambda_P f_P = 0 \quad (22)$$

The Lagrangian of the enthalpy is introduced below, where both λ_S and λ_P as well as \mathbf{u} are viewed as independent unknowns. For convenience, it also contains the dissipated energy,

$$\hat{H}(\mathbf{E}, \boldsymbol{\sigma}, \mathbf{P}_I, \mathbf{u}, \lambda_S, \lambda_P) = \Psi^R + \Psi^I + \Phi - \mathbf{E} \cdot \mathbf{D} - \boldsymbol{\sigma} : \boldsymbol{\varepsilon} + f_S(\mathbf{P}_I) \lambda_S + \lambda_P f_P(\hat{\mathbf{E}}) - \operatorname{div} \boldsymbol{\sigma} \cdot \mathbf{u}. \quad (23)$$

The optimization problem to be solved is now

$$\hat{H} \rightarrow \min_{\mathbf{u}} \max_{\mathbf{E}} \max_{\boldsymbol{\sigma}} \min_{\mathbf{P}_I} \max_{\lambda_P} \max_{\lambda_S} \quad (24)$$

As the Lagrangian multipliers λ_S and λ_P are constrained to be non-negative, the variation of \hat{H} leads to a variational inequality. Variation with respect to \mathbf{u} , \mathbf{E} , $\boldsymbol{\sigma}$ and \mathbf{P}_I can be done in the standard way, as any virtual values $\delta \boldsymbol{\sigma}$, $\delta \mathbf{u}$, $\delta \mathbf{E}$ and $\delta \mathbf{P}_I$ which fulfill the kinematic (Dirichlet) boundary conditions are admissible. A variational equation is obtained, where the right hand side has to be replaced by δW^{ext} when including external forces,

$$\frac{\partial \hat{H}}{\partial \mathbf{E}} \cdot \delta \mathbf{E} + \frac{\partial \hat{H}}{\partial \boldsymbol{\sigma}} : \delta \boldsymbol{\sigma} + \frac{\partial \hat{H}}{\partial \mathbf{P}_I} \cdot \delta \mathbf{P}_I + \frac{\partial \hat{H}}{\partial \mathbf{u}} \cdot \delta \mathbf{u} = 0. \quad (25)$$

The saturation and polarization condition, which are given as inequalities, cannot be treated in the standard way. As the set of admissible λ_P and λ_S is restricted $\delta \lambda_P$ and $\delta \lambda_S$ are not arbitrary. These conditions directly lead to variational inequalities, we refer to the monograph [6] for an introduction into variational inequalities in the framework of elasto-plasticity. For both, λ_P and λ_S a test function $\bar{\lambda}_P$ and $\bar{\lambda}_S$ is introduced. One directly deduces that \hat{H} is maximized with respect to λ_P if and only if for all other admissible choices $\bar{\lambda}_P \geq 0$ there holds

$$\bar{\lambda}_P f_P(\hat{\mathbf{E}}) \leq \lambda_P f_P(\hat{\mathbf{E}}) \quad \forall \bar{\lambda}_P \geq 0, \quad (26)$$

For λ_S , the situation is a bit more involved, as $\hat{\mathbf{E}}$ depends on λ_S . Writing $\tilde{\mathbf{E}}$ for $\hat{\mathbf{E}}(\bar{\lambda}_S)$ for some $\bar{\lambda}_S \geq 0$, one finds that \hat{H} is maximized with respect to $\bar{\lambda}_S$ if and only if

$$\tilde{\mathbf{E}} \cdot \dot{\mathbf{P}}_I + \bar{\lambda}_S f_S(\mathbf{P}_I) + \lambda_P f_P(\tilde{\mathbf{E}}) \leq \hat{\mathbf{E}} \cdot \dot{\mathbf{P}}_I + \lambda_S f_S(\mathbf{P}_I) + \lambda_P f_P(\hat{\mathbf{E}}) \quad \forall \bar{\lambda}_S \geq 0. \quad (27)$$

Inserting the definition of $\tilde{\mathbf{E}}$, which implies that $\tilde{\mathbf{E}} - \hat{\mathbf{E}} = -(\bar{\lambda}_S - \lambda_S) d\mathbf{f}_P / d\mathbf{P}_I$, the above inequality can be further reduced to

$$(\bar{\lambda}_S - \lambda_S) \left(-\frac{df_S}{d\mathbf{P}_I} \cdot \dot{\mathbf{P}}_I + f_S - \lambda_P \frac{df_P}{d\mathbf{E}} \frac{df_S}{d\mathbf{P}_I} \right) \leq 0 \quad \forall \bar{\lambda}_S \geq 0. \quad (28)$$

Summing up, the variational inequality to hold for all $\delta \mathbf{E}$, $\delta \boldsymbol{\sigma}$, $\delta \mathbf{P}_I$ and $\delta \mathbf{u}$ as well as $\bar{\lambda}_S \geq 0$ and $\bar{\lambda}_P \geq 0$ reads

$$\frac{\partial \hat{H}}{\partial \mathbf{E}} \cdot \delta \mathbf{E} + \frac{\partial \hat{H}}{\partial \boldsymbol{\sigma}} : \delta \boldsymbol{\sigma} + \frac{\partial \hat{H}}{\partial \mathbf{P}_I} \cdot \delta \mathbf{P}_I + \frac{\partial \hat{H}}{\partial \mathbf{u}} \cdot \delta \mathbf{u} + (\bar{\lambda}_P - \lambda_P) f_P + (\bar{\lambda}_S - \lambda_S) \left(f_S - \frac{df_S}{d\mathbf{P}_I} \cdot (\lambda_P \frac{df_P}{d\mathbf{E}} + \dot{\mathbf{P}}_I) \right) \leq 0. \quad (29)$$

3.2 Interpretation of the Lagrangian multipliers

For the uncoupled, purely electrical problem we briefly explain the meaning of the Lagrangian multipliers λ_P and λ_S . In this case, the driving force reduces to

$$\hat{\mathbf{E}} = \mathbf{E} - c\mathbf{P}_I - \lambda_S \frac{\mathbf{P}_I}{|\mathbf{P}_I|}. \quad (30)$$

The variational inequality (29) reads

$$\delta \left[-\frac{1}{2} \mathbf{E} \cdot \boldsymbol{\epsilon} \cdot \mathbf{E} - \mathbf{E} \cdot \mathbf{P}_I + \frac{c}{2} \mathbf{P}_I \cdot \mathbf{P}_I + \hat{\mathbf{E}} \cdot \dot{\mathbf{P}}_I \right] + \lambda_P \left(\frac{df_P}{d\hat{\mathbf{E}}} \frac{\partial \hat{\mathbf{E}}}{\partial \mathbf{E}} \delta \mathbf{E} + \frac{\partial f_P}{\partial \mathbf{P}_I} \delta \mathbf{P}_I \right) \quad (31)$$

$$+ (\bar{\lambda}_P - \lambda_P) f_P + (\bar{\lambda}_S - \lambda_S) \left(f_S - \frac{df_S}{d\mathbf{P}_I} \cdot (\lambda_P \frac{df_P}{d\hat{\mathbf{E}}} + \dot{\mathbf{P}}_I) \right) \leq 0 \quad (32)$$

We consider an update step with the (updated) solutions \mathbf{E} , \mathbf{P}_I , λ_P and λ_S . We introduce $\Delta \mathbf{P}_I$ as the update of the irreversible polarization between two calculation steps. As the considered process is rate independent and quasi-static the dissipation is given via $\hat{\mathbf{E}} \cdot \Delta \mathbf{P}_I$. Splitting up (31)-(32) into individual (in)equalities for the single variational quantities we get

$$\delta \mathbf{E} \left[\boldsymbol{\epsilon} \cdot \mathbf{E} - \mathbf{P}_I + \frac{\partial \hat{\mathbf{E}}}{\partial \mathbf{E}} \Delta \mathbf{P}_I + \lambda_P \frac{df_P}{d\hat{\mathbf{E}}} \frac{\partial \hat{\mathbf{E}}}{\partial \mathbf{E}} \right] = 0 \quad (33)$$

$$\delta \mathbf{P}_I \left[-\mathbf{E} + c\mathbf{P}_I + \hat{\mathbf{E}} + \frac{\partial \hat{\mathbf{E}}}{\partial \mathbf{P}_I} \Delta \mathbf{P}_I + \lambda_P \frac{df_P}{d\hat{\mathbf{E}}} \frac{\partial \hat{\mathbf{E}}}{\partial \mathbf{P}_I} + \lambda_S \frac{df_S}{d\mathbf{P}_I} \right] = 0 \quad (34)$$

$$(\bar{\lambda}_P - \lambda_P) f_P \leq 0 \quad (35)$$

$$(\bar{\lambda}_S - \lambda_S) \left(f_S - \frac{df_S}{d\mathbf{P}_I} \cdot (\lambda_P \frac{df_P}{d\hat{\mathbf{E}}} + \Delta \mathbf{P}_I) \right) \leq 0 \quad (36)$$

To get an interpretation of λ_P , consider a state, at which the polarization process has started, such that $f_P = 0$ and λ_P non-negative. From the variational equation (34), taking into account the definition (30) of $\hat{\mathbf{E}}$ and that $df_P/d\hat{\mathbf{E}} = \hat{\mathbf{E}}/|\hat{\mathbf{E}}|$, we get a relation between λ_P and $\Delta \mathbf{P}_I$

$$\frac{\partial \hat{\mathbf{E}}}{\partial \mathbf{P}_I} \left(\Delta \mathbf{P}_I + \lambda_P \frac{\hat{\mathbf{E}}}{|\hat{\mathbf{E}}|} \right). \quad (37)$$

From (37) one deduces that the polarization update $\Delta \mathbf{P}_I$ is in direction of $\hat{\mathbf{E}}$ with norm λ_P . On the other hand, if the coercive field is not reached and $f_P < 0$, (35) ensures that $\lambda_P = 0$ and further $\Delta \mathbf{P}_I = 0$.

Before we give an interpretation for λ_S , we first show that (36) really ensures the saturation condition. In case the coercive electric field is reached and $f_P = 0$, (37) holds, and thereby the last term in (36) reduces to zero, leaving KKT conditions for the saturation condition only. On the other hand, if the coercive field is not reached and $f_P < 0$, we have that $\lambda_P = 0$ and $\Delta \mathbf{P}_I = 0$, which again reduces the last term in (36) to zero. Thus the saturation condition has to be satisfied in any case.

For the interpretation of λ_S , we consider a fully poled state where the polarization condition is satisfied exactly. If one now takes a look at the polarization condition, which has to satisfy

$f_P = 0$ for this particular state, one observes

$$f_P = |\mathbf{E} - c\mathbf{P}_I - \lambda_S \frac{\mathbf{P}_I}{|\mathbf{P}_I|}| - E_C = 0. \quad (38)$$

If the electric field is reduced to a level below the coercive field, λ_S reduces to zero. A graphical interpretation of λ_P and λ_S can be found in Figure 1.

Figure 1: Graphical interpretation of Lagrange multipliers for polarization and saturation condition

4 FINITE ELEMENT METHOD

In this section, the proposed finite element discretization is described. For the electric potential continuous, nodal finite elements are used, while the polarization vector is approximated constant on each element. Also, the Lagrangian multipliers are realized taking one value per element. As already done in the derivations of Section 3, displacement and stress are considered independent unknowns. To do so, a mixed finite element scheme is used. The specific approach taken in this work uses tangential displacements and normal normal stresses as degrees of freedom, which motivate the abbreviation “TDNNS”. This method was originally developed for elastic solids [15, 16] and later extended for linear piezoelectric materials [17, 13] and for geometrically nonlinear electro-mechanically coupled problems [19].

This work is based on [17, 13] for linear piezoelectrics. Note that, for the mixed TDNNS method, the \mathbf{d} -tensor formulation can be used directly, and there is no need to transfer the electric permittivity at constant stress ϵ^σ to that at constant strain ϵ^ϵ algebraically, as is necessary in standard formulations. As the underlying mathematics of the TDNNS method are rather involved, we skip it here, and only mention that work pairs such as $\int_\Omega \boldsymbol{\sigma} : \boldsymbol{\epsilon}$ or $\int_\Omega \text{div } \boldsymbol{\sigma} \cdot \mathbf{u}$ need to be considered in distributional sense and involve additional integration on element boundaries.

To solve the variational inequality, an active-set strategy is proposed. This means, in each iterative step, two active sets are identified beforehand: the switching active set A_P where the switching condition shall be enforced as $f_P = 0$, and the saturation active set A_S where the polarization condition is enforced as $f_S = 0$. On the other hand, for all elements not in the active set, the Lagrangian multipliers λ_P and λ_S are set to zero, respectively. For these fixed active sets, the nonlinear equations are solved by Newton’s method, with λ_S and λ_P free in their

respective active sets. On convergence, the Kuhn-Tucker compatibility conditions are checked. All elements, where either saturation or switching condition are violated are added to the active set. On the other hand, all elements where a Lagrangian multiplier is found negative are removed from the respective active set. An according algorithm can be found in Algorithm 1

Data: values for $\mathbf{u}_0, \boldsymbol{\sigma}_0, \phi_0, \mathbf{P}_{I0}, \lambda_{S0}, \lambda_{P0}$ and active sets A_{S0}, A_{P0} from the last converged time step
Result: values for $\mathbf{u}, \boldsymbol{\sigma}, \phi, \mathbf{P}_I, \lambda_S, \lambda_P$, active sets A_S, A_P

5 NUMERICAL RESULTS

In this section we show numerical results for two examples. First we show the standard hysteresis curves for the fully coupled homogeneous (uni-axial) problem. We show that the method allows mechanical depolarization. Our second example is mechanical depolarization of a fully polarized ferroelectric beam. This example was introduced as a ferroelastic benchmark by Zouari et. al [22].

5.1 Butterfly hysteresis

In our first example we show, that our implementation is capable of both, electrical polarization as well as electrical and mechanical depolarization. We consider an initially unpolarized unit square (1 mm by 1 mm) with electrodes on top and bottom. The material parameters are listed in Table 1. First the electrical polarization is shown. An electric field with a strength of two times the coercive field strength $2E_C$ is applied, is then reduced to $-2E_C$, and again increased up to $2E_C$. The resulting electric hysteresis, as well as the corresponding (mechanical) butterfly hysteresis are shown in Figure 2. The electric field is normalized by E_C , the polarization and the dielectric displacement by P_{Sat} and the (mechanical) strain by S_{sat} .

Figure 2: Electrical polarization of ferroelectric material

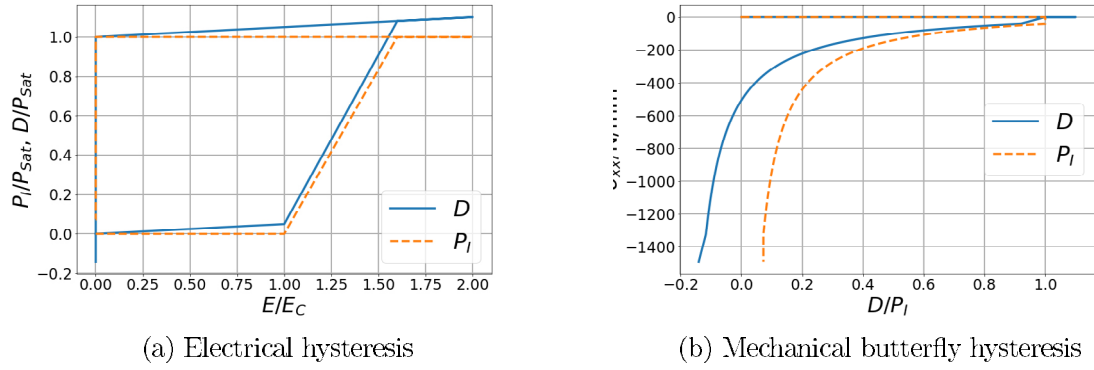

Figure 3: Electrical polarization of ferroelectric material

Next we show the effect of mechanical depolarization. The specimen is electrically polarized (field strength $2E_C$), then the electric field is reduced to 0. A mechanical compressive stress (aligned in polarization direction) is applied to the polarized material and mechanical depolarization can be observed. The mechanical depolarization curve is shown in Figure 3. Note, that the implemented constitutive material model leads to total mechanical depolarization ($\mathbf{P}_I = \mathbf{0}$) for sufficient high mechanical stress.

Table 1: Material parameter

Young's modulus	10^4 MPa	c	$2 \cdot 10^6$ Vm/C
Poisson's ratio	0.3	d_p	$5.93 \cdot 10^{-10}$ m/V
Coercive field	1 MV/m	d_n	$-2.74 \cdot 10^{-10}$ m/V
Saturation strain S_{sat}	0.002	d_t	$7.41 \cdot 10^{-10}$ m/V
Saturation polarization P_{sat}	0.3 C/m ²	ϵ	$1.5 \cdot 10^{-8}$ C/Vm

5.2 Depolarization of a ferroelectric beam

Our second example is a benchmark for ferroelastic media taken from the literature [23]. It is a cantilevered beam, fully polarized in its longitudinal direction and loaded with a tip force at its end. A sketch of the problem can be found in Figure 4. Grounded electrodes ($\phi = 0$) are located at the clamped and at the tip face (illustrated in red). The clamping is realized by restricting longitudinal displacement at the clamped face (blue dashed line) and transversal displacement in the middle of the beam (blue dot).

The tip force is realized as stress boundary condition, applying $\sigma_{xy} = 4 \text{ N/mm}^2$ at the tip face. Taking into account the dimensions this load equals the tip force in [23]. The bending of the beam leads to a compressive stress and therefore mechanical depolarization can be observed. The resulting polarization is shown in Figure 5. It decreases at the clamped face to 78% of the saturation polarization. The resulting stresses are shown in Figure 6. Due to the unsymmetrical remanent straining an unsymmetrical distribution of the bending stresses is to be observed. The results fit to [23]. Note that, in contrast to the reference, only ferroelectric but no ferroelastic effects are considered in the constitutive model.

Key words: Fe-SMAs, Finite-strain behavior law, Phase transformation, Plastic sliding, MATLAB

Abstract. Iron-based Shape Memory Alloys (Fe-SMAs) present a specific behavior compared to NiTi and Cu-based SMAs related to a high coupling between plastic sliding and phase transformation inducing only a partial recovering of inelastic strain during heating. Few models in literature describe such specific behavior. However, they are formulated with the framework of small perturbations. Therefore, they cannot predict the effect of an applied high loading level inducing large deformations and rotations. Against this background, a new thermomechanical behavior law for Fe-SMAs, is developed with the framework of finite transformations. This law is an extension of Khalil et al. [1] small-strain model. Two important characteristic behaviors of the Fe-SMA, the phase transformation and the plastic sliding, are considered in the development of this model. Two internal variables, the martensite volume fraction and the accumulative plastic strain, have been defined to integrate those latter specific behaviors. This model considers the classical multiplication of the kinematic deformation gradient into elastic and inelastic parts. The inelastic part is also decomposed into phase transformation and plastic slip related ones. The corresponding constitutive equations are solved with the Newton-Raphson method combined with an implicit integration scheme. Further, an exponential map approach is carried out to integrate the evolution equations. In order to validate this model, the numerical results have been compared with experimental results of Khalil et al. [2]. Obtained results are in a good agreement with the experimental data and enhance the small-strain model [1] by enhancing the prediction of the nonlinear plastic hardening at

high strain levels. Additional simulations with higher loading levels, showed that the present model well predict the Fe-SMA thermomechanical behavior in finite-strain.

1 INTRODUCTION

Since their discovery [3, 4], Iron-based Shape Memory Alloys (Fe-SMAs) have drawn the attention for their good quality / price ratio. Their thermomechanical behavior is different, than NiTi and Cu-based SMAs, by a high coupling between phase transformation and plastic sliding. The Shape Memory Effect (SME) for Fe-SMAs comes from mechanically induced forward phase transformation, austenite phase to martensite phase, and from the reverse phase transformation activated after heating, martensite phase to austenite phase [5, 6]. Also, and unlike Cu-SMAs and Ni-Ti SMAs, the plasticity activates only in the scale of austenite [2, 7].

There are several nuances of Fe-SMAs, different in chemical composition : Fe-Mn-Si, Fe-Pt, Fe-Ni-Co-Ti, Fe-Mn-Si-Cr ... Manganese (Mn) and Silicon (Si) are the two most important elements because of their positive effects on the SME and the resistance to corrosion. According to the literature, manganese helps the austenite formation [5] and silicon increases the activation stress of plastic slip [2], improves resistance to corrosion [8], facilitates the reversible movement of dislocations [9] and improves the SME [7].

The phase transformation-plasticity diagram of yield stresses, giving an inelastic deformation, as a function of temperature [7] describes the Fe-SMAs behavior. Two domains, Phase transformation and plasticity, are differentiated by a temperature that will be noted T_0 (labeled M_s^σ in [7]). If the the material temperature is lower than T_0 , the phase transformation of the austenite to martensite has priority, if not, the activation of the plasticity in the austenite will take place preventing the nucleation of the martensite.

In order to predict an Fe-SMA behavior, tremendous researchers investigated the material behavior and formulated constitutive laws describing Fe-SMA response [10]. Jemal et al. [11] developed the first 3D behavior law for this material. They defined, two internal variables which are χ , for the martensite volume fraction, and γ , for the accumulative plastic strain, and two control variables which are the stress Σ and the temperature T . A Gibbs energy has been used to describe different Fe-SMA specific behaviors (Phase transformation, Plasticity and their interactions). Khalil et al. [1] model present an enhancement for the latter one. They kept the same internal and control variables but with some modification to be more faithful to the material behavior. They defined a new loading function for the reverse phase transformation and change the plasticity yield force to make it temperature dependent. Recently, Cissé et al. [12] developed a behavior law for Fe-SMAs inspired from Zaki and Moumni Ni-Ti Behavior law [13]. An expression of Helmholtz energy has been defined as the sum of energies in austenite, martensite and an interaction one. All these models are developed in the small strain hypothesis. But, Fe-SMA can reach high deformation levels due to their plastic hardening. For this, a small strain behavior law is not suitable to predict material large strain response. This was the main idea to develop a new finite strain behavior law for Fe-SMAs.

In this present work, a finite strain thermomechanical behavior law based on an extension of Khalil et al. small strain model has been proposed. In order to describes the phenomena of phase transformation and plasticity, a Helmholtz free energy Ψ has been used and driving and yield forces has been defined. This new thermomechanically behavior law is based on the multiplicative decomposition of the total deformation gradient \mathbf{F} into elastic, \mathbf{F}_{el} , and inelastic, \mathbf{F}_{ine} , deformation gradients. This latter is decomposed into phase transformation and plasticity gradients, \mathbf{F}_{tr} and \mathbf{F}_{pl} , respectively. This model constitutive equations have been implemented using MATLAB software. The constitutive equations are

solved with a Newton-Raphson method mixed with prediction correction method. This model parameters have been set with Khalil et al. experimental results [2]. The model present a good agreement with experimental results and it is able to predict plastic hardening better then Khalil et al. model [1]. After that, large strain simulations have been done to predict Fe-SMA response for higher loading levels. Obtained results show a concordance with the expected Fe-SMAs response in large strain loading.

The paper organized as follows: Section 2 details the constitutive model derivation. In section 3 a model validation with Khalil et al. experimental results [2] in order to validate it, and a large strain simulations have been taken into account to predict Fe-SMA response in finite strain. Finally, Section 4 draws the conclusion of this work and some prospects.

2 IRON-BASED SMAs LARGE STRAIN THERMOMECHANICAL BEHAVIOR LAW

2.1 Deformation gradient

Fe-SMAs present a high coupling between the phase transformation and the plasticity. For that, an assumption of a tripartite multiplicative decomposition of the deformation gradient into elastic, phase transformation, and plastic components as follow:

$$\mathbf{F} = \mathbf{F}_{el}\mathbf{F}_{ine} = \mathbf{F}_{el}\mathbf{F}_{tr}\mathbf{F}_{pl} \quad (1)$$

where \mathbf{F}_{el} is defined with respect to an intermediate configuration, \mathbf{F}_{tr} with respect to the reference configuration, and \mathbf{F}_{pl} with respect to a phase transformed configuration, if the temperature is less than M_s^σ . Else, \mathbf{F}_{pl} is defined with respect to the reference configuration, and \mathbf{F}_{tr} with respect to plasticized configuration.

2.2 Inelastic strain rate

Phase transformation and plasticity coupling occur whatever is the material temperature, and it is difficult to justify the procedure to separate phase transformation and plastic deformation gradients for a Representative Volume Elementary (RVE). In this case, additive decomposition of inelastic strain rate [14] into phase transformation and plastic components is more appropriate:

$$\mathbf{D}_{ine} = \mathbf{D}_{tr} + \mathbf{D}_{pl} \quad (2)$$

with

$$\mathbf{D}_{tr} = \dot{\chi} \bar{\epsilon}_{max}^{tr} \mathbf{N}^{tr} \quad (3)$$

$$\mathbf{D}_{pl} = (1 - \chi) \dot{\gamma} \mathbf{N}^{pl} \quad (4)$$

where $\bar{\epsilon}_{max}^{tr}$ is the equivalent maximal transformation strain, \mathbf{N}_{tr} and \mathbf{N}_{pl} are the transformation and plastic flow direction vectors.

2.3 Free energy function

The Helmholtz free energy Ψ is the sum of elastic Ψ_{el} , inelastic Ψ_{ine} and inner potential Ψ_{IC} energies. The Helmholtz free energy depends on the elastic right Cauchy-Green C_{el} , martensite volume fraction χ , accumulative plastic strain γ and the temperature T :

$$\Psi = \Psi_{el} + \Psi_{ine} + \Psi_{IC} \quad (5)$$

with

$$\Psi_{el} = \frac{\mu}{2} (I_{C_{el}} - 3) - \mu \ln J + \frac{\lambda}{2} (\ln J)^2 \quad (6)$$

$$\Psi_{ine} = c_v \left[(T - T_0) - T \ln \left(\frac{T}{T_0} \right) \right] + B(T - T_0)\chi + G_g(\mathbf{E}_{ine}) + [G_v(\chi) + (1 - \chi)G_s(\gamma) + G_{sv}(\gamma, \chi)] \quad (7)$$

$$\Psi_{IC} = -\ell_1\chi - \ell_2(1 - \chi) \quad (8)$$

where:

For the elastic energy, μ and λ are equivalent Lamé constants by assuming an isotropic elastic behavior with the same properties at the martensitic and austenitic states. $I_{C_{el}}$ is the first cauchy invariant of \mathbf{C}_{el} and $J = \det(\mathbf{F})$ is the deformation Jacobian (third invariant of \mathbf{F}).

For the inelastic energy, T is the current temperature, c_v , B and T_0 are the material parameters, $G_g(\mathbf{E}_{ine})$ is the intergranular interaction energy and G_v , G_s , G_{sv} are, respectively, the interaction functions between martensite variants, between plastic slip systems and between martensite variants and plastic slip systems. They are defined as follow:

$$G_g(\mathbf{E}_{ine}) = \frac{H_g}{(n_g + 1)} (\mathbf{E}_{ine} : \mathbf{E}_{ine})^{n_g + 1} \quad (9)$$

$$G_v(\chi) = \frac{H_v}{n_v + 1} \chi^{n_v + 1} \quad (10)$$

$$G_s(\gamma) = \frac{H_s}{n_s + 1} \gamma^{n_s + 1} \quad (11)$$

$$G_{sv}(\gamma, \chi) = \frac{H_{sv}}{n_{sv} + 1} (\gamma\chi)^{n_{sv} + 1} \quad (12)$$

with H_g is a material parameter characterizing intergranular interactions and n_g is a coefficient characterizing the interaction non linearity evolution. The coefficients n_v , n_s and n_{sv} reflect the nonlinearities of these interactions. The terms H_v , H_s and H_{sv} are respectively the interaction coefficients between the martensite variants, the slip systems, and the martensite variants and the slip systems.

For the inner potentiel ℓ_1 and ℓ_2 are a Lagrangian multipliers reflect the reality that the martensite volume fraction is always between 0 and 1. This two multipliers obey the Kuhn-Tucker conditions :

$$\begin{cases} \ell_1 \geq 0 \text{ and } \ell_1\chi = 0 \\ \ell_2 \geq 0 \text{ and } \ell_2(1 - \chi) = 0 \end{cases} \quad (13)$$

2.4 Constitutive equations

Substituting The Helmholtz free energy in the Clausius-Duhem inequality and taking into account mathematical processing:

$$\Lambda_{dr}^\chi \dot{\chi} + \Lambda_{dr}^\gamma \dot{\gamma} \geq 0 \quad (14)$$

with Λ_{dr}^χ and Λ_{dr}^γ are respectively the phase transformation and plasticity driving forces defined as follow:

$$\Lambda_{dr}^\chi = \bar{\epsilon}_{\max}^{tr} (\mathbf{M} + H_g (\mathbf{E}_{ine} : \mathbf{E}_{ine})^{n_g} \mathbf{F}_{ine} \mathbf{E}_{ine} \mathbf{F}_{ine}^T) : \mathbf{N}^{tr} - B(T - T_0) - H_v \chi^{n_v} + \frac{H_s}{(n_s + 1)} \gamma^{n_s + 1} - H_{sv} \gamma (\chi \gamma)^{n_{sv}} + \ell_1 - \ell_2 \quad (15)$$

$$\Lambda_{dr}^\gamma = (1 - \chi) (\mathbf{M} + H_g (\mathbf{E}_{ine} : \mathbf{E}_{ine})^{n_g} \mathbf{F}_{ine} \mathbf{E}_{ine} \mathbf{F}_{ine}^T) : \mathbf{N}^{pl} - (1 - \chi) H_s \gamma^{n_s} - H_{sv} \gamma (\chi \gamma)^{n_{sv}} \quad (16)$$

where \mathbf{M} present the Mandel stress, \mathbf{E}_{ine} is the inelastic Green-Lagrange tensor.

The yield forces for, forward and reverse phase transformation, and plastic slip are defined respectively as follow:

$$\Lambda_y^{tr,m} = \sigma_y^m \bar{\epsilon}_{tr}^{\max} + \zeta_m (T_0 - M_s) - H_\gamma \gamma^2 \quad (17)$$

$$\Lambda_y^{tr,a} = \sigma_y^a \bar{\epsilon}_{tr}^{\max} + \zeta_a (T_0 - A_s) - H_\chi \chi \quad (18)$$

$$\Lambda_y^{pl} = \sigma_y^\gamma - K_T T \quad (19)$$

with σ_y^m , σ_y^a and σ_y^γ are respectively the yield stress of, forward and reverse phase transformation and plasticity, ζ_a and ζ_m are control parameters, M_s is the start forward martensitic transformation temperature, A_s is the start reverse martensitic transformation and K_T represents the evolution slope of the yield plastic stress with the temperature.

In addition, we emphasize that the evolution equations satisfy the loading functions for the direct phase transformation, reverse phase transformation and plasticity.

$$\Upsilon_{tr}^m = \Lambda_{dr}^\chi - \Lambda_y^{tr,m} \quad (20)$$

$$\Upsilon_{tr}^a = -\Lambda_{dr}^\chi - \Lambda_y^{tr,a} \quad (21)$$

$$\Upsilon_{pl}^a = \Lambda_{dr}^\gamma - \Lambda_y^{pl} \quad (22)$$

The solving of equations (20) to (22) for a given loading increment allow to determine the kind of behavior and the evolution of the unknown variables.

3 RESULTS AND DISCUSSIONS

The model constitutive equations has been solved using, a Newton-Raphson method implicitly integrated throw MATLAB software, and, an elastic predictor inelastic corrector technique to manage nonlinear responses. The Fe-SMA loading function have been calculated in every increments iterations. Based on their values, the Fe-SMA behavior is distinguished. To test the model validity, a comparison with khalil et al.[2] experimental results have been done. Then, a presentation of large strain response is discussed.

3.1 Small Strain results

This subsection presents the numerical results for tensile loading-unloading at different constant temperature followed by a heating. These results are compared to experimental ones from [2] regarding the alloy Fe-Mn_{31.6}-Si_{6.45}-C_{0.018}(wt%). The adopted model parameters are calibrated from experimental results and their values are illustrated in table 1.

Table 1: Model parameters

Parameter	Value	Parameter	Value
σ_y^m (MPa)	137.7	A_s (°C)	96
σ_y^a (MPa)	125.2	T_0 (°C)	79.4
σ_y^v (MPa)	210	H_v (MPa)	27.2
ν	0.3	H_s (MPa)	632.5
μ (MPa)	65385	H_{sv} (MPa)	1000
λ (MPa)	98077	H_g (MPa)	627
$\bar{\epsilon}_{\max}^{tr}$	0.048	n_v	0.44
ζ_m (MPa/°C)	0.086	n_s	0.55
ζ_a (MPa/°C)	0.036	n_{sv}	0.45
B (MPa/°C)	0.104	n_g	3.07
K_T (MPa/°C)	0.45	H_χ (MPa)	-3
M_s (°C)	-25	H_γ (MPa)	500

Figure 1: Comparison with Khalil et al. [2] experimental results

Figure 1 present comparisons, respectively for, 20°C, 50°C and 130°C. Figures show, as observed experimentally, that only phase transformation is occurring at 20°C, a coupled phase transformation and plasticity are observed at 50°C and only plasticity is activated at 130°C. The current model is able to predict different temperature behavior.

3.2 Finite Strain results

Large strain simulations have been carried out at different temperature to predict Fe-SMA tensile test response. Figure 2 presents loading-unloading-heating cycle for 20, 50 and 130°C, respectively, at 20% of strain. Results show that the plasticity dominates the Fe-SMA behavior for higher loading levels. These results are very faithful to experimental diagram seen in Bouraoui et al. work [7].

Figure 2: Stress-Strain curves for 20% of strain loading followed by unloading and heating

The evolution of the internal variables (χ and γ) shows that in 20°C (figure 3.a) the volume fraction of martensite begins to evolve first, then, the accumulative plastic strain activates. At this point, the martensite volume fraction slope evolution decreases until getting stabilized when it reaches 52%. At this range, the accumulative plastic strain slope evolution increases until the end of loading. Even at 50°C (figure 3.b), it is remarkable the same evolution of internal variables, but, at this range the martensite volume fraction stabilized at 26%. Figure 3.c shows the evolution of the internal variables with the strain at 130°C. At this temperature, the accumulative plastic strain starts first and only 5.5% of martensite has been created.

Fe-SMAs are a particular class of material, they are distinguished by a high coupling form between phase transformation and plasticity. High level strain simulations show that, going forward in loading favorite the plasticity and even the recovered strain due to the reverse phase transformation is so small in comparing with the plastic one. This model present good results and gives a prediction for an Fe-SMA high level loading response.

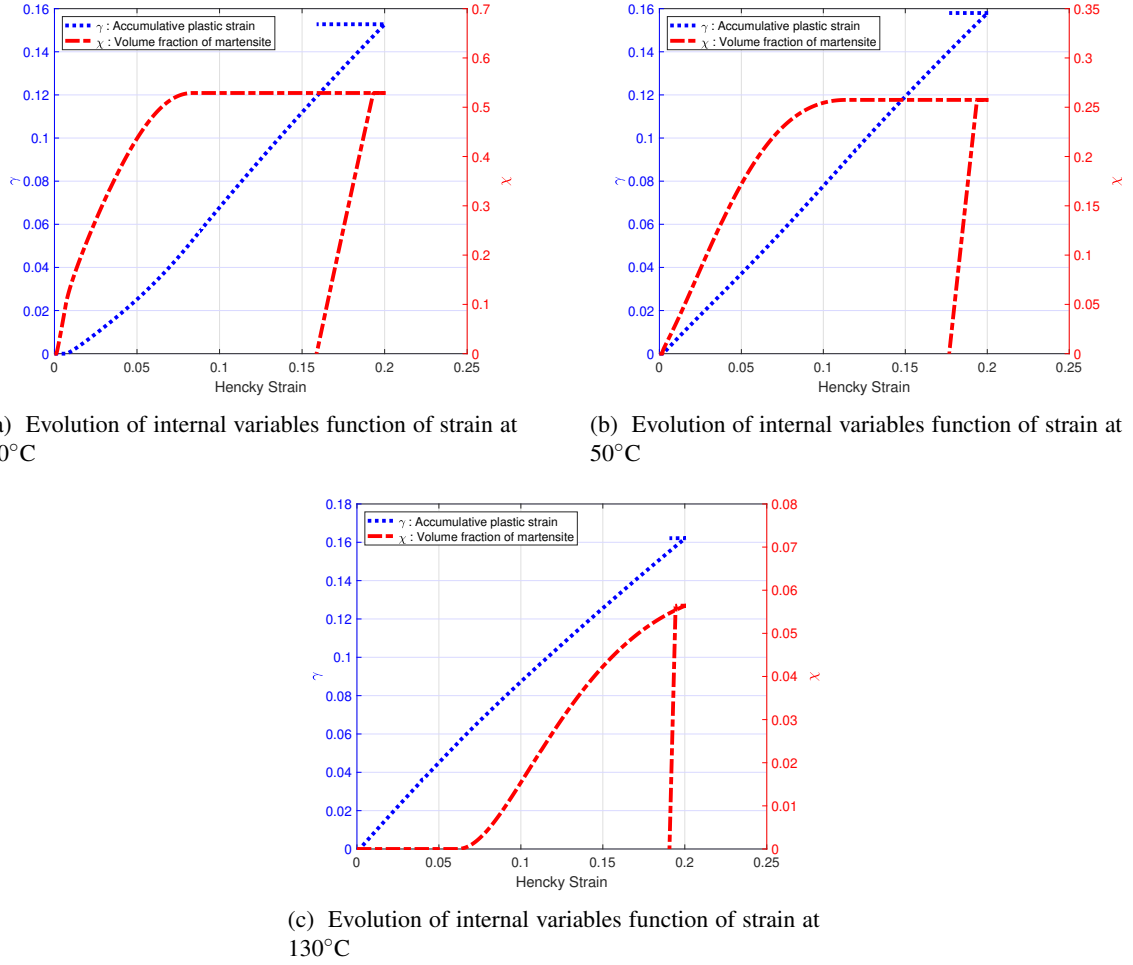

Figure 3: Evolution of the martensite volume fraction and the accumulative plastic strain function of strain

4 CONCLUSIONS

In this paper, a nonlinear finite strain model was proposed for Fe-SMAs. The model starts with a kinematic hypothesis that the deformation gradient is splitted in a multiplicative decomposition into, elastic, phase transformation and plastic sliding. The model constitutive equation was derived from the Helmholtz free energy. This latter, Helmholtz energy, is the sum of elastic, inelastic and inner potential energies. Using MATLAB software, time-discrete equations have been integrated implicitly.

This new model presents a good agreement with experimental results [2]. Also, it is able to predict finite strain response. The Large strain simulations show a consistent behavior of this type of materials.

As prospect, this model will be integrated in a finite element software via routine(UMAT). This UMAT will be used in order to predict complex configurations response in finite-strain.

Key words: Magnetic Shape Memory Actuator, Heat Transfer Effect, Strain Oscillation, Amplitude Modulation, Thermo-magneto-mechanical Coupling

ABSTRACT. Magnetic Shape Memory Alloy (MSMA) is a promising candidate for high-frequency large-stroke actuators applications as it is able to provide a large recoverable deformation with high-frequency magnetic-field-induced martensite reorientation. Recent experiments revealed that thermo-magneto-mechanical coupling effect needs to be considered to obtain a reliable performance of MSMA actuators. Particularly, the heat generation from the energy dissipation of the high-frequency martensite twin-boundary motions causes a temperature rise in the material, which influences the temperature-dependent martensite reorientation process and/or triggers the temperature-induced martensite-austenite phase transformation so that the output strain can be influenced significantly. Therefore, besides the usual magneto-mechanical conditions (such as the magnetic field frequency, the applied mechanical stress and the system mechanical stiffness), the ambient heat-exchange efficiency between MSMA actuator and the ambient (which counteracts the temperature rise) is important in controlling the output strain amplitude under the high-frequency magnetic actuation. In this paper, we study the strain amplitude modulation of MSMA actuator by controlling the ambient heat transfer efficiency by applying an ambient airflow (the airflow velocity can be tuned via a compressed air source). The results are helpful not only for the optimization design of the large-stroke MSMA actuators, but also for the insight into the principles of the multi-physics coupling in similar smart materials.

1. Introduction

Magnetic Shape Memory Alloy (MSMA) is a kind of smart material with thermo-magneto-mechanical coupling, which has capability to output a high-frequency large recoverable strain (up to 10%) through magnetic-field-induced martensite reorientation [1–4]. This advantage makes MSMA a very promising candidate for high-frequency large-stroke actuators [5–8], where the large output strain amplitude is one of the most important performances. So far, various studies have been attracted to investigate the governing factors on the high-frequency

strain of MSMA, such as the applied magnetic-field frequency, the initial compressive stress, and the system stiffness [9–13]. Moreover, recent experiments revealed that thermo-magneto-mechanical coupling effect needs to be considered to obtain a reliable strain performance of MSMA actuators[4,14]. Particularly, the heat accumulation from the energy dissipation of the high-frequency frictional twin-boundary motions causes a temperature rise in the material, which influences the temperature-dependent martensite reorientation process and is likely to trigger the temperature-induced martensite-to-austenite phase transformation so that the output strain can be influenced significantly[4,14,15]. Therefore, besides the well-known magneto-mechanical conditions (such as the magnetic field frequency, the applied mechanical stress and the system mechanical stiffness) [9–13], the heat transfer efficiency between MSMA actuator and the ambient (which counteracts the temperature rise) should be an important factor in controlling the output strain amplitude under the high-frequency magnetic actuation.

In this work, during the magneto-mechanical actuation on MSMA, the ambient heat transfer efficiency is controlled by applying an ambient airflow (whose velocity can be tuned via a compressed air source) to study the heat transfer effects on the output strain amplitude of the MSMA actuator. The experimental results demonstrate that the strain amplitude of MSMA depend on the heat transfer efficiency non-monotonically due to two competing (opposite) aspects of the thermal effect. On the one hand, the temperature rise triggers the phase transformation from martensite to austenite in some parts of the specimen, reducing the output strain amplitude (as austenite has no reorientation and the specimen has less martensite reorientation); On the other hand, the temperature rise reduces the dissipative force (twinning stress) of martensite reorientation so that the dynamic strain oscillation can be increased, leading to larger output strain amplitude. Therefore, changing the ambient heat transfer to control the temperature rise (or the specimen working temperature) can modify these two competing aspects. At certain critical ambient heat transfer efficiency, the compromise between these two aspects leads to a maximum output strain amplitude. Based on this study, an actuator with strain amplitude modulated by the heat exchange efficiency can be designed.

2. Material properties and experiment process

A $\text{Ni}_{50}\text{Mn}_{28}\text{Ga}_{22}$ (at. %) single crystal MSMA specimen (from ETO Magnetic GmbH) was used in the experiments. The specimen was cut to a rectangular bar with dimensions in $10 \times 5 \times 2$ mm from an ingot, with all faces of the specimen parallel to the $\{100\}$ planes of the parent cubic austenite (with a lattice parameter of a_0). The specimen is in the state of 10M martensite phase at room temperature. Note that the martensite variants are slightly monoclinic in this material, but in this work it is assumed that they are tetragonal with two long axes “ a ” and one short axis “ c ” for the simplicity of the analysis. The material characteristic phase transformation temperatures M_s , M_f , A_s and A_f were obtained as 38.6 °C, 36.3 °C, 44.8 °C and 46.8 °C respectively from a DSC test (differential scanning calorimetry).

To experimentally investigate the MSMA actuator performances, a magneto-spring loading system is developed as shown in Fig. 1(a). Before each test, the martensite specimen is fully compressed along y -axis (by applying a large mechanical compression stress, > 10 MPa) to obtain a single variant state with the short-axis (c -axis) along y -direction (so-called stress-preferred variant, shown as M_1 in Fig. 1(b)), so that all the tests can take the same reference

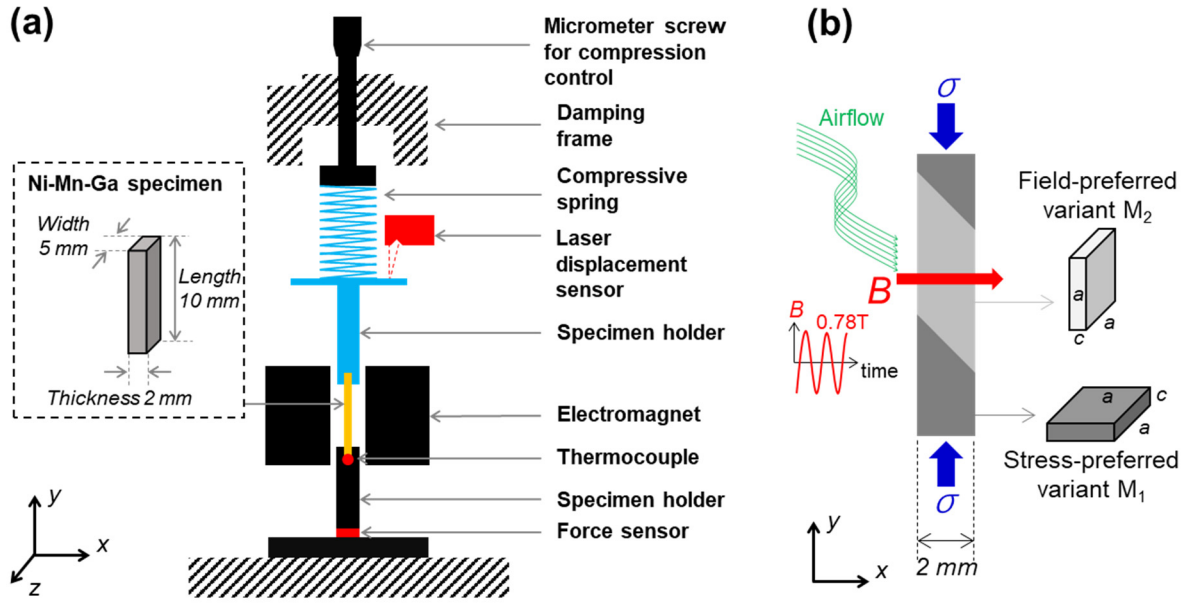

Figure 1. Experimental setup

state (i.e., zero strain) for calculations of the specimen deformation strain in this work. The specimen is installed between two magnetic poles with the long side along y -direction by two lightweight plexiglas holders. At the beginning of each test, an initial compressive stress σ_{ini} is applied on the specimen along y -direction by a compressed spring. Then a magnetic field (with magnetic flux density B cyclically varying between $[-0.78, 0.78]$ Tesla with a triangular waveform) of frequency f_{mag} is applied horizontally by the electro-magnet to drive the martensite reorientation from M_1 to M_2 (so-called magnetic field preferred variant with the short axis along x -direction and the long axis a along y -direction) as shown in Fig. 1(b). During this martensite reorientation process, the macroscopic specimen length L_y changes due to the microscopic difference between lattice parameters a (for M_2) and c (for M_1) along y -direction, which changes the spring length so that the spring compressive stress along y -direction changes at the same time. Thus, the interaction between the cyclic magnetic field (along x -direction) and the correspondingly evolving compressive stress (from the spring along y -direction) eventually leads to a cyclic deformation strain of MSMA (by cyclic martensite reorientation between the variants M_1 and M_2). In this experimental system, during the magneto-mechanical cyclic loading, the ambient heat transfer efficiency of the MSMA specimen can be controlled by forcing an ambient airflow of different velocities to pass through the specimen.

During the actuation, the deformation of the specimen along y -direction is measured by a laser displacement sensor (Keyence LK-H027) at the upper holder, and the average temperature of the specimen is monitored by a thermocouple (K-type, 0.5 mm sheath diameter) at bottom of the specimen. Because the specimen holders are made of plexiglas of low thermal conductivity to reduce the heat conduction from the specimen ends to the fixtures, it is assumed that the heat convection via the specimen surface is the most dominant path of the heat exchange rather than the heat conduction via the specimen ends. The heat transfer efficiency can be quantified by a characteristic heat transfer time t_h which depends on the ambient airflow velocities (this method has been employed in previous studies [4,16,17]). That means, a large

airflow velocity leads to a high heat transfer efficiency corresponding to a short characteristic heat transfer time t_h .

3. Experimental results and discussions

To investigate the heat transfer effect on the high-frequency strain amplitude of MSMA actuator, a magnetic actuation test is conducted under a stepwise increasing heat transfer efficiency (controlled by applying an airflow with increasing velocity step by step). The frequency of the applied field (f_{mag}) is 110 Hz, and the applied initial compressive stress (σ_{ini}) is 0.4 MPa. Under these loading conditions, the MSMA actuator is capable to achieve a large strain amplitude (with the strain oscillation frequency $f_{\text{strain}} = 2 f_{\text{mag}} = 220$ Hz). The strain and the temperature evolutions of the MSMA actuator are shown in Fig. 2(a) and the magnified strain curves for typical instants are shown in Fig. 2(b). It is seen that, at the beginning of the actuation (< 26 s) where the specimen is in the still air ambient, a large strain amplitude $\Delta\epsilon$ (the strain difference between the maximum and the minimum nominal strains) around 4.0% can be obtained. At the same time, the specimen temperature increases rapidly corresponding to the high-frequency large deformation, until a significant reduction in the strain amplitude at around $t \approx 27$ s (so-called strain drop phenomenon[4], marked by a red arrow in Fig. 2(a)), which is caused by the martensite-to-austenite phase transformation (non-active austenite phase appears in the specimen, as shown by the schematic of t_1 in Fig. 2(b)). After the strain drop, both the output strain amplitude $\Delta\epsilon$ and the specimen temperature T reach stable states with strain amplitude of 1.3% and temperature of 37.8 °C, see the evolutions of the strain and the temperature at $t_1 \approx 40$ s in Fig. 2.

Generally, the strain drop phenomenon is harmful for engineering applications as the output strain is significantly reduced. To overcome this drawback, during the test, the heat transfer time t_h is decreased stepwise by increasing the velocity of the ambient airflow passing through the specimen (note: for each step, the airflow changes rapidly in less than 1 second). It is seen that, when t_h decreases from 80.0 s to 14.9 s stepwise, the strain amplitude increases to 3.8% gradually, while the stable temperature only slightly decreases (see Fig. 2(a)). For example, at $t_2 \approx 100$ s where the t_h is 25.4 s, the strain amplitude increases to 2.6% and the stable temperature slightly decreases to 37.3 °C. When t_h is decreased to 14.9 s, the strain amplitude increases to 3.8% while the specimen temperature decreases to 36.7 °C (see the evolutions of the strain and the temperature at $t_3 \approx 180$ s); This recovered strain amplitude is close to that before the strain drop (4.0%). The temperature evolutions in these situations are within the material characteristic phase transformation temperatures, particularly $M_f < T_{\text{specimen}} < A_f$, which allows the coexistence of martensite and austenite. According to the ambient change (changing t_h), the MSMA specimen adjusts its volume fractions of the two phases so that the dissipative martensite reorientation (dissipative strain oscillation) generate a proper amount of heat that can be efficiently transformed to ambient without causing further temperature rise, see the schematics of the local phase evolution at the instants t_1 and t_2 in Fig. 2(b). In the case of $t_h = 14.9$ s, the specimen is almost fully occupied by martensite and the strain amplitude recovers to a large value (with large dissipation heat in the specimen).

However, when the heat transfer time t_h is further decreased, both the strain amplitude and the temperature decrease significantly as shown in Fig. 2(a). For example, when t_h decreases to 10.0 s, the strain amplitude and the specimen temperature decreases to 2.1% and 26.4 °C

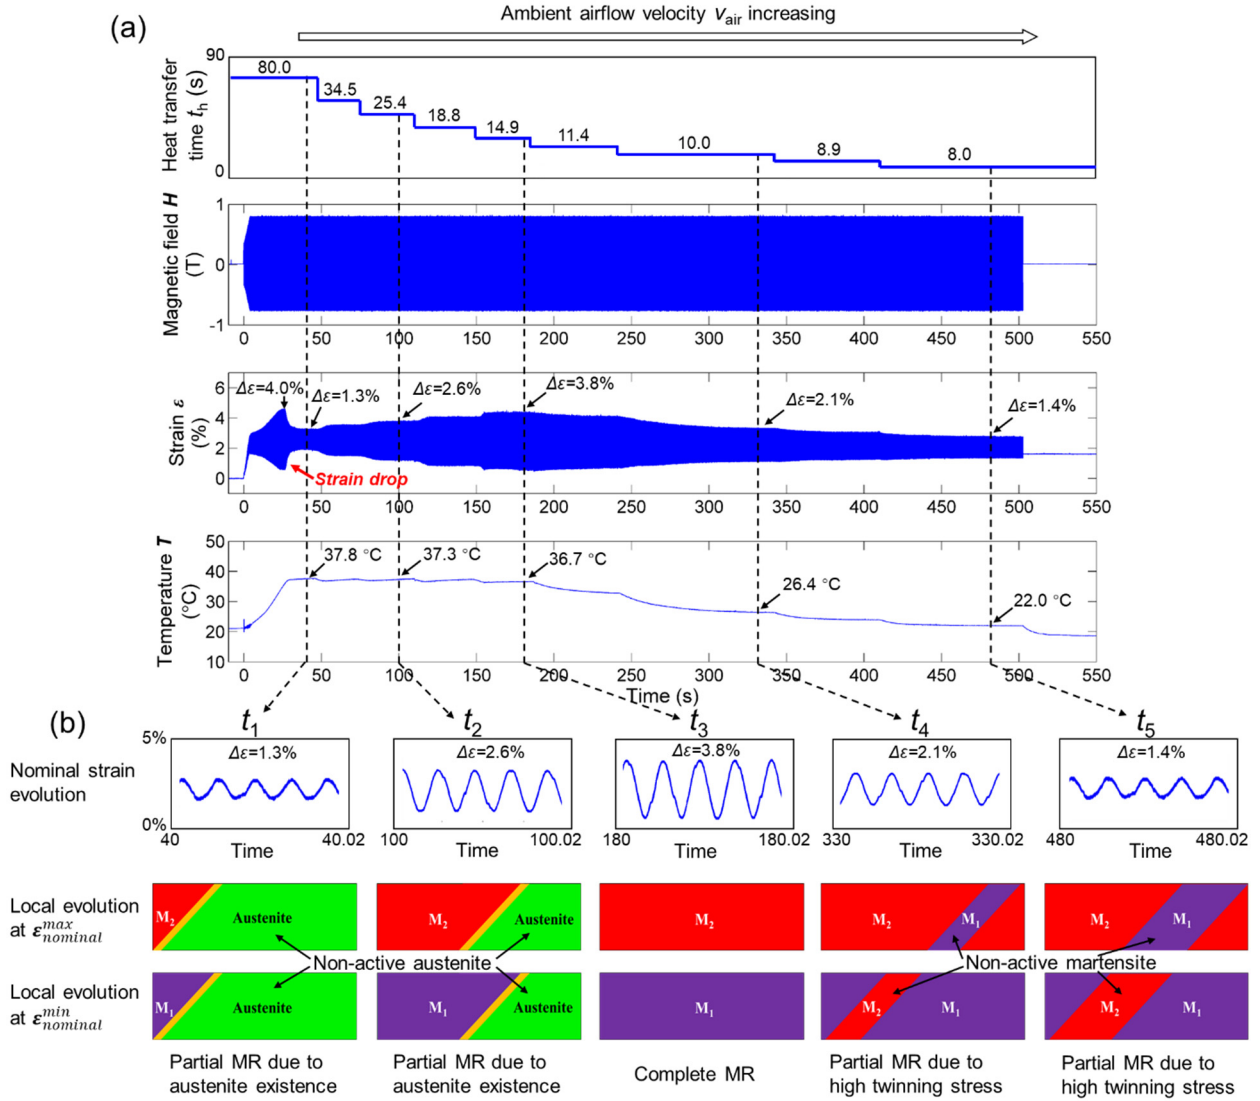

Figure 2. (a) The strain and temperature responses of MSMA under continuously increasing airflow velocities; (b) the nominal strain evolutions and sketches of the local phase/variant evolutions at 5 typical time instants ($t_1 \sim t_5$).

respectively (see the responses at $t_4 \approx 330$ s). When t_h is further decreased to 8.0 s, the strain amplitude and the stable temperature decrease to 1.4% and 22.0 °C respectively ($t_5 \approx 480$ s). The temperature evolutions in these situations are well below M_f , which means only martensite exists. But not all the martensite take reorientation to contribute to the strain oscillation as shown in the schematics of t_4 and t_5 of Fig.2(b) where there are some zones in the specimen with unchanged martensite states, fixed M_1 or M_2 (so-called non-active martensite zones). The volume fractions of the non-active zones change with the ambient condition (with the changing t_h). The reason for the existence of non-active martensite zone might be that, at strong ambient heat transfer making specimen temperature lower, the temperature-dependent dissipative force (twinning stress) increases [18,19], i.e. martensite reorientation becomes difficult; in other

Figure 3. The stable strain amplitude and the stable temperature of MSMA under different heat transfer time t_h . The dashed lines are for guiding eyes.

words, higher damping in the dynamic oscillating system leads to lower output oscillation amplitude.

The stable temperature and the stable strain amplitude at all the steps of the heat transfer time t_h are summarized in Fig. 3 where the output strain amplitude $\Delta\varepsilon_{\text{stable}}$ changes non-monotonically while the stable temperature T_{stable} decreases monotonically. For the cases under weak ambient heat transfer condition ($t_h = 80.0 \text{ s} \sim 14.9 \text{ s}$), the strain amplitude increases with decreasing t_h while the temperature decreases slightly, keeping higher than M_f . In contrast, for the cases under strong heat transfer condition ($t_h = 14.9 \text{ s} \sim 8.0 \text{ s}$), the increasing heat transfer efficiency (i.e. decreasing t_h) significantly reduces the output strain amplitude and the temperature simultaneously. Therefore, to achieve the maximum output strain amplitude, a proper ambient heat transfer condition is needed (here $t_h < 14.9 \text{ s}$) to make the specimen working temperature is close to (but lower than) M_f so that all the specimen is occupied by martensite phase and the temperature dependent twinning stress is relatively low.

4. Summary and conclusions

In this work, the experiments of high-frequency magnetic field actuation of MSMA are performed under the stepwise increasing heat exchange efficiency. It is found that the heat exchange between the MSMA actuator and the ambient influences the actuator working temperature **monotonically** (i.e. stronger ambient heat transfer leads to lower stable working temperature), but changes the strain oscillation amplitude **non-monotonically** (i.e. there is an optimal thermal boundary condition to achieve the maximum output strain amplitude). This

study enables us to tune the strain amplitude of MSMA actuator by controlling the ambient heat transfer efficiency without changing the magneto-mechanical loading condition. More systematic experiments and the associated modelling are on-going to further understand the thermo-magneto-mechanical coupling behaviors of MSMA.

Abstract. A new model is proposed for composite laminate beams comprising multiple alternating shape memory alloy (SMA) and elastic layers. The model fully considers asymmetry in SMA behavior, which is found to significantly influence the behavior of the laminates. Moreover, the equations governing the response of the SMA-reinforced beams are derived for a complete loading-unloading cycle considering a Timoshenko beam model combined with well-established constitutive relations for SMAs. The derivation procedure involves first identifying the solid phase structure of the beam for a given applied load, followed by integration of the stress and strain in a cross section to obtain moment and shear force equations.

1 INTRODUCTION

Because of their superelasticity and shape memory effect, shape memory alloys have been utilized for innovative applications in aerospace [1], automotive engineering [2], robotics [3] and in the biomedical field [4]. In particular, SMA-reinforced composite materials were successfully used for shape adaptation and control [5], enhancement of resistance to buckling [6], structural frequency tuning [7], damage repair [8], vibration control [9], and for reducing impact stress and energy [10, 11]. Research into smart SMA-reinforced composites, in particular, has been the focus of extensive theoretical and experimental research. From an experimental point of view, Lee et al. [12] investigated the use of SMA reinforcement to enable self-healing of cracked cement mortar beams; Alebrahim et al. [13] analyzed the behavior of a smart composite beam comprising SMA elements and subjected to quasi-static loading; Kim et al. [14] reported on the use of SMAs for improving resistance to low-velocity impact in composite plates; Han et al. [15] studied the response of SMA-glass fiber woven composites for shape morphing of UAV winglets; Thomson et al. [16] utilized SMA actuators to improve the post-buckling behavior of a composite panel; Wang et al. [17] showed improvement in average strain at failure and tensile and compressive strengths in laminates reinforced with SMA layers; etc. In conjunction with experimental work, a great deal of effort has been dedicated to modeling and simulating the response of SMA composites. In this regard, Hamada et al. [18] investigated the thermomechanical behavior of smart composites consisting of 6061 Al matrix reinforced with multiple SMA fibers; Viet and Zaki [19] introduced an analytical model for concrete beams comprising multiple SMA wires; Taya et al. [20] designed a

reversible bending actuator comprising an SMA core bonded to two shape memory polymer (SMP) layers; Park et al. [21] analytically and experimentally investigated the deflection of SMA-SMP laminates subjected to loading at the tip, etc. For the case of SMA-reinforced composite beams in particular, existing analytical and semi-analytical solutions present a number of limitations, including the assumption of uniform SMA layer thickness [18] and material properties of the matrix [21], the limitation of detailed analytical derivations to monotonic loading [22], the consideration of identical elastic stiffness for the austenite and martensite phases, and the assumption of symmetric SMA response in tension and compression [22,23]. These limitations are addressed in this work, in which a semi-analytical model is derived to describe the behavior of laminated composite cantilever beams with multiple embedded SMA layers. The proposed derivations are based on the ZM constitutive model [24] for SMAs and on Timoshenko beam theory. The model accounts for asymmetric behavior in tension and compression of the SMA elements and provides analytical and semi-analytical relations governing the behavior of the beam during a complete loading-unloading cycle.

2 MATHEMATICAL DERIVATIONS

The dimensions and boundary conditions of the beam are illustrated in Fig. 1 below.

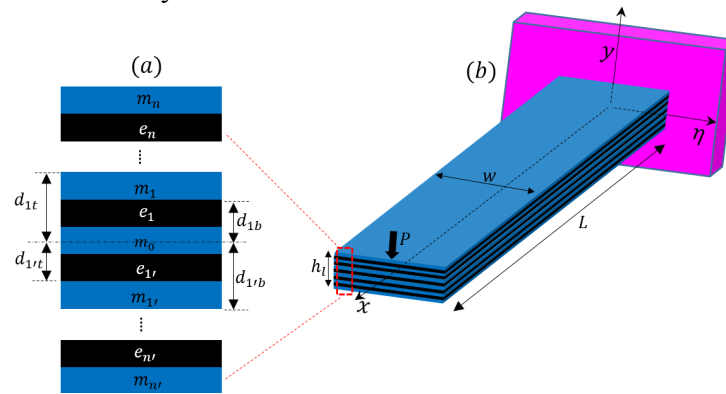

Fig. 1 Dimensions and boundary conditions of the laminated beam (a) layered structure; (b) 3D model.

As shown in the insert, the beam consists of alternating layers of SMA and elastic materials. The structures are such that the central, top and bottom layers are SMA. The total number of layers is therefore $n + n' + 1$ SMA and $n + n' - 1$ elastic. An elastic layer above (resp. below) the midplane is denoted e_h (resp. $e_{h'}$), where the index h is the layer number, starting from the midplane. The SMA layers are designated by m_h and $m_{h'}$. The distance from the midplane to the bottom (resp. top) of SMA layer m_h is denoted d_{hb} (resp. d_{ht}). The elastic stiffness of elastic layer e_h is E_{eh} .

2.1 Constitutive SMA relations

The behavior of the SMA is represented using constitutive equations from the ZM model [25], for which the evolution of the volume fraction z of martensite is governed by the following loading functions in the case of uniaxial tension/compression:

$$F_{j\pm} = \text{sign}(\times) \left[\left(\frac{El_{MA} + P_{MA}}{2} \right) \sigma_{j\pm}^2 + \sigma_{j\pm} \varepsilon_{0\pm} \right] + \left\{ a - b - \text{sign}(\times) \left(G + (\alpha - \beta) \left\{ k_h \left(\left(\frac{3}{4} \right)^{3/2} \varepsilon_{0\pm}^3 - c_h \frac{\varepsilon_{0\pm}^3}{3.8} \right) \right\}^{2/3} \right) \right\} z - \text{sign}(\times) \left(\frac{\beta}{2} \left\{ k_h \left(\left(\frac{3}{4} \right)^{3/2} \varepsilon_{0\pm}^3 - c_h \frac{\varepsilon_{0\pm}^3}{3.8} \right) \right\}^{2/3} + C(T) \right) - a \quad (1)$$

In Eq. (1), j is l during loading, in which case $\text{sign}(\times)$ is 1, or u during unloading, in which case $\text{sign}(\times)$ is -1 ; the sign \pm is $-$ for compression or $+$ for tension; P_{MA} , El_{MA} , ξ_T , a , b , α , β , and G are material parameters; $C(T)$ is an expression of temperature written $C(T) = \xi_T(T - A_f^0) + k_T$, where T is temperature, A_f^0 is the austenite finish temperature, and k_T is a material constant; k_h and c_h are parameters accounting for asymmetric hardening; ε_{0+} and ε_{0-} are the maximum transformation strains in tension and compression. The Young's moduli of austenite and martensite are denoted E_A and E_M respectively and both phases are considered to have the same Poisson ratio ν . A detailed introduction of the material parameters can be found in [25].

The uniaxial stress-strain relation for the SMA is written

$$\sigma_{j\pm} = \left[\frac{1}{E_A} + z_{j\pm} \left(\frac{1}{E_M} - \frac{1}{E_A} \right) \right]^{-1} [\varepsilon_{j\pm} - \varepsilon_{0\pm} z_{j\pm}] \quad (2)$$

which can be rearranged to get

$$z_{j\pm} = \frac{\varepsilon_{j\pm} - \sigma_{j\pm} / E_A}{(1/E_M - 1/E_A) \sigma_{j\pm} + \varepsilon_{0\pm}} \quad (3)$$

The stress-strain relation in the region of mixed austenite and martensite can be shown to obey [26, 27] the following equality:

$$\sigma_{j\pm}^3 + \Pi_{j1} \sigma_{j\pm}^2 + \Pi_{j2} \sigma_{j\pm} + \Pi_{j3} \varepsilon_{j\pm} + \Pi_{j4} = 0 \quad (4)$$

where

$$\Gamma_{\pm} = \left\{ k_h \left(\left(\frac{3}{4} \right)^{3/2} \varepsilon_{0\pm}^3 - c_h \frac{\varepsilon_{0\pm}^3}{3.8} \right) \right\}^{2/3}; \quad \Pi_{j1\pm} = \frac{2\varepsilon_{0\pm} \left(\frac{El_{MA} + P_{MA}}{2} + \frac{1}{E_M} - \frac{1}{E_A} \right)}{(El_{MA} + P_{MA})(1/E_M - 1/E_A)};$$

$$\Pi_{j2\pm} = 2 \frac{\varepsilon_{0\pm}^2 - \frac{\text{sign}(\times)[a - b - (\alpha - \beta)\Gamma_{\pm}] - G}{E_A} - \left(\frac{\beta}{2} \Gamma_{\pm} + C(T) + \text{sign}(\times)a \right) \left(\frac{1}{E_M} - \frac{1}{E_A} \right)}{(El_{MA} + P_{MA})(1/E_M - 1/E_A)};$$

$$\Pi_{j3\pm} = 2 \frac{\text{sign}(\times)(a - b) - G - (\alpha - \beta)\Gamma_{\pm}}{(El_{MA} + P_{MA})(1/E_M - 1/E_A)}; \quad \Pi_{j4\pm} = -2 \frac{\varepsilon_{0\pm} \left(\frac{\beta}{2} \Gamma_{\pm} + C(T) + \text{sign}(\times)a \right)}{(El_{MA} + P_{MA})(1/E_M - 1/E_A)};$$

Eq.(4) gives the explicit stress-strain relation

$$\sigma_{j\pm} = \Pi_{j1\pm}^* + \Pi_{j2\pm}^* \varepsilon_{j\pm} + \Pi_{j3\pm}^* \varepsilon_{j\pm}^2 + \Pi_{j4\pm}^* \varepsilon_{j\pm}^3 + \Pi_{j5\pm}^* \varepsilon_{j\pm}^4 \quad (5)$$

where the different coefficients are defined as follows:

$$Q_{j\pm} = \frac{3\Pi_{j2\pm} - \Pi_{j1\pm}^2}{9}, \quad \Omega_{1j\pm} = \frac{\pi}{2} - \frac{1}{\sqrt{-Q_{j\pm}}} \left(\frac{9\Pi_{1j\pm}\Pi_{2j\pm} - 2\Pi_{1j\pm}^3 - 27\Pi_{4j\pm}}{54} \right),$$

$$\Omega_{2j\pm} = \frac{\Pi_{3j\pm}}{2\sqrt{-Q_{j\pm}}},$$

$$\Pi_{j1+}^* = 2\sqrt{-Q_{j+}} \left(1 - \frac{\Omega_{1j+}^2}{18} + \frac{\Omega_{1j+}^4}{1944} \right) - \frac{\Pi_{j1+}}{3}; \Pi_{j2+}^* = 2\sqrt{-Q_{j+}} \left(\frac{4\Omega_{1j+}^2\Omega_{2j+}}{1944} - \frac{\Omega_{1j+}\Omega_{2j+}}{9} \right);$$

$$\Pi_{j3+}^* = 2\sqrt{-Q_{j+}} \left(\frac{6\Omega_{1j+}^2\Omega_{2j+}^2}{1944} - \frac{\Omega_{2j+}^3}{18} \right); \Pi_{j4+}^* = 2\sqrt{-Q_{j+}} \frac{4\Omega_{1j+}\Omega_{2j+}^3}{1944}; \Pi_{j5+}^* = 2\sqrt{-Q_{j+}} \frac{\Omega_{2j+}^4}{1944};$$

$$\Pi_{j1-}^* = 2\sqrt{-Q_{j-}} \left(1 - \frac{\Omega_{1j-}^2}{18} + \frac{\Omega_{1j-}^4}{1944} \right) \cos\left(\frac{2\pi}{3}\right) - 2\sqrt{-Q_{j-}} \sin\left(\frac{2\pi}{3}\right) \left(\frac{\Omega_{1j-}}{3} + \frac{\Omega_{1j-}^3}{162} \right) - \frac{\Pi_{j1-}}{3};$$

$$\Pi_{j2-}^* = 2\sqrt{-Q_{j-}} \left(\frac{4\Omega_{1j-}^2\Omega_{2j-}}{1944} - \frac{\Omega_{1j-}\Omega_{2j-}}{9} \right) \cos\left(\frac{2\pi}{3}\right) - 2\sqrt{-Q_{j-}} \sin\left(\frac{2\pi}{3}\right) \left(\frac{\Omega_{2j-}}{3} + \frac{3\Omega_{1j-}^2\Omega_{2j-}}{162} \right);$$

$$\Pi_{j3-}^* = 2\sqrt{-Q_{j-}} \left(\frac{6\Omega_{1j-}^2\Omega_{2j-}^2}{1944} - \frac{\Omega_{2j-}^3}{18} \right) \cos\left(\frac{2\pi}{3}\right) + 2\sqrt{-Q_{j-}} \sin\left(\frac{2\pi}{3}\right) \left(\frac{3\Omega_{1j-}\Omega_{2j-}^2}{162} \right);$$

$$\Pi_{j4-}^* = 2\sqrt{-Q_{j-}} \frac{4\Omega_{1j-}\Omega_{2j-}^3}{1944} \cos\left(\frac{2\pi}{3}\right) + 2\sqrt{-Q_{j-}} \sin\left(\frac{2\pi}{3}\right) \frac{\Omega_{2j-}^3}{162}; \Pi_{j5-}^* = 2\sqrt{-Q_{j-}} \frac{\Omega_{2j-}^4}{1944} \cos\left(\frac{2\pi}{3}\right).$$

Eq. (5) is used to plot the experimental curves used in characterizing the parameters of the SMA model in [25]. As shown in Fig. 2, the equation provides a good representation of the asymmetric behavior of the SMA.

Fig. 2 Model versus experimental data considering tensile-compressive asymmetry.

2.2 Moment and shear force relations

The Timoshenko theory gives the following equations for the beam:

$$\begin{cases} \varepsilon_{tx} = Yd\theta/dx = Yk \\ d\omega/dx = \gamma - \theta \end{cases} \quad (6)$$

where θ is the slope, ω is the vertical displacement of the beam, γ is the shear strain, $k = d\theta/dx$ is the curvature and Y is the vertical coordinate measured from the neutral axis.

Eq. (1) gives the martensite start and finish stresses σ_{\pm}^{Ms} and σ_{\pm}^{Mf} during loading

$$\begin{cases} \sigma_{\pm}^{Ms} = \frac{-\varepsilon_{0\pm} \pm \sqrt{\varepsilon_{0\pm}^2 + 2(El_{MA} + P_{MA})(\beta\Gamma_{\pm}/2 + C(T) + a)}}{El_{MA} + P_{MA}} \\ \sigma_{\pm}^{Mf} = \frac{-\varepsilon_{0\pm} \pm \sqrt{\varepsilon_{0\pm}^2 - 2(El_{MA} + P_{MA})(a - G - b - (\alpha - 3\beta/2)\Gamma_{\pm} + C(T) + a)}}{El_{MA} + P_{MA}} \end{cases} \quad (7)$$

To enable the derivation of the equations governing the deformation of the beam throughout a monotonic loading case, it is important to distinguish the different solid phase structures that develop within the beam as the load varies [26]. Indeed, different distributions of solid phase regions are possible, corresponding to the situations in Fig. 3.

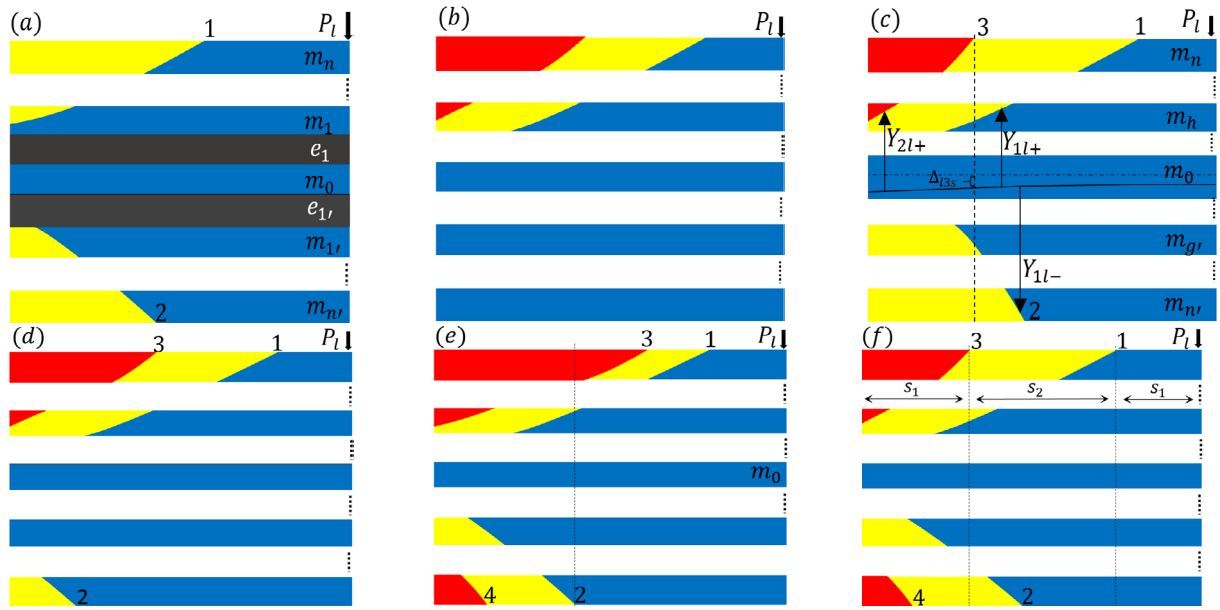

Fig. 3 Solid phase structure within the beam as the load is monotonically varied.

In the figure, austenite is shown in blue, martensite in red, and the regions of phase mixture are shown in yellow. Each longitudinal portion in which the number and order of solid phase structures in the vertical direction does not change is denoted s_i [26], where i is an index equal to one toward the free end and takes increasing integer values as one approaches the fixed end. For the problem addressed here, i can be anywhere between 1 and 4 (see figure). In each longitudinal section s_i , the moment, axial force, shear force, curvature, and deflection of the neutral axis are respectively denoted M_{ji} , F_{jxi} , Q_{ji} , k_{ji} and Δ_{ji} . Equivalent normalized properties are indicated with a hat symbol $\hat{\cdot}$, so that $\hat{M}_{ji} = M_{ji}/w$, $\hat{F}_{jxi} = F_{ji}/w$, and $\hat{Q}_{ji} = Q_{ji}/w$.

The vertical coordinate of the interface between adjoining solid phases in s_i (Fig.4) are given by the relations

$$\begin{cases} Y_{1l\pm} = \frac{\sigma_{\pm}^{Ms}}{k_{li}E_A} = \frac{\delta_{1\pm}}{k_{li}} \\ Y_{2l\pm} = \frac{\sigma_{\pm}^{Mf} + \varepsilon_{0\pm}E_M}{k_{li}E_M} = \frac{\delta_{2\pm}}{k_{li}} \end{cases} \quad (8)$$

in which $\delta_{1\pm} = \sigma_{\pm}^{Mf}/E_A$ and $\delta_{2\pm} = (\sigma_{\pm}^{Mf} + \varepsilon_{0\pm}E_M)/E_M$.

For the beam cross section containing boundary 3 (Fig. 3), the neutral surface is located using the following system of equalities:

$$\begin{cases}
 Y_{2l+} = \frac{\delta_{2+}}{k_{l3s}} = d_{nt} + \Delta_{l3s} \\
 \hat{F}_{lx3s} = \sum_{\lambda=1}^{n'} E_{e\lambda} \frac{k_{l3s} Y^2}{2} \Big|_{\Delta_{l3s}-d_{\lambda t}}^{\Delta_{l3s}-d_{(\lambda-1)b}} + \sum_{\lambda=1}^n E_{e\lambda} \frac{k_{l3s} Y^2}{2} \Big|_{d_{(\lambda-1)t}+\Delta_{l3s}}^{d_{\lambda b}+\Delta_{l3s}} + E_A \frac{k_{l3s} Y^2}{2} \Big|_{\Delta_{l3s}-d_{0b}}^{\Delta_{l3s}+d_{0t}} + \sum_{\lambda=1}^{h-1} E_A \frac{k_{l3s} Y^2}{2} \Big|_{\Delta_{l3s}+d_{\lambda b}}^{\Delta_{l3s}+d_{\lambda t}} \\
 + E_A \frac{k_{l3s} Y^2}{2} \Big|_{\Delta_{l3s}+d_{hb}}^{Y_{l+}} + E_A \frac{k_{l3s} Y^2}{2} \Big|_{Y_{l-}}^{\Delta_{l3s}-d_{g't}} + \sum_{\lambda=1}^{g'-1} E_A \frac{k_{l3s} Y^2}{2} \Big|_{\Delta_{l3s}-d_{\lambda b}}^{\Delta_{l3s}-d_{\lambda t}} \\
 + \sum_{\lambda=h+1}^n \left(\Pi_{l+}^* Y + \frac{\Pi_{l2+}^* k_{l3s} Y^2}{2} + \frac{\Pi_{l3+}^* k_{l3s}^2 Y^3}{3} + \frac{\Pi_{l4+}^* k_{l3s}^3 Y^4}{4} + \frac{\Pi_{l5+}^* k_{l3s}^4 Y^5}{5} \right) \Big|_{\Delta_{l3s}+d_{\lambda b}}^{\Delta_{l3s}+d_{\lambda t}} \\
 + \left(\Pi_{l+}^* Y + \frac{\Pi_{l2+}^* k_{l3s} Y^2}{2} + \frac{\Pi_{l3+}^* k_{l3s}^2 Y^3}{3} + \frac{\Pi_{l4+}^* k_{l3s}^3 Y^4}{4} + \frac{\Pi_{l5+}^* k_{l3s}^4 Y^5}{5} \right) \Big|_{Y_{l+}}^{\Delta_{l3s}+d_{ht}} \\
 + \sum_{\lambda=g'+1}^{n'} \left(\Pi_{l-}^* Y + \frac{\Pi_{l2-}^* k_{l3s} Y^2}{2} + \frac{\Pi_{l3-}^* k_{l3s}^2 Y^3}{3} + \frac{\Pi_{l4-}^* k_{l3s}^3 Y^4}{4} + \frac{\Pi_{l5-}^* k_{l3s}^4 Y^5}{5} \right) \Big|_{\Delta_{l3s}-d_{\lambda b}}^{\Delta_{l3s}-d_{\lambda t}} \\
 + \left(\Pi_{l-}^* Y + \frac{\Pi_{l2-}^* k_{l3s} Y^2}{2} + \frac{\Pi_{l3-}^* k_{l3s}^2 Y^3}{3} + \frac{\Pi_{l4-}^* k_{l3s}^3 Y^4}{4} + \frac{\Pi_{l5-}^* k_{l3s}^4 Y^5}{5} \right) \Big|_{\Delta_{l3s}-d_{g'b}}^{Y_{l-}} = 0
 \end{cases}
 \quad (9)$$

In the above system, Y_{2l+} is the Y coordinate of line 3, Δ_{l3s} is the deviation of the neutral axis, F_{lx3s} is the axial force, and k_{l3s} is the curvature. The following constraints must simultaneously be enforced:

$$\begin{cases}
 d_{hb} + \Delta_{l3s} < Y_{l+} = \frac{\delta_{1+}}{k_{l3s}} < d_{ht} + \Delta_{l3s} \\
 \Delta_{l3s} - d_{g'b} < Y_{l-} = \frac{\delta_{1-}}{k_{l3s}} < \Delta_{l3s} - d_{g't}
 \end{cases}
 \quad (10)$$

The bending moment M_{l3s} is then obtained by integration. It is worth noting that a correct solution requires proper determination of the correct sequence in which new solid phases form and evolve within the beam as the load is applied (Fig. 4).

Fig.4 Solid phase distribution within the beam during stage 3 of loading.

The mathematical details of this procedure are not presented here in the interest of brevity. In Fig. 4, each of the sections s_1 , s_2 and s_3 requires separate mathematical treatment because of different solid phase structure resulting in different governing equations. In section s_3 , the conditions of force and moment equilibria are given by

$$\begin{cases} \hat{F}_{lx1} = \hat{F}_e + \hat{F}_{m-} + \hat{F}_{m+} + \hat{F}_a + \hat{F}_{t+} + \hat{F}_{t-} = 0 \\ \hat{M}_{l1} = \hat{M}_e + \hat{M}_{m-} + \hat{M}_{m+} + \hat{M}_a + \hat{M}_{t+} + \hat{M}_{t-} \end{cases} \quad (11)$$

where the indices e , a , m and t indicate elastic, austenite, martensite and active phase transformation regions, respectively. Moreover, the tensile region is denoted with a $+$ and the compressive region with a $-$ symbol. By integration, the total force and moment acting on the section are such that

$$\begin{aligned} \hat{F}_{lx1} = & \sum_{\lambda=1'}^{n'} E_{e\lambda} \frac{k_{l1} Y^2}{2} \Big|_{\Delta_{l1}-d_{\lambda t}}^{\Delta_{l1}-d_{(\lambda-1)b}} + \sum_{\lambda=1}^n E_{e\lambda} \frac{k_{l1} Y^2}{2} \Big|_{d_{(\lambda-1)t}+\Delta_{l1}}^{d_{\lambda b}+\Delta_{l1}} + \sum_{\lambda=r'+1}^{n'} E_M \left(\frac{k_{l1} Y^2}{2} - \varepsilon_{0-} Y \right) \Big|_{\Delta_{l1}-d_{\lambda b}}^{\Delta_{l1}-d_{\lambda t}} \\ & + \sum_{\lambda=q+1}^n E_M \left(\frac{k_{l1} Y^2}{2} - \varepsilon_{0+} Y \right) \Big|_{\Delta_{l1}+d_{\lambda b}}^{\Delta_{l1}+d_{\lambda t}} + E_A \frac{k_{l1} Y^2}{2} \Big|_{\Delta_{l1}-d_{0b}}^{\Delta_{l1}+d_{0t}} + \sum_{\lambda=1}^g E_A \frac{k_{l1} Y^2}{2} \Big|_{\Delta_{l1}+d_{\lambda b}}^{\Delta_{l1}+d_{\lambda t}} + E_A \frac{k_{l1} Y^2}{2} \Big|_{Y_{1l-}}^{\Delta_{l1}-d_{v't}} \\ & + \sum_{\lambda=1'}^{v'-1} E_A \frac{k_{l1} Y^2}{2} \Big|_{\Delta_{l1}-d_{\lambda b}}^{\Delta_{l1}-d_{\lambda t}} + \sum_{\lambda=g+1}^{q-1} \left(\Pi_{l1+}^* Y + \frac{\Pi_{l2+}^* k_{l1} Y^2}{2} + \frac{\Pi_{l3+}^* k_{l1}^2 Y^3}{3} + \frac{\Pi_{l4+}^* k_{l1}^3 Y^4}{4} + \frac{\Pi_{l5+}^* k_{l1}^4 Y^5}{5} \right) \Big|_{\Delta_{l1}+d_{\lambda b}}^{\Delta_{l1}+d_{\lambda t}} \end{aligned}$$

$$\begin{aligned}
 & + \left(\Pi_{l1+}^* Y + \frac{\Pi_{l2+}^* k_{l1} Y^2}{2} + \frac{\Pi_{l3+}^* k_{l1}^2 Y^3}{3} + \frac{\Pi_{l4+}^* k_{l1}^3 Y^4}{4} + \frac{\Pi_{l5+}^* k_{l1}^4 Y^5}{5} \right) \Big|_{\Delta_{l1} + d_{qb}}^{Y_{2l+}} \\

 \hat{M}_{l1} & = \sum_{\lambda=1'}^{n'} E_{e\lambda} \frac{k_{l1} Y^3}{3} \Big|_{\Delta_{l1} - d_{\lambda t}}^{\Delta_{l1} - d_{(\lambda-1)b}} + \sum_{\lambda=1}^n E_{e\lambda} \frac{k_{l1} Y^3}{3} \Big|_{d_{(\lambda-1)t} + \Delta_{l1}}^{d_{\lambda b} + \Delta_{l1}} + \sum_{\lambda=r'+1}^{n'} E_M \left(\frac{k_{l1} Y^3}{3} - \frac{Y^2}{2} \varepsilon_{0-} \right) \Big|_{\Delta_{l1} - d_{\lambda b}}^{\Delta_{l1} - d_{\lambda t}} \\
 & + \sum_{\lambda=q+1}^n E_M \left(\frac{k_{l1} Y^3}{3} - \frac{Y^2}{2} \varepsilon_{0+} \right) \Big|_{\Delta_{l1} + d_{\lambda b}}^{\Delta_{l1} + d_{\lambda t}} + E_A \frac{k_{l1} Y^3}{3} \Big|_{\Delta_{l1} - d_{0b}}^{\Delta_{l1} + d_{0t}} + \sum_{\lambda=1}^g E_A \frac{k_{l1} Y^3}{3} \Big|_{\Delta_{l1} + d_{\lambda b}}^{\Delta_{l1} + d_{\lambda t}} + E_A \frac{k_{l1} Y^3}{3} \Big|_{Y_{l1-}}^{\Delta_{l1} - d_{v't}} \\
 & + \sum_{\lambda=1'}^{v'-1} E_A \frac{k_{l1} Y^3}{3} \Big|_{\Delta_{l1} - d_{\lambda b}}^{\Delta_{l1} - d_{\lambda t}} + \sum_{\lambda=g+1}^{q-1} \left(\frac{\Pi_{l1+}^* Y^2}{2} + \frac{\Pi_{l2+}^* k_{l1} Y^3}{3} + \frac{\Pi_{l3+}^* k_{l1}^2 Y^4}{4} + \frac{\Pi_{l4+}^* k_{l1}^3 Y^5}{5} + \frac{\Pi_{l5+}^* k_{l1}^4 Y^6}{6} \right) \Big|_{\Delta_{l1} + d_{\lambda b}}^{\Delta_{l1} + d_{\lambda t}} \\
 & + \left(\frac{\Pi_{l1+}^* Y^2}{2} + \frac{\Pi_{l2+}^* k_{l1} Y^3}{3} + \frac{\Pi_{l3+}^* k_{l1}^2 Y^4}{4} + \frac{\Pi_{l4+}^* k_{l1}^3 Y^5}{5} + \frac{\Pi_{l5+}^* k_{l1}^4 Y^6}{6} \right) \Big|_{\Delta_{l1} + d_{qb}}^{Y_{2l+}} \\
 & + \sum_{\lambda=v+1}^r \left(\frac{\Pi_{l1-}^* Y^2}{2} + \frac{\Pi_{l2-}^* k_{l1} Y^3}{3} + \frac{\Pi_{l3-}^* k_{l1}^2 Y^4}{4} + \frac{\Pi_{l4-}^* k_{l1}^3 Y^5}{5} + \frac{\Pi_{l5-}^* k_{l1}^4 Y^6}{6} \right) \Big|_{\Delta_{l1} - d_{\lambda b}}^{\Delta_{l1} - d_{\lambda t}} \\
 & + \left(\frac{\Pi_{l1-}^* Y^2}{2} + \frac{\Pi_{l2-}^* k_{l1} Y^3}{3} + \frac{\Pi_{l3-}^* k_{l1}^2 Y^4}{4} + \frac{\Pi_{l4-}^* k_{l1}^3 Y^5}{5} + \frac{\Pi_{l5-}^* k_{l1}^4 Y^6}{6} \right) \Big|_{\Delta_{l1} - d_{v'b}}^{Y_{l1-}}
 \end{aligned}$$

(12)

where the volume fraction of martensite is given by

$$z_{l1\pm} = \frac{k_{l1} Y}{\delta_{2\pm} - \delta_{1\pm}} - \frac{\delta_{1\pm}}{\delta_{2\pm} - \delta_{1\pm}} = a_{l1\pm} Y + b_{l1\pm} \quad (13)$$

In Eq. (15), $a_{l1\pm} = k_{l1} / (\delta_{2\pm} - \delta_{1\pm})$, $b_{l1\pm} = -\delta_{1\pm} / (\delta_{2\pm} - \delta_{1\pm})$ [26]. The total shear force is then written

$$\hat{Q}_{l1} = \hat{Q}_e + \hat{Q}_{m-} + \hat{Q}_{m+} + \hat{Q}_a + \hat{Q}_{t+} + \hat{Q}_{t-} \quad (14)$$

which can be fully developed into the following form:

$$\begin{aligned}
 \hat{Q}_{11} = & \sum_{\lambda=1}^{n'} K_s G_{e\lambda} \gamma_{11} Y \Big|_{\Delta_{11}-d_{1u}}^{\Delta_{11}-d_{(\lambda-1)b}} + \sum_{\lambda=1}^n K_s G_{e\lambda} \gamma_{11} Y \Big|_{d_{(\lambda-1)t}+\Delta_{11}}^{d_{\lambda b}+\Delta_{11}} + \sum_{\lambda=r'+1}^{n'} K_s G_M (\gamma_{11} - \gamma_{0-}) Y \Big|_{\Delta_{11}-d_{1b}}^{\Delta_{11}-d_{1u}} \\
 & + \sum_{\lambda=g+1}^n K_s G_M (\gamma_{11} - \gamma_{0+}) Y \Big|_{\Delta_{11}+d_{1b}}^{\Delta_{11}+d_{1u}} + K_s G_A \gamma_{11} Y \Big|_{\Delta_{11}-d_{0b}}^{\Delta_{11}+d_{0t}} + \sum_{\lambda=1}^g K_s G_A \gamma_{11} Y \Big|_{\Delta_{11}+d_{1b}}^{\Delta_{11}+d_{1u}} + K_s G_A \gamma_{11} Y \Big|_{Y_{1l-}}^{\Delta_{11}-d_{1t}} + \sum_{\lambda=1}^{v'-1} K_s G_A \gamma_{11} Y \Big|_{\Delta_{11}-d_{1b}}^{\Delta_{11}-d_{1u}} \\
 & + \sum_{\lambda=g+1}^{q-1} K_s G_M G_A \left[\frac{\ln\{G_M + b_{11+}(G_A - G_M)Y\}}{a_{11+}(G_A - G_M)} \gamma_{11} - \gamma_{0+} \frac{a_{11+}(G_A - G_M)Y - G_M \ln\{G_M(a_{11+}Y + b_{11+} - 1) - G_A(a_{11+}Y + b_{11+})\}}{a_{11+}(G_A - G_M)^2} \right] \Big|_{\Delta_{11}+d_{1b}}^{\Delta_{11}+d_{1u}} \\
 & + K_s G_M G_A \left[\frac{\ln\{G_M + b_{11+}(G_A - G_M)Y\}}{a_{11+}(G_A - G_M)} \gamma_{11} - \gamma_{0+} \frac{a_{11+}(G_A - G_M)Y - G_M \ln\{G_M(a_{11+}Y + b_{11+} - 1) - G_A(a_{11+}Y + b_{11+})\}}{a_{11+}(G_A - G_M)^2} \right] \Big|_{\Delta_{11}+d_{1b}}^{Y_{21+}} \\
 & + \sum_{\lambda=v'+1}^{r'} K_s G_M G_A \left[\frac{\ln\{G_M + b_{11-}(G_A - G_M)Y\}}{a_{11-}(G_A - G_M)} \gamma_{11} - \gamma_{0-} \frac{a_{11-}(G_A - G_M)Y - G_M \ln\{G_M(a_{11-}Y + b_{11-} - 1) - G_A(a_{11-}Y + b_{11-})\}}{a_{11-}(G_A - G_M)^2} \right] \Big|_{\Delta_{11}-d_{1b}}^{\Delta_{11}-d_{1u}} \\
 & + K_s G_M G_A \left[\frac{\ln\{G_M + b_{11-}(G_A - G_M)Y\}}{a_{11-}(G_A - G_M)} \gamma_{11} - \gamma_{0-} \frac{a_{11-}(G_A - G_M)Y - G_M \ln\{G_M(a_{11-}Y + b_{11-} - 1) - G_A(a_{11-}Y + b_{11-})\}}{a_{11-}(G_A - G_M)^2} \right] \Big|_{\Delta_{11}-d_{1b}}^{Y_{1l-}}
 \end{aligned}
 \tag{15}$$

where G_A , G_M and $G_{e\lambda}$ are the shear moduli of martensite, austenite, and the elastic layer, $\gamma_{0\pm} = \sqrt{3}\varepsilon_{0\pm}/2$ [26,27], $K_s = 5/6$ is a correction factor and γ_{11} is the shear strain. The shear stiffness G is such that [24]:

$$G = \frac{G_A G_M}{G_M + z(G_A - G_M)} \tag{16}$$

2.3 Solution during unloading

In the general case, unloading proceeds according to the following 4 stages, in sequence: elastic unloading, reverse transformation in part of the mixed region, reverse transformation in the entire mixed phase region until complete transformation to austenite, and elastic unloading of austenite. Because of space limitations, the corresponding derivations could not be reproduced here. The reader is referred to [26] for a complete discussion. The key complication in this case comes from the initial state of the beam, post-loading, which may comprise a non-homogeneous distribution of martensite.

3. CONCLUSION

A new analytical treatment of the problem of a multilayered elastic-SMA beam was proposed using a combination of the ZM constitutive relations for asymmetric SMAs and the Timoshenko theory. The procedure for deriving the governing equations of the beam was fully detailed for the case of monotonic loading and closed-form analytical formulations were pursued to the extent possible. A guide was also provided on the process to follow for solving the same problem during unloading. The model allows, in particular, the analytical determination of the bending moment, axial force and shear force in a cross section. It also allows finding the location of the neutral surface throughout the length of the beam as well as the beam deflection.
